### **REVIEW**

### Nanoparticles and organized lipid assemblies: from interaction to design of hybrid soft devices

Received 00th January 20xx. Accepted 00th January 20xx

DOI: 10.1039/x0xx00000x

Marco Mendozza, Lucrezia Caselli, Annalisa Salvatore, Costanza Montis\* and Debora Berti\*

This contribution reviews the state of art on hybrid soft matter assemblies composed of inorganic nanoparticles (NP) and lamellar or non-lamellar lipid bilayers. After a short outline of the relevant energetic contributions, we address the interaction of NPs with synthetic lamellar bilayers, meant as cell membrane mimics. We then review the design of hybrid nanostructured materials composed of lipid bilayers and some classes of inorganic NPs, with particular emphasis on the effects on the amphiphilic phase diagram and on the additional properties contributed by the NPs. Then, we present the latest developments on the use of lipid bilayers as coating agents for inorganic NPs. Finally, we remark the main achievements of the last years and our vision for the development of the field.

#### 1. Introduction

2

3 Lipid bilayers are ubiquitous structural motifs in natural and synthetic soft matter assemblies. Their interaction with 4 nanostructured matter, and in particular with nanoparticles 5 (NPs), is therefore of interest both for natural and engineered 6 systems. In addition, the shared length and energy scale 3,5 7 combined with the peculiar properties of inorganic matter  $\frac{36}{2}$ 8 the nanoscale, can be harnessed to use NPs to probe selected 9 10 physical properties of membranes or to modify the amphiphilites 39 11 phase diagram under external stimuli. In this contribution we will review the state of the  $\frac{40}{100}$ concerning research on hybrid soft matter assemblies 13 composed of inorganic NPs and synthetic lipid bilayers, either #2 14 15 lamellar or non-lamellar arrangement. This topic is currently a very active area of research, with 16 17 implications ranging from the design of smart nanostructured hybrid devices, where nanoparticles are included  $\frac{46}{9}$ 18 functionalized with lipid bilayers, to the quest for mechanistic 19 understanding of events taking place at the nano-bio-interface, 21 relevant for nanomedicine and toxicity of nanomaterials. This review will focus on some selected classes of inorganic 22 nanomaterials, namely metals (Au and Ag), metal oxides (like 23 iron and zinc oxide) and silica NPs. The interaction of several 24 other kinds of nanomaterials with lipid bilayers has been 25 described in the literature and we refer the readers to some 55

In this contribution, particular attention will be devoted to noncovalent interactions that take place when NPs and lipid bilayers are put into contact. Understanding the nature and the key determinants of these interactions is instrumental both for fundamental and applied soft matter research.

This review is organized as follows: a short theoretical section will introduce the main energetic contributions at stake when NPs interact with lipid bilayers (section 2). Then, we will provide an overview of the most relevant studies which have recently addressed the interaction of NPs with synthetic phospholipid bilayers, meant as simplified and highly controllable mimics of cell membranes (section 3). In this section, we will emphasize some examples where the investigation on model systems contributed disclosing non-covalent interactions at play in living systems. Then, we will review (section 4) the design of hybrid nanostructured materials composed of lipid bilayers and inorganic nanoparticles, with particular emphasis on the effects on the amphiphilic phase diagram and on the additional properties contributed by the NPs. Then, we will present the latest developments on the use of lipid bilayers as coating agents for inorganic NPs (section 5), whose aim is the of dispersibility, improvement biocompatibility pharmacokinetic properties. Finally, a conclusive paragraph will remark the main achievements of the last years and our vision for the development of the field.

## 2. Interaction of Nanoparticles with Lipid Membranes: the role of non-covalent forces

In this section we will consider the events following the exposure of a free-standing synthetic lipid bilayer to NPs,  $8\sqrt{9}$  outlining the different contributions to the total interaction energy.

#### 2.1 Theoretical description of NPs-lipid membrane interaction

The interaction between a NP and a lipid bilayer might lead  $\ref{199}$  NP's adhesion on the bilayer, which can be followed by partial or total engulfment by the membrane. In a well-define medium and at a given temperature, the NP docking to lip  $\ref{199}$  membranes is thermodynamically favoured if the adhesiog energy  $E_{adh}$ <0, i.e., if the attractive terms overcome the propositive ones. Considering a prototypical model of  $\ref{199}$  bioinorganic interface, with a spherical NP of radius  $\ref{199}$  interacting with a liposomal membrane with curvature  $\ref{1/R36}$  the energetic balance between repulsive and attractive forces can be approximately described by a classical DLVO (Derjaguing Landau-Verwey-Overbeek) formalism, as in eq. (1), including only the electrical double layer ( $\ref{E^{EL}}$ ) and the London-Van dato Waals ( $\ref{E^{LW}}$ ) contributions to the total energy of adhesion:  $\ref{199}$ 

$$E_{adh} = E^{EL} + E^{LW} \tag{1}$$

Where the terms  $E^{EL}$ , derived as a combination between the linear Debye-Huckel and the Derjaguin approximations and valid for surface potentials < 25 mV, and  $E^{LW}$  are described in eq. (2) and (3), respectively<sup>9</sup>:

$$\begin{split} E^{EL} &= \frac{\epsilon R_1 R_2 (\psi_1^2 + \psi_2^2)}{4 (R_1 + R_2)} \bigg[ \frac{2 \psi_1 \psi_2}{(\psi_1^2 + \psi_2^2)} ln \bigg( \frac{1 + e^{-kd}}{1 - e^{-kd}} \bigg) \\ &\qquad \qquad + ln \big( 1 - e^{-2kd} \big) \bigg] \end{split} \tag{2}$$

$$E^{LW} = -A \frac{R_1 R_2}{6(R_1 + R_2)} \left( \frac{1}{d} - \frac{1}{(d+h)} \right) - \frac{A}{6} \ln \left( \frac{d}{d+h} \right)$$
 (3)

Where  $\psi_1^2$  and  $\psi_2^2$  are the surface potentials of the NP and the membrane, d the NP-membrane distance, k the Debye length, h the membrane's thickness, and A is the Hamaker constant. Although the DLVO theory generally succeeds in predicting the colloidal stability of hard colloids (e.g. inorganic NPs) suspended in a liquid medium, it often fails in describing the interaction of NPs with free-standing bilayers; a more comprehensive description for  $E_{adh}$  includes additional repulsive hydration forces establishing at short NPs-membrane distances, as well as hydrophobic NP-lipid chain attraction (the interested reader is referred to a recent report for the analytical expression of the these two supplementary energetic contributions<sup>9</sup>).

Once the NP is adsorbed onto the lipid surface (i.e.  $E_{adh}$ <0), the elastic properties of the membrane comes into play, and their balance with the adhesion forces determines the degree of

52

53

54

60

61

62

63

membrane deformation and NP's wrapping. Specifically, the 2 energetic gain due to the adhesion forces is maximized 49 3 increasing the contact area between the NP and the lip 500 membrane, according to equation (4)10:

$$E_{adh} = -w \int_{0}^{Sad} dS \qquad (4)$$

with w adhesion energy per unit area and  $S_{ad}$  the contact area. between the membrane and the NP. On the other side, the NP.  $\frac{56}{5}$ wrapping is associated with a free energy cost of imposing membrane deformation ( $E_{\rm el}$ ), which is expressed through the 59 Cahnam-Helfrich-Evans formalism<sup>10</sup>:

11 
$$E_{el} = \int_{0}^{S} dS [\gamma + 2k_{B}(H - c_{0})^{2} + \bar{k}K]$$
 (5)

12 with S the entire interfacial area.

41

As we can see from eq. (5), the deformation penalty depends both on the membrane's topology, through the mean H and Gaussian K curvatures, and on the interface's mechanical and elastic properties, expressed by the surface tension  $\gamma$ , bending rigidity  $k_B$ , spontaneous curvature  $c_0$  and Gaussian saddle splay modulus  $\overline{k}$ . It is the fine interplay between  $E_{adh}$  and  $E_{el}$  that ultimately defines the NP-membrane arrangement which minimizes the system's energy, ranging from complete unwrapped NPs (e.g. for small nanoparticles and/or weakly interacting with the lipid phase), to larger and/or strongly adhered nano-objects, eventually fully engulfed by the lipid membrane (See Figure 1A).

