Fig. 1 (a) Location of Sakurajima volcano indicated within a sketch map of the Japan archipelago; (b) locations of the ash samples (indicated with circles) reported in the map with variable colors according to the different stages observed in the eruptive activity: Weak Ash Emission (blue circle), Vulcanian Explosion (red circles), Continuous ash venting (violet circle), and activity renewal (green circle). The yellow triangle marks the site of the thermal camera video recording (31.588974° N 130.707363 °E).

Fig. 2 Phases of the Vulcanian eruption considered in this study. Important transients clearly characterize either the style and the intensity of the captured eruptive phases (a,b,c). Eruptive parameters (Temporal duration and estimated plume height) and information about tephra sedimentation (tephra sedimentation rates and images of the impact tracks left by the settling particles during fallout) associated to the different phases are also reported.

Fig. 3 Thermal images (a-c-e-g) taken at different timings (1.06 - 14.84 - 42.40 and 575.00 s) after the onset of the prominent Vulcanian explosion, reported close to the corresponding iso-thermal segmentation of the plume (b-d-f-h). Time series of plume elevation above the crater (i) and local ascent velocity of the plume head (l) derived for the most intense phase of the eruption (first 22 s after the onset). Dotted line in panel *l* indicate the height limit of the camera Field of View (FOV).

please indicate at the beginning of caption or in bracktes afte prominent Vulcanian explosion (phase 2??) which phase is this plume from 1.3 or

Fig. 4 Grain size distributions (GSDs) of tephra fallout samples collected during different stages of eruptive activity (color of the histograms). The internal deposit subpopulations are also represented with colored dotted lines and the position of the mean of each gaussian curve is marked by a vertical arrow (SP1=red and SP2=green).

Fig. 5 Images of the identified ash components: (a) Blocky Angular (BA), (b) Blocky Rounded (BR) and (cd) Vesicular (VS). Characteristic features of external surfaces are displayed in stereo-binocular and SE-SEM images (used in secondary electron mode), while images of the internal textures are shown in BS-SEM images (used in back scattered mode). The characteristic low vesicularity shown by the V type particles is also clearly shown in (d).

Fig. 6 a) Average microlites contents measured for the three ash components collected during different stages of activity. Variations of the total crystal contents are compared with plagioclase contents. Squares (BR), diamonds (BA) and circles (VS). Values are all corrected for the vesicle content.

(b) 3D crystal size distributions (CSDs) of plagioclase microlites for the recognized ash components (indicated by colors in the legend) selected from different phases of activity: the size is compared to the logarithm of the population density of plagioclase crystals. c) Log-log cumulative frequency distribution of the plagioclase size 'log(S)' against the number of particles coarser than the size 'log(#UnderSize-S)'.

Fig. 7 The shape-versus-size trends of ash resulting from different activity styles was quantified based on four representative shape parameters (Elongation, Circularity, Solidity and Convexity). Different colors of dots in the plots refer to the identified styles of activity. Vertical bars indicate the variability (first and third quartiles) of each data window considered in the moving average plots.

Fig. 8 Model of the vertical gradients of Sakurajima conduit inferred from analysis of ash. Three endmember clasts of the ash componentry are also presented as representative of the different conduit regions which corresponds to different depths in the magma column.

Fig. 9 Conceptual model presenting the main process controlling the eruptive dynamics of Sakurajima within the distinguished phases of activity.

Tab. 1 Localization of the collected bulk ash samples are reported together with a set of statistical descriptors (defined according to Folk, 1968) characterizing the GSDs of tephra-fallouts deposits and information upon deconvoluted subpopulations internal to the total deposits. In particular, the 'VolFraction' columns report also the deposit fraction (Volume %) corresponding to the coarser and, where present, the finer subpopulations (SP1 and SP2, respectively); the relative importance of these subpopulations is pointed out by the values of SP-ratio (Vol(%)SP2 / Vol(%)SP1).

Tab. 3 Average microlite, vesicle and glass contents and areal MND of the ash grains in the different stages of activity. Average relative abundance of the crystal phases and vesicles are reported together with the MND calculated for the three classes of components Blocky Angular (BA), Blocky Rounded (BR), Vesicular (VS) considering the whole mineral assemblage. Relative abundance and MND calculated for single particles are reported in Tab. S2 and Tab. S3, in the Supplementary Material. Note that vesicularity and microlites were measured using images with different magnifications in order to ensure a good compromise between resolution and representativity.

15	Abstract
16 17 18 19 20 21	Quantitative morpho-textural analysis of volcanic ash is one of the most effective tools to characterize the style of ash-dominated volcanic activity, and to investigate the complex interplay between conduit processes and the associated eruptive dynamics. In this framework, many questions still remain unanswered about the role of conduit processes, and in particular of the magma fragmentation processes, in controlling the eruptive dynamics of the unsteady and highly-transient Vulcanian explosions. For this reason, we analyzed ash samples collected during a 5 days-long eruptive sequence at Sakurajima
22 23 24 25 26 27	volcano (Japan), to derive information about ash morphometry and textural features over the entire sequence. During the observed sequence, eruptive activity showed high unsteadiness in the modalities of ash emission, including all the main different eruptive styles showed during the recent period of Sakurajima activity. Three main intra-eruptive phases were recognized based on visual observations and thermal data, and quantitative information about external ash morphometry (i.e. shape) and internal textures were measured for the particles associated with the different phases and discussed in terms of
27 28 29 30 31	the observed eruptive variability. Crystallinity and vesicularity of ash grains, together with the crystal size distribution (CSD) of microlites and the microlite number density (MND) in the groundmass were quantified for a representative set of ash particles. Links existing between the eruptive dynamics, and the dominant processes of magma fragmentation are here discussed, as showed by the combination of
32 33 34	the morpho-textural features of ash throughout the whole eruptive sequence and the observed variations of the eruptive phases. All the evidences presented in this work confirm the constant presence at Sakurajima of a highly stratified and degassed magma within the conduit, and led us to interpret the

35 transient dynamics of the eruption as strongly controlled by variations in the process of magma 36 fragmentation driving the eruptions during the different phases. In particular, the morpho-textural 37 characteristics of ash suggest that Vulcanian eruptions at Sakurajima can be controlled by the 38 progressive pressurization of the upper portion of magma conduit and involves material comprised in a 39 range of depth between 10 and 50m. Moreover, using crystal textures, we inferred that the rate of conduit 40 refilling during intra-eruptive stages is comprised between 1-10 month. The resulting information on 41 the eruptive dynamics of Sakurajima is of primary importance for a wider comprehension of the low-42 to-mid intensity, ash-dominated explosive activities.

43

44 1. Introduction

45 Large amounts of volcanic ash are frequently produced during low- to mid-intensity explosive eruptions 46 at many active volcanoes worldwide (e.g. Heiken and Wohletz, 1985; Sparks et al., 1997; Dingwell et 47 al., 2012; Makie et al., 2016; Bernard et al., 2016; Oishi et al., 2018; Battaglia et al., 2019). The sudden 48 ash discharge related to explosive eruptions often represents a critical source of hazard for population 49 living near active volcanoes, as well as for the civil aviation (Casadevall and Krohn, 1995; Sparks et 50 al., 1997; Guffanti et al., 2010). Despite the high yearly frequency of ash dominated activity at the 51 global scale, and the consequent relevant societal impact, the mechanisms responsible for ash generation 52 and dispersal during these eruptions are still not fully understood. On the other hand, volcanic ash is 53 widely recognized to represent a powerful tool for the investigation of the eruptive dynamics and of all 54 the processes affecting magma during its upward migration in the conduit (e.g. Taddeucci et al. 2004; 55 Wright et al., 2012; Cioni et al., 2014). Many efforts were spent by the scientific community to improve 56 the knowledge about physical processes responsible for ash generation, transport and dispersal (e.g. 57 Dellino & La Volpe, 1996; Cioni et al., 2008; Miwa & Geshi 2012; Cioni et al., 2014; Bonadonna et 58 al., 2015; Cashman & Scheu, 2015; Liu et al., 2015; Liu et al., 2017; Durant, 2015; Hantusch et al., 59 2021). Since the pioneering work of Heiken and Wholetz (1985), who firstly provided a comparative 60 study of ash textures and morphological features over various types of eruptive styles, several studies 61 have been later focused on volcanic ash to investigate in detail both conduit and eruptive processes, and 62 to make inferences on the nature of magma fragmentation mechanisms (Buttner et al., 1999; Cashman 63 et al., 2008; Miwa et al. 2013b; Cioni et al., 2014; Jordan et al., 2014; Leibrandt et al., 2015; Mackie et 64 al., 2016; Battaglia et al., 2019). Quantifying the physical features (e.g. vesicularity, crystallinity, 65 external and surface morphology) of volcanic ash resulted in better constraints for the mechanisms of 66 magma fragmentation, and informed about their role in influencing the eruptive dynamics (Cashman et 67 al. 1992; Cashman & Hoblitt, 2004; Aldibirov & Dingwell, 2000; Wright et al., 2012; Miwa et al. 68 2013a,b; Cioni et al., 2014; Cashman & Scheu, 2015; Gaunt et al., 2016; Liu et al., 2017). Importantly, 69 information on the internal texture of ash were also used to better understand and interpret the highly 70 unsteady (i.e. transitory) behavior often observed in the dynamics of mid-intensity and high-frequency 71 explosive eruptions (Miwa et al., 2009; Cashman et al., 2008; Miwa et al., 2013a, b; Cioni et al., 2014). 72 As a matter of facts, while a lot of work has been done for the comprehension of sustained volcanic

activity (e.g. Plinian eruptions), several questions still remain unsolved about the role that mechanisms
of magma fragmentation have in the control of the intra-eruptive variability in the intensity and style
often observed during low- to mid-intensity, ash-dominated eruptions (e.g. Vulcanian-like activity).

