REVIEW

Nanoparticles and organized lipid assemblies: from interaction to design of hybrid soft devices

Received 00th January 20xx, Accepted 00th January 20xx

DOI: 10.1039/x0xx00000x

Marco Mendozza, Lucrezia Caselli, Annalisa Salvatore, Costanza Montis* and Debora Berti*

This contribution reviews the state of art on hybrid soft matter assemblies composed of inorganic nanoparticles (NP) and lamellar or non-lamellar lipid bilayers. After a short outline of the relevant energetic contributions, we address the interaction of NPs with synthetic lamellar bilayers, meant as cell membrane mimics. We then review the design of hybrid nanostructured materials composed of lipid bilayers and some classes of inorganic NPs, with particular emphasis on the effects on the amphiphilic phase diagram and on the additional properties contributed by the NPs. Then, we present the latest developments on the use of lipid bilayers as coating agents for inorganic NPs. Finally, we remark the main achievements of the last years and our vision for the development of the field.

1 1. Introduction

30 2 3 Lipid bilayers are ubiquitous structural motifs in natural and synthetic soft matter assemblies. Their interaction with 4 nanostructured matter, and in particular with nanoparticles 5 (NPs), is therefore of interest both for natural and engineered 46 systems. In addition, the shared length and energy scales, 7 combined with the peculiar properties of inorganic matter $\frac{36}{20}$ 8 the nanoscale, can be harnessed to use NPs to probe selected $\frac{37}{2}$ 9 10 physical properties of membranes or to modify the amphiphilite 39 11 phase diagram under external stimuli. In this contribution we will review the state of the a^{40}_{r} 12 concerning research on hybrid soft matter assemblies 13 composed of inorganic NPs and synthetic lipid bilayers, either 11 14 43 15 lamellar or non-lamellar arrangement. This topic is currently a very active area of research, with 16 17 hybrid devices, where nanoparticles are included $\frac{46}{0}$ 18 functionalized with lipid bilayers, to the quest for mechanistic⁴⁷ 19 understanding of events taking place at the nano-bio-interface, $\frac{48}{2}$ 20 49 21 relevant for nanomedicine and toxicity of nanomaterials. This review will focus on some selected classes of inorganic 100022 nanomaterials, namely metals (Au and Ag), metal oxides (like 23 iron and zinc oxide) and silica NPs. The interaction of several 24 other kinds of nanomaterials with lipid bilayers has been 25 described in the literature and we refer the readers to some 26 55 27 excellent recent reports on these topics¹⁻⁸. 56

In this contribution, particular attention will be devoted to noncovalent interactions that take place when NPs and lipid bilayers are put into contact. Understanding the nature and the key determinants of these interactions is instrumental both for fundamental and applied soft matter research.

This review is organized as follows: a short theoretical section will introduce the main energetic contributions at stake when NPs interact with lipid bilayers (section 2). Then, we will provide an overview of the most relevant studies which have recently addressed the interaction of NPs with synthetic phospholipid bilayers, meant as simplified and highly controllable mimics of cell membranes (section 3). In this section, we will emphasize some examples where the investigation on model systems contributed disclosing non-covalent interactions at play in living systems. Then, we will review (section 4) the design of hybrid nanostructured materials composed of lipid bilayers and inorganic nanoparticles, with particular emphasis on the effects on the amphiphilic phase diagram and on the additional properties contributed by the NPs. Then, we will present the latest developments on the use of lipid bilayers as coating agents for inorganic NPs (section 5), whose aim is the of dispersibility, improvement biocompatibility and pharmacokinetic properties. Finally, a conclusive paragraph will remark the main achievements of the last years and our vision for the development of the field.

2. Interaction of Nanoparticles with Lipid 1 Membranes: the role of non-covalent forces 2

3 In this section we will consider the events following the 4 exposure of a free-standing synthetic lipid bilayer to NPs, $B \sqrt{}$ 5 outlining the different contributions to the total interaction 28 6 energy.

7 2.1 Theoretical description of NPs-lipid membrane interaction

8 The interaction between a NP and a lipid bilayer might lead 29 9 NP's adhesion on the bilayer, which can be followed by partial 10 or total engulfment by the membrane. In a well-defines, 11 medium and at a given temperature, the NP docking to liptor 12 membranes is thermodynamically favoured if the adhesion 13 energy E_{adh} <0, i.e., if the attractive terms overcome the 14 repulsive ones. Considering a prototypical model of 34 bioinorganic interface, with a spherical NP of radius B5 15 interacting with a liposomal membrane with curvature 1/R36 16 17 the energetic balance between repulsive and attractive forces 18 can be approximately described by a classical DLVO (Derjaguigg Landau-Verwey-Overbeek) formalism, as in eq. (1), including 19 only the electrical double layer (E^{EL}) and the London-Van dag 20 21 Waals (E^{LW}) contributions to the total energy of adhesion: 41

$$E_{adh} = E^{EL} + E^{LW}$$
(1)

Where the terms E^{EL} , derived as a combination between the 23 linear Debye-Huckel and the Derjaguin approximations and valid for surface potentials < 25 mV, and E^{LW} are described in eq. (2) and (3), respectively9:

$$\begin{split} E^{EL} &= \frac{\epsilon R_1 R_2 (\psi_1^2 + \psi_2^2)}{4(R_1 + R_2)} \bigg[\frac{2\psi_1 \psi_2}{(\psi_1^2 + \psi_2^2)} ln \bigg(\frac{1 + e^{-kd}}{1 - e^{-kd}} \bigg) \\ &+ ln \big(1 - e^{-2kd} \big) \bigg] \quad (2) \end{split}$$
$$E^{LW} &= -A \frac{R_1 R_2}{6(R_1 + R_2)} \bigg(\frac{1}{d} - \frac{1}{(d+h)} \bigg) - \frac{A}{6} ln \bigg(\frac{d}{d+h} \bigg) \quad (3) \end{split}$$

Where ψ_1^2 and $\psi_2^2~$ are the surface potentials of the NP and the membrane, d the NP-membrane distance, k the Debye length, h the membrane's thickness, and A is the Hamaker constant. Although the DLVO theory generally succeeds in predicting the colloidal stability of hard colloids (e.g. inorganic NPs) suspended in a liquid medium, it often fails in describing the interaction of NPs with free-standing bilayers; a more comprehensive description for E_{adh} includes additional repulsive hydration forces establishing at short NPs-membrane distances, as well as hydrophobic NP-lipid chain attraction (the interested reader is referred to a recent report for the analytical expression of the these two supplementary energetic contributions⁹).

42 Once the NP is adsorbed onto the lipid surface (i.e. E_{adh}<0), the 43 elastic properties of the membrane comes into play, and their 44 balance with the adhesion forces determines the degree of

1 membrane deformation and NP's wrapping. Specifically, tl48 2 energetic gain due to the adhesion forces is maximized 449

2 energetic gain due to the adhesion forces is maximized $\mathfrak{B}\mathfrak{P}$ 3 increasing the contact area between the NP and the lip $\overline{\mathfrak{L}0}$

increasing the contact area between
 membrane, according to equation (4)¹⁰:

$$E_{adh} = -w \int_{0}^{Sad} dS$$
 (4) 53
54

6 with w adhesion energy per unit area and S_{ad} the contact area 7 between the membrane and the NP. On the other side, the NP 8 wrapping is associated with a free energy cost of imposing 9 membrane deformation (E_{el}), which is expressed through the 10 Cahnam-Helfrich-Evans formalism¹⁰: 60

11
$$E_{el} = \int_0^S dS[\gamma + 2k_B(H - c_0)^2 + \bar{k}K]$$
 (5) 61
12 with S the entire interfacial area 63

12 with S the entire interfacial area.

As we can see from eq. (5), the deformation penalty depends 6413 both on the membrane's topology, through the mean H and 14 15 Gaussian K curvatures, and on the interface's mechanical and 16 elastic properties, expressed by the surface tension γ , bending rigidity k_B , spontaneous curvature c_0 and Gaussian saddle splay 17 modulus $\bar{k}.$ It is the fine interplay between E_{adh} and E_{el} that 18 19 ultimately defines the NP-membrane arrangement whic 20 minimizes the system's energy, ranging from complete unwrapped NPs (e.g. for small nanoparticles and/or weakly 21 interacting with the lipid phase), to larger and/or strongly $\frac{1}{74}$ 22 adhered nano-objects, eventually fully engulfed by the lipid 23 24 membrane (See Figure 1A).