Based on the above treatment, we will now discuss the several NPs- and membrane-related factors implicated in this interaction, with particular attention on size, shape, surfac coating of NPs and NP-NP correlations; on the "membrang side, we will take into account some selected physicochemical 81 properties and the zero or non-zero curvature.

Depending on their size, the adhesion of NPs on a targe planar membrane can result in different effects: small NPs can 84 either remain embedded in the lipid membrane or directive diffuse through it; relatively larger particles (>10 nm) can I wrapped by the membrane<sup>11</sup>. This process is finely controlle by the energetic balance between the adhesion forces (eq.  $(48)^{\circ}_{88}$ and the membrane's elastic deformation penalty (eq.(5)) leading to an optimal size for wrapping, as first observed by Roiter et al. 12. In particular, two characteristic NPs' limiting radii for a successful engulfment by lipid membranes can theoretically predicted<sup>10</sup>: 93

$$R_{kw} = \sqrt{\frac{2k_b}{E_{adh}}} \qquad (6)$$

43 
$$R_{k\gamma} = \sqrt{\frac{2k_b}{E_{adh} - \gamma}} \qquad (7) \qquad \begin{array}{c} 96 \\ 97 \\ 98 \\ 99 \\ 100 \end{array}$$

Within the bending-dominated regime (i.e. for relatively small 45 membrane's deformation), the membrane tension can 1/092 46 neglected, and the wrapping process is mainly controlled by the competition between membrane's bending and NP's adhesion

strength, defining a critical radius  $R_{\rm kw}.$  NPs with  $R < R_{\rm kw}$ remain unwrapped, while larger NPs  $(R > R_{kw})$  are fully engulfed inside the lipid scaffold. For larger membrane's deformation (e.g. induced by micron-sized particles), a characteristic length scale  $\lambda = (2k_b/\gamma)^{1/2}$ , which depends solely on membrane's properties, marks the crossover from the bending-dominated to the stretching-dominated regime<sup>9,13</sup> (Figure 1 B), where the γ-dependent wrapping extent gradually increases with NP's size. The full engulfment is reached for a second crossover NP's radius  $R_{ky}$  (eq. (7)), representing a larger NP's limiting size, which is required for the internalization in the case of finite tension-membranes.

#### 2.2 Key NPs features in the interaction with lipid membranes

Concerning NPs shape, the increase of the surface area/volume ratio from spherical to asymmetrical NPs (e.g. nanorods, nanoprisms and nanocubes), maximizes the surface available for absorption onto lipid membranes (eq. (4)), enhancing their reactivity<sup>14</sup>; on the other side, the local particle's surface curvature is predicted to increase the energy barrier associated to membrane's deformation, stabilizing partial-wrapping states also for tensionless membranes<sup>9,10</sup>. Moreover, the interaction of asymmetric NPs with target lipid membranes can lead to preferential wrapping orientations, to minimize the energy cost for wrapping<sup>15,16</sup> (See Figure 1C). Eventually, the asymmetric shape of NPs can drive peculiar selfassembly phenomena at the nano-bio interface, some examples of which are given in Section 3.

The NPs surface functionalization represents another important factor affecting the interaction with membranes; in particular, NPs surface charge has a major impact on adhesion both onto charged and zwitterionic interfaces, setting the sign and magnitude of the electrostatic long-range contribution of (eq.1)3,17-21. Furthermore, the adhesion of charged NPs to a target membrane is also associated to an entropic gain, deriving from the release of small counterions from the NP surface<sup>22</sup> (See Figure 1D). On the other side, the presence of polymeric steric stabilizers on the NPs surface, like for PEGylated particles, often decreases the adhesion energy; this effect can be understood considering the mobility loss experienced by the polymer chains approaching the lipid surface, which entails a considerable entropic penalty for membrane adhesion. Moreover, NPs' surface functionalization determines their polarity, which is key in controlling their spontaneous localization when challenging a free-standing lipid membrane: generally, hydrophilic nanomaterials with size larger than 10 nm reside at the membrane surface, with the possibility to be partially or fully wrapped by the membrane. Conversely, depending on their hydrophobicity<sup>23</sup>, small particles can either spontaneously cross<sup>24,25</sup> or be entrapped<sup>24</sup> within the lipid membrane, provoking an alteration of the bilayer's frustration packing energy<sup>26-31</sup>.

Eventually, interparticle forces between different membranebound NPs may originate cooperative phenomena, ultimately leading to the simultaneous wrapping and engulfment of

94

95

58

multiple NPs (see Figure 1D), which will be discussed in detail 56 section 3.

#### 2.3 Key membrane features in the interaction with NPs

Membrane-related characteristics have a crucial role in the interaction with NPs. In particular, the composition of lipid bilayers determines specific physico-chemical, viscoelastic and thermodynamic properties of relevance in the interaction with NPs. Membrane's surface potential, determined by the percentage of non-ionic, anionic and cationic lipids, strongly affects the electrostatic contribution to NPs adhesion (eq. 1)4 while the presence of specific components (e.g. cholestered)5 and their relative abundance, give rise to characteristics behaviours, which will be extensively discussed in section 3. 67

Equally important, the molecular geometry of the membrane's components determines the equilibrium arrangement of lipids within the bilayer. The molecular packing represents the main factor affecting both the physical state and the overall topological curvature of membranes, which are two prominent determinants in the interactions with nanomaterials.

In particular, the interactions at the nano-lipid interface  $\dot{j}$ extremely affected by the gel-liquid crystalline phase behaviour of lipid membranes: by increasing temperature, lipid bilayer,  $\frac{1}{6}$ undergo a main phase transition from the so-called "gel state"  $\frac{1}{7}$  $(L_B)$ , where hydrocarbon chains are tightly packed and almost locked in place, to a "fluid state" (L\_ $\alpha$ ), where lipids freely diffuse  $\bar{\rho}$ within the 2D membrane's plane. The "melting transition" temperature" ( $T_m$ ) is specific for a given lipid composition and determines the elastic response of membranes at a given temperature. In particular, gel phase bilayers show a reduced reactivity with nanomaterials, mostly due to the high value  $\bar{g}\bar{f}_{4}$ their bending rigidity  $(k_B)$  with respect to the fluid phase  $85^{\circ}$ which strongly hampers the membrane's bending and wrapping  $\bar{g}$ around NPs (see eq. (5-7)). On the other side, the interaction  $\bar{5}$ with NPs, which can proceed through polar headgroups (hydrophilic NPs) or hydrophobic chains (hydrophobic NP $\S_0^{-}$ might affect the lipid molecular packing, leading to micro and macroscopic modifications in the membrane structure  $a \bar{p} \bar{q}_1$ thermotropic behaviour (specific examples will be provided in the following paragraphs).

As predicted from eq.5, the membrane's topology plays a crucial role in its elastic response to NP's induced deformations. Although lipid membranes are generally visualized as flat bilayers (H and G in eq. (5) equal to zero), both biomembranes and synthetic lipid assemblies may fold into more organized non-lamellar bilayered structures<sup>32</sup>. The interaction of nanomaterials with such non-lamellar structures may have a noteworthy relevance both for biomimetic and technological applications<sup>33,34</sup>, (as discussed in details in the following paragraphs)while it remains, to date, a highly unexplored research area.

Differently from planar membranes, curved membranes are defined by positive (direct phases) or negative (inverse phases) mean curvature (H) and non-zero Gaussian curvature  $(K)^{35}$  in

each point of their surface, with H and G described by eq. 8 and 9, respectively:

$$H = \frac{1}{2}(c_1 + c_2)$$
 (8)

$$K = c_1 c_2 \tag{9}$$

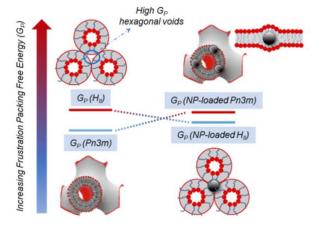

with  $c_1$  and  $c_2$  minimum and maximum values of curvature at a specific point of membrane surface.

