Abstract: *Pseudomonas savastanoi* pv. *savastanoi* is the causal agent of Olive knot disease, relying on the Type Three Secretion System (TTSS) for its pathogenicity. In this regard, nothing was known about the two other pathovars belonging to this species, pv. *nerii* and pv. *fraxini*, characterized by a different host range. Here we report on the organization of the entire TTSS cluster on the three pathovars, and a phylogenetic analysis including the TTSS of those bacteria belonging to the *P. syringae* complex sequenced so far, highlighting the evolution of each operon (*hrpC*, *hrpJ*, *hrpRS*, *hrpU* and *hrpZ*). Moreover, by Real-Time PCR we analyzed the *in vitro* expression of four main TTSS genes, revealing different activation patterns in the three pathovars, hypothetically related to their diverse virulence behaviors.

Keywords: Type Three Secretion System; *hrp*; *Pseudomonas syringae*; *Pseudomonas savastanoi*; evolution; recombination; gene expression; regulation

1. Introduction

The Type III Secretion System (TTSS) is a multi-molecular device which is essential for the pathogenicity of Gram-negative bacteria infecting plants, animals and humans, which use this system for the one-step delivery of effector proteins from the bacterial cytoplasm into that of the eukaryotic host cells.

It has been widely demonstrated that in plant pathogenic bacteria, both the triggering of the hypersensitive response (HR) in non-host or host resistant cultivars, and the pathogenicity on the susceptible cultivars of the hosts, strictly depends on the correct functionality of their TTSS. For this reason, the genes coding for the TTSS of phytopathogenic bacteria are indicated by the acronym *hrp* (*hypersensitive response* and *pathogenicity*). The additional acronym *hrc* is used for those *hrp* genes highly conserved in the TTSSs of bacterial pathogens of plants and animals [1].

According to the most recent model drawn for the bacteria belonging to the *Pseudomonas syringae* complex, at the beginning of the bacterium-plant interaction, specific effectors secreted via TTSS are involved in the suppression of the plant basal defences, which are elicited by the so called Pathogen or Microbe-Associated Molecular Patterns (PAMPs or MAMPs) and named PAMP-Triggered Immunity (PTI) [2-5]. On the other hand, when injected into the cytoplasm of a resistant cultivar of the host, TTSS effectors can be individually recognized by intracellular Nucleotide-Binding site, Leucine-Rich Repeat (NB-LRR) Resistance proteins (R), activating a second line of defence known as Effector-Triggered Immunity (ETI) [2-5] characterized by the development of HR. Various models have been recently elaborated to explain the molecular mechanisms at the basis of this recognition. As far as the susceptible hosts are concerned, the disease occurs through the activities of those TTSS effectors which are not recognized by host R proteins or able to suppress ETI [2-6]. In several phytopathogenic bacteria belonging to the *P. syringae* complex, the expression of *hrp/hrc* genes has been demonstrated to be triggered and regulated by both environmental and host factors [7-12]. *In vitro* expression of these genes is low or partially repressed when bacteria are grown in nutrient-rich media, whereas it rapidly increases when bacteria are grown in minimal medium, with or without plant cell exudates added, or are infiltrated into host tissues [7-9,11-16].

The regulation of TTSS in bacteria of the *P. syringae* complex has been described and dynamically modeled. Within this regulatory network HrpRS, HrpA, HrpV play an essential role and HrpL is one of the most important information processing points [11,17,18]. Moreover, critical linkages were found between TTSS transcriptional regulators and several global signal transduction systems [11,14,19-22].