Based on the above treatment, we will now discuss the several NPs- and membrane-related factors implicated in this interaction, with particular attention on size, shape, surface coating of NPs and NP-NP correlations; on the "membrane" side, we will take into account some selected physicochemical properties and the zero or non-zero curvature.

31 Depending on their size, the adhesion of NPs on a targe planar membrane can result in different effects: small NPs can 84 32 either remain embedded in the lipid membrane or directive 33 34 diffuse through it; relatively larger particles (>10 nm) can l 35 wrapped by the membrane¹¹. This process is finely controlle by the energetic balance between the adhesion forces (eq. $\binom{47}{88}$ 36 and the membrane's elastic deformation penalty (eq.(5)) $\tilde{5}$ 37 leading to an optimal size for wrapping, as first observed $\beta_{0}^{\prime\prime}$ 38 Roiter et al.¹². In particular, two characteristic NPs' limiting radii 39 40 for a successful engulfment by lipid membranes can Бе 92 41 theoretically predicted¹⁰: 93

42
$$R_{kw} = \sqrt{\frac{2k_b}{E_{adh}}}$$
 (6) 94
95
96

43
$$R_{k\gamma} = \sqrt{\frac{2k_b}{E_{adh} - \gamma}}$$
 (7) 97
98
99

Within the bending-dominated regime (i.e. for relatively smgh
membrane's deformation), the membrane tension can 1002
neglected, and the wrapping process is mainly controlled by the
competition between membrane's bending and NP's adhesion

strength, defining a critical radius R_{kw} . NPs with $R < R_{kw}$ remain unwrapped, while larger NPs $(R > R_{kw})$ are fully engulfed inside the lipid scaffold. For larger membrane's deformation (e.g. induced by micron-sized particles), a characteristic length scale $\lambda = (2k_b/\gamma)^{1/2}$, which depends solely on membrane's properties, marks the crossover from the bending-dominated to the stretching-dominated regime^{9,13} (Figure 1 B), where the γ -dependent wrapping extent gradually increases with NP's size. The full engulfment is reached for a second crossover NP's radius $R_{k\gamma}$ (eq. (7)), representing a larger NP's limiting size, which is required for the internalization in the case of finite tension-membranes.

2.2 Key NPs features in the interaction with lipid membranes

Concerning NPs shape, the increase of the surface area/volume ratio from spherical to asymmetrical NPs (e.g. nanorods, nanoprisms and nanocubes), maximizes the surface available for absorption onto lipid membranes (eq. (4)), enhancing their reactivity¹⁴; on the other side, the local particle's surface curvature is predicted to increase the energy barrier associated to membrane's deformation, stabilizing partial-wrapping states also for tensionless membranes^{9,10}. Moreover, the interaction of asymmetric NPs with target lipid membranes can lead to preferential wrapping orientations, to minimize the energy cost for wrapping^{15,16} (See Figure 1C). Eventually, the asymmetric shape of NPs can drive peculiar selfassembly phenomena at the nano-bio interface, some examples of which are given in Section 3.

The NPs surface functionalization represents another important factor affecting the interaction with membranes; in particular, NPs surface charge has a major impact on adhesion both onto charged and zwitterionic interfaces, setting the sign and magnitude of the electrostatic long-range contribution of (eq.1)^{3,17-21}. Furthermore, the adhesion of charged NPs to a target membrane is also associated to an entropic gain, deriving from the release of small counterions from the NP surface²² (See Figure 1D). On the other side, the presence of polymeric steric stabilizers on the NPs surface, like for PEGylated particles, often decreases the adhesion energy; this effect can be understood considering the mobility loss experienced by the polymer chains approaching the lipid surface, which entails a considerable entropic penalty for membrane adhesion. Moreover, NPs' surface functionalization determines their polarity, which is key in controlling their spontaneous localization when challenging a free-standing lipid membrane: generally, hydrophilic nanomaterials with size larger than 10 nm reside at the membrane surface, with the possibility to be partially or fully wrapped by the membrane. Conversely, depending on their hydrophobicity²³, small particles can either spontaneously cross^{24,25} or be entrapped²⁴ within the lipid membrane, provoking an alteration of the bilayer's frustration packing energy^{26–31}.

Eventually, interparticle forces between different membranebound NPs may originate cooperative phenomena, ultimately leading to the simultaneous wrapping and engulfment of

multiple NPs (see Figure 1D), which will be discussed in detail 56
 section 3. 57
 3

4 2.3 Key membrane features in the interaction with NPs

5 Membrane-related characteristics have a crucial role in the interaction with NPs. In particular, the composition of lipid 6 bilayers determines specific physico-chemical, viscoelastic and 7 8 thermodynamic properties of relevance in the interaction with 9 NPs. Membrane's surface potential, determined by the percentage of non-ionic, anionic and cationic lipids, strongty 10 11 affects the electrostatic contribution to NPs adhesion (eq.144 12 while the presence of specific components (e.g. cholesterod); and their relative abundance, give rise to characteristig 13 behaviours, which will be extensively discussed in section 3. 67 14 15 Equally important, the molecular geometry of the 16 membrane's components determines the equilibriu arrangement of lipids within the bilayer. The molecular packing 17 represents the main factor affecting both the physical state and 18 the overall topological curvature of membranes, which are two 119 20 with prominent determinants in the interactions 21 nanomaterials. 73 In particular, the interactions at the nano-lipid interface $\frac{1}{4}$ 22 extremely affected by the gel-liquid crystalline phase behaviours 23 of lipid membranes: by increasing temperature, lipid bilayers 24 undergo a main phase transition from the so-called "gel state", \vec{q}_7 25 (L_{β}) , where hydrocarbon chains are tightly packed and almost 26 locked in place, to a "fluid state" (L_{\alpha}), where lipids freely diffused 27 within the 2D membrane's plane. The "melting transition 28 temperature" (T_m) is specific for a given lipid composition and 29 determines the elastic response of membranes at a given 30 temperature. In particular, gel phase bilayers show a reduce $\overline{d_3}$ 31 reactivity with nanomaterials, mostly due to the high value $\bar{\varrho}\bar{f}_4$ 32 their bending rigidity (k_B) with respect to the fluid $\mbox{phase}_{85}^{9^{\circ}}$ 33 which strongly hampers the membrane's bending and wrapping 34

around NPs (see eq. (5-7)). On the other side, the interaction,
with NPs, which can proceed through polar headgroups
(hydrophilic NPs) or hydrophobic chains (hydrophobic NPs)
might affect the lipid molecular packing, leading to micro and
macroscopic modifications in the membrane structure and
thermotropic behaviour (specific examples will be provided in
the following paragraphs).

42 As predicted from eq.5, the membrane's topology plays a crucial role in its elastic response to NP's induced deformations. 43 44 Although lipid membranes are generally visualized as flat 45 bilayers (H and G in eq. (5) equal to zero), both biomembranes 46 and synthetic lipid assemblies may fold into more organized 47 non-lamellar bilayered structures³². The interaction of 48 nanomaterials with such non-lamellar structures may have a 49 noteworthy relevance both for biomimetic and technological 50 applications $^{\rm 33,34}\!$, (as discussed in details in the following 51 paragraphs)while it remains, to date, a highly unexplored 52 research area.

53 Differently from planar membranes, curved membranes are 54 defined by positive (direct phases) or negative (inverse phases) 55 mean curvature (H) and non-zero Gaussian curvature (K)³⁵ in each point of their surface, with H and G described by eq. 8 and 9, respectively:

$$H = \frac{1}{2}(c_1 + c_2)$$
(8)
$$K = c_1 c_2$$
(9)

with c_1 and c_2 minimum and maximum values of curvature at a specific point of membrane surface.

