## Abstract

**Background** Immuno-oncology combinations have achieved survival benefits in patients with metastatic renal cell carcinoma (mRCC).

**Objective** The ARON-1 study (NCT05287464) was designed to globally collect real-world data on the use of immunocombinations as first-line therapy for mRCC patients.

**Patients and Methods** Patients aged  $\geq$  18 years with a cytologically and/or histologically confirmed diagnosis of mRCC treated with first-line immuno-combination therapies were retrospectively included from 47 International Institutions from 16 countries. Patients were assessed for overall survival (OS), progression-free survival (PFS), and overall clinical benefit (OCB).

**Results** A total of 729 patients were included; tumor histology was clear-cell RCC in 86% of cases; 313 patients received dual immuno-oncology (IO+IO) therapy while 416 were treated with IO-tyrosine kinase inhibitor (IO+TKI) combinations. In the overall study population, the median OS and PFS were 36.5 and 15.0 months, respectively. The median OS was longer with IO+TKI compared with IO+IO therapy in the 616 patients with intermediate/poor International mRCC Database Consortium (IMDC) risk criteria (55.7 vs 29.7 months; p = 0.045). OCB was 84% for IO+TKI and 72% for IO+IO combination (p < 0.001).

**Conclusions** Our study may suggest that immuno-oncology combinations are effective as first-line therapy in the mRCC real-world context, showing outcome differences between IO + IO and IO + TKI combinations in mRCC subpopulations. **Clinical Trial Registration** NCT05287464.

# **Key Points**

We showed real-world data on the use of immuno-combinations in patients with metastatic renal cell carcinoma.

Our data seem to suggest a better outcome for patients treated with immunotherapy plus anti-angiogenic agents compared with dual immunotherapies.

### 1 Introduction

Renal cell carcinoma (RCC) is one of the most frequent urinary tract tumors worldwide, and its incidence has been predicted to increase in the coming years [1, 2]. About 30% of patients present with local or distant recurrence after nephrectomy for localized disease [3]. Systemic treatment of metastatic RCC (mRCC) has been completely revolutionized by the development of immunotherapy-based combinations, which have improved the outcome and quality of life of mRCC patients [4–13].

Two distinct type of immuno-oncology (IO) combinations have been developed. The first one, defined as IO+IO, involves the use of two different immune checkpoint inhibitors, anti-programmed death (PD)-1 nivolumab and anticytotoxic T-lymphocyte antigen 4 (CTLA-4) ipilimumab. The second combination, defined as IO + tyrosine kinase inhibitors (TKIs), involves the use of agents directed against-PD1 (nivolumab, pembrolizumab) or its ligand PD-L1 (avelumab, atezolizumab) combined with anti-vascular endothelial growth factor (VEGF) monoclonal antibody (bevacizumab) or VEGF receptors (VEGFR)-TKIs (axitinib, lenvatinib, cabozantinib) [4–13].

Although the rate of patients experiencing progression as best response (defined as primary refractory) to immunebased combinations is significantly lower than with anti-VEGFR TKIs [14–16], the necessity of identifying potential factors influencing their prognosis still represents a hot topic for uro-oncologists.

Currently, the choice of the best combination is mainly based on patients' clinical and histological characteristics and, even more, on clinicians' experience. In this scenario, real-world data may offer a crucial contribution to guide the decision-making process in patients with mRCC [17–19]. The ARON project has been designed to create a global network to allow uro-oncologists to share and discuss their experiences on the use of immunotherapy and other emerging drugs for patients with genitourinary tumors. Specifically, the ARON-1 study (ClinicalTrials.gov identifier NCT05287464) was designed to globally collect real-world data on the use of immuno-oncologycombinations as firstline therapy for mRCC.

# 2 Patients and Methods

# 2.1 Study Population

The ARON-1 study (NCT05287464) retrospectively collected data from patients aged  $\geq 18$  years with a cytologically and/or histologically confirmed diagnosis of mRCC treated with first-line immuno-combination therapies.