76 Here we present the results of a study designed to quantitatively characterize texture of the ash produced 77 during the most recent (post 1955), highly-transient activity of Sakurajima volcano (Japan). Ash was 78 directly collected during a five-days eruptive sequence occurred during October 2014 characterized by 79 repeated (from seconds to hours) transitions in intensity and style of the activity. At least three different 80 phases of activity were identified, encompassing a large spectrum of intensity. This feature makes the 81 collected samples particularly valuable for the investigation of the mechanisms that are responsible for 82 the important variations observed in the eruptive dynamics. We quantified the main physical 83 characteristics (grain-size, morphology, crystallinity and texture) of ash products related to the different 84 eruptive stages, discussing the results in the light of conduit dynamics. We finally made inferences on 85 the nature of magma fragmentation processes during the different stages of the activity.

86 All the collected data suggest the constant presence at Sakurajima of a highly stratified and degassed 87 magma plug that led us to interpret the unsteady dynamics of the observed eruption as related to a 88 variable process of magma fragmentation, mainly driven by the progressive overpressure accumulation 89 by gas transfer into the plug, without an important pre-eruptive magma ascent. Detailed analysis (e.g. 90 crystallinity, vesicularity and grain-size distribution of microlites) of the ash fragments also allowed to 91 reconstruct the internal structure of the upper volcanic conduit, and to estimate the volumetric 92 contribution of the different portions of plug in the process of ash production during all the eruptive 93 stages.

94

95 1.1. The recent Vulcanian activity at Sakurajima Volcano

96 Sakurajima is an andesitic stratovolcano located in the Kagoshima prefecture (southern Kyushu, Japan; 97 Fig. 1a) well known for the high-frequency, nearly continuous Vulcanian eruptions which characterize 98 the volcano activity since 1955 (Miwa et al., 2013b; Iguchi et al., 2008). The stratovolcano is formed 99 by two overlapping cones, Kitadake, which ended its activity at 4850 ka, and the presently active 100 Minamidake (Takahashi et al., 2013). Since 1955, the activity occurred mainly at Minamidake summit 101 crater, with no significant change in the chemical composition of the erupted products (Matsumoto et 102 al., 2013; Kurniawan et al., 2016). However, during June 2006, major change in the activity occurred, 103 marked by the shift of the activity to the parasitic Showa crater and the corresponding deactivation of 104 Minamidake crater (Iguchi, 2013b). In August 2015, activity interrupted for several months until 105 February 2016, when it restarted first from Showa crater, with small explosive events, and then (March 106 2016) also from Minamidake crater, with high intensity explosions (Japan Meteorological Agency, 107 JMA; http://www.jma.go.jp/jma/indexe.html). Since 2016, activity alternated between the two vents, 108 with variable energy, intensity and frequency. As reported by the JMA, Vulcanian activity of Sakurajima 109 is still ongoing and it consists of sequences of small tephra emissions often culminating in strong 110 Vulcanian explosions, eventually separated by a short period during which no ash emission is observed 111 (Oba et al., 1980; Ishihara, 2000; Yamanoi et al., 2008; Iguchi et al., 2008; Iguchi, 2013b; Miwa et al.,

112 2013a). A recurrent eruptive pattern in the recent activity of Sakurajima has been recognized, including 113 different eruptive styles characterized by a range of intensity and modalities of products emission (e.g. 114 Kamo, 1978; Fukuyama, 1981; Ishihara, 1990; Yamanoi et al., 2008; Iguchi et al., 2008; Iguchi et al., 115 2013a; Miwa et al., 2013b). Monitored variations in the dynamics of the volcanic activity, coupled to 116 recorded ground deformations and other geophysical data, allowed to quantitatively characterize the 117 typical eruptive pattern (Iguchi et al., 2008; Iguchi, 2013b; Yokoo et al., 2013). Normally, an eruptive 118 cycle starts with the migration of andesitic magma that accumulates in a shallow reservoir, as testified 119 by the distribution of volcano-tectonic hypocenters and by the volcanic edifice inflation which precedes, 120 from hours to several days, the onset of an eruption (Ishihara, 1990; Iguchi et al., 2008; Iguchi et al., 121 2013a, Yokoo et al., 2013). For those eruptions occurring at Showa crater, Yokoo et al. (2013) identified 122 the depth of magma accumulation to be comprised between 0 and 2 km beneath the crater, at a level 123 considerably shallower respect to the 2 to 6 km deep magma reservoir previously identified by Ishihara 124 (1990). During this stage, the eruptive activity is typically marked by the onset of a low-intensity, 125 intermittent activity characterized by phases of no-to-weak ash and gas emissions, punctuated by small 126 explosions associated with the ejection of ballistic bombs and lapilli (e.g. Miwa et al., 2013a). This 127 phase can last from hours to days. An increasing trend of upward inflation (0.01 to 0.2 µrad) starts from 128 minutes to several hours (~20 h) before the onset of the major explosion, which is also marked by a 129 downward and contractive signal immediately before (seconds) and after the eruption (Iguchi et al., 130 2013a; Iguchi, 2013b, Yokoo et al., 2013). At the same time, a decrease in SO₂ discharge rate is 131 recorded, together with a progressive weakening of the nighttime glowing (Yokoo et al., 2013). These 132 evidences have been interpreted by Ishihara (1985) and Yokoo et al. (2013) as due to the progressive 133 formation of a degassed and viscous magma plug sealing the upper part of the volcanic conduit prior to 134 the occurrence of a Vulcanian explosion. Aerial photos and textural data on ash reported by Miwa et al. 135 (2013b) agree in indicating the presence of a viscous and outgassed plug in the upper conduit of 136 Sakurajima. Typically, a Vulcanian explosion occurs after a variable period of quiescence or very weak 137 intermittent activity, as the magma column achieves sufficient pressure to overcome the lithostatic 138 strength of the plug (Tameguri et al., 2002). Large Vulcanian explosion are typically associated to the 139 production of variably ash-laden plumes that can reach several kilometers in the atmosphere (up to 5-6 140 km during stronger events). During the largest events, meter- to cm-sized ballistic fragments are often 141 ejected up to a few km far from the vent (Iguchi et al., 2008). These events are also accompanied by 142 violent air-shocks (exceeding 500 Pa at 2.7 km from the vent) that commonly precede the formation of 143 convective, ash-rich plumes (Iguchi et al., 2008). Miwa et al. (2013a) interpreted the intensity of the 144 produced air shocks as related to the amount of gas accumulated in the magma conduit before eruptions. 145 Immediately after strong Vulcanian explosions, it is frequent to observe a phase of continuous ash 146 venting, accompanied by a persistent tremor without any visible associated explosion. This activity 147 typically lasts from minutes to hours and it is characterized by the quasi-sustained emission of gas and 148 tephra to form a weak, dense, low-level ash plume rising from the vent (Kamo and Ishihara, 1989; 149 Nogami et al., 2006; Yamanoi et al., 2008; Iguchi et al., 2008; Iguchi et al., 2013a; Miwa et al., 2013b). 150 Typically, the ash emission ceases with the gradual decrease in frequency and intensity of the seismic 151 signals (Iguchi et al., 2008). Then, a variable period lasting from hours to days of no visible activity

- 152 commonly precedes a low-level ash or gas emission, which corresponds with the start of a new cycle.
- 153 While the sequence of activity of the different Vulcanian outbursts results clear and well described by
- geophysics, the underlying mechanisms of magma fragmentation operating during the different phasesof the activity are still poorly understood (Yokoo et al., 2013).
- 155 of the activity are still poorly understood (10k00 et al., 2015).
- 156 1.2. Previous studies on volcanic ash from Sakurajima activity
- 157

158 The first quantitative studies and descriptions of Sakurajima ash were made by Oba et al. (1980), who 159 distinguished ash components based on their color identifying two types of fragments: 'red ash', 160 interpreted as a mixture of hydrothermally altered and juvenile ash particles, and 'black ash', 161 representing ash produced by the disruption of the plug hosted in the vent. Miyagi et al. (2010) described 162 Sakurajima ash deposits as mostly formed by juvenile, dense, glassy and blocky fragments, surrounded 163 by planar surfaces with few large and irregular vesicles. Minor and occasional pumiceous and fluidal 164 particles were also identified. Finally, Miwa et al. (2009) distinguished juvenile components from 165 lithics based on external features like 'smooth' (i.e. glossy) surfaces, typical of juvenile components, 166 and 'non-smooth' surfaces, interpreted as indicative of non-juvenile material. Miwa et al. (2013b) 167 confirmed that pumice-like and fluidal fragments are poorly present at Sakurajima, except for very large 168 explosions. Fluidal particles collected during these events consist of glassy fragments characterized by 169 smooth external surfaces reflecting the molten state of magma at the time of fragmentation. Conversely, 170 the highly vesicular fragments described by Miwa & Toramaru (2013) show a complex external outline 171 related to the presence of abundant, spherical vesicles (on average 40% in volume).

