

Amaranthus cruentus L. is suitable for cultivation in Central Italy: field evaluation and response to plant densities

Paolo Casini, Felice La Rocca

Department of Agrifood and Environmental Science, University of Florence, Italy

Abstract

The aim of this study was to determine the possibility of amaranth cultivation in Central Italy and to determine the optimum plant density. Field trials were carried out in 2011 and 2012 under non-irrigated conditions in Tuscany (43° 18' N, 11° 47' E). Twelve accessions of two amaranth species (Amaranthus cruentus L. and A. hypochondriacus L.) were utilised. Genotypes were evaluated over a two-year period using a RCB design with three replicates. The effects of plant density were investigated in 2012. A with a split-plot design was used, where the A. cruentus accessions (AMES 5148, PI 511719 and PI 643045) constituted the main plots. Plant densities (7.5, 15, 30 and 60 plants m⁻²) constituted the subplots. Plants were transplanted at the 3-4 true leaf stage. Morphological traits were determined using 5 plants selected from the two central rows of the sampling area. Plots were hand-harvested and cleaned with a mechanical grid with appropriate sieve diameters. A. cruentus was shown to be more suitable to the Central Italy agro-ecological conditions than A. hypochondriacus. The accessions derived from Mexico (PI 477913, PI 576481, PI 643045, PI 643053, and PI 6495079), Guatemala (PI 511719) and Puerto Rico (AMES 5148), had both higher grain yields and a greater stability over the two-year period, with a mean grain production ranging from 2.8 to 3.2 t ha⁻¹. The severe climatic stress in 2012 (high temperatures and aridity), resulted in a 43-60% reduction in seed production compared to that of the previous year. Under these conditions, PI 511719, AMES 26015, AMES 5386, AMES 5148, PI 477913 yielded on average 1.9 t ha⁻¹. Yields of A. hypochondriacus were negligible in both years, probably attributable to greater photoperiod sensitivity, resulting in reduced

By increasing density up to 60 and 30 plants m^{-2} for PI 511719 and AMES 5148, respectively, grain production was increased by 55%. As the plant population increased, plant height, panicle length and diameter, basal stem diameter and branches per plant were reduced. AMES 5148 plants were composed of one single stem with apical panicles at a density of 30 plants m^{-2} , whilst the other two accessions were similar at the highest plant density. Branch number per plant was negatively correlated with grain production (r=-0.536**). Hence, *A. cruentus* may be grown in Central Italy even under arid conditions, using a density of either 30 or 60 plants m^{-2} according to the genotype used.

Introduction

The rediscovery and valorisation of both indigenous and exotic pseudo-cereals for cultivation in Italy has led to a renewed interest in species that have remained largely neglected worldwide (National Research Council, 1984). Buckwheat (Fagopyrum esculentum Moench.) and quinoa (Chenopodium quinoa Willd.) (Casini and Proietti, 2002) have contributed to the creation of markets in both the food and non-food sectors. An additional species that has recently managed to gain some market popularity is amaranth (Amaranthus spp.), native to Mexico and Central America, which along with corn, beans, various pumpkin species and guinoa constituted one of the principle foods of the Maya and Aztecs (Pola Lopez et al., 2007; Rastogi and Shukla, 2013). The cultivation of these plants was in progressive decline until the early twentieth century, as they were prohibited in the days of conquistadores, who considered their use in the religious ceremonies of the locals offensive to Christian traditions (National Research Council, 1984). For centuries, these species were confined to small communities in Mexico and the Andean Plateau, where, fortunately, some degree of biodiversity was preserved (Saunders and Becker, 1984).

The rediscovery of amaranth as a valuable food resource dated back to the 1970s when, studies, undertaken by Dowton (1973), demonstrated the remarkable nutritional properties of the most common species: *Amaranthus cruentus* L., *A. hypochondriacus* L., *A. caudatus* L. and *A. edulis* Speg. Research on the first two species resulted in the development of a major market for amaranth in the United States, China, India and the Czech Republic. Amaranth is currently cultivated in the aforementioned countries, and is given similar recognition along with other industrial crops (Tucker, 1986; Granados and Lopez, 1990; Gimplinger *et al.*, 2007).

The main characteristics of this species include the high protein (15-18%), as well as lysine and calcium contents, with averages of 5.2 and 0.37 g/100 g dry matter, respectively (Petr *et al.*, 2003). Importantly, the species is distinguishable by the absence of gluten and is, therefore, suitable for people with celiac disease (Ballabio *et al.*, 2011). In particular, the lysine content is higher in amaranth than in certain plant products (such as grains, beans, soya) and animal sources (meat, milk, eggs), thereby ensuring a high market potential.