The ARON-1 study collected data of patients treated from January 1, 2016 to July1, 2022 in 47 International Institutions from 16 countries. Clinical data and laboratory parameters from patients' paper and electronic charts were collected. The study population included adults with clearcell RCC (ccRCC) or non-clear-cell RCC (nccRCC). Data on histology, nephrectomy status, International mRCC Database Consortium (IMDC) criteria, sites of metastases, type of immuno-combination, and response to therapy were retrospectively collected. Patients without enough data on tumor assessment or response to therapy were excluded from our study.

Follow-up was usually carried out by means of physical examination and laboratory tests every 4–6 weeks, while imaging was performed following standard local procedures every 8–12 weeks.

#### 2.2 Study Endpoints

Disease status was evaluated using standard RECIST 1.1 criteria [20]. Overall survival (OS) was calculated from the start of first-line immuno-oncology combination until death. Progression-free survival (PFS) was defined as the time from the start of treatment to progression or death from any cause, whichever occurred first. Patients without tumor progression or death or lost to follow-up at the time of the analysis were censored at the last follow-up visit. Data on tumor response (complete [CR] or partial responses [PR], stable [SD] or progressive disease [PD]) were collected and analyzed.

#### 2.3 Statistical Analysis

The Kaplan-Meier method with Rothman's 95% confidence intervals (CI) was used to estimate the survival curves of both OS and PFS. Comparisons were performed using the log-rank test. Univariate and multivariate analyses were carried out with Cox proportional hazard models. A survival receiver operating characteristic (ROC) analysis was adopted to identify potential cut-offs that better stratify patients into risk groups. The chi-square test was used to compare categorical endpoints. Differences were considered statistically significant when the *p* value was <0.05, and all *p* values were two-sided. The statistical analysis was performed by MedCalc version 19.6.4 (MedCalc Software, Broekstraat 52, 9030 Mariakerke, Belgium).

The research was carried out in accordance with approval from the ethics committee of the Marche Region (2021-492) and was performed in accordance with the Declaration of Helsinki.

#### 3 Results

#### 3.1 Study Population

Seven hundred and twenty-nine patients were included in our analysis. The median follow-up time was 18.1 months (95% CI 14.4–67.8); 540 patients (74%) were male. The median age was 63 years (range 25–88). Tumor histology was predominantly ccRCC (625, 86%); among the 104 nccRCC patients, histology showed a papillary type I or II RCC in 28 cases and chromophobe RCC in 11 cases (Table 1); sarcomatoid differentiation was observed in 117 patients (16%).

Lung (70%), lymph nodes (51%), and bone (34%) were the most common sites of metastasis. Basing on IMDC criteria, 113 patients (16%) were at favorable risk, 425 (58%) at intermediate risk, and 191 (26%) at poor risk. Patients' characteristics are summarized in Table 1. No significant differences were found in terms of baseline clinicopathological features between patients receiving IO+IO and those treated with IO+TKI, except for a higher proportion of patients with lung metastases treated with nivolumab and ipilimumab and for a different IMDC group stratification, related to the fact that the IO+IO combination was approved only for intermediate- and poor-risk RCC patients (Table 1).

Nivolumab and ipilimumab comprised first-line therapy in 313 patients (43%), while 416 patients (57%) received IO + TKI combinations; by the time of analysis, 101 (32%) and 60 patients (14%), respectively, treated with IO + IO or IO + TKI had died at the time of analysis.

#### 3.2 Survival Analysis

In the overall study population, the median OS was 36.5 months (95% CI 24.8–60.8). One hundred and sixty-one patients (22%) were dead at the time of analysis. Male patients showed longer median OS than females, although the difference was not statistically significant (55.8 vs 28.4; p = 0.104, Fig. 1). Furthermore, no statistically significant differences were observed between patients aged  $\geq$  70 years and < 70 years (28.1 months, 95% CI 25.9–60.8, vs 41.0 months, 95% CI 32.7–55.7; p = 0.117, Fig. 1).