P. savastanoi pv. *savastanoi* (*Psv*) was demonstrated to fully rely on the functionality of its TTSS to successfully induce knot formation in Olive trees [23,24]. So far, no information is available on this system for the other two pathovars belonging to this species, *nerii* (*Psn*) and *fraxini* (*Psf*), which attack woody plants as well, Oleander and Ash respectively. Here, for the first time, we report the whole sequence and organization of the TTSS clusters of *Psn* and *Psf*, together with that of a well-known *Psv*

strain. These data were used to determine the phylogenetic position of these pathogens into the *P. syringae* complex, using the *hrp* clusters fully sequenced until now in these bacteria. Moreover, for the first time to our knowledge, through Real-Time PCR we analyzed the kinetics of the *in vitro* expression of TTSS in *Psv*, *Psn* and *Psf*, to investigate if the timing and/or the wiring of TTSS regulation could have any potential concerning the evolution of virulence across these *P. savastanoi* pathovars.

2. Results and Discussion

2.1. Organization of TTSS Cluster in *P. savastanoi* Pathovars

The organization of the TTSS clusters of *Psv5* (FR717896), *Psn23* (FR717897) and *Psf134* (FR717898) was discovered to be identical among these pathovars as shown in Figure 1.

Figure 1. Organization of Type III Secretion System (TTSS) cluster of *Psv5*, *Psn23* and *Psf134*. Red arrows represent the single nucleotide polymorphisms (SNPs) found among pathovar TTSS sequences. Black triangle indicates the localization of a partial insertion sequence, remnant of an IS66 element. Names of operons are not in italics to differentiate from gene names. For the part of the sequence highlighted by the black square, corresponding to the hypervariable region between *hrpC* and *hrpU* operons, the alignment among the sequences derived from the seventeen *Pseudomonas* species examined in this study is schematically reported. These species are ordered from top to bottom as: (1) *P. savastanoi* pv. *savastanoi* ITM317 (*Psv5*); (2) *P. savastanoi* pv. *nerii* ESC23 (*Psn23*); (3) *P. savastanoi* pv. *fraxinii* NCPPB1006 (*Psf134*); (4) *P. syringae* pv. *aesculi* str. 2250; (5) *P. syringae* pv. *phaseolicola* 1448A; (6) *P. syringae* pv. *tabaci* ATCC11528; (7) *P. syringae* pv. *syringae* str. 61; (8) *P. syringae* Cit 7; (9) *P. syringae* pv. *syringae* B728a; (10) *P. syringae* pv. *aceris* M302273PT; (11) *P. syringae* pv. *pisi* 1704B; (12) *P. syringae* pv. *aptata* DSM50252; (13) *P. syringae* pv. *japonica* M301072PT; (14) *P. syringae* pv. *tomato* DC3000; (15) *P. syringae* pv. *tagetis* LMG5090; (16) *P. viridiflava* PNA3.3a; (17) *P. viridiflava* LP23.

The TTSS cluster is 23,835 bp long, and it is composed of twenty-seven genes, most of which arranged in five operons organized in two main blocks having convergent genes transcription (*hrpRS*,

hrpZ and *hrpC* on one hand, and *hrpU* and *hrpJ* on the other, conventionally reported on the right and left side of the cluster in Figure 1). These two blocks are separated by an hypervariable region, with a very low level of conservation between closely taxonomically related bacteria and containing a remnant of an insertion sequence of the IS66 family [25] (Figure 1). The two genes *hrpL* and *hrpK*, coding for a sigma-54 factor [26] and for a protein involved in translocation [27] respectively, are not included in any operon. This kind of organization is known to be shared among other bacterial phytopathogens, like *P. syringae*, having the so called “Group I Hrp TTSS” [28,29]. The GC content of the entire TTSS cluster of *Psv5*, *Psn23* and *Psf134* is 58.8%. The same value was calculated for TTSS cluster of *Psv* strain NCPPB3335, whose genome was reported to have a GC% content appreciably lower (57.1%) [30]. In all the three *P. savastanoi* pathovars examined here it was demonstrated that the TTSS cluster is chromosomally located and that each gene is present in a single copy, as assessed by Southern blot and Real-Time PCR, respectively (data not shown).