The non-zero values of H and K lead, as predicted from eq. (5), to a modification of their Helfrich energy and elastic response towards externally induced deformations (e.g. NPs' wrapping) with respect to the case of lamellar membranes. Moreover, different topologies are associated with a frustration packing free energy ( $E_P$ ), which varies according to eq. (10)<sup>36</sup>:

$$E_P = k(l - l_r)^2$$
 (10)

with k stretching rigidity of lipid chains, l and l<sub>r</sub> hydrophobic chain extension in the stretched and relaxed state, respectively. Phase transitions between different geometries, including changes in both elastic and frustration packing energies, have high biological relevance, sharing similar energy barriers and molecular re-arrangements with membrane fusion processes<sup>37</sup>. Several recent studies, which will be addressed in section 4, demonstrated that both hydrophilic and hydrophobic NPs can promote phase transitions between model mesophases with different geometry<sup>26,27,34,37-41</sup>, lowering the energy barrier required to switch from low to high curvature phases. One of the first attempts to elucidate this effect is represented by recent works<sup>26,42</sup>, where the transition temperature from cubic to hexagonal phases in monoolein liquid crystals is demonstrated to be finely controlled by inclusion of hydrophobic iron oxide NPs (see section 4). This behaviour was explained by combining the Helfrich theory in eq. (5) with geometrical considerations: NPs increase the frustration packing energy of the cubic phase (eq. (10)), while they have a milder effect on the hexagonal arrangement, by inserting into its hydrophobic voids (See Figure 2).

In the framework of this theoretical description, in recent years the interaction of NPs with lipid membranes has been

**Figure 2 Effects of NPs on lipid mesophases architectures.** Illustrative scheme of the NP-induced modification of the Frustration Packing Energy of both cubic and hexagonal mesophases.

In section 3 we will review the interaction of NPs wi67 synthetic lipid bilayers, taken as simplified models of re68 plasma membranes: in line with section 2, we will consider th69 main physicochemical factors, either related to NPs or to th70 lipid membrane, affecting the interaction under simplified1 conditions. We will provide relevant examples from the rece72 literature, highlighting the connections, whenever they a78 relevant, between the findings on cell models and the *in vitro*/74 vivo observations.

# 3. NPs/biomembrane Interactions: from biophysical studies of nano-bio interfaces to applications

One of the main issues limiting the development 84nanomedicine and the translation of engineered nanomaterials2 into medical practice, is the poor understanding of their fate 83 biological fluids, and their short-term and long-term possible adverse cytotoxic effects<sup>37,43–49</sup>. Recent reports have al highlighted how nanodevices designed for nanomedicin applications, whose functionality/efficiency has been proved 87 the lab-scale, completely fail reaching their biological targe once in a living organism<sup>50</sup>. As a matter of fact, to date, nan<sup>89</sup> therapeutics available on the market are mainly limited  $\mathfrak{B}$ polymeric- and liposomal-based formulations<sup>51,52</sup>, while, apa<sup>94</sup> from some iron oxide NPs-based formulations, inorganic and metallic particles are at research stage or in clinical trials 93 With the ultimate aim to fill the gap between the design/synthesis/development of nanomaterials f**9**/5 nanomedicine and their end use application, it is necessary to improve our fundamental knowledge on the interaction g nanomaterials with biologically relevant interfaces, particular  $\bar{\psi}_8$ cell membranes.

Plasma membrane, primarily composed by a mixed phospholipid bilayer with embedded proteins, protects the 46½ interior and ensures its communication with the externed environment. The mechanisms of cell signalling processes 403 extremely complex and length scale-dependent, with smaller molecules spontaneously crossing the lipid barrier and larges and/or polar molecules harnessing protein-mediates transportations across the membrane 13. The nanoscale, shaller by engineered particles and biologically relevants

macromolecules (i.e., DNA, viruses, surface proteins), is mostly associated with endocytic pathways, where the internalisation of nano-objects is generally controlled by the membrane through specific receptor-protein binding for the case of biological species<sup>54,55</sup>. However, it has been demonstrated that synthetic NPs can be wrapped and internalized by both model and real cell membranes in the absence of any receptor-mediated interaction<sup>43,55,56</sup>, under exclusive control of non-specific interactions taking place at the nano-bio interface, and membrane's elasticity.

In this context, synthetic lipid membranes (together with more complex systems, as organ-on-a-chip and 3D cells arrays, mimicking an entire tissue<sup>57</sup>), are interesting biomimetic systems, which, by mimicking the main structural unit of plasma membranes, allow investigating phenomena at the nano-bio interface in simplified and highly controlled conditions<sup>44,45,58</sup>.

In recent years, both experimental and theoretical studies have addressed the interaction of NPs with synthetic lipid membranes, aimed at establishing clear connections between the results in simplified model systems and what observed in real cells, in order to enabling predictive strategies for the design of evermore efficient and non-toxic nanomaterials for nanomedicine.

In the following sections recent relevant studies on NPssynthetic lipid membranes interactions, together with their implications for the understanding of real nano-bio interfaces, will be revised, particularly focusing on: the effect of NPs coating (surface charge, exchangeability of the ligand, steric hindrance of the coating, impact of the protein corona) (3.1); the effect of NPs size and shape (with particular interest on the relevance of NPs clusterization in cell uptake) (3.2); the effect of NPs adhesion on the composition, integrity and viscoelastic properties of the target membrane (3.3). In addition, the interaction of inorganic NPs and lipid membranes has been exploited for analytical purposes, in order to label/signal/probe selected properties of cells or lipid assemblies in complex biological media, both exploiting specific and non-specific interactions of NPs with the target membranes. This latter research field will be reviewed in section 3.4.

#### 3.1 Biophysics of nano-bio interfaces: NPs coating

#### 3.1.1 NPs surface charge

The intrinsic characteristics of NPs (i.e., core composition, size, shape) often have a secondary impact on the interaction with a target lipid membrane, which is primarily mediated by the ligands coating the NP's surface: the surface characteristics of NPs determine polarity and interfacial properties, directly involved in the electrostatic and London-Van der Waals contributions to NPs' adhesion to a lipid interface (see paragraph 2.1 for the theoretical background). The interaction of NPs with target membranes is primarily affect by the charge of both components (see equation 2). In order to closely resemble real plasma membranes, most of the employed model bilayers in biomimetics are characterized by a zwitterionic or slightly anionic nature. Therefore, negatively charged NPs tend to be electrostatically repelled from the

membrane, undergoing to weaker interactions with respect 168 cationic ones: remarkably, this is also observed for real call  $\!\theta\!$ membranes, where the uptake is generally much lower falo anionic NPs than for cationic ones<sup>59-61</sup>. However, the situation 21 of real cells is complicated by the presence of other interaction 2pathways of specific nature, representing an alternative wi23 respect to non-specific forces. Several studies have highlight 24 that nonionic, anionic and cationic NPs of similar sizes under 265 different internalization routes, from clathrin- or caveola 26mediated endocytosis to non-endocytic pathways, like passi29 diffusion<sup>62,63</sup>. Even if characterized by limited interaction 28 capability, yet anionic NPs are attractive for biomedic 29 applications, due to limited adverse cytotoxic effects. **30** addition, despite the dominantly repulsive electrostatic forces several reports have shown successful internalization of anionic NPs, as silica or Gold NPs (AuNPs)<sup>63–65</sup>. Conversely, cationic NBs

2

y (nm)

membranes: it has been shown that cationic NPs adhere and clusterize onto synthetic target membranes, extract lipids from the membrane, ultimately provoking localized membrane disruption or integrity loss<sup>22,66,67</sup>. In line with this findings, they are often characterized by limited stability in biological media and, above all, relevant toxic effects on real cells<sup>13,68,69</sup>. Recently, Lee et al.<sup>70</sup> hypothesized, by means of a systematic study using a charge library of modified AuNPs, that the magnitude of the positive charge is not the sole factor determining the extent of interaction with target membranes and, thereby cytotoxicity. They conclude that spatial proximity of positively charged functional groups within a hydrophobic moiety is a common characteristic of toxic gold colloids.