In patients with good-, intermediate- and poor-risk criteria, the median OS was not reached (NR, 95% CI NR–NR), 55.7 months (95% CI 28.4–60.8), and 19.2 months (95% CI 12.5–32.7), respectively (p < 0.001, Fig. 1). Previous nephrectomy was associated with median longer OS (55.7 months, 95% CI 41.0–60.8, vs 18.4 months, 95% CI 16.2–28.1; p < 0.001, Fig. 1).

Patients with ccRCC showed longer median OS compared with those with nccRCC histology (41.0 months, 95% CI 29.7–60.8, vs 18.0 months, 95% CI 12.6–36.5; p = 0.005, Fig. 1). Of note, the presence of sarcomatoid differentiation

*IMDC* International mRCC Database Consortium, *IO* immuno-oncology, *RCC* renal cell carcinoma, *TKI* tyrosine kinase inhibitor

was correlated with shorter median OS (26.4 months, 95% CI 20.0-41.0, vs 36.5 months, 95% CI 28.4-60.8; p = 0.014, Fig. 1).

The best cut-off for the number of metastatic sites was > 3, calculated by ROC curve. In our study population, 141 patients (19%) presented with more than three metastatic sites and had a significantly shorter median OS (22.1 months, 95% CI 16.8–41.0) compared with patients with three or fewer metastatic sites (55.7 months, 95% CI 30.7–60.8; p < 0.001; Fig. 2). Brain metastases were associated with the worst median OS (18.4 months, 95% CI 13.2–41.0 vs 36.5 months, 95% CI 29.7–60.8; p = 0.024, Fig. 2), followed by bone (26.0 months, 95% CI 20.0–29.7 vs 60.8 months, 95% CI 36.5–NR; p < 0001, Fig. 2) and

**Fig. 1** Median overall survival in metastatic renal cell carcinoma (mRCC) patients treated with first-line immuno-combinations stratified by clinicopathological features

liver metastases (28.4 months, 95% CI 19.1–60.8 vs 41.0 months, 95% CI 29.7–60.8; *p* = 0.024, Fig. 2).

In the overall study population, median PFS was 15.0 months (95% CI 12.2–17.1). No statistically significant differences in terms of PFS were found between men and women (14.6 months, 95% CI 12.0–17.0 vs 15.9 months, 95% CI 9.9–44.5; p = 0.979) and between patients aged

 $\geq$  70 years and < 70 years (15.5 months, 95% CI 10.4–21.5, vs 15.0 months, 95% CI 12.2–18.8; p = 0.742).

Patients with good, intermediate, and poor risk criteria showed a median PFS of 28.4, 15.0, and 11.0 months, respectively (p < 0.001, Fig. S1 in the electronic supplementary material [ESM]). Longer median PFS was observed in patients who underwent previous nephrectomy

Fig. 2 Median overall survival in metastatic renal cell carcinoma (mRCC) patients treated with first-line immuno-combinations stratified by number and type of metastatic site

(20.1 months, 95% CI 15.9–25.1, vs 9.0 months, 95% CI 6.8–11.3; p < 0.001, Fig. S1, see ESM), while no significant difference was found between ccRCC and nccRCC patients (15.2 months, 95% CI 12.2–18.7, vs 13.0 months, 95% CI 6.9–25.1; p = 0.168). Sarcomatoid differentiation was correlated with shorter PFS (6.7 months, 95% CI 5.5–15.8, vs 15.5 months, 95% CI 12.9–21.6, p < 0.001, Fig. S1, see ESM), as well as the presence of more than three metastatic sites (6.9 months, 95% CI 4.8–11.3, vs 16.4 months, 95% CI 14.1–21.5; p < 0.001, Fig. S1, see ESM). Bone metastases were associated with worst PFS (10.4 months, 95% CI 8.0–12.9, vs 20.1 months, 95% CI 15.2–28.4; p < 0.001, Fig. S1, see ESM), while no statistically significant differences were

found with the presence of liver (11.3 months, 95% CI 7.5–21.7, vs 15.8 months, 95% CI 12.9–18.8; p = 0.129) or brain metastases (10.4 months, 95% CI 5.5–13.0, vs 15.8 months, 95% CI 12.9–18.8; p = 0.088).