As far as TTSS sequences of *Psv5*, *Psn23* and *Psf134* are concerned, just nine Single Nucleotide Polymorphisms (SNPs) were found to be differentially present in the clusters of these bacteria, eight of which located into an open reading frame (ORF) (Figure 1). In Table S1 and S2 the characteristics of the putative proteins coded by *hrp/hrc* genes are reported [31-36]. This bioinformatic analysis encourages hypothesizing that these SNPs do not affect the presence of conserved domains on predicted proteins and their subcellular localization, even when non-synonymous mutations were considered. In the same tables, the homologies between Hrp/Hrc predicted proteins of *P. savastanoi* and of *P. syringae* pv. *phaseolicola* 1448A are reported as well. These values range between 97% and 100%, to further support the close relationship between these bacteria and their Hrp systems.

2.2. Phylogenetic Analysis of TTSS Cluster in *P. savastanoi* and Other Species of *P. syringae* Complex

Fourteen different *P. syringae* pathovars or closely related species, whose TTSS clusters have been completely sequenced, were selected (Table 1) [37-45] to be included in a global phylogenetic sequence analysis together with the three *P. savastanoi* pathovars previously mentioned. Comparisons were carried out analyzing both the entire TTSS cluster and each operon separately, in order to better understand the fundamental steps driving the evolution of TTSS in these bacteria.

In Figure 2 and in Table 2 the results obtained are shown and statistically evaluated, respectively. The analysis of the entire TTSS cluster and of each operon generated four major branches, with the three *P. savastanoi* pathovars always in the same minor branch, because of their very small sequence differences. The composition of three of the major branches, corresponding to Groups I, II and III, was coherent with data already obtained using *hrpS* and *hrpL* genes [46] or the single *hrpZ* operon [47]. For the first time the composition of these groups and their organization can be definitely confirmed both analyzing the entire TTSS cluster and using a representative range of species of the *P. syringae* complex. Here in Group I, only the bacteria belonging to genomospecies 1 were included [48,49]. Similarly, Group IV was exclusive of *P. viridiflava*, which was the only one in this analysis belonging to genomospecies 6. The three *P. savastanoi* pathovars examined here were always included in Group II, together with *P. syringae* pv. *aesculi*, another phytopathogenic bacterium attacking woody plants. Other bacteria belonging to genomospecies 2 were also clustered in Group II, such as *P. syringae* pv. *tabaci* and pv. *phaseolicola* [48,49]. As far as *P. syringae* pv. *tomato* and pv. *tagetis* are concerned,

although belonging to genomospecies 3 and 7 respectively [48,49], here they clustered in Group III. The only exception was the phylogenetic tree derived from the analysis of operon *hrpRS*, where Group III was split and *pv. tagetis* was on a minor branch closely related to that of Group II. Moreover, a change occurred in the topology of the phylogenetic trees obtained from *hrpZ* and *hrpC* operons towards those referred to the entire TTSS cluster and to *hrpJ* and *hrpU* operons, with the inversion of Groups III and IV (Figure 2).

Figure 2. ML phylogenetic trees of TTSS cluster and of five single operons. The operon referred to each tree is indicated above each image. Groups are numbered from I to IV, and are related to the tree obtained analyzing the entire TTSS cluster. The trees are drawn to scale, with branch lengths measured in the number of substitutions per site. The congruence between trees and data (SH test) is reported in Table 2. “*P. savastanoi savastanoi*”, “*P. savastanoi fraxini*” and “*P. savastanoi nerii*” are strains ITM317, NCPPB1006 and ESC23, respectively. Names of operons are not in italics to differentiate from gene names.

^a P-value identifies the probability that the data fits the tree. Bolded values indicate trees that fit the data significantly worse than the best tree given the data. Names of operons are not in italics to differentiate from gene names; ^b hrpTOT refers to the tree or the data obtained from the analysis of the entire TTSS cluster.