Until recently, this plant has been confined almost exclusively to specialised health sectors (Hackman and Mayers, 2003). Amaranth, in addition to constituting the basis of a large number of cooked or baked products, is also used in the preparation of food-bars, snacks, muesli, popped seeds, and other products such as biscuits and bread (Teutonico and Dietrich, 1985).

Equally interesting, is the use of amaranth in the non-food sector, which has not been investigated to the extent as that of the food sector. The cosmetic and pharmaceutical industries benefit primarily due to the high squalene content (4-5%) of the oil (He *et al.*, 2002; Berganza *et al.*, 2003). This compound is structurally very similar to β -carotene, an intermediate metabolite in the synthesis of cholesterol. Recent studies (Shin *et al.*, 2004; Gonor *et al.*, 2006) have shown that squalene can be included among the drugs effective at reducing blood cholesterol.

Amaranth oil, contained in the seeds, comprises an average of 6.0% of the seed mass (He *et al.*, 2003). Of particular interest are the tocopherols (compounds generally referred to as *vitamin E*) used in the cosmetic industry especially in the field of skin and hair care, and, more generally, in various formulas for allergy sufferers. The recognised properties are attributable to the high *anti-aging* antioxidant power (Khandaker *et al.*, 2008).

Although the potential of this pseudo-cereal is well established outside the areas of origin, in Italy amaranth has received limited attention. Only very few papers on amaranth cultivation in Italy for seed production are available. Moreover, all trials were carried out in the South (Alba *et al.*, 1997; Lovelli *et al.*, 2005; Rivelli *et al.*, 2008). In fact, works of Massantini *et al.* (1987) and Ercoli *et al.* (1987) (Pisa, Central Italy) were devoted to protein production from fresh leaves. There are no papers that report seed production in Central Italy as well as on the effects of planting densities.

The aim of the research presented in the present work was to analyse twelve amaranth accessions for their potential cultivation in Central Italy. Therefore, seed protein and oil content was examined in each accession. In addition, effects of increasing plant densities were examined in order to determine the optimal planting density for cultivation. plant development. Due to a flea beatle attack (*Chaetocnema tibialis* Illiger), an insecticide treatment (deltamethrine) was applied 10 days after transplanting. Morphological characteristics (plant height, length and basal diameter of the main panicle, stem diameter) were carried out on a sample of 5 plants, which were selected from the two central rows. Hand-harvesting was carried out at maturity by cutting the plants at soil level over a period of 30 days, starting from the 26 July 2011 and the 19 July 2012, respectively, according to genotype maturation. Climatic data, registered during the field experiments, are shown in Figure 1.

Crude protein and oil content of the seeds were analysed in triplicate. The protein content was calculated by multiplying the nitrogen content by 6.25. Nitrogen content of 500 mg flour samples was determined by the FlashEA 1112 Series analyser (Thermo Fisher Scientific Inc., Waltham, MA, USA). Oil content was carried out on a 5 g sample using the Soxhlet extraction procedure with petrolether as solvent.

Experiment 2: plant density

The experiment was carried out in 2012 according to a RCB splitplot design with three replicates with a plot size of 20.0×2.0 m, which constituted the main factor (accessions AMES 5148, PI 511719 and PI 643045). The subplots were 2.0 m wide (four rows wide with 0.5 m row spacing) and 5.0 m long. The main plots were split into four sub-plots containing the densities of 7.5, 15.0, 30.0 and 60.0 plants m^{-2} . The sampling area was comprised of two central rows, each 3 m long. In order to attain the correct planting density within each plot, seedlings at the 3-4 true leaf stage, were transplanted on May 22 in the designated spacing. Fertilisers were distributed before transplanting as follows: 46 kg ha⁻¹ of N and 100 kg ha⁻¹ of P₂O₅. Plots were hand-weeded twice during the growth cycle. Moreover, 15 days after transplanting, the seedlings were treated with the insecticide deltamethrine. Morphological traits of the crop were evaluated by considering five sample plants marked in each sample area. During crop development, the visual ground cover of the plants was estimated at 28, 40, 55, 68 and 77 days after transplanting (DAT). Relative increments of ground cover, branch per plant and plant height were calculated as follows:

Materials and methods

Experiment 1: genotype evaluation

Two field experiments were carried out in 2011 and 2012 in Tuscany, Central Italy at the *Centro per il Collaudo ed il Trasferimento dell'Innovazione di Cesa (Arezzo)* (43° 18' N; 11° 47' E), on a neutral, loamy-sandy soil. The principle physical and chemical characteristics of the soil were as follows: sand 36.4%; loam 37.7%; clay 25.9%; total N 0.114%; P (Olsen) 11 ppm; exchangeable calcium, magnesium and potassium: 4250, 620 and 136 ppm respectively; pH 7.2.