#### 3.3 Role of Prognostic Factors

In the univariate analysis, IMDC criteria, previous nephrectomy, tumor histology, sarcomatoid differentiation, number of metastatic sites greater than three, bone, liver and brain metastases were significant predictors of OS (Table 2). At multivariate analysis, IMDC criteria, previous nephrectomy, tumor histology, sarcomatoid differentiation, and bone metastases proved to be significantly associated with OS (Table 2).

As for PFS, previous nephrectomy, sarcomatoid differentiation, number of metastatic sites greater than three, and bone metastases were significantly associated with OS in both univariate and multivariate analyses, while IMDC criteria did not prove to be significantly correlated with PFS in the multivariate analysis (Table 2).

# 3.4 Comparison of Overall Survival: IO + IO vs IO + TKI

At the time of data cut-off, nivolumab plus ipilimumab was ongoing in 158 of the 313 patients. The median follow-up time for this combination was 18.8 months (95% CI 15.5–88.8). At the time of data cut-off, treatment with IO + TKI was ongoing in 307 of the 416 patients, with a median follow-up time of 17.6 months (95% CI 16.9–64.3). Second- and third-line treatments stratified by first-line immuno-combination are reported in Table S1 (see ESM).

In the 616 patients with intermediate/poor IMDC risk criteria, the use of an IO + TKI combination yielded a longer median OS, as compared with the IO+IO doublet (55.7 months, 95% CI 27.3–60.8, vs 29.7 months, 95% CI 25.9–41.0; p = 0.045, Fig. 3).

We further stratified IMDC intermediate-/poor-risk patients by clinico-pathological features. Stratified by sex, no significant differences were observed in male patients treated with IO + TKI versus IO + IO (male: 55.7 months, 95% CI 22.1–60.8, vs NR, 95% CI NR–NR; p = 0.364; females: NR, 95% CI NR–NR, vs 25.0 months, 95% CI 16.0–41.0; p = 0.089). The two combinations showed similar median OS in intermediate-/poor-risk patients aged > 70 years (IO+TKI: 28.1 months, 95% CI 18.4–60.8, vs IO+IO: 26.4 months, 95% CI 22.2–28.4; p = 0.859).

A trend toward a longer median OS was observed in intermediate-/poor-risk patients who underwent nephrectomy treated with IO + TKI, although the difference was not statistically significant (55.7 months, 95% CI 32.7–60.8, vs 41.0 months, 95% CI 29.7–41.0; p = 0.682).

 Table 2
 Univariate and multivariate analyses of predictors of progression-free survival and overall survival in mRCC patients treated with first-line immuno-combinations

	Univariate Cox regression		Multivariable Cox regression

Statistically significant values are reported in bold

ccRCC clear-cell renal cell carcinoma, CI confidence interval, HR hazard ratio, mRCC metastatic renal cell carcinoma, nccRCC non-clear-cell renal cell carcinoma, OS overall survival, PFS progression-free survival

Fig. 3 Comparison between the median overall survival obtained by dual immuno-oncology (IO+IO) vs immuno-oncology plus tyrosine kinase inhibitor (IO+TKI) combinations in intermediate-/poor-risk

metastatic renal cell carcinoma (mRCC) patients stratified by clinicopathological features

Stratified by tumor histology, the IO+TKI combination registered a not statistically significant longer median OS in both ccRCC (55.7 months, 95% CI 27.3–60.8, vs 30.2 months, 95% CI 26.0–41.0; p = 0.162) and nccRCC intermediate-/poor-risk patients (18.0 months, 95% CI 12.6–18.0, vs 15.2 months, 95% CI 7.6–16.5, p = 0.107).