#### 3.1.2 NPs coated with steric stabilizers

A common strategy to increase the colloidal stability of NPs in biological media consists in the passivation of NPs with bulky ligands, to endow them with steric stabilization. This kind of coating also improves the pharmacokinetic properties of NPs: For instance, it is well known that PEGylation prevents opsonisation, improving the circulation time of the nanomaterial. This stealth effect of PEG in preventing opsonisation depends on its steric hindrance: it has been shown that both NPs uptake and circulation time depend on the molecular weight of PEG coating the NPs<sup>71</sup>. Moreover, thanks to molecular dynamic simulations, Lin et al. 72 elucidated the effect of both the grafting density and polymer's chain length on the shielding ability of PEG layers bounded to gold NPs of varying size. Similar examples of steric stabilization of NPs have recently been proposed by Jiang and co-workers, who have employed poly(zwitterionic)protein functionalization (for instance poly(carboxybetaine)) to improve pharmacokinetic properties of NPs<sup>73,74</sup>, while other examples of polyzwitterionic coatings are poly(acrylic acid) derivatives, poly(maleic anhydride-alt-1alkene) derivatives or poly(sulfobetaine) derivatives, which offer several advantages over PEGylation (see as a reference the Review from Garcia et al.73).

PEGylation or steric stabilization affects the interaction of NPs with synthetic target membranes, with possible implications also at the real membranes' level. Indeed, the use of steric stabilizers, like PEG, is theoretically predicted to decrease the adhesion of NPs to lipid membranes, due to the high entropic loss associated to the adsorption process (see paragraph 2).

Through large scale molecular dynamic simulations, In a recent study<sup>75</sup>, Gal and coworkers extensively characterized the interaction of PEGylated SPIONs of different size with both synthetic membranes of different composition and real cancer and kidney cells. In the frame of classic DLVO theory (paragraph 2), they presented a direct comparison of NP-synthetic and real membrane interactions, linking weak NP adsorption to anionic lipid membranes, due to NP-bilayer electrostatic interactions, with eukaryote cell uptake, without membrane penetration. Moreover, they showed that the NP-membrane electrostatic

(C)

77

78

2 and NP size, which they correlated with low cell uptake and n58 3 cytotoxicity in two cell lines. 4 A common strategy to circumvent the poor ability of steri60 5 stabilized NPs to interact with cells via non-specific interaction 19.7 6 limiting their cell uptake and therapeutic/diagnostic efficiency? is to exploit exploiting NP-membrane specific interaction § 3 7 which are available for the case of real plasma membrane \$4. 8 endowing NPs surface with targeting moieties, might result in 9 promoting the effective docking of NPs on cell membranes and 10 improving the successful achievement of their biological target 11 For instance, in a proof-of-concept study it was shown that 12

attraction is suppressed by increasing PEG molecular weig 67

adding biotin or streptavidin moieties allows specific binding \( \frac{7}{6} \) polymer-coated NPs to beads carrying the complementary unit \( \frac{7}{6} \); Kaaki et al. \( \frac{77}{7} \) highlighted the efficient targeting of humary breast carcinoma cells by folic acid-conjugated iron oxide NPs with a PEG coating; however, partially contradictory.

resultswere obtained by Krais et al. on similar system, where 775

19 folate-dependent targeting was highlighted 78

#### 3.1.3 NPs coating with exchangeable ligands

The binding mode and strength between the NPs and the coating agent determine both single NP-membrane interactio and collective NP-NP interactions at the nano-bio interface1 physisorbed ligands, which can be easily displaced from the NP's surface through ligand-exchange, are associated enhanced reactivity of NPs, which can be considered &4 "naked". Recently, hydrophobic physisorbed ligands, i.e. ole 5 acid/oleylamine coatings on iron oxide NPs, have be&6 associated to small NPs' pearl-necklace aggregation inside7 monoolein bilayers<sup>26</sup>. Moreover it has been shown th**88** hydrophilic weakly absorbed ligands on the surface of AuN®9 can promote peculiar aggregation phenomena occurring on the lipid membrane<sup>18,19</sup>, which are particularly significative also f**9**1 the case of repulsive NPs/membrane electrostatic interactio 82 (e.g. between negatively charged gold NPs and slightly anion 93 synthetic free-standing bilayers). Moreover, weakly bour 94 physisorbed ligand onto the NPs surface can be easily replaces with other molecules establishing covalent or stronger no96 specific interaction with the bare NPs surface: remarkably, it h957 been recently demonstrated by Wang et al<sup>79</sup>, that weak ligand 98 as citrate and short DNA fragments onto the gold surface, capa be effectively replaced with lipid components of 100 membranes, resulting in unique interfacial phenomena. Inde**£61** when ligand exchange processes occur at the interface, 1002 might aggregate into ordered monolayers on the lipos membrane, which might affect membrane integrity and 104 internalization efficiency and pathway. 105

#### 3.1.4 Protein corona coating of NPs

An interesting aspect is the functionalization of NPs surf**108** with the so-called protein corona<sup>14,55,80,81</sup>. From the pioneer**109** studies of K. Dawson<sup>82–84</sup> and coauthors, it has b**1410** progressively established that NPs in biological fluids **141** spontaneously covered by a self-assembled layer of proteins **141** inner non-exchangeable layer and an external exchangeable

one), which determines a "biological identity" of the NPs and, ultimately, their ability to interact with cells 44,80,85,86. The composition of the protein corona depends on the nature of NPs core, on their shape and on their surface coating. In particular, the surface charge of NPs also affects the adhesion of biomolecules present in biological media, modifying the protein corona, in terms of composition and orientation<sup>62,87,88</sup>. It has also been highlighted that during NPs internalization, the tendency of corona proteins is, at least partially, to remain attached to NPs surface83,89,90. Since proteins are generally characterized by significant steric hindrance and amphiphilic nature, they specifically mediate the interaction of the NPs with plasma membranes. In this context, it has been highlighted that slight physicochemical modifications of the proteins modify their binding and orientation on NPs, strongly affecting the biological uptake of NPs<sup>91</sup>. Recently, the controlled formation of the protein corona has been exploited both for application purposes (e.g., for applications in cancer vaccines<sup>92</sup>) and also to control in a predictable way the protein-corona-mediated interaction of NPs with cell membranes. For instance, preincubation of NPs with serum has been exploited to prevent NPs aggregation in biological media, improve their cell uptake and decrease their cytotoxic effects<sup>69</sup>. The comprehension, control and exploitation of protein corona formation is therefore a key milestone in determining and predicting NPs fate in living organisms.

#### 3.2 Biophysics of nano-bio interfaces: NPs size and shape

As discussed in section 2, when a NP adheres to a planar lipid membrane, it locally imposes a curvature modification, which depends on the size of NPs and on the viscoelastic properties of the membrane (equation 5), which eventually controls the occurrence and extent of NPs wrapping by the membrane; therefore, NPs size also determines the response of the bilayer to its adhesion and, ultimately, the effects on the target membrane and the internalization pathway. NPs with size comparable or smaller than the lipid bilayer thickness can either be entrapped within the membrane<sup>30</sup> or translocate across the lipid bilayer by diffusing through<sup>25,93,94</sup> or by opening pores in the membrane<sup>95</sup>, which is normally associated to a high cytotoxicity in vivo<sup>56,96</sup>. On the contrary, wrapping represents the dominant mechanism for larger particles (>10 nm) interacting with bilayers, which is associated to their entrance into cells in living organisms<sup>11</sup>. Often, depending on NPs size, adhesion to a target membrane might result in the NPs clusterization: indeed, under specific conditions, membranes actively drive the self-assembly of adsorbed NPs, as a result of the tendency of the membrane to minimize the NP-induced deformation and its associated elastic cost (eq. 5)97. As a result, small-sized NPs have been observed to preferentially interact with membranes as clusters<sup>67,98</sup>, while fluid membranes have been theoretically predicted to mediate the asymmetric aggregation of spherical nanoparticles onto lipid surface<sup>99</sup>. This aspect is particularly significant for medical application of nanomaterials, since NPs uptake in model and real membranes is often preceded by aggregation at the nano-bio interface<sup>11</sup>.In addition, mathematical models and molecular dynamic simulations have revealed that membrane-induced interactions between bound particles can lead

106

to collective NPs wrapping and internalization: in particular, Zhang 26 al. 100 revealed that NPs translocation proceeds in a cooperative wa/7 with a key role played by NPs quantity, while Lipowsky et al. 101. 28 showed that spherical NPs can be cooperatively wrapped in tubul 29 membrane invaginations.