The non-zero values of H and K lead, as predicted from eq. (5), to a modification of their Helfrich energy and elastic response towards externally induced deformations (e.g. NPs' wrapping) with respect to the case of lamellar membranes. Moreover, different topologies are associated with a frustration packing free energy (E_P), which varies according to eq. (10)³⁶:

$$E_{\rm P} = k(l - l_{\rm r})^2$$
 (10)

with k stretching rigidity of lipid chains, l and l_r hydrophobic chain extension in the stretched and relaxed state, respectively. Phase transitions between different geometries, including changes in both elastic and frustration packing energies, have high biological relevance, sharing similar energy barriers and molecular re-arrangements with membrane fusion processes³⁷. Several recent studies, which will be addressed in section 4, demonstrated that both hydrophilic and hydrophobic NPs can promote phase transitions between model mesophases with different geometry^{26,27,34,37–41}, lowering the energy barrier required to switch from low to high curvature phases. One of the first attempts to elucidate this effect is represented by recent works^{26,42}, where the transition temperature from cubic to hexagonal phases in monoolein liquid crystals is demonstrated to be finely controlled by inclusion of hydrophobic iron oxide NPs (see section 4). This behaviour was explained by combining the Helfrich theory in eq. (5) with geometrical considerations: NPs increase the frustration packing energy of the cubic phase (eq. (10)), while they have a milder effect on the hexagonal arrangement, by inserting into its hydrophobic voids (See Figure 2).

In the framework of this theoretical description, in recent years the interaction of NPs with lipid membranes has been

Figure 2 Effects of NPs on lipid mesophases architectures. Illustrative scheme of the NP-induced modification of the Frustration Packing Energy of both cubic and hexagonal mesophases.

14 In section 3 we will review the interaction of NPs with7 15 synthetic lipid bilayers, taken as simplified models of re68 16 plasma membranes: in line with section 2, we will consider the 17 main physicochemical factors, either related to NPs or to the 018 lipid membrane, affecting the interaction under simplified 19 conditions. We will provide relevant examples from the receard 20 literature, highlighting the connections, whenever they are 21 relevant, between the findings on cell models and the in vitro/jn4 22 vivo observations. 75

23 3. NPs/biomembrane Interactions: from24 biophysical studies of nano-bio interfaces to

25 applications

26 One of the main issues limiting the development 84 27 nanomedicine and the translation of engineered nanomaterials? 28 into medical practice, is the poor understanding of their fate \$29 biological fluids, and their short-term and long-term possibled 30 adverse cytotoxic effects^{37,43–49}. Recent reports have al 31 highlighted how nanodevices designed for nanomedicines 32 applications, whose functionality/efficiency has been proved 87 33 the lab-scale, completely fail reaching their biological targe \$34 once in a living organism⁵⁰. As a matter of fact, to date, nan8935 therapeutics available on the market are mainly limited \mathfrak{B} polymeric- and liposomal-based formulations^{51,52}, while, apapt 36 37 from some iron oxide NPs-based formulations, inorganic and \mathbb{R}^2 38 metallic particles are at research stage or in clinical trials 93 39 With the ultimate aim to fill the gap between the 40 design/synthesis/development of nanomaterials førs nanomedicine and their end use application, it is necessary to 96 41 improve our fundamental knowledge on the interaction $\check{g}\check{f}$ 42 nanomaterials with biologically relevant interfaces, particular $\delta_{\mathbf{8}}$ 43 44 cell membranes. 99

Plasma membrane, primarily composed by a mixed 45 46 phospholipid bilayer with embedded proteins, protects the 頓力 47 interior and ensures its communication with the externation environment. The mechanisms of cell signalling processes and 48 49 extremely complex and length scale-dependent, with smaller 50 molecules spontaneously crossing the lipid barrier and larges polar molecules harnessing protein-media 51 and/or transportations across the membrane¹³. The nanoscale, sha 52 53 by engineered particles and biologically releva08

macromolecules (i.e., DNA, viruses, surface proteins), is mostly associated with endocytic pathways, where the internalisation of nano-objects is generally controlled by the membrane through specific receptor-protein binding for the case of biological species^{54,55}. However, it has been demonstrated that synthetic NPs can be wrapped and internalized by both model and real cell membranes in the absence of any receptormediated interaction^{43,55,56}, under exclusive control of nonspecific interactions taking place at the nano-bio interface, and membrane's elasticity.

In this context, synthetic lipid membranes (together with more complex systems, as organ-on-a-chip and 3D cells arrays, mimicking an entire tissue⁵⁷), are interesting biomimetic systems, which, by mimicking the main structural unit of plasma membranes, allow investigating phenomena at the nano-bio interface in simplified and highly controlled conditions^{44,45,58}.

In recent years, both experimental and theoretical studies have addressed the interaction of NPs with synthetic lipid membranes, aimed at establishing clear connections between the results in simplified model systems and what observed in real cells, in order to enabling predictive strategies for the design of evermore efficient and non-toxic nanomaterials for nanomedicine.

In the following sections recent relevant studies on NPssynthetic lipid membranes interactions, together with their implications for the understanding of real nano-bio interfaces, will be revised, particularly focusing on: the effect of NPs coating (surface charge, exchangeability of the ligand, steric hindrance of the coating, impact of the protein corona) (3.1); the effect of NPs size and shape (with particular interest on the relevance of NPs clusterization in cell uptake) (3.2); the effect of NPs adhesion on the composition, integrity and viscoelastic properties of the target membrane (3.3). In addition, the interaction of inorganic NPs and lipid membranes has been exploited for analytical purposes, in order to label/signal/probe selected properties of cells or lipid assemblies in complex biological media, both exploiting specific and non-specific interactions of NPs with the target membranes. This latter research field will be reviewed in section 3.4.

3.1 Biophysics of nano-bio interfaces: NPs coating

3.1.1 NPs surface charge

The intrinsic characteristics of NPs (i.e., core composition, size, shape) often have a secondary impact on the interaction with a target lipid membrane, which is primarily mediated by the ligands coating the NP's surface: the surface characteristics of NPs determine polarity and interfacial properties, directly involved in the electrostatic and London-Van der Waals contributions to NPs' adhesion to a lipid interface (see paragraph 2.1 for the theoretical background). The interaction of NPs with target membranes is primarily affect by the charge of both components (see equation 2). In order to closely resemble real plasma membranes, most of the employed model bilayers in biomimetics are characterized by a zwitterionic or slightly anionic nature. Therefore, negatively charged NPs tend to be electrostatically repelled from the

1 membrane, undergoing to weaker interactions with respect **fb** 2 3 membranes, where the uptake is generally much lower f $\partial 0$ 4 anionic NPs than for cationic ones^{59–61}. However, the situation1 of real cells is complicated by the presence of other interaction 225 6 pathways of specific nature, representing an alternative wizh 7 respect to non-specific forces. Several studies have highlighted 8 that nonionic, anionic and cationic NPs of similar sizes under 25 9 different internalization routes, from clathrin- or caveola 2610 mediated endocytosis to non-endocytic pathways, like passi297 diffusion^{62,63}. Even if characterized by limited interaction 8 11 12 capability, yet anionic NPs are attractive for biomedic29 13 applications, due to limited adverse cytotoxic effects. **BO** 14 addition, despite the dominantly repulsive electrostatic forces, several reports have shown successful internalization of aniong 15 NPs, as silica or Gold NPs (AuNPs)⁶³⁻⁶⁵. Conversely, cationic NBs 16 have a strong tendency to interact with negatively charged 17

membranes: it has been shown that cationic NPs adhere and clusterize onto synthetic target membranes, extract lipids from the membrane, ultimately provoking localized membrane disruption or integrity loss^{22,66,67}. In line with this findings, they are often characterized by limited stability in biological media and, above all, relevant toxic effects on real cells^{13,68,69}. Recently, Lee et al.⁷⁰ hypothesized, by means of a systematic study using a charge library of modified AuNPs, that the magnitude of the positive charge is not the sole factor determining the extent of interaction with target membranes and, thereby cytotoxicity. They conclude that spatial proximity of positively charged functional groups within a hydrophobic moiety is a common characteristic of toxic gold colloids.