More important considerations can be raised following a deeper statistical analysis carried out performing the Shimodaira-Hasegawa (SH) test [50], aimed to determine if the phylogenetic trees obtained by analysing the entire TTSS or any of its operons are as good as the best trees derived from each of the different data sets. In other terms, SH test ascertains if different data sets share the same evolutionary history. Therefore, the significance of the topological differences among *hrp* operons and the whole cluster was tested and evaluated to understand their contribution to the global phylogenetic variation of TTSS. The results obtained are reported in Table 2. The operon *hrpU* and *hrpJ* data were found to be congruent with all but the *hrpRS* and *hrpZ* trees. The operon *hrpZ* and *hrpC* data were found to be congruent with the tree generated from the whole TTSS cluster and with the trees of all the other operons but *hrpRS*'. In this regard, a remnant of an insertions sequence was found in the hypervariable region between *hrpC* and *hrpU* operons of the three *P. savastanoi* pathovars here examined, as previously reported in the TTSS clusters of other *P. syringae* pathovars [41,42,51]. Together these data seem to suggest that an important recombination event has occurred early in the evolution of TTSS cluster in the *P. syringae* complex, that it was more likely to happen via Horizontal Genetic Transfer (HGT) from an enteric bacterium pathogenic on animals or humans [52,53]. The direction of this hypothetical HGT event is also suggested by the different genomic localization of the TTSS clusters in pathogenic bacteria of animals and plants. Mainly these clusters are located on plasmidic pathogenicity islands (PAI) among the enteric bacteria pathogens for animals and humans, while they are often integrated into the bacterial chromosome in those pathogenic on plants [53,54]. Moreover, it is worth noticing that when the architecture of *P. savastanoi* TTSS was compared with that of enterobacterial phytopathogens, belonging to Group I Hrp TTSS cluster with *P. syringae*, genes of *hrpC* and *hrpZ* operons appeared to be transposed upstream of *hrpL* gene, and *hrpJ* and *hrpU* operons, though maintaining their orientation [54]. In accordance with all these data, the most widely accepted hypothesis is that a common ancestor of *P. syringae* and of enterobacterial plant pathogens likely acquired TTSS cluster by a single HGT prior to their speciation [53]. Then multiple interspecific HGT events would have occurred during their evolution, both among *P. syringae* and the enteric phytopathogens. The acquisition of information essential to allow the adaptation of these pathogens to new hosts were stably maintained in their genomes, thus explaining the incongruences found among the phylogenies of TTSS genes and operons [53].

Another important finding derived from the SH test refers to the operon *hrpRS*. Here for the first time we demonstrated the complete incongruence between operon *hrpRS* data and any of the trees obtained except its own. The *hrpS* and *hrpR* genes are two of the most important regulators of TTSS physiology. HrpS and HrpR proteins are supposed to act as a dimer to promote the expression of *hrpL*, coding for a sigma-54 factor [17]. Our data seem to fit the theory recently hypothesized by Jovanovich and colleagues [55] assessing that the operon *hrpRS* was crucial in the evolution and the expression of pathogenicity/virulence in these bacteria. According to their data, it seems that a co-evolution of *hrpR* and *hrpS* genes has occurred, probably following a gene duplication event during the *P. syringae* adaptive evolution to its different hosts. Besides TTSS regulatory elements, this evolution appears to have been positively driven also by several mutations involving bacterial effectors. This was very recently assessed by profiling the TTSS effectors of bacteria belonging to the *P. syringae* complex [56], with results highly consistent with those obtained here. Together these data suggest the hypothesis that during the patho-adaptive differentiation of the *P. syringae* complex, elements of the flexible genome

follow an evolution strictly consistent with that of the core genome [57]. To support this hypothesis, a common evolutionary history has already been reported for two TTSS regulatory genes, among which *hrpS*, and the two housekeeping genes *gyrB* and *rpoD* [46]. If this was further confirmed, phylogenetic studies focused on TTSS would make an important contribution in the determination of the evolutionary relationships among bacteria of the *P. syringae* complex. In this regard, our data confirmed previous findings about *hrpZ* operon [24,47], that was proved to be the best candidate to unveil the evolutionary shaping of TTSS, together with *hrpC* operon. Moreover, the potential of *hrpRS* operon to display the patho-adaptive forces acting on this system was also revealed.