23

24

25

While the effect of NP's size has been extensively investigate 31 much less is known on the impact of NP's geometry. Asymmetrica 82 shaped NPs, like nanorods, nanodisks and nanostars, are particula 3 attractive materials, due to the peculiar properties (opticals) magnetic, electronic and so on) arising from anisotropy<sup>10</sup> Depending on their shape, anisotropic NPs can efficiently interact with a target membrane and translocate across it. MD studies on the interaction of NPs of different non-spherical shapes highlighted reorientation of NPs in proximity to the target membrane,  $\frac{38}{100}$ maximize the interaction, leading to strong shape and orientational dependence on the translocation  $^{104}$  (See Figure 3A); in addition,  $^{40}$ has to be considered that, from a theoretical standpoint, it  $\frac{41}{s}$ thermodynamically more favourable for a lipid membrane to wrap 4 spherocylinder than a sphere of the same radius 105. Consistently with the theoretical predictions, non-spherical NPs, from nanostars  $\frac{44}{10}$ nanorods, are efficiently internalized by cells, in a shape and, for nanorods, aspect-ratio dependent manner. 106,107 Experimental studies on biomimetic membranes have shown that the asymmetric shape of NPs can drive peculiar self-assembly phenomena at the nano-bio interface<sup>10,37</sup>: as an example, we recently demonstrated

that gold nanorods (Au NRs) are wrapped by model and real cell membranes as end-to-end NPs' clusters<sup>67</sup>, reducing the energy penalty required for the membrane to bend around highly curved edges. The induced tension due to the adhesion of asymmetric NPs determines effects of lipid extraction, observed both on model membranes and macrophage cells, eventually provoking extensive disruption of the membrane, related to a significant *in vitro* cytotoxicity<sup>67</sup>.

#### 3.3 Biophysics of nano-bio interfaces: Membrane composition

Cell membranes are characterized by a high degree of compositional heterogeneity, typically comprising of thousands of different lipids, carbohydrates and proteins<sup>108</sup>, which is reproduced, at different complexity levels, by model membranes. The chemical composition of both synthetic and natural bilayers strongly affects their elasticity, physical state and structure, thereby determining their response towards external *stimuli*. A clear example is the recent work of Lunnoo et al.<sup>109</sup>, in which model bilayers with different compositional complexity levels correspond, as predicted by their proposed MD simulations, to diverse cellular uptake pathways of neutral 10-nm gold NPs,. Going more into details, the presence of charges on the lipid membrane emphasizes the interaction with oppositely charged particles, as expected from eq. (2)<sup>96</sup> in

75

76

section 2; however, it has been demonstrated that electrostated interactions play a major role also for neutral zwitterionic lipi 58 facing anionic and cationic NPs<sup>110,111</sup>. In addition, it has beef 9 observed that the molecular structure of membrane's lip60 components (e.g. saturation degree of hydrophobic chain 6)1 represents another factor to take into account, affecting the 2 penetration level of NPs inside the lipid region 112. Furthermor 63 cholesterol, one of the most abundant sterols in real lip64 membranes, deeply affects the structure and fluidity of lip  $\mathbf{6}\mathbf{5}$ bilayers; moreover, it is involved in the formation of lip666 rafts<sup>113</sup>, which, for reasons not yet fully understood, increasor the extent of NPs-membrane interactions: as an examples Melby et al.<sup>114</sup> showed that positively charged AuNPs bind significantly more to phase-segregated bilayers with respect to single phase ones, while Hartono et al. 115 associated high **2**0 cholesterol concentrations in lipid monolayers to strong ₹1 interactions with protein-coated AuNPs, leading to monolay ₹2 disruption. 73

#### 3.4 Biophysics of nano-bio interfaces: NPs-induced membrane modifications

The self-assembled nature and lateral fluidity of plasma membranes determine a capability of the membrane 768 reorganize and locally and transiently restructure itself 79 response to biological stimuli. This is the case considering f80 instance the transient formation of lipid rafts, in relationsh [91] with cell trafficking phenomena, or considering ligand(drug)2 receptor interactions at cell surface, triggering completo biological responses. In this respect, several studies have addressed the effects on NPs on a target lipid membrane upon adhesion. A first effect is the induced lateral phase separation within the target membrane: theoretical studies on cationic  $N\breve{g}$ have highlighted their tendency to recruit anionic lipids in the adhesion area, determining the formation of phase separated patches within the membrane (See Figure 3B).<sup>22,116</sup> The old alteration of membrane's phase behaviour induced by NPs is a growing research topic, with several studies contributing building-up a complex picture, which is far from being understood. As an example, the group of Granick<sup>111</sup> reported<sup>93</sup> different effect of silica anionic<sup>117</sup> and cationic particles of phospholipid membranes, with negative NPs inducing gelation and positive ones provoking fluidification. Considering anion 96 silica NPs with different size, the group of Zhang et al. 118 repc 97 that the gelation, or "freeze effect" on DOPC giant unilamell98 vesicles (GUV) is promoted by small NPs (18 nm), while lar 99 particles (>78 nm) promote membrane wrapping. 1500 significantly decreasing the phospholipid lateral mobility, three release of tension through stress-induced fracture mechanics results in a microsize hole in the GUVs after interaction. On the other hand, membrane wrapping leads to increased lipid lateral mobility and the eventual collapse of the vesicles. Von White et al.<sup>30</sup> registered an increase in the gel-to-liquid crystalline transition temperature of synthetic lipid vesicles 107 induced by the embedding of hydrophobic AuNPs, while Chakraborty at al. 119 reported the opposite effect, phospholipid bilayer softening, due to hydrophobic AuNPS

inclusions; on the other side, recent studies demonstrated that hydrophilic (negatively and positively charged) AuNPs induce the same effect at the nanoscale, promoting the formation of rigidified lipid domains around the NPs' surface, characterized by a reduced lipid motion with respect to the surrounding fluid phase<sup>21,22,120,121</sup>. Both the induced lateral phase separation on a target membrane and the induced modification of the viscoelastic properties might represent, at the biological level, both biologically relevant signals, activating cell entry pathways, or else might be of relevance in inducing cytotoxic effects (Figure 3 C).

#### 3.5 Analytical Applications of NP-lipid membrane interactions

An interesting research topic related to the interaction of NPs with lipid membranes is its exploitation for analytical purposes. Inorganic NPs are characterized by peculiar properties, making them suitable to provide a readout, generally an optical (fluorescence, scattering) or magnetic signal, which can provide qualitative or quantitative information of different nature. Knowles and coworkers have shown how the spontaneous formation of a supported lipid bilayer on a polystyrene NPs patterned support can be exploited to form membrane regions of high curvature, due to NPs partial wrapping: these areas spontaneously accumulate specific, single-tailed lipids, of higher spontaneous curvature, and can be exploited to monitor the interaction of biomolecules with membrane areas of high curvature<sup>122</sup>; Liu et al.<sup>123</sup> have formed AuNPs patterned surfaces (See Figure 4B), for mechanical tension measurements in living cells. Cho and coworkers<sup>124</sup> have designed a nanoplasmonic biosensor made of an array of gold, silicon oxide or titanium oxide nanodisks coated with different lipid architectures (See Figure 4C), vesicles arrays, supported lipid bilayers or a coexistence of the two systems, spontaneously formed due to different pathways of interaction between lipid vesicles and the nanodisks of different material: localized surface plasmon resonance experiments detecting a membrane-active peptide highlighted a strong dependence of the interaction between the peptide and the lipid bilayer, depending on the architecture of the lipid scaffold. Limaj et al. 125 designed an infrared biosensor to monitor the molecular behaviour and dynamics of lipid membranes, based on the adsorption of lipid vesicles on an engineered substrate functionalized with gold nanoantennas for surface enhanced infrared absorption (SEIRA) experiments. Suga et al.<sup>126</sup> exploited the interaction of hydrophobic (dodecanthiol-modified) AuNPs with phospholipids and phospholipid assemblies, to investigate the behavior of lipid membranes at a molecular length-scale through Surface-Enhanced Raman Spectroscopy (SERS). The same technique is employed by Bhowmik et al. 127, who exploit the formation of a lipid coating wrapping Silver NPs (AgNPs) to probe through SERS the molecular behavior of protein oligomers spontaneously binding to the lipid coating of AgNPs (this example will be also discussed in section 5) (See Figure 4A). Recently, we have shown that synthetic Giant Unilamellar Vesicles of POPC promote the