Among the 114 mRCC cases with sarcomatoid differentiation, 54 received an IO+TKI combination, reporting a statistically nonsignificant prolongation of the median OS compared with the 60 patients treated with IO+IO therapy (NR, 95% CI NR–NR, vs 25.0 months, 95% CI 8.9–41.0; p = 0.190).

Finally, based on site of metastases, the difference in favor of IO + TKI combinations was statistically significant in intermediate-/poor-risk patients with lung (60.8 months, 95% CI 27.3–60.8, vs 28.3 months, 95% CI 20.0–41.0;

p = 0.028, Fig. 3) and liver metastases (55.7 months, 95% CI 22.1–60.8, vs 25.9 months, 95% CI 10.0–30.2; p = 0.033, Fig. 3), while it was not significant in patients with bone (27.3 months, 95% CI 19.1–55.7, vs 22.2 months, 95% CI 15.4–28.3; p = 0.159) or brain metastases (22.1 months, 95% CI 18.0–22.1, vs 13.2 months, 95% CI 6.0–41.0; p = 0.221).

# 3.5 Comparison of Progression-Free Survival: IO + IO Versus IO + TKI in Intermediate-/ Poor-Risk Patients

The median PFS was longer in patients with intermediate-/ poor-risk IMDC criteria treated with IO+TKI compared with an IO+IO combination (15.9 months, 95% CI 11.0–20.6 vs 11.1 months, 95% CI 7.2–14.6; p = 0.011, Fig. S2, see ESM).

The median PFS was longer in females treated with IO+TKI vs IO+IO combination (44.5 months, 95% CI 9.6-44.5, vs 5.9 months, 95% CI 4.4-15.8; p = 0.004, Fig. S2, see ESM). No significant differences were observed in males (13.0 months, 95% CI 10.4-20.1, vs 12.2 months, 95% CI 8.3-15.2; p = 0.208), patients aged > 70 years (23.2 months, 95% CI 8.5-27.6, vs 11.3 months, 95% CI 6.3-16.4; p = 0.097), and those with previous nephrectomy (16.6 months, 95% CI 11.4-27.6 vs 15.8 months, 95% CI 10.4-23.9; p = 0.612, clear-cell histology (14.7 months, 95% CI 10.4-20.1 vs 12.0 months, 95% CI 7.8-15.2; p = 0.078), or sarcomatoid differentiation (6.6 months, 95%) CI 4.0–18.8 vs 6.7 months, 95% CI 4.2–17.1; *p* = 0.723). On the other hand, nccRCC patients showed longer median PFS with an IO+TKI combination (NR, 95% CI NR-NR vs 6.9 months, 95% CI 4.0–15.2; p = 0.018, Fig. S2, see ESM).

By stratifying patients according to metastatic sites, the use of an IO + TKI combination registered a statistically significant longer median PFS compared with IO+IO only in intermediate-/poor-risk patients with liver metastases (16.6 months, 95% CI 10.8–27.6 vs 5.8 months, 95% CI 3.6–11.5; p = 0.004, Fig. S2, see ESM), while no significant differences were found in patients with lung (11.4 months, 95% CI 9.6–18.8 vs 10.4 months, 95% CI 6.5–15.0; p = 0.120), bone (11.0 months, 95% CI 8.0–16.6 vs 6.8 months, 95% CI 4.8–11.3; p = 0.077), or brain metastases (10.4 months, 95% CI 3.6–13.0 vs 5.5 months, 95% CI 2.1–10.4; p = 0.306).

# 3.6 Comparison of Response to First-Line Therapy: IO + IO vs IO + TKI

In the overall study population, the percentages of patients experiencing a CR, PR, SD, and PD were 6%, 43%, 30%, and 21%, respectively. In patients treated with an IO + IO combination, the response rates were CR = 11%, PR = 32%, SD = 29%, and PD = 28% (Table S1, see ESM). Otherwise, IO + TKI combinations yielded CR = 3%, PR = 51%, SD = 30% and PD = 16% (Table S1, see ESM). The difference between the type of responses obtained by these two combinations were statistically significant (p < 0.001, Table S1, see ESM).