172 Based on ash features, many authors tried to relate eruptive dynamics with the processes affecting 173 magma during ascent in the conduit. A variation in vesicularity coupled to a variation in Cl and F 174 contents of the groundmass glass of the ash from different stages of activity, allowed Nogami et al. 175 (2006) to suggest the occurrence of two distinct magma components with different volatile contents as 176 a possible explanation of the large variability observed in the eruptive patterns. In particular, 177 fragmentation of a more volatile-rich magma was related with an ash emission activity described as 178 'Strombolian-like emission' by Nogami et al. (2006), while a more degassed magma was related to 179 activity like Vulcanian eruptions and continuous ash venting. Alternatively, Yamanoi et al. (2008) 180 proposed that eruptive dynamics was controlled by the migration of vesicles within the shallower part 181 of the conduit prior to Vulcanian explosions, resulting in a vertically layered magma column. Finally, 182 Miwa et al. (2013b) and Iguchi et al. (2013b), based on ash textures and seismic signals, identified in 183 the gradual formation of a sealing plug at the top of the system and in the repeated upward migration 184 of magma from the shallower reservoir, two important processes controlling both the intensity and the 185 dynamics of Vulcanian explosion at Sakurajima.

- 186
- 187 2 Analytical Methods
- 188

189 We planned an experiment of ash collection using different observational and collection approaches in190 order to sample the products of a sequence of activity representative of an entire eruptive cycle: i) the

- 191 phases preceding a major explosion (Phase 1); ii) the vulcanian explosion (Phase 2); iii) the restoring
- 192 conditions preceding the following explosion (Phase 3).
- 193 Thermal infrared videos along the entire period of sampling were recorded with a FLIR SC660 thermal 194 camera (3.77 Hz of frame Rate; 7.5-14 µm of spectral range; 680 x 480 of image size; 24° x 18° of field 195 of view [FOV]), in order to follow the eruptive dynamics and to estimate plume height and ascent 196 velocity of the eruptive mixture. Location of the camera position at the moment of the main explosion 197 is indicated in Figure 1. The distance of the camera from the vent was used to estimate the pixel size 198 (in meters) of the video frames. Geometrical corrections were applied to the values of pixel size 199 according to the inclination of the optical plane of the camera respect to the real vertical motion of the 200 plume (section S1 of Supplementary Materials for details). Each frame was then segmented based on 201 three customized temperature thresholds (25°C, 75°C and 125°C) in order to map the regions of the 202 plume characterized by different temperature and track their spatial evolution in time. Considering the 203 segmented images, the coordinates of the highest pixel of the plume outline were determined for each 204 frame of the video. This information was then used to estimate the evolution in time of the plume height 205 and its ascent velocity, calculated as the relative difference in plume height between two contiguous 206 frames.
- 207 A total of 8 fallout tephra samples were collected during deposition from the plume using several plastic 208 trays of 0.33 x 0.39 m located under the ash fallout along the main dispersal axis at distances comprised 209 between 2.5 and 14 km from the active vent (Fig. 1b, Fig. 2). The ash plume relative to each eruptive 210 phase was visually identified and the associated deposit collected in the trays, registering the duration 211 of sample acquisition to estimate the average deposition rate (Fig. 2). Three deposits representative of 212 the main Vulcanian event were collected at different distances from the vent: the first sample (SKJ24-213 10-5) was collected during the fallout at around 5 km from the active vent, 2 minutes after the onset of 214 explosion. A second sample (SKJ24-10-14bis) was collected about 1.5 hours after the explosion, 215 approximately 11 km distant from the vent (Fig. 1b). Additionally, a third sample of selected lapilli 216 relative to the onset of the Vulcanian explosion (SKJ 24-10-15), was collected over large leaves 217 approximatively a few hundreds of meters west of SKJ 24-10-5.
- 218 The grain-size distribution (GSD) of the ash samples was measured through a combined approach of 219 mechanical and optical sieving. In particular, the deposit fraction coarser than 4 Φ (64 μ m) was sieved 220 using the dry mechanical sieving technique, while the finer portion of the samples (particle size < 64221 μm) was analyzed down to 1 μm in size using a wet, laser-diffraction particle-size analyzer (CILAS 222 1180). Data from the two methods were then recombined by overlapping the two partial distributions 223 and assuming a constant density of the ash fragments in the different deposit class sizes. Based on the presence of asymmetries and bimodality in the resulting GSDs, grain-size data were then fitted through 224 225 one or two gaussian subpopulations (named SP1 and SP2) using MagicPlotStudent, a dedicated software 226 for non-linear data fitting; the fit residuals were ealways fficiently minimized ($R^2 > 0.96$). The ratio 227 between the weight % of deposit attributed to each gaussian subpopulation (SP-ratio = wt. % SP2 / wt. 228 % SP1) was used to characterize each distribution together with the main statistical parameters 229 associated to each subpopulation (Table 1).

230 Ash componentry was evaluated investigating the modal class of the grain-size (250-500 µm). This 231 operation was based on visual inspection and textural description of the grain surfaces (morphology, 232 surface roughness, color and apparent vesicularity), distinguishing different types of juvenile or lithic 233 material, and loose crystals. Where available, a coarser grain-size (500-710 µm) was also considered 234 for component analysis. Analyses of external surfaces and internal groundmass textures were carried 235 out on randomly picked subset of around 30 juvenile particles for each deposit, using a Zeiss EVO 236 MA15 Scanning Electron Microscope at the MEMA laboratories of the University of Florence (SEM). 237 The shape of the particles was quantitatively determined calculating different dimensionless shape 238 parameters on a random 2D projected outline of the particles (APASH; Leibrandt et al., 2015). In each 239 eruptive phase, the characteristic 2D shape of the different ash components that were identified was 240 fully described for each particle type. Following Liu et al. (2015), we selected four dimensionless shape 241 parameters (Circularity, Elongation, Solidity, Convexity) considered to efficiently represent all the 242 various morphological features of the clasts. In particular, the macro-morphological features were 243 accounted by measuring the clast Circularity (the ratio of the circular equivalent circumference to the 244 perimeter of the particle [Ceq/P]) and Elongation (defined according to Leibrandt et al., 2015 as the 245 ratio of the particle width to the particle length [W/L]). The meso- and the micro-morphological features 246 were instead monitored calculating respectively the clast Solidity (the ration of the particle area to the 247 area of the convex hull $[A/A_{CH}]$) and Convexity (perimeter of the convex hull to the perimeter of the 248 particle $[P_{CH}/P]$), as defined in Liu et al. (2015).

249 Back-scattered electrons SEM images collected on polished random sections of the same grains were 250 analyzed to extract information on the size and content of bubbles and microlites using *Fiji*, a dedicated 251 software for the image analysis (Schindelin et al., 2012). Bubbles and microlites, identified on the SEM 252 images, were manually traced and segmented in order to compute all the primary geometrical parameters 253 (Area, Feret diameters, Perimeter). Vesicularity was calculated as the ratio of the total surface area of 254 the vesicles to the total analyzed cross-sectional area. In order to ensure a good representativity also 255 for large and sparse vesicles, the vesicularity was determined using lower magnification images. The 256 shape of the vesicles was measured directly from the images (2D cross-section), and their size was 257 estimated as the diameter of the equivalent circle (D_{eq}) .

258 The crystal content was computed as the total surface area of crystals to the total analyzed cross-259 sectional area, corrected for the area of vesicles. Information on microlites abundance was extracted 260 using several high-magnification images for each particle, in order to ensure a good representativity 261 also for the smallest classes of crystals (down to 1 μm in size).

- Information on the dimension of plagioclase microlites (maximum and minimum Feret) were also used
 to determine the Crystal Size Distribution (CSD) for the different ash grains introducing a stereological
 correction using the software *CSDcorrections* (Higgins, 2000).
- Finally, an automatic image analysis of the ash grains of the different deposits was performed using a
- static imagine analysis approach with the Malvern Morphology 3GS particle analyzer. Aliquots of 13
- 267 mm³ were randomly picked from the deposit $< 355 \mu$ m fraction of each sample. During analysis, the
- apparent maximum projected ash shape (APASH) of a large set of ash grains (2000 3000) from each
- 269 size class in the range 64-355 μ m (2 4 Φ , where Φ =-log₂d, with d being the particle diameter in mm)

270 was automatically traced and the selected shape parameters calculated. These data were used to 271 construct simple moving average (SMA) plots in order to monitor the variability of the particles shape 272 (calculated as the median of the sliding windows) with the size. Data dispersion range, calculated as 273 the first and the third quartiles, was also associated to these measures. The samples were analyzed using 274 an appropriate set of optical magnifications (5x; 10x; 20x) in order to maintain image resolution 275 (expressed in terms of the number of pixels entering within the 2D particle projection) as constant as 276 possible for particles having very different size, thus avoiding scaling effects due to 'pixellation' of the 277 outlines of the finer particles. The use of standard operative procedures (SOPs) allowed us to provide 278 comparable results among different samples, since an invariant optical setting was used during all the 279 data acquisition procedure.

282

3. The 22-25 October 2014 eruptive sequence

283 An entire Vulcanian eruptive sequence was observed and sampled at Sakurajima in the period from 22 284 to 25 October 2014. According to Oishi et al. (2018)and JMA reports 285 (https://volcano.si.edu/volcano.cfm?vn=282080) and based on the frequency of the explosions, the rate of 286 Sakurajima activity during October 2014 was classified as "moderate", with a total of 19 major Vulcanian explosions recorded, each associated to ash plumes with height always below 2.5-3.5 km 287 288 a.s.l. During the whole month, the alert level of the volcano remained at 3 in a scale of 5.