2.3. Time Course Expression Analysis of TTSS in *P. savastanoi* Pathovars

According to the recent findings concerning the importance of TTSS regulatory genes, such as *hrpS*, in the adaptive evolution of these bacteria to their hosts [55], for the first time we also investigated the time course expression of several TTSS genes of the three *P. savastanoi* pathovars here examined. This analysis was carried out by Real-Time PCR on cells grown *in vitro* on *hrp*-inducing minimal medium (MM) [7] and on nutrient-rich medium King's B medium (KB) [58]. To this purpose, *hrpS*, *hrpL* and *hrpV* genes were selected, the last two coding for a positive and a negative regulator of HrpS-promoted TTSS transcription, respectively [17]. Together with these genes, the structural gene *hrpA*, coding for the main protein subunit of the TTSS pilus, was also tested [17]. Using the primers reported in Table 3, amplification efficiencies ranged from 95% and 105%. The efficiency of the primer pairs for *hrpA*, *hrpL*, *hrpS* and *hrpV* genes was less than 5% different from that of the primer pair for the housekeeping gene *16S rDNA*, used for data normalization [59]. At an annealing temperature of 60 °C, efficiency values for *hrpA*, *hrpS*, *hrpL* and *16S rDNA* were 100.7%, 100.3%, 98.5% and 100.2%, respectively. At an annealing temperature of 62 °C, the values for *hrpV* and *16S rDNA* were 99.6% and 100.2%, respectively. The normalized relative expression of each gene was analyzed in MM vs. KB medium grown cells, at 3, 6, 18 and 24 h after inoculation of a starter culture in the corresponding fresh medium.

^a Gene targeted by the corresponding primer pair.

The results obtained are reported in Figure 3 and in Table S3. For the first time it was demonstrated that TTSS genes are overexpressed in cultural conditions mimicking the plant apoplast in each of the

three *P. savastanoi* pathovars here examined. Moreover pathovar-specific expression patterns were observed. In particular, the highest values for the relative expression of both *hrpA* and *hrpS* were reached by *Psf134* after three hours, while *hrpL* peaked at six hours (Figure 3). The expression of all genes dropped off after 18 h with the exception of *hrpV*, supposed to be an inhibitor of HrpS action [12,17], that increased up to a level of 80 fold after one day from the beginning of the simulated infection. Different expression patterns were shown by *Psv5* (Figure 3). Relative expression levels of *hrpA*, *hrpL* and *hrpS* remained low for the first 18 h of growth on MM, after which they started to rise and reached levels ranging from 124.7 to 152.1 fold at 24 h. As expected, *hrpV* followed an opposite trend, since its highest relative expression level was reached after 6 h of bacterial growth on MM (53.2 fold). As far as *Psn23* is concerned, the expression pattern of TTSS genes seemed to be more finely tuned (Figure 3). In particular, the highest relative expression levels for *hrpA* and *hrpS* were reached after 18 h, and then they started to decrease. The genes *hrpV* and *hrpL* peaked at 3 h of growth on MM. While *hrpV* signals progressively decreased until the end of the experiment, *hrpL* had a slight but continuous recovery up to 24 h (22.4 fold).

Several models have been proposed to describe the regulatory network for *hrp/hrc* gene expression in *P. syringae* and other phytopathogens, according to data collected in experiments mainly carried out *in vitro* using different *hrp*-inducing media and less frequently *in planta* [7-17,19-22,60]. These models are considerably variable among different bacterial phytopathogens even when closely related. However the importance of HrpL as a central point within this network and for the transcription of the other TTSS genes is constantly reported, as confirmed very recently by Boolean model simulating the activity of the *hrp* regulon in *P. syringae* [18]. Furthermore this model gave an important although theoretical contribution to clarify some conflicting data concerning the role of GacS/GacA system on the dynamical regulation of TTSS gene expression [12,61]. According to this model, the TTSS appears to be very tightly regulated, following the sequence of events rather than the timing as the most critical regulating factor. This would guarantee a more robust stability to any casual perturbation, such as evolutionary changes in the sequences of any TTSS components involved. In this frame GacS/GacA is here indicated as the only determinant of the expression of *hrp* regulon, although some important points still need to be elucidated. Among these there are the biotic and abiotic signals perceived by GacS sensor kinase, the production of the response regulator GacA, the mode of interaction between GacS and GacA, and the integration of this system with other regulatory elements known to act on *hrp* regulon. To this concern, a main role was demonstrated to be played by Lon protease, essential for switching on and off the *P. syringae* TTSS genes in inducing and repressive conditions, respectively [12,21].