3.1.2 NPs coated with steric stabilizers

A common strategy to increase the colloidal stability of NPs in biological media consists in the passivation of NPs with bulky ligands, to endow them with steric stabilization. This kind of coating also improves the pharmacokinetic properties of NPs: For instance, it is well known that PEGylation prevents opsonisation, improving the circulation time of the nanomaterial. This stealth effect of PEG in preventing opsonisation depends on its steric hindrance: it has been shown that both NPs uptake and circulation time depend on the molecular weight of PEG coating the NPs⁷¹. Moreover, thanks to molecular dynamic simulations, Lin et al.⁷² elucidated the effect of both the grafting density and polymer's chain length on the shielding ability of PEG layers bounded to gold NPs of varying size. Similar examples of steric stabilization of NPs have recently been proposed by Jiang and co-workers, who have employed poly(zwitterionic)protein functionalization (for instance poly(carboxybetaine)) to improve pharmacokinetic properties of NPs73,74, while other examples of polyzwitterionic coatings are poly(acrylic acid) derivatives, poly(maleic anhydride-alt-1alkene) derivatives or poly(sulfobetaine) derivatives, which offer several advantages over PEGylation (see as a reference the Review from Garcia et al.73).

PEGylation or steric stabilization affects the interaction of NPs with synthetic target membranes, with possible implications also at the real membranes' level. Indeed, the use of steric stabilizers, like PEG, is theoretically predicted to decrease the adhesion of NPs to lipid membranes, due to the high entropic loss associated to the adsorption process (see paragraph 2).

Through large scale molecular dynamic simulations, In a recent study⁷⁵, Gal and coworkers extensively characterized the interaction of PEGylated SPIONs of different size with both synthetic membranes of different composition and real cancer and kidney cells. In the frame of classic DLVO theory (paragraph 2), they presented a direct comparison of NP-synthetic and real membrane interactions, linking weak NP adsorption to anionic lipid membranes, due to NP-bilayer electrostatic interactions, with eukaryote cell uptake, without membrane penetration. Moreover, they showed that the NP-membrane electrostatic

78

attraction is suppressed by increasing PEG molecular weig57
 and NP size, which they correlated with low cell uptake and n58
 cytotoxicity in two cell lines.

is to exploit exploiting NP-membrane specific interaction §3, 7 which are available for the case of real plasma membranes? 8 endowing NPs surface with targeting moieties, might result 9 promoting the effective docking of NPs on cell membranes and 10 improving the successful achievement of their biological target 11 For instance, in a proof-of-concept study it was shown that 12 adding biotin or streptavidin moieties allows specific binding 9/h 13 polymer-coated NPs to beads carrying the complementary 14 unit⁷⁶; Kaaki et al.⁷⁷ highlighted the efficient targeting of human 15 16 breast carcinoma cells by folic acid-conjugated iron oxide NPs with a PEG coating; however, partially contradictory 17 18 resultswere obtained by Krais et al. on similar system, where not 19 folate-dependent targeting was highlighted⁷⁸ 76

20

21 **3.1.3** NPs coating with exchangeable ligands

22 The binding mode and strength between the NPs and the 23 coating agent determine both single NP-membrane interactio 24 and collective NP-NP interactions at the nano-bio interface1 25 physisorbed ligands, which can be easily displaced from the 26 NP's surface through ligand-exchange, are associated to 27 enhanced reactivity of NPs, which can be considered 84 28 "naked". Recently, hydrophobic physisorbed ligands, i.e. ole85 29 acid/oleylamine coatings on iron oxide NPs, have be&6 30 associated to small NPs' pearl-necklace aggregation inside7 31 monoolein bilayers²⁶. Moreover it has been shown th**88** 32 hydrophilic weakly absorbed ligands on the surface of AuN89 33 can promote peculiar aggregation phenomena occurring on the 34 lipid membrane^{18,19}, which are particularly significative also for 35 the case of repulsive NPs/membrane electrostatic interactio 62 36 (e.g. between negatively charged gold NPs and slightly anion 93 37 synthetic free-standing bilayers). Moreover, weakly bour944 38 physisorbed ligand onto the NPs surface can be easily replaced 39 with other molecules establishing covalent or stronger no9640 specific interaction with the bare NPs surface: remarkably, it h957 41 been recently demonstrated by Wang et al⁷⁹, that weak ligance B8 42 as citrate and short DNA fragments onto the gold surface, cap 43 be effectively replaced with lipid components of 100 44 membranes, resulting in unique interfacial phenomena. Inde **201** 45 when ligand exchange processes occur at the interface, MO2 46 might aggregate into ordered monolayers on the lipos 47 membrane, which might affect membrane integrity and 104 48 internalization efficiency and pathway. 105

49 50

3.1.4 Protein corona coating of NPs

An interesting aspect is the functionalization of NPs surfaces with the so-called protein corona^{14,55,80,81}. From the pioneer**109** studies of K. Dawson^{82–84} and coauthors, it has been progressively established that NPs in biological fluids **1**del spontaneously covered by a self-assembled layer of proteins **1**an inner non-exchangeable layer and an external exchangeable one), which determines a "biological identity" of the NPs and, ultimately, their ability to interact with cells 44,80,85,86. The composition of the protein corona depends on the nature of NPs core, on their shape and on their surface coating. In particular, the surface charge of NPs also affects the adhesion of biomolecules present in biological media, modifying the protein corona, in terms of composition and orientation^{62,87,88}. It has also been highlighted that during NPs internalization, the tendency of corona proteins is, at least partially, to remain attached to NPs surface^{83,89,90}. Since proteins are generally characterized by significant steric hindrance and amphiphilic nature, they specifically mediate the interaction of the NPs with plasma membranes. In this context, it has been highlighted that slight physicochemical modifications of the proteins modify their binding and orientation on NPs, strongly affecting the biological uptake of NPs⁹¹. Recently, the controlled formation of the protein corona has been exploited both for application purposes (e.g., for applications in cancer vaccines⁹²) and also to control in a predictable way the protein-corona-mediated interaction of NPs with cell membranes. For instance, preincubation of NPs with serum has been exploited to prevent NPs aggregation in biological media, improve their cell uptake and decrease their cytotoxic effects⁶⁹. The comprehension, control and exploitation of protein corona formation is therefore a key milestone in determining and predicting NPs fate in living organisms.

3.2 Biophysics of nano-bio interfaces: NPs size and shape

As discussed in section 2, when a NP adheres to a planar lipid membrane, it locally imposes a curvature modification, which depends on the size of NPs and on the viscoelastic properties of the membrane (equation 5), which eventually controls the occurrence and extent of NPs wrapping by the membrane; therefore, NPs size also determines the response of the bilayer to its adhesion and, ultimately, the effects on the target membrane and the internalization pathway. NPs with size comparable or smaller than the lipid bilayer thickness can either be entrapped within the membrane³⁰ or translocate across the lipid bilayer by diffusing through^{25,93,94} or by opening pores in the membrane⁹⁵, which is normally associated to a high cytotoxicity in vivo^{56,96}. On the contrary, wrapping represents the dominant mechanism for larger particles (>10 nm) interacting with bilayers, which is associated to their entrance into cells in living organisms¹¹. Often, depending on NPs size, adhesion to a target membrane might result in the NPs clusterization: indeed, under specific conditions, membranes actively drive the self-assembly of adsorbed NPs, as a result of the tendency of the membrane to minimize the NP-induced deformation and its associated elastic cost (eq. 5)⁹⁷. As a result, small-sized NPs have been observed to preferentially interact with membranes as clusters^{67,98}, while fluid membranes have been theoretically predicted to mediate the asymmetric aggregation of spherical nanoparticles onto lipid surface⁹⁹. This aspect is particularly significant for medical application of nanomaterials, since NPs uptake in model and real membranes is often preceded by aggregation at the nano-bio interface¹¹.In addition, mathematical models and molecular dynamic simulations have revealed that membrane-induced interactions between bound particles can lead