289 Our sample collection started on 22 October, at the end of a relatively long-lasting (5 days) period of 290 low-intensity, weak ash emission. This activity followed three major explosions occurred on 14-17 291 October. After two days of weak emissions (Phase 1; 22-23 October) (Fig. 2a), a strong Vulcanian 292 explosion from Showa crater was recorded on 24 October at 12:05 Japanese Standard Time (JST) (Phase 293 2; Fig. 2b). The major explosion formed a strong ash plume that reached a height of 4.6 km a.s.l. and 294 drifted E. The plume height is comparable to that of the typical major events occurring at Showa crater. 295 The explosion was immediately followed by a phase of intense ash emission (Phase 3; Fig. 2c), with 296 the formation of a quasi-sustained low-level plume which progressively decreased in intensity until 297 stopping after 1 hour from the onset of the Vulcanian explosion. After about 3 hours the activity renewed 298 with a continuous weak ash and gas emission which marks the onset of a new cycle (Phase 1).

299 All the activity was recorded with a FLIR SC660 thermal camera, deployed at around 2 km East of the 300 Showa crater (Fig. 1). The data reported in Figure (3i-l) clearly show the unsteady character of the 301 activity during the different days. After no significant thermal signal registered prior to the eruption 302 onset, the explosion started with the abrupt injection in the atmosphere of the eruptive mixture that 303 immediately experienced a rapid acceleration until reaching the maximum vertical velocity of 220 ms⁻ 304 ¹ within 1 s after the eruption onset (Fig. 3a-e). Within the following 8 s, the plume gradually decelerates 305 down to ascent velocity < 50 m/s, reaching an elevation of about 850 m above the crater (Fig. 3b-f). By 306 this time, the external portion of the plume partially collapsed to feed a very small pyroclastic density 307 current flowing over the Showa crater external slope with a runout of hundreds of meters. After 9 s 308 from the eruption onset, the top region of the plume maintained a fairly constant and low ascent velocity 309 with values rarely > 30 m/s, before exceeding the camera field of view at around 21 s. The thermal

- 310 anomaly associated with Phase 2 progressively decreased from the first few seconds until its almost 311 complete disappearance at about 42 s from the eruption onset (Fig. 3 c-g). However, starting from 2 312 minutes after the onset of the explosion, a recurrent, although very modest in intensity, thermal signal 313 was recorded (Fig. 3d, h) associated to a phase of continuous ash-venting. Phase 3 produced a dense 314 and low-level, ash-rich plume which spread out to northeast from the crater, transporting important 315 quantities of fine ash (Fig. 2c). After 20-30 minutes from the eruption onset, this activity, and the related 316 thermal signal, progressively decreased and the ash emission ceased completely after about one hour. 317 Activity resumed around 3 hours later as a weak ash emission (Phase 1 {New Cycle}), similar to that 318 preceding the explosion (i.e. 22 October) and representing the very initial stage of the Phase 1 of a new
- 319 eruptive cycle.
- Ash fallout samples representative of the different activity phases forming the entire eruptive cyclewere collected and analyzed. The ash deposits of the four Phases were thus associated to a specific style
- of eruption:
- *i)* Phase 1 (*Weak Ash Emission*): preceding the eruption and lasting for a few days, characterized by
 no evident explosive activity, low intensity ash emission (Fig. 2a) and very low sedimentation rate
 (1.91x10⁻⁶ kg/m²s⁻¹).
- *ii)* Phase 2 (*Vulcanian Explosion*): strong and impulsive explosion associated with the production of
 an ash-rich plume reaching about 4.6 km in height (Fig. 2b), with a sedimentation rate of 2.38 x 10⁻⁵
 kg/m²s⁻¹ at a distance of about 5 km from the vent.
- *iii)* Phase 3 (*Continuous Ash Venting*): weak, highly-concentrated ash plume emitted continuously from
 the vent 2-5 minutes after the onset of the *Vulcanian explosion* and lasting for about 1 hour (Fig. 2c),
 resulting in a high sedimentation rate (2.54 x 10⁻⁴ kg/m²s⁻¹) at about 3 km from the vent.
- *iv)* Phase 1 {New Cycle}: weak ash emission with no visible explosions observed to occur from several
 hours after the explosion. This activity could be considered prodromal to another *Vulcanian Explosion*,
 as it is completely similar to the Phase 1 preceding the explosion.

- 336
- **337 4. Results**
- 338

339 4.1. Grain size distributions

- 340
- 341 The GSD curves of the ash samples from the different phases of activity show significant differences 342 in the shape (unimodal vs. bimodal) (Fig. 4) and in the corresponding parameters of skewness and 343 sorting (Table 1). In general, the deposits belonging to the same phase of activity, collected at different 344 times (e.g., deposits from Phase 3) or places (e.g. Phase 2) display very similar and consistent GSDs 345 (Fig. 4). Accordingly, either the MdΦ and the relative volume fraction of subpopulations (SP1 and SP2, 346
- coarse- and fine-grained, respectively) forming the bulk deposits, show specific variations according tothe activity phase (Table 1).
- 348 The two phases of *Weak Ash Emission* (Phases 1 and 4), preceding and following the main explosion,
- 349 were sampled at different distances (4 km for the two samples of Phase 1; 14 for the sample of Phase 1

350 {New Cycle}). The GSD of the proximal samples, *SKJ22 10 2* and *SKJ23 10 2* (Table 1 and Fig. 4) 351 clearly shows the contribution of the two SPs, with the most abundant SP1 always peaked at 2.5Φ and 352 accounting respectively for the 86 and 94% of the total sample, and SP2 peaked at $3.6-4.3\Phi$ (Table 1). 353 On the other hand, the distal sample of Phase 1 {New Cycle} (SKJ25 10 1; Table 1 and Fig. 4) is 354 characterized by a unimodal distribution and a single population SP1 with descriptive parameters (Md Φ 355 = 4.3 Φ ; $\sigma\Phi$ = 0.48 Φ), very close to those of the SP2 of the other samples of Phase 1. Ash from Phase 2 356 clearly differentiates from all the other phases due to the nearly symmetric (Skewness = 0.06), 357 leptokurtic (Kurtosis = 1.04) GSDs, with only a minor fine mode in the proximal sample (Fig. 4). In the 358 GSD of the sample SKJ24 10 5 (proximal deposit: 5 km from the vent; Fig. 1b), the coarse 359 subpopulation SP1 represents about the 98 wt. % of the deposit, with an Md Φ of 1.2 Φ (Table 1). SP2 360 has an Md Φ of around 3.5 Φ and only represents the 2 wt. % of deposit. The distal deposit of Phase 2 (SKJ24 10 14, collected 11 km far from the vent along the dispersal axis; Fig. 1b) still shows a main 361 362 SP1, with Md Φ = 3 Φ and with an only minor presence of SP2, with Md Φ = 5.2 Φ (Table1) accounting 363 again for only the 2 vol.% of the bulk GSD. The samples from Phase 3, collected at different times, are 364 characterized by asymmetric, positively skewed distributions with a main mode set between $3-3.5\Phi$ 365 (Fig. 4 and Table 1). These samples show a very pronounced fine-grained tail, with a secondary mode 366 at around 5 Φ (in two out of three samples; Fig. 4). Again, the bulk GSD can be deconvoluted (R² > 367 0.96) as the sum of two SPs. The finer subpopulation SP2, with an Md Φ around 5 Φ , is more represented 368 respect to the other samples, reaching about 30-35 wt.% of the total (Table 1). The SP1 of these samples 369 has an Md Φ between 2.8-3.6 Φ (Fig. 4 and Table 1) and represents around the 65-71 wt. % of the bulk 370 deposit. Interestingly, for the three samples from Phase 3 (SKJ24 10 9bis; SKJ24 10 10; 371 SKJ24 10 11) Md Φ of SP1 records a progressive increase from towards higher values with time of 372 collection (Table 1). This variation is accompanied by a decrease of the relative weight of SP1 (from 373 71 to 65%) and a corresponding increase in the weight of SP2, however with no visible change in its 374 MdΦ.

375

377

376 4.2. Characterization of the ash components

378 Ash deposits from the different phases are dominated by glassy, dense and blocky particles showing 379 variably glossy external surfaces with conchoidal fractures and sharp edges, and with variable 380 roundness. The different fragments are characterized by color ranging from intense and shiny dark grey 381 to a translucent grey; in many cases, opaque grey colored particles were also recognized, characterized 382 by pitted and non-glossy external surfaces. Poorly vesicular particles, translucent, brownish to dark in 383 color, are also a primary component, particularly in the deposits of the high intensity Phase 2. Loose, 384 often broken crystals (i.e. plagioclase, clinopyroxene, orthopyroxene, Fe-Ti Oxides and rare olivine), 385 are present in very minor amounts, together with sparse lithics, variably colored from white to yellow 386 and brownish-red. These are generally recognized for the incipient to pervasive alteration of the 387 fragment, and mainly correspond to fragments of preexisting lava flows. Considering the very low 388 amounts of the loose crystals and lithics classes, these will be not further considered in this analysis.