# 4 Discussion

The selection of the ideal candidate to receive IO + IOor IO + TKI combinations is challenging due to the lack of direct comparisons between these different approaches. In this situation, the use of real-world data is integral to understanding the utilization patterns and outcomes of new treatments among cancer patients treated in both academic and community settings and provides fundamental data on the outcome of patients ineligible for clinical trials [21, 22], who constitute a not negligible proportion in daily clinical practice; and indeed, the use of rigorous realworld evidence has been advocated for across different malignancies [23].

The ARON-1 study has been designed to investigate the presence of factors influencing the prognosis of mRCC treated with immuno-oncology combinations and to retrospectively compare the efficacy of the different combinations available across the globe. Our data showed that the main prognostic factors validated for mRCC patients treated with targeted monotherapy can also be applied to patients treated with immuno-combinations (i.e., IMDC, liver-bone-brain metastases, nephrectomy, sarcomatoid differentiation, number of metastatic sites, clear-cell vs non-clear-cell histology).

If some of these factors are well known, some more insight is needed on the putative favorable prognostic role of a previous cytoreductive nephrectomy. For years, this role has been a cornerstone in the overall management of mRCC, being supported not only by old, randomized data from the age of cytokine-based immunotherapy, but also by huge retrospective series [24, 25] and by at least one meta-analysis [26]. Our results further increase the amount of data still suggesting a positive role for cytoreductive nephrectomy, leading to a key question: in terms of evidence making, which is more important, a single, randomized, controlled, phase III clinical trial (itself not free from criticism) or a bulk amount of retrospective evidence from real-world practice? In the absence of a clearcut answer, the clinical judgment for each given patient should replace any dogmatic attitude, as already claimed by Motzer and Russo in the editorial comment to the CAR-MENA publication [27].

As far as the indirect comparison between the two strategies goes, the median OS was longer with IO + TKI compared with IO + IO therapy in patients with intermediate-/ poor-risk features. Furthermore, OCB was + 11% higher with the IO + TKI combination. These data were consistent with those recently published in a meta-analysis on firstline immuno-combinations [28].

Another interesting (and to a certain extent worrisome) finding emerging from our study is the extremely low percentage of patients who did receive a second- or thirdline treatment. Although the relatively short follow-up may account, at least in part, for this finding, it is clear that the use of combinations ultimately limits our choice for further treatment lines.

Of course, our study presents several limitations, including its retrospective nature. At first, our follow-up of 18 months and the 22% of deaths may represent a bias for OS assessment. Secondly, we did not perform a centralized review of radiological imaging, and we had no available data on the concomitant use of medications that could influence the efficacy of first-line therapy. As a consequence of all the above, our findings should be interpreted with caution and are possibly in need of a larger prospective validation.

Nevertheless, our data clearly suggest for patients for whom dimensional reduction of disease burden is needed (e.g., spinal cord compression, pain), one of the available IO-TKI combinations might be the best choice, considering the lower percentage of primary refractory patients compared with IO-IO combinations in the present study; moreover, these data are consistent with the data from randomized trials [6–11].

In 2019, Dudani et al. [29] published a first retrospective comparison between 75 patients treated with IO + IO and 113 with IO + TKIs from the IMDC dataset, with a median follow-up of 11.7 months. In our study, reporting a longer follow-up and a larger study population, the efficacy of IO + IO and IO + TKI combinations varies across different clinico-pathological subgroups.

# **5** Conclusions

Our study may suggest that immuno-oncology combinations are effective as first-line therapy in the mRCC real-world context, showing outcome differences between IO + IO and IO + TKI combinations in mRCC subpopulations. Prospective clinical trials directly comparing distinct IO + IO and IO + TKI combinations are thus sorely needed.