Our results clearly suggest that the *in vitro* expression of TTSS is differently regulated in the three *P. savastanoi* pathovars here examined. A pathovar-specific regulation of *hrp/hrc* genes could be hypothesized to occur also *in planta*, matching the environmental conditions found by these *P. savastanoi* pathovars in their respective hosts, and possibly having some role in host-range determination. Intriguingly, in the first hours of growth on *hrp*-inducing medium the overexpression of the gene coding for the negative regulator HrpV was higher in those pathovars having the broadest host ranges, which are *Psn* and *Psv*. In contrast in *Psf*, which is able to attack just Ash, the early and apparently HrpV-unrestricted overexpression of *hrpA* could contribute to narrow its host range. Until now there is no clear evidence of any elicitor activity for HrpA. However this protein is the main

component of TTSS pilus and its coding gene was demonstrated to be under strong diversifying selection into *P. syringae* species, presumably to avoid recognition by the host [47].

Figure 3. Time course of *hrpL*, *hrpA*, *hrpS* and *hrpV* expression in *P. savastanoi* pv. *fraxinii* (*Psf134*), pv. *savastanoi* (*Psv5*) and pv. *nerii* (*Psn23*). Relative expression in minimal medium (MM) is reported, setting expression in King's B medium (KB) as reference [59]. The pathovar referred to each graph is reported as graph title. The color used for each gene is indicated in the label. The vertical lines indicate standard deviation values, and where they are absent, the limits were within the symbol dimensions. The numerical values for each point analyzed are reported in Table S3.

Nothing is known yet about regulatory systems acting upstream to TTSS, such as GacS/GacA and Lon protease, in none of the *P. savastanoi* pathovars here studied. Therefore it cannot be ruled out that their pathovar-specific expression patterns for the *hrp* genes examined could depend on their different abilities to perceive and translate environmental stimuli, such as those given by *hrp*-inducing medium. Actually differential modes for *hrpR* and *hrpS* expression were already found in *P. syringae* pv. *syringae* and pv. *tomato* [62-64], as well as for their regulation by GacS/GacA [61]. Furthermore, some of the SNPs we found in the TTSS sequences of these *P. savastanoi* pathovars mapped in the regulatory genes *hrpS*, *hrpL* and *hrpV*. It is worth noticing that just in these cases these SNPs gave rise to changes in the coiled-coil regions of the corresponding proteins (Table S1 and Table S2). Coiled-coil regions are known to be essential in several protein-protein interactions, particularly in the formation of multimeric complexes and in molecular recognition events [65,66].

Further experiments need to be carried out to prove if the pathovar-specific expression of *hrp/hrc* genes in *P. savastanoi* is dependent on a differential regulation of this system and if coiled-coil interactions are involved.

3. Experimental Section

3.1. Bacterial Strains and Growth Conditions

The *P. savastanoi* strains used in this study are *Psv5*, *Psn23* and *Psf134*, belonging to the pathovars *savastanoi*, *nerii*, and *fraxini* respectively (Table 1). They were routinely grown at 26 °C, on KB [58] or on MM [7], in solid or in liquid cultures according to the experimental purposes.

Bacterial growth was monitored by determining the optical density at 600 nm (OD₆₀₀) at different times during incubation, and bacterial concentration was estimated by serial dilutions and plate counts. For long-term storage, bacteria were maintained at -20 °C and -80 °C on 40% (v/v) glycerol.