106

107

to collective NPs wrapping and internalization: in particular, Zhang 26
 al.¹⁰⁰ revealed that NPs translocation proceeds in a cooperative wa?
 with a key role played by NPs quantity, while Lipowsky et al.¹⁰¹.
 showed that spherical NPs can be cooperatively wrapped in tubul 29
 membrane invaginations. 30

6 While the effect of NP's size has been extensively investigated 1 7 much less is known on the impact of NP's geometry. Asymmetrica B_2 8 shaped NPs, like nanorods, nanodisks and nanostars, are particula $B\beta$ 9 attractive materials, due to the peculiar properties (optical 10 magnetic, electronic and so on) arising from anisotropy¹⁰ Depending on their shape, anisotropic NPs can efficiently interact 11 with a target membrane and translocate across it. MD studies on the 12 13 interaction of NPs of different non-spherical shapes highlighted reorientation of NPs in proximity to the target membrane, $\frac{38}{10}$ 14 maximize the interaction, leading to strong shape and orientational 15 dependence on the translocation¹⁰⁴ (See Figure 3A); in addition, 4016 has to be considered that, from a theoretical standpoint, it $\frac{41}{5}$ 17 18 thermodynamically more favourable for a lipid membrane to wrap 42spherocylinder than a sphere of the same radius¹⁰⁵. Consistently with 19 the theoretical predictions, non-spherical NPs, from nanostars to 20 nanorods, are efficiently internalized by cells, in a shape and, fd^{5} 21 nanorods, aspect-ratio dependent manner.^{106,107} Experimenta 22 studies on biomimetic membranes have shown that the asymmetric A23 shape of NPs can drive peculiar self-assembly phenomena at the 24 nano-bio interface^{10,37}: as an example, we recently demonstrated 25

that gold nanorods (Au NRs) are wrapped by model and real cell membranes as end-to-end NPs' clusters⁶⁷, reducing the energy penalty required for the membrane to bend around highly curved edges. The induced tension due to the adhesion of asymmetric NPs determines effects of lipid extraction, observed both on model membranes and macrophage cells, eventually provoking extensive disruption of the membrane, related to a significant *in vitro* cytotoxicity⁶⁷.

3.3 Biophysics of nano-bio interfaces: Membrane composition

Cell membranes are characterized by a high degree of compositional heterogeneity, typically comprising of thousands of different lipids, carbohydrates and proteins¹⁰⁸, which is reproduced, at different complexity levels, by model membranes. The chemical composition of both synthetic and natural bilayers strongly affects their elasticity, physical state and structure, thereby determining their response towards external *stimuli*. A clear example is the recent work of Lunnoo et al.¹⁰⁹, in which model bilayers with different compositional complexity levels correspond, as predicted by their proposed MD simulations, to diverse cellular uptake pathways of neutral 10-nm gold NPs,. Going more into details, the presence of charges on the lipid membrane emphasizes the interaction with oppositely charged particles, as expected from eq. (2)⁹⁶ in

1 section 2; however, it has been demonstrated that electrostated 2 interactions play a major role also for neutral zwitterionic lipi 3 facing anionic and cationic NPs^{110,111}. In addition, it has been 9 4 observed that the molecular structure of membrane's liptod 5 components (e.g. saturation degree of hydrophobic chain6)1 6 represents another factor to take into account, affecting the 2 7 penetration level of NPs inside the lipid region¹¹². Furthermore3 8 cholesterol, one of the most abundant sterols in real lipfer4 9 membranes, deeply affects the structure and fluidity of ${\sf lip} {\rm f} {\rm d} {\rm b}$ 10 bilayers; moreover, it is involved in the formation of lipto rafts¹¹³, which, for reasons not yet fully understood, increase7 11 12 the extent of NPs-membrane interactions: as an examples Melby et al.¹¹⁴ showed that positively charged AuNPs bind 13 significantly more to phase-segregated bilayers with respect to 14 single phase ones, while Hartono et al.¹¹⁵ associated high **2**0 15 16 cholesterol concentrations in lipid monolayers to strong and 17 interactions with protein-coated AuNPs, leading to monolay $\overline{e}2$ 18 disruption. 73

3.4 Biophysics of nano-bio interfaces: NPs-induced membrane modifications 76

22 The self-assembled nature and lateral fluidity of plasma 23 membranes determine a capability of the membrane table24 reorganize and locally and transiently restructure itself 79 25 response to biological stimuli. This is the case considering f80 26 instance the transient formation of lipid rafts, in relationsh 27 with cell trafficking phenomena, or considering ligand(drug)2 receptor interactions at cell surface, triggering complexed 28 29 biological responses. In this respect, several studies have addressed the effects on NPs on a target lipid membrane upogs 30 adhesion. A first effect is the induced lateral phase separation 31 within the target membrane: theoretical studies on cationic $N\tilde{87}$ 32 have highlighted their tendency to recruit anionic lipids in the 33 adhesion area, determining the formation of phase separated 34 patches within the membrane (See Figure 3B).^{22,116} The alteration of membrane's phase behaviour induced by NPs is a 35 36 growing research topic, with several studies contributing 37 building-up a complex picture, which is far from being 38 understood. As an example, the group of Granick¹¹¹ reported 93 39 40 different effect of silica anionic¹¹⁷ and cationic particles of 41 phospholipid membranes, with negative NPs inducing gelation 42 and positive ones provoking fluidification. Considering anion 96 43 silica NPs with different size, the group of Zhang et al.¹¹⁸ repo 44 that the gelation, or "freeze effect" on DOPC giant unilamell 98 45 vesicles (GUV) is promoted by small NPs (18 nm), while large 46 particles (>78 nm) promote membrane wrapping. 100 47 significantly decreasing the phospholipid lateral mobility, the 48 release of tension through stress-induced fracture mechanics results in a microsize hole in the GUVs after interaction. On the 49 other hand, membrane wrapping leads to increased lipid lateral 50 51 mobility and the eventual collapse of the vesicles. 105 Von White et al.³⁰ registered an increase in the gel-to-liquid 52 crystalline transition temperature of synthetic lipid vesicles 53 induced by the embedding of hydrophobic AuNPs, while 54 55 Chakraborty at al.¹¹⁹ reported the opposite effect, phospholipid bilayer softening, due to hydrophobic Autors 56 110

inclusions; on the other side, recent studies demonstrated that hydrophilic (negatively and positively charged) AuNPs induce the same effect at the nanoscale, promoting the formation of rigidified lipid domains around the NPs' surface, characterized by a reduced lipid motion with respect to the surrounding fluid phase^{21,22,120,121}. Both the induced lateral phase separation on a target membrane and the induced modification of the viscoelastic properties might represent, at the biological level, both biologically relevant signals, activating cell entry pathways, or else might be of relevance in inducing cytotoxic effects (Figure 3 C).

3.5 Analytical Applications of NP-lipid membrane interactions

An interesting research topic related to the interaction of NPs with lipid membranes is its exploitation for analytical purposes. Inorganic NPs are characterized by peculiar properties, making them suitable to provide a readout, generally an optical (fluorescence, scattering) or magnetic signal, which can provide qualitative or quantitative information of different nature. Knowles and coworkers have shown how the spontaneous formation of a supported lipid bilayer on a polystyrene NPs patterned support can be exploited to form membrane regions of high curvature, due to NPs partial wrapping: these areas spontaneously accumulate specific, single-tailed lipids, of higher spontaneous curvature, and can be exploited to monitor the interaction of biomolecules with membrane areas of high curvature¹²²; Liu et al.¹²³ have formed AuNPs patterned surfaces (See Figure 4B), for mechanical tension measurements in living cells. Cho and coworkers¹²⁴ have designed a nanoplasmonic biosensor made of an array of gold, silicon oxide or titanium oxide nanodisks coated with different lipid architectures (See Figure 4C), vesicles arrays, supported lipid bilayers or a coexistence of the two systems, spontaneously formed due to different pathways of interaction between lipid vesicles and the nanodisks of different material: localized surface plasmon resonance experiments detecting a membrane-active peptide highlighted a strong dependence of the interaction between the peptide and the lipid bilayer, depending on the architecture of the lipid scaffold. Limaj et al.¹²⁵ designed an infrared biosensor to monitor the molecular behaviour and dynamics of lipid membranes, based on the adsorption of lipid vesicles on an engineered substrate functionalized with gold nanoantennas for surface enhanced infrared absorption (SEIRA) experiments. Suga et al.¹²⁶ exploited the interaction of hydrophobic (dodecanthiol-modified) AuNPs with phospholipids and phospholipid assemblies, to investigate the behavior of lipid membranes at a molecular length-scale through Surface-Enhanced Raman Spectroscopy (SERS). The same technique is employed by Bhowmik et al.127, who exploit the formation of a lipid coating wrapping Silver NPs (AgNPs) to probe through SERS the molecular behavior of protein oligomers spontaneously binding to the lipid coating of AgNPs (this example will be also discussed in section 5) (See Figure 4A). Recently, we have shown that synthetic Giant Unilamellar Vesicles of POPC promote the