69

70

clusterization of Turkevich-Frens citrated AuNPs on the lip55 membrane itself  $^{121}$ . This phenomenon, which has be -662 3 investigated by other groups, provokes a modification of the 4 plasmon resonance peak of AuNPs, which is visible also 58 5 naked eyes as a colour change of AuNPs dispersion from red 6 blue<sup>17,128</sup>. Interestingly, this effect is similarly observed when the same AuNPs challenge biogenic natural vesicles 7 (extracellular vesicles, EVs)<sup>120,129</sup> and it has been found as 8 9 strongly dependent on the concentration of EVs and on the 10 presence of protein contaminant. Therefore, an analytical method for EVs has been developed, offering an easy and fa assay for purity and concentration of EVs, based on nonspecific interactions between NPs and lipid membranes 130-132 (See 13 14 Figure 4D).

49

50

51

52

53

Depending on their molecular structure and on the environmental conditions, lipids in water self-assemble in 55 very diverse structures, from simple planar lamellar phases, 36 vesicles, to non-lamellar curved bilayered structures (as cub) mesophases) arrangements (as inverse monolayered tubula arrangements (as inverse hexagonal mesophases). The 59 different structural arrangements, formed by spontaneous se 50 assembly, can host hydrophilic-coated NPs in the aqueo 12 regions and/or hydrophobic-coated NPs in the hydrophob 12 domains.

NPs can spontaneously insert in the lipid scaffolds, due to no**8**4 specific forces, such as hydrophobic, electrostatic and Van d**8**5 Waals interactions (see paragraph 2), thus representing a fac**8**6 approach to obtain a complex hybrid material with controll**8**7 structure and defined properties arising from the combinati**8**8 of lipid and NP building blocks.

In particular, the inclusion of NPs in lipid scaffolds allows obtaining materials with specific interesting features: (i) the biocompatibility of the lipid scaffold (dependent on igs2 composition) allows envisioning the employment of thesa hybrid materials for biomedical applications; (ii) the self4 organization and phase behavior of lipid mesophases 95 generally responsive to the inclusion of external species, 196 temperature, hydration and other experimental conditions7 which variations can be triggered, in a space and time controllegs manner, by external stimuli applied to the NPs included in the lipid scaffold (e.g., magnetoliposomes). This is a very interest 100 opportunity for several applications, for instance 102 development of drug delivery systems (DDS) with control of release abilities; (iii) the inclusion and confinement of NP103 lipid scaffolds has the effect to locally concentrate them and to impose them a spatial arrangement. This localized 1955 concentration increase might be of relevance to enhance NP96 related signals (for instance optical or MRI readout 107 diagnostic applications); in addition, the concentration, together with a defined structural architectures might induce peculiar collective properties of NPs, arising from the lipid scaffold-imposed arrangement.

In the following sections we will revise this topic, in particular focusing on the effect of NPs inclusion on the overall features of lipid/NP hybrid materials (4.1), and, subsequently, on applicative examples of NP/lipid hybrids made of NPs included in lamellar (4.2) and non-lamellar (4.3) lipid mesophases.

### 4.1 NPs inclusion in Lipid Scaffolds: Structural and Physicochemical Effects

The hydrophobic or hydrophilic nature of NPs, which depends on the coating agent, is the key factor in determining the localization in a lipid assembly. Both lamellar (i.e. liposomes, Giant Unilamellar Vesicles) and non-lamellar (i.e. cubic or hexagonal structures) lipid assemblies are characterized by the coexistence of hydrophobic and hydrophilic domains, capable to host NPs of different nature. In all NPs-lipid hybrids, the inclusion of NPs in the lipid architecture affects the physicochemical and structural properties of the lipid scaffold, modifying for instance the fluidity and bending properties of the membrane, its local thickness, the phase behavior and the viscoelastic properties. For instance, it has been shown that the inclusion of hydrophobic superparamagnetic iron oxide NPs (SPIONs) in the lipid membrane of DPPC liposomes increases the average thickness of the membrane and modifies the orientation of the phospholipid chains, affecting the lipid melting temperature 136,137. In addition, depending on the chemical nature of hydrophobic NPs embedded in a lipid bilayer, they can either stabilize or destabilize the lipid ordering, causing opposite effects on the phase behavior of the lipid scaffold; it has been shown that 4 and 5.7 nm AgNPs<sup>31</sup> increase the fluidity of the membrane, reducing the degree of ordering of the lipid tails, while 5 nm maghemite NPs29 increase membrane rigidity. Finally, the inclusion of nanoparticles can also modify the final structure of the bilayer: for instance, a Cryo-TEM investigation of Chen et al. on liposomes containing hydrophobic SPIONs has highlighted the formation of liposomes' aggregates with SPIONs clusters acting as bridging agents (See Figure 5A-B). These local perturbations highlight that some structural rearrangement of a planar lipid membrane can be possible preserving the overall lipid mesophase architecture; however, as reported by Briscoe et al.40, significant amounts of NPs inclusion might promote, for defined lipid compositions and specific temperature/pressure conditions, a phase transition from lamellar to hexagonal mesophases. In general, as already pointed out in section 2, the inclusion of NPs in a planar bilayer increases the frustration packing energy of the lipid molecules eventually promoting the re-organization in a different mesophase, characterized by a more negative curvature; the mismatch between the equilibrium curvature and the perturbed arrangement due to NP inclusion, favors the transition to a more thermodynamically stable structure.

These examples highlight how the effect of NPs on lipid membranes is variable, but possibly predictable, on the basis of minimum energy considerations; therefore, the physicochemical properties of the target lipid membrane and of the NPs to be inserted in the lipid scaffold can be tuned in order to

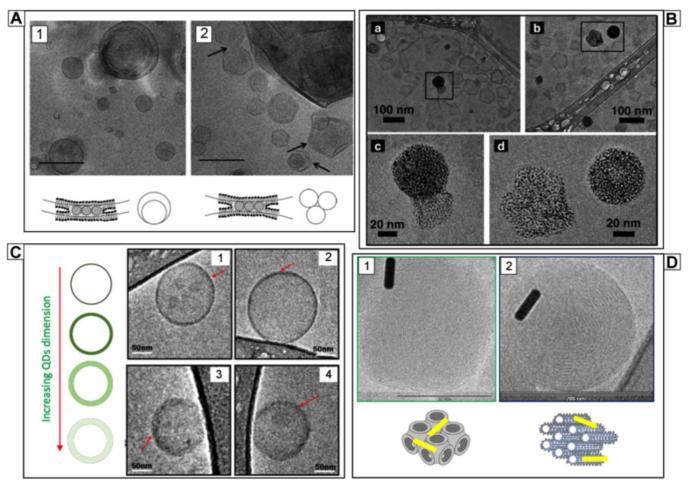

Figure 5 Cryo-Microscopies of Lamellar and Non-Lamellar Lipid membranes assembled with hydrophobic NPs. Panel (A) Cryo-TEM images highlighting the structural changes induced by hydrophobic SPIONs interacting with liposomes: on the left, TEM image showing liposomes arranged in a multiwalled configuration with SPIONs bridging; on the right, TEM image of liposomes' aggregates bridged by SPIONs clusters embedded in the bilayer. 17