389 Based on these general observations, three classes of ash fragments were identified (Fig. 5):

390

391 i. **Blocky Angular** (BA) are formed by very poorly vesicular to dense, blocky particles with sharp 392 edges and equant outlines, characterized by variably glossy and shiny surfaces, sometimes intercepting 393 sparse, large and isolated vesicles (100-200 µm in diameter). These clasts commonly show planar 394 surfaces with typical indentation patterns, possibly resulting from the brittle fracturing of viscous 395 magma (Fig. 5a). The external surfaces are typically characterized by a sparse, small-scale roughness, 396 where asperities (generally in the order of few micrometers) are mainly related to the crystallization of 397 microlites from the groundmass glass. No evidence of magma-water interaction was revealed for these 398 clasts after the SEM analysis (eg. surface pitting and cracking). The average values of Solidity and 399 Convexity determined by image analysis on selected BA particles are respectively 0.930 ± 0.025 and 400 0.876 ± 0.022 , indicating a generally solid shape with significantly convex external outlines (Table 2). 401 The average value of Circularity is 0.794 ± 0.040 , indicating fairly regular outlines for the clasts, 402 associated to a blocky and a massive structure (Table 2). However, fragments with smoother external 403 surfaces are also present. The most abundant groundmass microlites are represented by prismatic, 404 euhedral and elongated (20-60 µm), sometimes acicular microlites of plagioclase, followed by pyroxene 405 and sparse oxide crystals. Importantly, swallowtail and skeletal morphologies of microlites are never 406 observed among the investigated samples. A secondary population, only occasionally present within the 407 BA clasts, is represented by sparse clusters, irregularly arranged in space, of Fe-Ti oxides crystals 408 typically smaller than 5 μ m in size. Up to 60 vol.% of the groundmass is represented by residual glass. 409 BA particles possibly correspond to the 'High-Crystallinity-Particles (HCP)' showing "glossy surfaces" 410 reported by Miwa et al. (2013b) and with the "Black Volcanic Rocks" (BVR) descripted in the study of 411 Kurniawan et al. (2016).

412

413 ii. Blocky Rounded (BR) are blocky, massive, poorly vesicular to dense particles generally 414 characterized by opaque from dark to grey colors (Fig. 5b). They show average values for Solidity and 415 Convexity of 0.954 ± 0.015 and 0.889 ± 0.019 , respectively (Table 2), suggesting largely convex shapes 416 and rather external smooth surfaces. The average Circularity of 0.830 ± 0.029 accounts for the sub-417 rounded to rounded outlines, which, along with the pitted aspect of the external surfaces (Fig. 5b), make 418 the BR particles very distinct from the BA particles. Groundmass of BR particles is characterized by 419 the presence of two populations of microlites: the coarser-grained population (15-30 µm length) is made 420 up of plagioclase, mafic minerals (cpx, opx, and rare olivine) and sub-euhedral Fe-Ti oxide crystals, 421 while the finer-grained population is represented by diffuse clusters of very small ($< 5 \mu m$) Fe-Ti Oxides 422 crystals. Differently from BA, the presence of the small Fe-Ti oxides population is pervasive in the 423 groundmass texture (Fig. 5b), and a more diffuse µm-sized roughness affects the external surfaces. BR 424 clasts also show the highest values of crystallization of the groundmass glass (42-45%; Table 3). 425 Occasionally, small acicular salt crystals (possibly Ca-sulphates) are found above the external surfaces. 426 BR clasts are very similar in the external aspect to those briefly descripted by Miwa et al. (2013b) as 427 non-juvenile particle showing 'non-glossy' surfaces (also corresponding to the NS-Type of Miwa et al. 428 2009). On the other hand, the diffuse recrystallization of the groundmass glass is strongly suggestive

429 of processes of intra-crater recycling of previously ejected juvenile material under high-T conditions
430 (D'Oriano et al., 2011, 2014; Deardorff et al., 2017).

431

432 iii. Vesicular (VS) clasts consist of incipiently to poorly vesicular particles (Houghton and Wilson, 433 1989) characterized by glossy external surfaces, translucent-brown to dark in color with external 434 surfaces intercepting sparse vesicles, from 30 to 60 µm in size (Fig. 5c). Both Solidity and Convexity 435 show average values that are significantly lower (0.915 ± 0.036 and 0.838 ± 0.038 , respectively; Table 436 2) respect to the other categories, testifying for more irregular and convoluted external outlines. Also, 437 the Circularity of particles is significantly lower respect to other categories (0.756 \pm 0.059). Vesicles 438 are never interconnected and their abundance is largely variable, from few percent up to maximum 30 439 vol.%. Very high values of vesicularity, typical of pumice-like material (>40-50%), have been never 440 observed in the analyzed material, although they have been described in other eruptions (Miwa et al., 441 2009). The glass of VS particles always presents unaltered with a microlite-poor groundmass (crystal 442 content around 30 vol. %) when compared with the other two categories. Microlites are dominated by a 443 single population, with an average size of 10-20 μ m, consisting of single prismatic, euhedral 444 plagioclase, together with sparse mafic minerals and oxides. Importantly, the population of small Fe-Ti 445 oxide clusters is totally absent in these clasts. VS clast can be easily associated with the 'vesicular' and 446 'Low-Crystallinity-Particles (LCP)' presented by Miwa et al. (2013b), and with the "Black Vesicular 447 Volcanic Rocks" (BVVR) of Kurniawan et al. (2016). On the other hand, they result significantly 448 different from the *pumiceous particles* identified by Miwa et al. (2009) due to their lower and isolated 449 vesicularity (rarely exceeding 30%).

450

451 The relative proportions of the different components change during the different phases of the eruptive 452 activity (Table 4). Ash componentry is largely dominated by BA and BR clasts. Although VS clasts 453 represents only a minor fraction in Phase 1 products (less than 10%), they tend to significantly increase 454 respect to BA as the eruptive sequence progresses (VS/BA ratio from 0.20 to 1.07; Table 4). An opposite 455 trend is shown either by the BA and the BR clasts, whose relative abundances progressively decrease 456 throughout the sequence, reaching a minimum in Phase 3 and coupled to a continuous increase of VS 457 clasts (Table 4). As a matter of facts, the dense fraction is shown to be by far dominant respect to the 458 vesicular fraction ((BA + BR)/V) during all the phases of the eruptive sequence. Moreover, the relative 459 proportions of BA vs. BR remain nearly constant throughout the entire sequence (Table 4).

460 Finally, while the abundance of the lithic component is always very low and nearly constant, loose
461 crystals abundance progressively increase (from 4 to 18%) along the sequence (Table 4). Unfortunately,
462 the very fine grain-size of Phase 1 {New Cycle} has not allowed to estimate componentry for this stage
463 of activity.

464

465 4.3. Quantitative characterization of ash groundmass textures

466

467 The analysis of the groundmass texture of the different clast types was addressed to characterize the 468 relative abundance of vesicles (Table 3) and crystals phases (Fig. 6a), the areal microlite number density 469 (MND; Table 3) of the different ash components, the shape and the crystal size distribution (CSD) of470 the plagioclase microlites (Fig. 6b).

The average values calculated for the microlite contents (Table 3) of BA and BR clasts are similar (around 40-45 vol.%) being nearly constant throughout all the eruptive sequence. BR clasts display, in

473 general, a higher content of microlites, with the highest values of 45.6% during Phase 3 (Fig. 6a, b;

- 474 Table 3). VS clasts show instead a larger variability (29-36 vol.%) in terms of crystal content, with a
- 475 marked decrease during Phase 2 (Fig. 6a, b; Table 3). All these values agree with the crystal content
- 476 reported by Miwa et al. (2013b) respectively for HCP and LCPs ash fragments, and by Smith et al.477 (2018).
- MND is calculated for all the mineral phases identified during the image analysis (Plagicalse, Femics,
 Oxydes). Excluding the two extreme values, MND varies by a factor of 5 (between 1.9 x 10⁴ and 5.1 x 10⁴ mm⁻²; Tables 3 and S3), in good agreement with data reported by Kurniawan et al. (2016).
- 481 All the CSDs calculated for plagioclase microlites display invariant linear trends for the different types
- tor interest of the anti-term of the ant
- 482 of clasts regardless of the eruptive phases (Fig. 6a, b). A single BR sample from Phase 3 (red squares
- 483 in Fig. 6c) exhibits a more pronounced tail in the coarser size regions (more than 100 μ m). CSDs display 484 a regression slope (-1/G τ , where G is the crystal growth rate and τ is the time of crystallization) variable
- 485 between -77 and -109, resulting in a dominant size of microlites, on average, around 30-40 μ m (3G τ ; 486 Cashman, 1992; Table 5). The extrapolated nuclei number density n₀ (corresponding to intercept of the 487 linear regression of the CSD) is poorly variable among all the analyzed samples being comprised 488 between 17.56 ± 0.06 and 18.75 ± 0.10 (Table 5). Despite the weak variability, n₀ shows a clear negative 489 relation with 3Gt indicating that larger crystal sizes were related to lower nucleation rates. Importantly,
- 490 the latter relation is totally unrelated with the style and timing of the activity.
- 491 All the CSD trends clearly display an overturn of the population density for the size classes smaller 492 than 10 μ m, also present in data reported by Miwa et al. (2013b). Typical axial ratios (short; 493 intermediate; long) of plagioclase in the different phases are also nearly invariant (1 : 3.4 : 9 - 1 : 4 : 494 10 - 1 : 3.4 : 10, respectively for Phases 1, 2, and 3; Table 6). Again, these values are very close to 495 those reported by Miwa et al. (2013b) for plagioclase microlites in both LCPs and HCP fragments (1: 496 2.3 : 9 and 1 : 3.2 : 10, respectively).
- 497 Finally, the cumulative number frequency distributions of the plagioclase size in the bi-logarithmic
 498 space (Fig. 6c, d) display curvilinear distribution trends, suggestive of not-scale invariant
 499 crystallization. All the data have a similar distribution trend, regardless of the type of ash component
 500 and the activity phase, confirming thus the very small variability already suggested by CSD plots.
- 501