ARTICLE

1 clusterization of Turkevich-Frens citrated AuNPs on the lip55 membrane itself^{121}. This phenomenon, which has be $\pounds 6$ 2 3 investigated by other groups, provokes a modification of the 7 4 plasmon resonance peak of AuNPs, which is visible also 58 5 naked eyes as a colour change of AuNPs dispersion from red 10^{-9} 6 blue^{17,128}. Interestingly, this effect is similarly observed where the same AuNPs challenge biogenic natural vesicles 7 (extracellular vesicles, EVs)^{120,129} and it has been found as 8 9 strongly dependent on the concentration of EVs and on the 10 presence of protein contaminant. Therefore, an analytica4 11 method for EVs has been developed, offering an easy and fast assay for purity and concentration of EVs, based on nonspecifie 12 interactions between NPs and lipid membranes^{130–132} (See 13 68 14 Figure 4D). 69

4. Engineering Lipid Assemblies: Inclusion of NPs⁷¹ in Lipid Scaffolds 73

17 Depending on their molecular structure and on the 18 environmental conditions, lipids in water self-assemble into 5 19 very diverse structures, from simple planar lamellar phases, 36 20 vesicles, to non-lamellar curved bilayered structures (as cubic) 21 mesophases)^{133–135}, to inverse monolayered tubularg 22 arrangements (as inverse hexagonal mesophases). These 23 different structural arrangements, formed by spontaneous sego 24 assembly, can host hydrophilic-coated NPs in the aqueogs 25 regions and/or hydrophobic-coated NPs in the hydrophob 26 domains. 83

NPs can spontaneously insert in the lipid scaffolds, due to no84
specific forces, such as hydrophobic, electrostatic and Van d85
Waals interactions (see paragraph 2), thus representing a faci86
approach to obtain a complex hybrid material with controlleg7
structure and defined properties arising from the combinations
of lipid and NP building blocks.

33 In particular, the inclusion of NPs in lipid scaffolds allows 34 obtaining materials with specific interesting features: (i) the 35 biocompatibility of the lipid scaffold (dependent on igg 36 composition) allows envisioning the employment of the 93 37 hybrid materials for biomedical applications; (ii) the self 4 38 organization and phase behavior of lipid mesophases 95 39 generally responsive to the inclusion of external species, 96 40 temperature, hydration and other experimental condition 97 41 which variations can be triggered, in a space and time controllers manner, by external stimuli applied to the NPs included in the 42 43 lipid scaffold (e.g., magnetoliposomes). This is a very interesting 44 opportunity for several applications, for instance the 45 development of drug delivery systems (DDS) with control release abilities; (iii) the inclusion and confinement of NP103 46 47 lipid scaffolds has the effect to locally concentrate them and to 4 48 impose them a spatial arrangement. This localized MOS 49 concentration increase might be of relevance to enhance NP96 50 related signals (for instance optical or MRI readout 107 51 diagnostic applications); in addition, the increa**₫€08** 52 concentration, together with a defined structural architecture9 53 might induce peculiar collective properties of NPs, arising from 0 54 the lipid scaffold-imposed arrangement.

In the following sections we will revise this topic, in particular focusing on the effect of NPs inclusion on the overall features of lipid/NP hybrid materials (4.1), and, subsequently, on applicative examples of NP/lipid hybrids made of NPs included in lamellar (4.2) and non-lamellar (4.3) lipid mesophases.

4.1 NPs inclusion in Lipid Scaffolds: Structural and Physicochemical Effects

The hydrophobic or hydrophilic nature of NPs, which depends on the coating agent, is the key factor in determining the localization in a lipid assembly. Both lamellar (i.e. liposomes, Giant Unilamellar Vesicles) and non-lamellar (i.e. cubic or hexagonal structures) lipid assemblies are characterized by the coexistence of hydrophobic and hydrophilic domains, capable to host NPs of different nature. In all NPs-lipid hybrids, the inclusion of NPs in the lipid architecture affects the physicochemical and structural properties of the lipid scaffold, modifying for instance the fluidity and bending properties of the membrane, its local thickness, the phase behavior and the viscoelastic properties. For instance, it has been shown that the inclusion of hydrophobic superparamagnetic iron oxide NPs (SPIONs) in the lipid membrane of DPPC liposomes increases the average thickness of the membrane and modifies the orientation of the phospholipid chains, affecting the lipid melting temperature^{136,137}. In addition, depending on the chemical nature of hydrophobic NPs embedded in a lipid bilayer, they can either stabilize or destabilize the lipid ordering, causing opposite effects on the phase behavior of the lipid scaffold; it has been shown that 4 and 5.7 nm AgNPs³¹ increase the fluidity of the membrane, reducing the degree of ordering of the lipid tails, while 5 nm maghemite NPs²⁹ increase membrane rigidity. Finally, the inclusion of nanoparticles can also modify the final structure of the bilayer: for instance, a Cryo-TEM investigation of Chen et al. on liposomes containing hydrophobic SPIONs has highlighted the formation of liposomes' aggregates with SPIONs clusters acting as bridging agents (See Figure 5A-B). These local perturbations highlight that some structural rearrangement of a planar lipid membrane can be possible preserving the overall lipid mesophase architecture; however, as reported by Briscoe et al.40, significant amounts of NPs inclusion might promote, for defined lipid compositions and specific temperature/pressure conditions, a phase transition from lamellar to hexagonal mesophases. In general, as already pointed out in section 2, the inclusion of NPs in a planar bilayer increases the frustration packing energy of the lipid molecules eventually promoting the re-organization in a different mesophase, characterized by a more negative curvature; the mismatch between the equilibrium curvature and the perturbed arrangement due to NP inclusion, favors the transition to a more thermodynamically stable structure.

These examples highlight how the effect of NPs on lipid membranes is variable, but possibly predictable, on the basis of minimum energy considerations; therefore, the physicochemical properties of the target lipid membrane and of the NPs to be inserted in the lipid scaffold can be tuned in order to

4 4.2 Applications of NPs/Lamellar Lipid Assemblies Hybrids

Among hybrid nanostructures where NPs are included $\frac{23}{10}$ 5 aře 6 lamellar assemblies, particularly relevant magnetoliposomes (MLs), where hydrophobic SPIONs a_{re}^{25} 7 included in the lipid bilayers of lipid vesicles¹³⁸⁻¹⁴⁰. There 8 responsivity to static (SMF) and alternating magnetic fields 9 (AMF) makes MLs good candidates in nanomedicine as $DDS1\frac{28}{2}$ 10 able to release drugs confined in the lumen of liposomes in 29 11 time and space controlled manner, upon application of external 3012 stimuli^{142,143}. Despite their potentiality, the inclusion of small 13 NPs in the bilayer can be exploited only for drug delivery 14 15 purposes, while generally, no bulk heating effect can be induced by small NPs subjected to AMFs, as shown in several studies^{1,3}4: 16 therefore, they cannot be applied in hyperthermia therapies $\frac{35}{2}$ 17 for the thermal ablation of cells; however, as reported by $\tilde{B}\underline{\hat{P}}$ 18