Among hybrid nanostructures where NPs are included 273 lamellar assemblies, particularly relevant magnetoliposomes (MLs), where hydrophobic SPIONs are included in the lipid bilayers of lipid vesicles 138-140. The responsivity to static (SMF) and alternating magnetic fields (AMF) makes MLs good candidates in nanomedicine as DDS $^{128}$ able to release drugs confined in the lumen of liposomes in a time and space controlled manner, upon application of external stimuli<sup>142,143</sup>. Despite their potentiality, the inclusion of small NPs in the bilayer can be exploited only for drug delivery purposes, while generally, no bulk heating effect can be induced by small NPs subjected to AMFs, as shown in several studies 124: therefore, they cannot be applied in hyperthermia therapies  $\frac{35}{2}$ for the thermal ablation of cells; however, as reported by  $\underline{\underline{\mathfrak{g}}}\underline{\underline{\mathfrak{g}}}$ 

Corato et al. 145, using hydrophilic SPIONs loaded in the vesicles' lumen combined with a photosensitizer, results in a synergistic effect, observed both in vitro and in vivo, making this strategy, exploiting a multifunctional nanomaterial, very promising for therapeutic applications. Recently, MLs decorated both with hydrophobic and hydrophilic SPIONs have been shown to release on-demand hydrophilic or hydrophobic payloads, depending on the frequency and application time of an AMF. 127 Besides SPIONs, hydrophobic AuNPs were recently used146 to build-up photoresponsive and thermosensitive hybrid liposomes. In addition, multifunctional hybrid liposomes containing magneto-plasmonic nanoparticles (SPIONs@Au), merging the possibility to combine hypothermic and photothermal treatments were recently shown<sup>147,148</sup> for imageguided delivery of anti-HIV drugs to the brain: generally, the successful delivery of antiretroviral drugs to the brain is limited due to the presence of the blood-brain barrier (BBB); in this case the authors reported an enhanced BBB transmigration efficiency under AMF without its disruption; moreover, the

68

treatment of HIV virus with multifunctional liposom 537 successfully reduced the viral replication. 588 Several studies have addressed the inclusion of quantum do 599 in lipid assemblies: despite their unique optical properties, the 600 are characterized by significant acute cytotoxic effects. With the 1614 aim to realize a contrast agent for imaging applications 138,149,1892 several studies have shown that the confinement of CdSe do 653 in lipid bilayers increases their biocompatibility, which 1614 preserving their fluorescence features, making the system mo 655 suitable for biomedical applications (See Figure 5 C).

#### 4.3 Applications of NPs/Non-Lamellar Lipid Assemblies Hybrids

As anticipated in section 2, the inclusion of NPs into non lamellar lipid assemblies mostly affects the structure of the mesophase, in terms of the lattice parameter and  $\frac{1}{2}$ consequently, of the diameter of the nanochannels and amount of water contained in the lipid architecture. If the size of NPs-ja similar or smaller than the lattice parameter, NPs can be easily encapsulated in the architectures. Venugopaal et al 36 investigated the encapsulation of hydrophilic Silica NPs of 8 npg diameter in monolinolein mesophase: in this case, the NPs were too large to be encapsulated in the nanochannels (of  $\frac{3}{9}$ 3.8 nm diameter); nevertheless, the addition of NPs determined the overall dehydration of the lipid scaffold, eventually causing  ${\bf g}_1$ for high concentration, the transition of the assembly geometry to a gyroid cubic structure (Ia3d). The authors interpret this behavior considering that, since the energy cost to include the NPs in the nanochannels is extremely high (above 100  $k_BT$ ), the NPs tend to minimize their interfacial energy, aggregating along the grain boundaries of the mesophase, similarly to whreported concerning lamellar structures 151. The same authors investigated also the structural features of monolinole mesophases loaded with hydrophilic SPIONs. Upon application of a SMF, a reorganization of the lipid domains along the direction of the field 152,153 was found, highlighting how the responsiveness of SPIONs to magnetic fields can be exploited to induce structural modifications in the whole lipid mesophas 2. This effect has been applied for instance to control the release of drugs confined in the lipid mesophases<sup>152</sup> or, as the same authors reported<sup>154</sup>, for the application in optical memory storage.

The inclusion of hydrophobic NPs in non-lamellar mesophases can be easily achieved exploiting the hydrophobic interactions that spontaneously drive the NPs localization in the hydrophobic regions of the self-assembly. However, also in this case, the size of NPs is of paramount importance, to avoid the disruption of the lipid scaffold. Recently, the inclusion of hydrophobic SPIONs into 1-monoolein diamond cubic phases was reported, highlighting that the amount of included NP3, together with temperature, control the phase transition from cubic to hexagonal phase. Since this transition is accompanied by a significant dehydration of the mesophase, the structure rearrangement is accompanied by the release of most of the water content of the nanochannels. This thermoresponsive hybrid material was also found to be responsive to AMP3, representing, therefore, a promising system for the delivery of

hydrophilic drugs in a time and space-controlled manner.<sup>33</sup> Recently, it was shown that this thermotropic effect of liquid crystalline phases loaded with hydrophobic NPs is a general phenomenon, highlighted e.g. also by cubic mesophases formed of phytantriol and hydrophobic AuNPs. <sup>20</sup>

Very few examples in the literature address the inclusion of non-spherical NPs in non-lamellar lipid assemblies: Boyd et al. 155 reported on hydrophobic NRs included in phytantriol, selachyl alcohol and monoolein lipid mesophases, with the aim to buildup photo-responsive hybrid materials (See Figure 5D). The authors investigate the effect of NRs on the cubic mesophases, highlighting a slight reduction in the phase transition temperature and in the lattice parameter. Interestingly, similarly to spherical hydrophobic NPs, gold NRs shift the cubicto-hexagonal boundaries to lower temperature 156. For hexosomes of selachyl alcohol, it was shown that the lattice parameter or water volume fraction<sup>26,27</sup> are not affected by the presence of AuNRs; the authors suggest that NRs are positioned along the direction of hexosomes, but, due to their large sizes (55.5 nm in length and 16 nm in width) they are in close proximity of the lipid bilayer, without being efficiently included inside it. Nevertheless, the application of a NIR laser on the hybrid structure promoted the phase transition from cubic to hexagonal phase, similarly to what observed with the application of AMF on monoolein-SPIONs hybrids.

## 5. Surface Engineering of Inorganic NPs: Functionalization of NPs with a Lipid Coating

Recently, several research groups have addressed the functionalization of inorganic NPs or clusters of NPs with lipids to form lipid-coated NPs with a supported lipid bilayer (SLB and liposomes³). The validity of this approach is twofold: first, a lipid coating of appropriate composition might strongly improve the biocompatibility of inorganic NPs: this is particularly critical for the very toxic quantum dots. The second advantage is the increased dispersibility in body fluids and improved pharmacokinetic properties. As a matter of fact, without a proper coating, bare NPs introduced by parenteral administration, are rapidly opsonized and removed by phagocytes from the blood stream<sup>54</sup> and accumulated in liver and spleen<sup>157,158</sup>, often causing oxidative stress<sup>159,160</sup>.

Although this could be even convenient for those treatments where the desired aim is to modulate local immune responses<sup>161</sup>, it is worth considering the use of a capping agent that prevents leakage of the drug, protects the carrier from degrading enzymes, and shields them from the immune system avoiding side effects<sup>162,163</sup>. Among several potential capping systems, lipid bilayers are especially advantageous <sup>164</sup> for several reasons: (i) the escape from endosomal vesicles of the nanomaterial and successful reaching of its biological target, upon endocytic uptake, in strongly favoured in the presence of a lipid coating, improving the ability of NPs to passively permeate to the inner core of the cell<sup>165,166</sup>; (ii) the presence of a lipid coating is helpful in preventing NPs aggregation in biological environment; (iii) lipid coating is highly tuneable in

42

43

composition (for instance PEGylated lipids, to further improved nanoparticle pharmacokinetic properties<sup>167</sup>, can be eas **2**/7 incorporated, as well as cholesterol, added as a controlling 8 fluidity agent) and can be easily functionalized and designed 29 match the specific requirements of the desired application <sup>18</sup>0  $^{170}$ . As introduced in section 2, the achievement of such 3acoating depends on the size of the NP to be coated and on the viscoelastic properties of the membrane. Generally, relative 33 large NPs, imposing a low curvature to the target membran 34 can be successfully completely wrapped and coated by a lip365 membrane, while small particles need to be wrapped and coated as clusters. In the following sections we will review? the most relevant examples and applications of lipid-coate 88 inorganic nanoparticles, considering one by one the differe 39 types of nanoparticles, Silica NPs (5.1), Gold and Silver NPs (5.40) and Iron Oxide NPs (5.3). 41

Leveraging the pioneering works of Rapuano'groups<sup>171,172</sup>, over the last years several research groups have addressed the decoration of silica nanoparticles with SLBs<sup>173</sup>. Recently Mousseau et al. showed an example of fluorescent silica NPs covered by a pulmonary surfactant Curosurf®. They found that a complete SLB coverage of silica nanoparticles is obtained only through sonication, which disrupts lipid vesicles and promotes

full wrapping of the NPs. *In vitro* assays confirmed that the presence of the SLB mitigated the particle toxicity and improved internalization rates<sup>174</sup>.