503

502 4.4 Quantitative investigation of the ash shape

The variability of ash morphology along the sequence is well described by some selected shape parameters (Cioni et al., 2014; Liu et al., 2015; Leibrandt et al., 2015), and by the correlation between their variability trend with the particle size. Ash from Phases 1 and 3 shows very similar trends of variation with size and, more importantly, very similar values of all the different shape parameters (Fig. 7). Conversely, despite the partial overlap of the data dispersion ranges, ash from Phase 2 displays very distinct variability trends respect to the other samples, being also associated to a marked variation of the parameters values with the particle size (Fig. 7). In general, ash from all the samples is characterized by a quite regular outline, with high Solidity and Convexity values (higher than 0.94 and 0.96, respectively), and by an elongated shape (Circularity < 0.93, Elongation between 0.15 - 0.40).</p>

513 As suggested by Elongation and Circularity values (Fig. 7a, b) particle shape is nearly invariant respect 514 to the ash size for samples from Phases 1 and 3, while Circularity shows a marked, progressive increase 515 with decreasing size for the sample from the Phase 2 (Fig. 7b). On the other hand, a consistent variation 516 of the particle shape with size is evident for Solidity and Convexity (Fig. 7c, d) with size, suggesting 517 the prevalence of a coarse roughness (lower values of the two parameters in the coarser particles) on 518 the particle outline. Again, this trend is more marked for the ash of Phase 2, while ash from the other 519 two phases display very similar values of the different parameters (Fig. 7). Importantly, the trends of 520 Circularity, Solidity and Convexity for the ash of Phase 2 clearly diverge from the variability trends of 521 ash from Phase 1 and Phase 3, starting from particles size greater than 100 and 150 µm in diameter (Fig. 522 7). This indicate the presence of a constant size threshold for the outline roughness that characterize 523 ash particles from Phase 2, which is possibly coarser than about 100 µm.

524

525

526 5. Discussion

527

528 Ash-dominated, cyclic explosive activity represents the typical behavior of many volcanoes worldwide 529 which are mainly characterized by the eruption of mildly-evolved magmas. Sakurajima activity can be 530 considered a typical case-study for such volcanoes, since it is characterized by cyclic Vulcanian 531 eruptions with important shifts both in the intensity of the explosions and in the style of the ash 532 emissions (Miwa et al., 2009; Iguchi et al., 2013a; Yokoo et al., 2013). Differently from most of the 533 previous works on Sakurajima ash products, which were mainly focused on the products related to the 534 Vulcanian explosions, the dataset presented in this study involves not only the products of a major 535 explosion, but also ash from the precursory eruptive phases and ash emitted immediately after the high-536 intensity event, allowing thus an exhaustive characterization of the different phases defining a complete 537 Vulcanian activity cycle. Data will be used to critically discuss the main conduit and fragmentation 538 processes involved in such cycles, and how they can be reconciled with the general knowledge about 539 the mechanisms driving classical Vulcanian activity. Several questions are currently pending about the 540 conduit processes that effectively control the occurrence of high-frequency Vulcanian explosions:

- What are the internal gradients of the magma plug (i.e., vesicularity, crystal contents,
 permeability, viscosity) and which portions of the magma conduit are involved in the process
 of ash production during the different phases of the eruptive sequence?
- 544 Which process controls the sudden transition observed between passive ash emission and
 545 Vulcanian explosions?
- 546 Is the fresh, volatile-rich magma coming from the deep always directly involved into the 547 activity? Is the fresh magma input the general trigger mechanism of Vulcanian explosions?

- 548 What is the approximate volume of the magma conduit involved in each phase, also considering 549 the characteristic time of plug re-generation and recharge?
- 550 What is the variability in the intensity of explosive processes over periods much longer than a 551 cycle?

All these questions will be addressed in the following sections, comparing our results with the numerous

- data existing in the literature on Sakurajima activity and discussing them in the light of a new schematic
 model of the processes controlling the dynamics of Sakurajima throughout a complete Vulcanian
 eruption cycle.
- 556

557 5.1 Structure of the magma conduit from morphological and textural ash features

558

559 Vulcanian activity is generally described as the result of the fragmentation of a rigid to visco-plastic, 560 variably crystallized and variably degassed magma plug or lava dome sealing the top of a volcanic 561 conduit (Clarke et al., 2002b; Clarke et al., 2013; Gaunt et al., 2020). Formation of evident summit lava 562 domes has been observed to occur very sporadically at Sakurajima (Ishihara, 1990). Conversely, a 563 variably degassed, vertically stratified magma plug is considered to be commonly present, sealing the 564 upper portions of the conduit and generally modulating the dynamics of gas escape (Ishihara 1990; 565 Miwa et al., 2013b; Iguchi et al., 2013a, 2013b; Yokoo et al., 2013; Oláh et al., 2019). Morpho-textural 566 analysis on ash fragments efficiently informs about the variability of the internal structure of the 567 fragmented portions of magma. Accordingly, the relative proportions of ash components can help to 568 define the internal gradients of the magma conduit (e.g. Cioni et al., 2014).

The general invariance revealed in the ash componentry throughout the eruptive cycle (i.e. constant type of components involved; Fig. 5), together with, minimal time- and style-unrelated variation in the CSD of plagioclase microlites (Fig. 6c, d) possibly reflects the presence of internal gradients into the syn-eruptive magma column, and also indicate a common pre-eruptive evolution for the different parcels of magma from which these components derive. Conversely, the variability in the total crystal content indicates a progressive, although slight, change of the emitted material along the eruptive cycle (Fig. 6a, b).

576 All the samples of the studied sequence are characterized by the common presence of three types of ash 577 fragments (Fig. 5) displaying very distinct external shapes and internal textures. Several authors 578 provided analyses of ash componentry on tephra products erupted during different activity periods at 579 Sakurajima (Oba et al., 1980; Miwa et al., 2009; Miwa et al., 2013a; Miwa et al., 2013b, Kurniawan et 580 al., 2016). Regardless of the nomenclature assigned to the different ash components, we found a 581 substantial agreement in the identification of the main ash types. In fact, their textural features can be 582 easily correlated with those of the ash components described by several authors studying previous stages 583 of activity at Sakurajima (Oba et al., 1980; Miwa et al., 2009; Miwa et al., 2013b; Kurniawan et al., 584 2016). However, differently from what observed by Miwa et al. (2013b) for the 2010 activity, no 585 particles with 'fluidal' external morphology as well as no pumice-like particles (Miwa et al., 2013a; 586 Kurniawan et al., 2016) characterized by very high vesicularity were recognized in our samples, despite 587 the observed activity closely reflects the typical eruptive pattern and intensity of Vulcanian activity at

- 588 Sakurajima (JMA on-line reports). VS clasts, in fact, represent always a minor volume fraction in all 589 the analyzed deposits, furthermore displaying a low average vesicularity, rarely exceeding 20 vol.%, 590 which is considerably lower respect to values reported (60 vol%) for the pumiceous fragments by Miwa 591 and Toramaru (2013) (Fig. 5c, d). The generally low abundance of highly-vesicular material in the 592 studied deposits might be reconciled with the lower rates of the volcano activity (i.e. number of 593 explosion per month) respect to the periods investigated by other authors, as evidenced by data reported 594 in Oishi et al. (2018) (Table S4).
- 595 All the analyzed deposits are largely dominated by BA particles, characterized by high microlite 596 contents (mostly comprised between 35 and 40 vol. %), very low vesicularity (around 1 vol.%), and 597 sharp external outlines with planar, shiny and glossy external surfaces (Fig. 5a; Table 3). As a matter 598 of facts, all these features are typical of fragments derived from the brittle disruption of a highly viscous, 599 semi-rigid magma portion, in agreement also with the rhyolitic composition of the residual melt 600 determined for similar fragments by Kurniawan et al. (2016) (SiO₂ = 74.2 \pm 1.7 wt. %; BVR fragments). 601 We suggest that these clasts derive from the fragmentation of a highly degassed, highly crystallized 602 (30-40%) parcel of the magma developed in the topmost portion of the plug (Fig. 8). Further elements 603 supporting this interpretation come from the textural analysis of the ash fragments. In particular, the 604 observed turn-down of the linear trends of CSDs for crystals smaller than 10 µm (Fig. 6c), possibly 605 indicates the occurrence of a coarsening process typical of highly crystallized melts (Higgins, 2006). 606 Furthermore, the euhedral and prismatic morphology of plagioclase microlites (Table 6) together with 607 the clear evidence of a time-unrelated, negative relation between n_0 and 3Gt (Table 5), likely indicate 608 crystallization under constant and low undercooling conditions (Morgan and Jerram, 2006; Brugger and 609 Hammer, 2010b; Shea and Hammer, 2013) experienced during prolonged stages of decompression-610 induced crystallization (Cassidy et al., 2015). Both these observations suggest stalling, or very slow 611 ascent, of magma at low-pressure, that indirectly confirms the interpretation made for BA particles as 612 derived from a highly viscous, nearly rigid magma-plug (Fig. 8).
- 613 BR particles share several morphological features with BA clasts, although differing from them mainly 614 for the lower angularity of the external outlines (Circularity: 0.830 ± 0.029 ; Table 2), the diffuse, low-615 scale roughness and the dull color of the external surfaces (Fig. 5b). The µm-sized population of Fe-Ti 616 oxides overprinted on sub-euhedral microlites (Fig. 5b) is very similar to that produced during 617 experimental re-heating of glass-bearing fragments that are interpreted as thermally-induced glass 618 recrystallization during recycling in the vent area (D'Oriano et al., 2011, 2014; Deardorff and Cashman, 619 2017). These features suggest that BR clasts invariably derive from the intra-crateric recycling of mostly 620 BA-type particles fragmented and ejected during preceding cycles of activity (Fig. 8). This is also 621 indirectly confirmed by the invariant groundmass textures shown by this type of fragments among all 622 the different phases of activity, as testified for example by their constant microlite abundance and 623 invariant CSD features (Fig. 6c, d). The gradual decrease in the relative abundance of these clasts from 624 the initial Phase 1 to the Phase 3 (Table 4) possibly reflects the progressive clearing of the vent area 625 due to the significant increase in the intensity of the activity, and therefore the increasing importance 626 of the involvement of newly fragmented ash in the progressing eruptive cycle. Importantly, in previous 627 studies BR clast type has never been accurately described, as they were often classified as not-vesicular,