Corato et al.145, using hydrophilic SPIONs loaded in the vesicles' lumen combined with a photosensitizer, results in a synergistic effect, observed both in vitro and in vivo, making this strategy, exploiting a multifunctional nanomaterial, very promising for therapeutic applications. Recently, MLs decorated both with hydrophobic and hydrophilic SPIONs have been shown to release on-demand hydrophilic or hydrophobic payloads, depending on the frequency and application time of an AMF.¹²⁷ Besides SPIONs, hydrophobic AuNPs were recently used¹⁴⁶ to build-up photoresponsive and thermosensitive hybrid liposomes. In addition, multifunctional hybrid liposomes containing magneto-plasmonic nanoparticles (SPIONs@Au), merging the possibility to combine hypothermic and photothermal treatments were recently shown^{147,148} for imageguided delivery of anti-HIV drugs to the brain: generally, the successful delivery of antiretroviral drugs to the brain is limited due to the presence of the blood-brain barrier (BBB); in this case the authors reported an enhanced BBB transmigration efficiency under AMF without its disruption; moreover, the

1 treatment of HIV virus with multifunctional liposom 57 2 successfully reduced the viral replication. 58 3 Several studies have addressed the inclusion of quantum dob9 4 in lipid assemblies: despite their unique optical properties, the $\mathfrak{G} \mathfrak{O}$ 5 are characterized by significant acute cytotoxic effects. With the 6 aim to realize a contrast agent for imaging applications^{138,149,1}82 7 several studies have shown that the confinement of CdSe dobs 8 in lipid bilayers increases their biocompatibility, white 9 preserving their fluorescence features, making the system motes 10 suitable for biomedical applications (See Figure 5 C). 66 11 67

12 4.3 Applications of NPs/Non-Lamellar Lipid Assemblies Hybrids $\frac{68}{62}$

69 As anticipated in section 2, the inclusion of NPs into non 13 14 lamellar lipid assemblies mostly affects the structure of the mesophase, in terms of the lattice parameter an q_{2} 15 consequently, of the diameter of the nanochannels and amounts 16 17 of water contained in the lipid architecture. If the size of NPs-js similar or smaller than the lattice parameter, NPs can be easily 18 encapsulated in the architectures. Venugopaal et alg 19 investigated the encapsulation of hydrophilic Silica NPs of 8 nm 20 21 diameter in monolinolein mesophase: in this case, the NPs were too large to be encapsulated in the nanochannels (of $\frac{3}{29}$ 22 3.8 nm diameter); nevertheless, the addition of NPs determined 23 the overall dehydration of the lipid scaffold, eventually causing ${}_{1}$ 24 25 for high concentration, the transition of the assembly geometry 26 to a gyroid cubic structure (Ia3d). The authors interpret this 27 behavior considering that, since the energy cost to include the 28 NPs in the nanochannels is extremely high (above 100 k_BT), the 29 NPs tend to minimize their interfacial energy, aggregating along the grain boundaries of the mesophase, similarly to what 30 reported concerning lamellar structures¹⁵¹. The same authors 31 investigated also the structural features of monolinole \$632 mesophases loaded with hydrophilic SPIONs. Upon application 33 of a SMF, a reorganization of the lipid domains along the 100034 35 direction of the field^{152,153} was found, highlighting how the 36 responsiveness of SPIONs to magnetic fields can be exploited $\frac{90}{10}$ induce structural modifications in the whole lipid mesophas 37 This effect has been applied for instance to control the release 38 of drugs confined in the lipid mesophases 152 or, as the same $^{\mbox{93}}$ 39 authors reported $^{154},$ for the application in optical memory 94 40 95 41 storage.

The inclusion of hydrophobic NPs in non-lamellar mesophases 42 can be easily achieved exploiting the hydrophobic interactions 9743 that spontaneously drive the NPs localization in the 44 hydrophobic regions of the self-assembly. However, also in this 45 case, the size of NPs is of paramount importance, to avoid the 46 disruption of the lipid scaffold. Recently, the inclusion 10147 hydrophobic SPIONs into 1-monoolein diamond cubic phase 48 was reported, highlighting that the amount of included NPS^3 49 together with temperature, control the phase transition from 50 cubic to hexagonal phase. Since this transition is accompanied 51 52 by a significant dehydration of the mesophase, the structural 53 rearrangement is accompanied by the release of most of the water content of the nanochannels. This thermoresponsive 54 hybrid material was also found to be responsive to ANHQ? 55 representing, therefore, a promising system for the deliver $\frac{1}{2}$ 56

hydrophilic drugs in a time and space-controlled manner.³³ Recently, it was shown that this thermotropic effect of liquid crystalline phases loaded with hydrophobic NPs is a general phenomenon, highlighted e.g. also by cubic mesophases formed of phytantriol and hydrophobic AuNPs.²⁰

Very few examples in the literature address the inclusion of non-spherical NPs in non-lamellar lipid assemblies: Boyd et al.¹⁵⁵ reported on hydrophobic NRs included in phytantriol, selachyl alcohol and monoolein lipid mesophases, with the aim to buildup photo-responsive hybrid materials (See Figure 5D). The authors investigate the effect of NRs on the cubic mesophases, highlighting a slight reduction in the phase transition temperature and in the lattice parameter. Interestingly, similarly to spherical hydrophobic NPs, gold NRs shift the cubicto-hexagonal boundaries to lower temperature¹⁵⁶. For hexosomes of selachyl alcohol, it was shown that the lattice parameter or water volume fraction^{26,27} are not affected by the presence of AuNRs; the authors suggest that NRs are positioned along the direction of hexosomes, but, due to their large sizes (55.5 nm in length and 16 nm in width) they are in close proximity of the lipid bilayer, without being efficiently included inside it. Nevertheless, the application of a NIR laser on the hybrid structure promoted the phase transition from cubic to hexagonal phase, similarly to what observed with the application of AMF on monoolein-SPIONs hybrids.

5. Surface Engineering of Inorganic NPs: Functionalization of NPs with a Lipid Coating

Recently, several research groups have addressed the functionalization of inorganic NPs or clusters of NPs with lipids to form lipid-coated NPs with a supported lipid bilayer (SLB and liposomes³). The validity of this approach is twofold: first, a lipid coating of appropriate composition might strongly improve the biocompatibility of inorganic NPs: this is particularly critical for the very toxic quantum dots. The second advantage is the increased dispersibility in body fluids and improved pharmacokinetic properties. As a matter of fact, without a proper coating, bare NPs introduced by parenteral administration, are rapidly opsonized and removed by phagocytes from the blood stream⁵⁴ and accumulated in liver and spleen^{157,158}, often causing oxidative stress^{159,160}.

Although this could be even convenient for those treatments where the desired aim is to modulate local immune responses¹⁶¹, it is worth considering the use of a capping agent that prevents leakage of the drug, protects the carrier from degrading enzymes, and shields them from the immune system avoiding side effects^{162,163}. Among several potential capping systems, lipid bilayers are especially advantageous¹⁶⁴ for several reasons: (i) the escape from endosomal vesicles of the nanomaterial and successful reaching of its biological target, upon endocytic uptake, in strongly favoured in the presence of a lipid coating, improving the ability of NPs to passively permeate to the inner core of the cell^{165,166}; (ii) the presence of a lipid coating is helpful in preventing NPs aggregation in biological environment; (iii) lipid coating is highly tuneable in

1 composition (for instance PEGylated lipids, to further improved) 2 nanoparticle pharmacokinetic properties¹⁶⁷, can be eas 3 incorporated, as well as cholesterol, added as a controlling 4 fluidity agent) and can be easily functionalized and designed 29 5 match the specific requirements of the desired application¹ $\mathfrak{B}\mathfrak{O}$ 6 $^{170}\!.$ As introduced in section 2, the achievement of such $3a\!\!1$ 7 coating depends on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on the size of the NP to be coated and on 8 viscoelastic properties of the membrane. Generally, relative 33 9 large NPs, imposing a low curvature to the target membran 3,4 10 can be successfully completely wrapped and coated by a lip3b11 membrane, while small particles need to be wrapped and 12 coated as clusters. In the following sections we will revie $3\sqrt{7}$ 13 the most relevant examples and applications of lipid-coated 14 inorganic nanoparticles, considering one by one the differe 3915 types of nanoparticles, Silica NPs (5.1), Gold and Silver NPs (5.40) 16 and Iron Oxide NPs (5.3). 41

17

18 5.1 Lipid-coated Silica NPs

43

42

Leveraging the pioneering works of Rapuano'groups^{171,172}, over
the last years several research groups have addressed the
decoration of silica nanoparticles with SLBs¹⁷³. Recently
Mousseau et al. showed an example of fluorescent silica NPs
covered by a pulmonary surfactant Curosurf[®]. They found that
a complete SLB coverage of silica nanoparticles is obtained on the

25 through sonication, which disrupts lipid vesicles and promotes 50

full wrapping of the NPs. *In vitro* assays confirmed that the presence of the SLB mitigated the particle toxicity and improved internalization rates¹⁷⁴.