The strains were periodically monitored by *16S rDNA* amplification followed by enzymatic restriction with *AluI* [67,68], and by *P. savastanoi* PCR specific assays [69].

3.2. Molecular Techniques and DNA Sequences Analysis

Standard general recombinant DNA techniques were performed according to Sambrook *et al.* [70]. Genomic DNA was purified from bacterial liquid cultures (OD₆₀₀ = 0.8) using Gentra[®] Puregene kit (Qiagen, Valencia, CA, USA), according to manufacturers' instructions. DNA amplicons were purified from agarose gels with PureLink[®] Quick Gel Extraction Kit (Invitrogen Inc., Carlsbad, CA, USA), under the conditions recommended by the manufacturer. DNA concentration was evaluated both spectrophotometrically, with NanoDrop[™] ND-1000 (NanoDrop Technologies Inc., DE, USA), and visually by standard agarose gel electrophoresis [1% agarose (w:v) in TBE 1X] [70].

Oligonucleotide primers for overlapping amplicons targeting all the *hrp/hrc* genes were designed according to the data available on the main databases on *P. savastanoi* and on bacteria taxonomically related, and then used to screen the genomic libraries of strains *Psv5*, *Psn23* and *Psf134* by PCR. Primers were designed by using Beacon Designer 8.0 software (Premier Biosoft International, Palo Alto, CA, USA) (Table S4). For each library, those clones giving positive amplification signals with all the primer pairs here used were identified. Among those, one clone for each *P. savastanoi* pathovar

was selected and isolated (clones ST-5-22-4A, ST-23-19-2F and ST-134-31-7G for *Psv5*, *Psn23* and *Psf134*, respectively).

The nucleotide sequences of the entire TTSS clusters of *Psv5*, *Psn23* and *Psf134* were then determined by sub-cloning and double-strand sequencing the library clones (Eurofins MWG Operon Ltd., Ebersberg, Germany).

DNA sequences were annotated with the aid of Basic Local Alignment Search Tool (BLAST) [71], and predicted proteins were analyzed with the online Structure Prediction Suite SOSUI [31-34].

The presence of insertion sequences was assessed through ISfinder database [72,73].

Predicted proteins were analyzed for the presence of conserved domains and for homologies, by BLAST-CD search [35] and by ClustalW2 software [36], respectively.

3.3. Phylogenetic Analysis

A phylogenetic analysis was performed on the complete TTSS cluster of the bacterial strains listed in Table 1 [37-45] and on each of its major operons (*hrpRS*, *hrpZ*, *hrpC*, *hrpU* and *hrpJ*). The analysis involved seventeen nucleotide sequences that were aligned using ClustalW2 software [36], with the “Slow” Pairwise Alignment Type, and manually adjusted, if needed. The evolutionary history was inferred by using the Maximum Likelihood method based on the Tamura-Nei model, with the aid of Mega software ver. 5 [74-76]. The congruence of branching order was assessed with 1,000 bootstrap replications. Initial trees for the heuristic search were automatically obtained as follows. If the number of common sites was <100 or less than one fourth of the total number of sites, the maximum parsimony method was used. Otherwise, BIONJ method with MCL distance matrix was used. The tree is drawn to scale, with branch lengths related to the number of substitutions per site. All the positions containing gaps and missing data were eliminated.

Phylogenetic congruence between trees was inferred by SH test [50] with dnaML software contained in the Phylip package (ver 3.69) [77]. This test quantitatively evaluates the likelihood of alternative trees given a data set and basically establishes if the evolutionary histories between different data sets are the same.

3.4. Quantitative Real-Time PCR Analysis

Starter liquid cultures of strains *Psv5*, *Psn23* and *Psf134* were grown overnight in 20 mL KB, at 26 °C and under continuous shaking at 100 rpm. Cells were washed in sterile physiological solution (0.85% NaCl in distilled water) twice and used to inoculate 6 mL of fresh KB and MM medium, adjusting the concentration at 0.5 OD₆₀₀. The cultures were then incubated as above, sampled after 3 h, 6 h, 18 h and 24 h, and used for RNA extraction performed with RNeasy Midi Kit (Qiagen). About 1 µg of RNA for each treatment was reverse transcribed using QuantiTect Reverse Transcription Kit (Qiagen), according to the manufacturer’s instructions.