628 not-smooth, glassy juvenile material (Miwa et al., 2009), as lithic clasts (Kurniawan et al., 2016), or 629 even included in the altered material (Miwa et al., 2013b, 2015). This possibly explains our generally 630 lower estimates of lithic fragments respect to data reported from other authors (e.g. Kurniawan et al., 631 2016). In fact, these clasts display very low relative abundances (less than few vol.%) in all the analyzed 632 deposits, in agreement with the low to moderate energy of the observed activity. This indirectly implies 633 that an important portion (in terms of mass) of produced ash, although not directly involved in the 634 process of primary magma fragmentation, could still have a first order role in driving the convective 635 ascent of the plume, thanks to its high temperature and abundance. The fact that BR clasts are not 636 involved in the active fragmentation process is also in agreement with their higher abundance during 637 periods of quasi-constant and passive ash emission (Table 4), which are indeed characterized by a very 638 low energy of the activity (Iguchi et al., 2008). For all these reasons, we suggest that the presence of 639 significant quantities of high-temperature, pre-fragmented and remobilized material occupying the 640 crater area during the low energy activity phases (Fig. 8) could represent an aspect of primary 641 importance for the definition of a general energy balance of ash production and emission at Sakurajima. 642 We suggest this aspect could be relevant not only at Sakurajima volcano but also in similar activity 643 contexts dominated by cyclic low-to-mid intensity activity. For example, in the 2009-2010 activity of 644 Tungurahua volcano "Vitreous oxidized" ash particles, representing up to 15% of the fallout deposit, 645 were interpreted as vent-hosted and recycled materials, and their abundance throughout the eruptive 646 sequence is similar to that observed at Sakurajima, with a general decrease in correspondence with the 647 more energetic and vulcanian stages of the activity (Battaglia et al., 2019).

648 The specific characteristics that distinguish VS particles from the other types of fragments are the 649 presence of a modest vesicularity (<30%) associated with a lower crystal content (Fig. 6a, b). The low 650 vesicularity value, the rounded shape and the isolated nature of the vesicles (Fig. 5c, d) suggest a low 651 internal permeability of this magma portion. The planar external surfaces, with no signs of fluidal 652 deformation, and the microlite-rich groundmass, although with slightly lower MND values respect to 653 other types (5.0e10³ mm⁻², Table 5), still testify a rigid behavior at fragmentation for these clasts, 654 possibly related with the rhyolitic composition of the residual melt (average SiO₂ = 70.7 ± 1.5 wt. %; 655 BVVR fragments, Kurniawan et al., 2016). Consequently, also for VS fragments we suggest derivation 656 from a still rigid portion of the plug, although slightly volatile-richer and less crystalline respect to that 657 represented by BA fragments. As a matter of facts, we suggest that the portion of magma originating 658 VS type clasts was possibly deeper respect to that forming BA particles (Fig. 8). This part of the magma 659 plug possibly corresponds to the region where several authors (Ishihara, 1990; Yokoo et al., 2013) 660 identified the presence of a gas pocket interpreted to be responsible for the violent pressure shock waves 661 often recorded at the onset of the Vulcanian explosions (Fig. 8).

The presence of a magma plug with small internal gradients of vesicularity, crystal content and possibly dissolved gas is also confirmed by the poor variability observed in the internal texture of the different fragments (Table 5). The linear and nearly invariant CSDs (Fig. 6c) observed in all the ash fragments can be used to give constraints to the timing of plug reformation. Considering a possible range of growth rates data for plagioclase crystals growing under low to intermediate undercooling conditions (10^{-8} to 10^{-9} mm s⁻¹ (Blundy and Cashman, 2000; Brugger and Hammer, 2010), the crystallization time scale of 668 the fragmented plug results in the order of around 1-10 months, thus confirming the fact that newly 669 arrived magma is not involved in the eruption.

670

671 5.2 Dynamics of the recent Vulcanian activity at Sakurajima

672

The systematic variability revealed in the GSDs of the ash deposits, along with the sudden shifts observed in the style of the activity (Figs. 2 and 3; Table 1) record important variations in the eruptive conditions, and therefore possibly fragmentation mechanisms during the observed sequence of activity at Sakurajima. A critical review about the variability of the conduit processes operating during the different stages of Vulcanian activity at Sakurajima is based on evidences obtained from data collected on tephra GSD, and on information of conduit stratification inferred from the study of the ash morphotextural features and componentry.

680 A conceptual model of the activity cycle is introduced in Figure 9, in order to discuss the variability of 681 conduit process along the eruptive sequence. Phase 1 (Fig. 9a) preceding the Vulcanian explosion (Phase 682 2) is mainly characterized by a passive, low-energy degassing during which very low amounts of fine 683 ash are dispersed at short distances, with very low sedimentation rates (1.91E-06 kg/m²/s; Figs. 1, 3). 684 The absence of clear signs of transient explosive activity during this phase suggests that magma 685 fragmentation cannot be driven by a large pressure accumulation within the magma plug. According to 686 these evidences, we suggest that during Phase 1 magma fragmentation is a nearly continuous process, 687 likely driven by the low-pressure gas release escaping from the permeable fracture network that 688 characterize the upper rigid portion of the outgassed plug. Under these conditions, ash conveyed in the 689 plume possibly derives from two different processes: i) the fragmented material present in the crater 690 infilling and produced during previous explosions (Hantusch et al., 2021), ii) clastic material produced 691 through not-explosive, frictional fragmentation inside the fracture network in the plug (similar to fault 692 gouges fragmentation observed in several plugs/domes elsewhere; e.g. Cashman et al., 2008) (Fig. 9a). 693 Elutriation from an ash-filled crater (Hantusch et al., 2021) or from ash-filled fractures internal to the 694 plug, could be a feasible mechanism for justifying the high abundance of BR type clasts in the plume. 695 Given the average size of the fragments during this phase (Md Φ = 2.5 Φ =180 µm), gas ascent velocities 696 of the order of few m s⁻¹ could be enough for the fluidization of these beds and elutriation of the sampled 697 material (Tasirin & Geldart, 1999). Low ascent velocities of the gas-ash plume are also testified by the 698 observed rapid, low-level drifting of the plume under low wind shear.

699 Conversely, Phase 2 (Fig. 9b) represents a short-lived, high-energy event, able to eject both large 700 ballistic blocks along the slopes of the volcano and to form a forced-thermal plume which ascended 701 vertically up to 3-4 km height before being drifted away by the wind (Fig. 3). Shape analysis revealed 702 that ash deposits from Phase 2 clearly differs from other deposits (Fig. 7). The observed variability in 703 particle shape is interpretable as related to larger amounts of vesicular particles (generally characterized 704 by highly irregular contours) in the fine ash ejected during the Phase 2 and to the presence of a vesicle 705 population with a size possibly between 50-100 µm, which mainly affects and modifies the external 706 shape of the coarser particles. On the other hand, resulting ash deposits are still largely populated by

707 dense to poorly vesicular (rarely exceeding the 20%), microlite-rich particles (\sim 30%). This indicates, 708 also for the most energetic activity, the prevalence of a brittle magma fragmentation mechanism (Fig. 709 9b) with no or scarce participation of fresh hot magma from a deeper reservoir. The lack of the fluidal 710 or pumice-like material, often observed during other periods of Sakurajima activity, along with the 711 substantial invariance revealed in the CSDs of plagioclase microlites and in the ash componentry, all 712 suggest that activity was possibly fueled by the progressive magma degassing and consequent pressure 713 loading of the upper, partially to totally degassed portion of the conduit. The short duration and the 714 impulsive character of the explosion of Phase 2 displayed by thermal imagery (Fig. 3) is furthermore 715 consistent with a rapid and abrupt release of pressurized gas. Gas migration is possibly due to the 716 gradual development of partially permeable regions, in the form of a fractures network, within the upper 717 viscous portions of the conduit, as a result of the high internal shear of the ascending and degassing 718 viscous magma column. This hypothesis implies to discard an important role of new magma input as an 719 eruption trigger, and it requires a relatively slow ascending dynamics for the magma column, in order 720 to allow a significant magma degassing and the consequent pressure loading. As a matter of facts, this 721 agrees with the significantly lower rate of explosive activity that characterized Sakurajima in the 722 October 2014 (Oishi et al., 2018). These considerations are also confirmed by Yokoo et al. (2013) who, 723 interpreting geophysical signals, recognized the unlikelihood for the injection of new magma from the 724 deeper magma reservoir to actively participate and trigger the onset of the eruption itself, as instead 725 suggested by several other authors (Iguchi et al., 2008; Miwa et al., 2009; Miwa and Toramaru, 2013). 726 Moreover, a significant temporal stagnation in terms of both activity and seismic signals is often 727 observed to characterize the time gap between the input of new fresh magma and the consequent 728 Vulcanian activity (Yokoo et al., 2013). All these data, suggest that the mechanisms responsible for 729 triggering at least part of the Vulcanian explosions at Sakurajima are mostly related to the gradual over-730 pressurization of the upper portions of a rigid plug (upper portions of degassing conduit) by progressive 731 volatile exsolution from degassing column, however without important outgassing in the plug itself 732 (Fig. 9b). Conversely, mechanisms of pressure increase related to addition of gas-rich magma below 733 the plug occur in relation with major explosions during periods the high-rate activity (high frequency 734 of explosions).