Tada and co-workers tested the impact of a lipid coating (using different types of lipid bilayers) on the cytolocalization of silica NPs prepared with methylene blue, for applications in Photodynamic Therapy (PDT) ^{175,176}.

Mackowiak et al.¹⁷⁷ showed an example of mesoporous silica NPs surrounded by a cationic DOPC/DOTAP SLB with targeting ligands on the surface of the nanoconstruct and a photosensitizer molecule covalently attached to the surface of mesoporous silica NPs, for controlled and targeted drug delivery applications. In this case, the presence of the SLB coating was also aimed at improving the capability of the system to retain a drug inside the mesoporous structure of NPs before photoactivation to induce the release of the cargo.

An alternative route to obtain controlled release of drugs from lipid-coated mesoporous silica NPs, based on the use of thermoresponsive lipids, was recently presented by Zhang et al.: they combined the high drug loading capacity of mesoporous silica NPs with the thermal responsiveness of a mixture of lipids, DPPC/DSPC/Chol/DSPE-PEG2000, allowing the possibility to release on-demand the payload at hyperthermia temperature, circumventing the premature leakage at physiological temperature¹⁷⁸ (See Figure 6C).

Taking advantage of their antimicrobial properties, AgNPs have 3 been widely used in the last decades both in industrial and $\frac{60}{10}$ 4 5 biomedical application^{179–181}. Furthermore, due the localized surface plasmon resonance (LSPR) of AgNPs, they can 162 6 7 exploited for the development of biosensors. For this purpose3 8 Bhowmik et co-workes¹²⁷ developed a method to determine the 9 conformation of membrane-bound proteins: unlik6e5 10 conventional SERS, that requires immobilization of molecules β 11 they exploit the spontaneous binding of proteins to lipid bilaye67 12 coated AgNPs. In this way, they probed the behavior **68** 13 membrane-attached oligomers of Amyloid- β 40 (A β 40), who **6** 14 conformation is of relevance in Alzheimer's disease. AuNPs a740 15 the most widely studied inorganic NPs, thanks to their facile 16 synthetic and functionalization routes, and their plasmon 72 17 properties that can be harnessed in a plethora of application 23 18 ranging from optical imaging, spectroscopy and phototherm24 19 therapy. Du et al. formed a liposomes-AuNPs hybrid system **3**5 20 a vector for nucleic acids, for applications in gene therapy¹⁸².76 England and co-workes^{183,184} (See Figure F) prepared AuNPS 21 22 functionalized with multiple layers (two or three) 78 23 phosphatidylcholine, alkanethiol, high density lipoprotein and 24 phosphatidylcholine/alkanethiol for the delivery 8Ð 25 hydrophobic and hydrophilic drugs for the treatment of sol&1 26 tumours. By exploiting the optical properties of AuNPs, Reed 82 27 al. developed a novel hybrid for sensitive detection of protei83 28 based on apposition and aggregation of liposomes induced BA 29 Ca2+ ions using Forster resonance energy transfer (FRE85 30 assays¹⁸⁵ (See Figure E). Wang et al recently proposed a nove6 31 approach to overcome the low delivery efficiency of plasmi 32 by condensing them on peptide-modified AuNPs, successive 33 covered with a mixture of phospholipids¹⁸⁶. 89 34 In addition to spherical NPs, liposomes-coated goft 35 nanocages¹⁸⁷ (See Figure 6A-B) have been reported as possible 36 nanovaccines for cancer immunotherapy: the authors?

37 demonstrated that the hybrid carrier exhibited enhances 38 antitumor effects, inhibiting tumour growth in lung metasta 94 39 models. In addition, lipid-coated hollow gold nanoshells have 40 been recently developed for synergistic chemotherapy and 41 photothermal therapy for the treatment of pancreatie 42 cancer¹⁸⁸. By taking advantage of the unique structure of hollogy gold nanoshells, the authors successfully demonstrated the cg7 43 44 delivery of two drugs, one loaded in the lipid bilayer and the 45 other one loaded in the hydrophilic interior of the nanoshell. 99 46 Furthermore, the possibility to extend lipid coverage to Au Mon 47 has been recently explored. Recent studies have addressed the 48 functionalization of Au NRs with a phospholipid bilay grap composed of POPC189 and, more recently, DMPC190, to increase 49 biocompatibility and bioavailability of NRs. In addition, lipiph 50 51 capped Au NRs (obtained with DPPC vesicles containing lipids 52 with a thiol headgroup) have been demonstrated to be suitable label-free biosensors¹⁹¹ for the detection of lipophilic drugging 53 aqueous solutions or lipopeptides in serum. Finally, moving tros 54 55 more complex architecture, Han et al¹⁹² (See Figure **6b**) 56 demonstrated the possibility to use silica and phospholipids to

cover Au NRs, coupling the photothermal and thermoresponsive properties in the same nanoplatform.

5.3 Lipid-coated Iron Oxide NPs

SPIONs are among the most attractive NPs for biomedical applications, ranging from applications in MRI to responsive nanocarriers for drug delivery to therapeutic applications in hyperthermia (See Figure G). Bao et al¹⁹³ synthesized DSPE-PEG coated SPIONs loaded with indocyanine green molecules as superparamagnetic carriers capable to easily accumulate in tumours sites and act as biodegradable nanotheranostic agents. In the emerging field of nanovaccines, the group of Ruiz-de-Angulo¹⁹⁴ presented a biocompatible multifunctional system designed to both act as delivery vehicle and radiotracer for PET/SPECT imaging: using lipid-coated magnetite nanoparticles, they efficiently included in the construct 67Ga3+ as radiotracer, plus an antigen and an adjuvant. In vivo imaging highlighted the efficient targeting capability of the system and cell uptake. Recently, the same authors presented bacteria-mimicking NPs, that is, a similar construct (i.e., lipid coated magnetite nanoparticles), coated with lipooligosaccharides, which efficiently act as adjuvants¹⁹⁵ for application in cancer vaccine field.

Enveloping a magnetic iron oxide core with a lipid shell facilitates bioconjugation, biocompatibility, and delivery, as well reported by Wang et al.¹⁹): in their work they provide a general solution for coating iron oxide and other metal oxides with a simple mixing in water, facilitating applications in biosensing, separation, and nanomedicine.

A multifunctional system for dual imaging (fluorescence and MRI) of hepatocellular carcinoma was reported by Liang et al¹⁹⁶: through the thin film hydration method, they covered magnetite NPs previously conjugated with a NIR fluorescent dye; the lipid bilayer was decorated with a polymer targeting tumour hepatocytes, able to steer the carrier to the specific site. By flow cytometry and confocal laser scanning microscopy they assessed the specific cellular uptake, followed by *in vivo* tests on tumor-bearing mice.

6. Conclusions

In this contribution we have reviewed the latest developments concerning the interaction of NPs with amphiphilic bilayers arranged in lamellar and non-lamellar mesophases.

This area is a very lively research field, where efforts are motivated by several scientific purposes. First of all, the application of nanostructured materials in the biomedical field requires a precise knowledge of the nano-bio-interface: bilayered synthetic assemblies are a very convenient and simple platform to elucidate the interactions with cell membranes and internalization of nanomedical devices. In addition, the design of smart nanostructured hybrid devices, where NPs are included in soft matter assemblies to contribute new properties and modulate their phase diagram is a very relevant and active research field. Related to this latter area is the use of lipid