Quantitative Real-Time PCR (RT-qPCR) was carried out on iQ5 Cyclo—Real-Time PCR Detection System (Bio-Rad Laboratories, Inc., Hercules, CA, USA), in 96 well PCR plates, with 25 µL reaction mixture volume, using iQ SYBR[®] Green Supermix (Bio-Rad), according to the manufacturer’s instructions. The primers used for Real-Time expression analysis are reported in Table 3. As housekeeping gene, *16S rDNA* was used. Each sample was run in triplicate, including standards and

negative controls, using three different batches of cDNA obtained from three independent RNA preparations. The PCR protocol was 40 cycles with 95 °C for 20 seconds, 60 °C (or 62 °C exclusively for *hrpV* gene) for 20 seconds, and 72 °C for 20 seconds, after an initial step of 95 °C for 3 min. The amount of fluorescence given by incorporation of the SYBR Green dye into double-stranded DNA was evaluated for each sample at the end of each cycle, and analyzed to determine the resulting threshold cycle (Ct) values by iQ5 Optical System Software 2.0 (Bio-Rad). Dissociation analysis of amplicons was performed (from 60 to 95 °C, with a 0.5 °C increase every 5 seconds) at the end of each PCR run to check for aspecific amplifications. The comparative Livak ($2^{-\Delta\Delta CT}$) method [60] was used to analyze the mRNA level. The Ct values of each gene tested were normalized to the Ct values of the housekeeping gene, to obtain relative expression data for each gene examined.

In order to avoid significant measurement inaccuracies, the amplification efficiency of each primer pair was estimated producing Real-Time PCR curves for a ten-fold dilution series of *Psn23* genomic DNA (from 50 ng to 0.5 pg) used as template. The slope of the log-linear phase of each curve reflects the amplification efficiency, which should range between 90% and 100%, with slope value between -3.2 and -3.4, and R^2 of at least 0.998.

All the data obtained represent the mean of three independent replication \pm SD. Statistical analyses were performed using the two-tailed t-test.

4. Conclusions

For the first time here the TTSS clusters of the pathovars *nerii* and *fraxini* of the species *P. savastanoi* were sequenced. Moreover the TTSS sequence of another *Psv* strain was also obtained, in addition to that of *Psv* strain NCPPB3335 whose genome was recently published. The availability of these data provided an important opportunity to carry out a more robust phylogenetic and statistical analysis than has occurred in the past on the evolution of this secretion system during the differentiation of the species belonging to the *P. syringae* complex.

By comparing the congruence among the sequences of the entire TTSS and its five major operons from seventeen species and pathovars of this complex, here we found that operons *hrpZ* and *hrpRS* have been the most affected by the dynamical processes occurring in the shaping of this system during the adaptive evolution of these bacteria to their hosts. The positive selection acting on some structural genes belonging to *hrpZ* operon, such as *hrpA*, was reasonably functional to avoid recognition by the host defenses. For a phytopathogenic bacterium, it is also important to be able to finely regulate *hrp/hrc* gene expression to successfully interact with its hosts. The incongruence between *hrpRS* data, and any of the other trees but its own, supports the hypothesis that the evolution of this operon was crucial for the adaptive process of these bacteria to new hosts. Moreover, according to our results the evolution of TTSS across *P. syringae* bacteria was quite coherent with that of the core genome and of the rest of the flexible genome.

In this regard, differential patterns were found for the *in vitro* expression of four *hrp/hrc* genes under inducing conditions in the three *P. savastanoi* pathovars examined here. According to our hypothesis, this could be related to a pathovar-specific regulation of TTSS genes. Further studies are needed to ascertain if this occurs also *in planta*, and has any role in the determination of the host-range of these *P. savastanoi* pathovars.

Acknowledgments