735 Importantly, as already discussed for Phase 1, the large presence of recycled clasts with clear thermally-736 induced glass recrystallization (BR clasts) also during the Vulcanian phase can be of primary 737 importance in determining the convective power of the resulting plume. In fact, albeit these clasts should 738 be classified as lithic material since they were already fragmented at the moment of being engulfed in 739 the plume, they can still represent an important heat source for the plume development, due to their hot 740 state and their abundance in the ejected material (up to around 50 vol.%). BR clasts so assume a primary 741 role in the total heat budget driving the plume ascent and ash dispersal at Sakurajima, and they should 742 be distinguished from other lithic material. The forced-thermal power of the plume related to Phase 2 743 is well recorded by thermal analysis (Fig. 3). The coarser average grain size of the material transported 744 in this phase (around 500 μ m), considerably larger than that of the other phases, and the higher 745 sedimentation rate (2.38 E-05 kg/m²/s; Fig. 4) are, in part, evidence of the forced thermal nature of the 746 plume. The comparison of proximal and distal deposits (Table 1) evidences the substantial absence of

747 an important fine-grained subpopulation (SP2) in this phase. This can be related to two concurrent 748 processes: i) the inefficiency of ash aggregation, which prematurely force ash fallout, and ii) the absence 749 of an actively fragmentating region of high vesicularity magma. In fact, in the absence of processes like 750 magma-water interaction, the most efficient process to produce very fine ash is the disintegration of the 751 thin septa between the vesicles of a highly vesicular foam, not present in this phase (Dufek et al., 2012). 752 As inferred from visual observations of the ash deposits (Fig. 2), ash aggregation had in fact only a 753 minor impact in terms of mass of fine material involved in early sedimentation, possibly for the general 754 absence of a very fine-grained subpopulation (SP2). The high-energy, explosive fragmentation of the 755 plug during the Phase 2 is however clearly evidenced by the concurrent abundance of both BA and VS 756 fragments (Table 4), which suggests the involvement in the explosion of a large part of the upper portion 757 of the plug. The contribution of vesicular ash in the Vulcanian Explosion (well indicated by the 758 morphology of ash fragments in the range 50-300 µm; Fig. 7), further confirms a more intense and 759 deeper fragmentation of the plug during this phase. In this respect, it is interesting to note that the very 760 low, around 0.2 wt.%, water content measured by Miwa et al. (2013a) in the glass of BA-type ash with 761 MND similar to those measured here in the October 2014 fragments, converts into a saturation pressure 762 of only few bars (Newman and Lowenstern, 2002) and to a maximum depth of around 40-50 m. 763 Consequently, we suggest that only the very upper portion of the plug was destroyed by the explosion, 764 also according to the average mass emitted during similar explosions (Oishi et al., 2018) and to the 765 observed upper diameter of the plug (10-20 m; Iguchi et al., 2010).

766 Very fine ash is instead mostly erupted during Phase 3 (Fig. 9c). This activity can be interpreted as a 767 continued degassing phase following the partial unloading of the plug and the depressurization 768 determined by the removal of its upper part during the *Vulcanian Explosion*. In these terms, the large 769 presence of a fine-grained (around 5 Φ) subpopulation in the ash could be the result of the sudden 770 foaming and partial fragmentation of a slightly deeper, volatile-richer portion of the plug (Fig. 9c) 771 unloaded by the partial removal of the plug during Phase 2. The general highly crystallized groundmass 772 texture, and especially the important increase of the free crystals recorded during Phase 3 (Table 4), 773 clearly denote that fragmentation always occurred over a largely crystallized magma.

774 All the above considerations can be used to discuss and integrate the model proposed on the basis of 775 geophysical observations by Yokoo et al. (2013) about the Vulcanian activity at Showa crater. Several 776 lines of evidence revealed by geophysics well agree in fact with the characteristics of the observed 777 products. Firstly, the pattern of deformation preceding and accompanying Vulcanian activity from the 778 Showa crater reveals a quite shallow source (few hundred of meters), interpreted by Yokoo et al. (2013) 779 through the possible build-up and following explosive disruption of a gas pocket. In this view, the 780 fragmentation of this viscous, degassed portion of the conduit triggered a decompression wave 781 travelling throughout the most rigid part of the plug. This well agrees with our observation of a very 782 shallow derivation of the erupted material, and with the generally small volume ejected during each 783 explosion (Oishi et al., 2018). Similarly, evolution of deformation preceding each large eruption shows 784 a long-term (up to several hours) inflation of the upper part of the volcano, during which the gas pocket 785 is formed and some gas can be leaked from the upper part of the plug, possibly carrying and elutriating 786 ash particles already present in the fracture network or in the crater area. The final continuous

787 contraction of the system, following Phase 2, is characterized by the rapid degassing of the unloaded, 788 gas-richer portion of the magma below the removed part of the plug, occurring under unconfined 789 conditions. Conversely, no evidence derives from our data supporting the alternative hypotheses of 790 Yokoo et al. (2013) about the origin of gas accumulation as possibly related to the occurrence of 791 repeated events of magma migration at a depth between 0-2 km, or of any important role of newly 792 intruded magma in the system (Iguchi et al., 2013) during this type of activity. This aspect can be 793 reconciled considering the low activity rates of Sakurajima during the investigated period. This could 794 also explain the generally lower energy associated with explosions from Showa crater respect to those 795 occurring from Minamidake crater (Iguchi et al., 2010), that often show the presence of highly vesicular, 796 poorly crystallized, pumice-like material or of fluidal, vesicular material that we never observed in the 797 studied sequence.

798

799 6. Conclusion

eruptive sequence at Sakurajima.

800

801 The studied eruptive sequence encompassed the whole spectrum of eruptive activities that are typically 802 associated to Vulcanian eruptions at Sakurajima, being characterized by episodes of highly energetic 803 explosions interspersed within prolonged periods of variably intense, not-explosive ash and gas 804 emission. Differently from previous works on Sakurajima ash, mainly focused on the products of single 805 Vulcanian eruption, we investigated here the cyclic styles of activity driving and following a main 806 Vulcanian eruption. We identified four different phases that were all analyzed in detail: a low-energy, 807 preparatory activity of Weak Ash Emission (Phase 1), preceding a main Vulcanian Explosion (Phase 2), 808 then followed by a typical activity of Continuous Ash Venting (Phase 3). Activity renewed three hours 809 later with a post-event weak ash emission (Phase 1 {New Cycle}), however considered to represent the 810 very initial stage of a new cycle and prodromal to the onset of the following major Vulcanian event. 811 This approach allowed us to clarify the critical role of conduit processes in controlling the mechanisms 812 of ash formation have and the eruptive dynamics in a typical Vulcanian activity, and to critically discuss 813 pre-existing models concerning the dynamics of Sakurajima activity.

814 Analyzed deposits from the different phases of activity revealed to be largely dominated by degassed 815 and largely crystallized particles, despite significant variability observed both in the intensity and in 816 the eruptive style of the activity. The morpho-textural variability of the analyzed ash samples suggests 817 that a significant layering and differentiation in terms of physical properties (i.e. vesicularity and 818 crystallinity), and hence magma rheology, must have characterized the volcanic conduit of Sakurajima 819 prior and/or during the observed activity. The specific characteristics of the different ash components 820 also suggest that a variable mechanism of magma fragmentation operated during the eruptive sequence. 821 Consequently, we register a large variability of conduit processes participating to the dynamics of the 822

823 Based on the comparison with data reported from previous studies on Sakurajima ash, a general large-824 scale temporal invariance of the textural features is revealed to characterize the products of typical 825 Vulcanian activity. This aspect, together with reported evidences on ash texture concurs to indicate the 826 dominancy at Sakurajima of a cyclic, degassing-driven eruptive dynamics, which is mostly controlled 827 by a quasi-static column of vertically stratified, poorly permeable, high-crystallinity magma conduit. 828 We estimated a characteristic time-scale for the plug renewal to be around 1-10 months. Our data also 829 confirm what yet suggested by Yokoo et al. (2013) that gas accumulation in the plug, rather than the 830 arrival of a new, volatile-richer magma batch as suggested by other authors (Iguchi et al., 2013b; Miwa 831 et al., 2013b), can be the most probable trigger for Vulcanian explosions at Sakurajima during periods 832 of "ordinary" activity. Based on these evidences we interpret the dynamics of Vulcanian eruptions at 833 Sakurajima as controlled by the progressive pressurization of a degassed upper portion of the conduit, 834 comprised in a range of depth between 10 and 50 m, that undergoes brittle fragmentation as the tensile 835 strength of the viscous magma cap is reached. Finally, based on the general high-frequency occurrence 836 of Vulcanian explosion at Sakurajima (typically from 20 up to 400 eruption per month), and according 837 with the long time-scale estimates provided for the plug regeneration, we suggest that the magma cap 838 is only partially removed during the Vulcanian events.