Tada and co-workers tested the impact of a lipid coating (using different types of lipid bilayers) on the cytolocalization of silica NPs prepared with methylene blue, for applications in Photodynamic Therapy (PDT) <sup>175,176</sup>.

Mackowiak et al.<sup>177</sup> showed an example of mesoporous silica NPs surrounded by a cationic DOPC/DOTAP SLB with targeting ligands on the surface of the nanoconstruct and a photosensitizer molecule covalently attached to the surface of mesoporous silica NPs, for controlled and targeted drug delivery applications. In this case, the presence of the SLB coating was also aimed at improving the capability of the system to retain a drug inside the mesoporous structure of NPs before photoactivation to induce the release of the cargo.

An alternative route to obtain controlled release of drugs from lipid-coated mesoporous silica NPs, based on the use of thermoresponsive lipids, was recently presented by Zhang et al.: they combined the high drug loading capacity of mesoporous silica NPs with the thermal responsiveness of a mixture of lipids, DPPC/DSPC/Chol/DSPE-PEG2000, allowing the possibility to release on-demand the payload at hyperthermia temperature, circumventing the premature leakage at physiological temperature<sup>178</sup> (See Figure 6C).

Taking advantage of their antimicrobial properties, AgNPs have 3 been widely used in the last decades both in industrial and in 4 5 biomedical application<sup>179–181</sup>. Furthermore, due the localized surface plasmon resonance (LSPR) of AgNPs, they can 1662 7 exploited for the development of biosensors. For this purpos 63 8 Bhowmik et co-workes<sup>127</sup> developed a method to determine the 9 conformation of membrane-bound proteins: 10 conventional SERS, that requires immobilization of molecule 66 11 they exploit the spontaneous binding of proteins to lipid bilaye67 12 coated AgNPs. In this way, they probed the behavior **68** 13 membrane-attached oligomers of Amyloid-β40 (Aβ40), who 69 conformation is of relevance in Alzheimer's disease. AuNPs a 740 15 the most widely studied inorganic NPs, thanks to their facille 16 synthetic and functionalization routes, and their plasmon 72 17 properties that can be harnessed in a plethora of application 23 18 ranging from optical imaging, spectroscopy and phototherm 34 19 therapy. Du et al. formed a liposomes-AuNPs hybrid system 35 20 a vector for nucleic acids, for applications in gene therapy<sup>182</sup>. 76 England and co-workes 183,184 (See Figure F) prepared AuN \$\overline{P}\overline{S}\$ 21 22 functionalized with multiple layers (two or three) 78 23 phosphatidylcholine, alkanethiol, high density lipoprotein an 189 24 phosphatidylcholine/alkanethiol for the delivery 25 hydrophobic and hydrophilic drugs for the treatment of sol8126 tumours. By exploiting the optical properties of AuNPs, Reed 82 27 al. developed a novel hybrid for sensitive detection of protei83 28 based on apposition and aggregation of liposomes induced 184 29 Ca<sup>2+</sup> ions using Forster resonance energy transfer (FRE**8**5 30 assays<sup>185</sup> (See Figure E). Wang et al recently proposed a nov**&6** 31 approach to overcome the low delivery efficiency of plasmi&7 32 by condensing them on peptide-modified AuNPs, successive 88 33 covered with a mixture of phospholipids 186. 34

In addition to spherical NPs, liposomes-coated go 900 nanocages<sup>187</sup> (See Figure 6A-B) have been reported as possibled. nanovaccines for cancer immunotherapy: the autho92 demonstrated that the hybrid carrier exhibited enhances antitumor effects, inhibiting tumour growth in lung metasta 94 models. In addition, lipid-coated hollow gold nanoshells have been recently developed for synergistic chemotherapy and photothermal therapy for the treatment of pancrea ਸੋਂਦੇ cancer<sup>188</sup>. By taking advantage of the unique structure of hollogy gold nanoshells, the authors successfully demonstrated the c97 delivery of two drugs, one loaded in the lipid bilayer and the other one loaded in the hydrophilic interior of the nanoshell. 99 Furthermore, the possibility to extend lipid coverage to Au 🔥 🔊 has been recently explored. Recent studies have addressed 109 functionalization of Au NRs with a phospholipid bilayay composed of POPC<sup>189</sup> and, more recently, DMPC<sup>190</sup>, to increase biocompatibility and bioavailability of NRs. In addition, lipiple capped Au NRs (obtained with DPPC vesicles containing lipids with a thiol headgroup) have been demonstrated to be suitable. label-free biosensors<sup>191</sup> for the detection of lipophilic drug**g**07 aqueous solutions or lipopeptides in serum. Finally, moving too more complex architecture, Han et al<sup>192</sup> (See Figure 6bb demonstrated the possibility to use silica and phospholipids to

cover Au NRs, coupling the photothermal and thermoresponsive properties in the same nanoplatform.

#### 5.3 Lipid-coated Iron Oxide NPs

SPIONs are among the most attractive NPs for biomedical applications, ranging from applications in MRI to responsive nanocarriers for drug delivery to therapeutic applications in hyperthermia (See Figure G). Bao et al<sup>193</sup> synthesized DSPE-PEG coated SPIONs loaded with indocyanine green molecules as superparamagnetic carriers capable to easily accumulate in tumours sites and act as biodegradable nanotheranostic agents. In the emerging field of nanovaccines, the group of Ruiz-de-Angulo<sup>194</sup> presented a biocompatible multifunctional system designed to both act as delivery vehicle and radiotracer for PET/SPECT imaging: using lipid-coated magnetite nanoparticles, they efficiently included in the construct 67Ga3+ as radiotracer, plus an antigen and an adjuvant. In vivo imaging highlighted the efficient targeting capability of the system and cell uptake. Recently, the same authors presented bacteria-mimicking NPs, that is, a similar construct (i.e., lipid coated magnetite nanoparticles), coated with lipooligosaccharides, which efficiently act as adjuvants<sup>195</sup> for application in cancer vaccine field.

Enveloping a magnetic iron oxide core with a lipid shell facilitates bioconjugation, biocompatibility, and delivery, as well reported by Wang et al.<sup>19</sup>): in their work they provide a general solution for coating iron oxide and other metal oxides with a simple mixing in water, facilitating applications in biosensing, separation, and nanomedicine.

A multifunctional system for dual imaging (fluorescence and MRI) of hepatocellular carcinoma was reported by Liang et al<sup>196</sup>: through the thin film hydration method, they covered magnetite NPs previously conjugated with a NIR fluorescent dye; the lipid bilayer was decorated with a polymer targeting tumour hepatocytes, able to steer the carrier to the specific site. By flow cytometry and confocal laser scanning microscopy they assessed the specific cellular uptake, followed by *in vivo* tests on tumor-bearing mice.

#### 6. Conclusions

In this contribution we have reviewed the latest developments concerning the interaction of NPs with amphiphilic bilayers arranged in lamellar and non-lamellar mesophases.

This area is a very lively research field, where efforts are motivated by several scientific purposes. First of all, the application of nanostructured materials in the biomedical field requires a precise knowledge of the nano-bio-interface: bilayered synthetic assemblies are a very convenient and simple platform to elucidate the interactions with cell membranes and internalization of nanomedical devices. In addition, the design of smart nanostructured hybrid devices, where NPs are included in soft matter assemblies to contribute new properties and modulate their phase diagram is a very relevant and active research field. Related to this latter area is the use of lipid