A comparative study was carried out on 10 accessions of *Amaranthus cruentus* and 2 accessions of *A. hypochondriacus* (Table 1), provided by the North Central Regional Plant Introduction Station (Iowa State University, USA). The experimental design was a complete randomised block with three replicates. Plots were 2.0 m wide (four rows wide with 0.5 m row spacing) and 5.0 m long. The sampling area was comprised of two central rows, each 3 m long. In order to ensure the success of the trial, a density of 33 plants m⁻² was chosen and seeds were sown in seedling trays in the first days of April, after which seedlings were transplanted on 13 May and 22 May 2012.

Fertilisers were applied before transplanting as follows: 46 kg ha⁻¹ of N and 100 kg ha⁻¹ of P₂O₅. Plots were hand-weeded twice during

were R_i =relative increment at time i; X_i =variable measured at time i; $X_{(i,1)}$ =variable measured at previous time.

 $\Lambda_{(i-1)}$ =variable illeasureu at previous tille.

The harvest was performed manually starting from 9 August. Duration of maturation was genotype dependent, and the different plots were harvested accordingly.

Statistical analysis

Data collected in experiment 1 were processed utilising a mixed model of analysis of variance (ANOVA), where accession was considered as a fixed effect factor, and year as random effect factor. The expected components of the variance, and the ANOVA model are both reported in Table 2. For Experiment 2, data were processed utilising a fixed model of ANOVA, where both factors of variability (plant density and accessions) were considered as fixed effect factors. The expected components of the variance and the ANOVA model are reported in Table 3. To verify the difference between the means, the multiple comparison Tukey's test was performed.

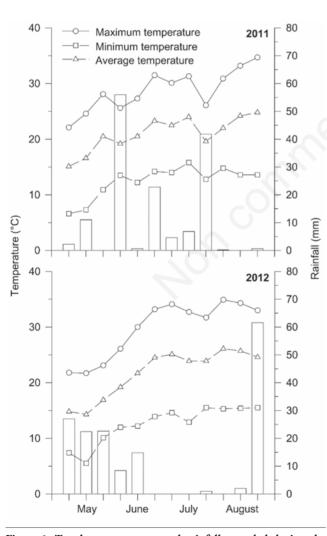

Figure 1. Ten-day temperature and rainfall recorded during the field plot experiments.

(1) Results

Experiment 1: genotypes evaluation

The seasonal trend was characterised by particularly warm and dry conditions, thereby placing strain on the hardiness and drought tolerance of this plant. The total rainfall recorded during the trials (Figure 1) was 147 and 160 mm, in 2011 and 2012, respectively. However, from the second week of June until the end of August in 2012, the observed maximum temperatures were almost always above 30.0°C (maximum 34.9°C). In addition to high temperatures, the period was also characterised by drought with only 5 mm of rain being measured up to the second week of August. Therefore, immediately after the development of the panicle (the budstage phase) and throughout subsequent development and flowering, plants had to cope with water stress that was not relieved by irrigation. The ANOVA analysis reported in Table 4 showed how the effect of both year and genotype had a significant impact on almost all the parameters measured, with the exception of panicle length and diameter, as well as stem diameter. The interaction Accession × Year was significant at P≤0.01 for seed yield, several biometric characters and time of harvest.

The averages reported in Table 5 show that, for all accessions, the

development of the panicle began in a period between 20 and 29 DAT and that, only in the genotypes of A. cruentus, maturation was achieved within 77 DAT. Ripening was significantly delayed by an average of 30 days in the two A. hypochondriacus genotypes (AMES 5615 and PI 633596). As part of the morphological characteristics, the length of the main panicle was predominantly affected by the prolonged drought in the second year of experimentation. The values were shown to decrease by 60%, from 43.2 to 17.4 cm. A. hypochondriacus was characterised by more developed panicles, even if no significant differences were observed between the two accessions. The panicle branches varied significantly among accessions and this trait was also sensitive to the different climatic conditions between the two years. Similar to panicle length, branch number was significantly reduced by 65% in the 2012 season in comparison to the previous year. Average seed production was very variable according to both genotype and year, with maximum yields clearly detectable across all species of Mexican origins, with AMES 5148 (Puerto Rico) and PI 511719 (Guatemala), yielding 3.2 and 2.8 t ha⁻¹, respectively. Significantly lower production yields were observed in both genotypes of A. hypochondriacus (0.5-0.1 t ha^{-1}). Significant genotype variation was evident for both protein and total oil

content in the seeds. Values greater than 16% for the protein content were recorded for AMES 2003, AMES 5386, AMES 26015, PI 649507 (*A. cruentus*), as well as for IP 633596 (*A. hypochondriacus*). With regard to oil content, values greater than 5% were reported for the Mexican genotypes PI 477913, PI 649507 and PI 643053.

Figure 2 shows the significant interactions Years × Accessions as sources of variability. Worthy of attention was the negative impact of the 2012 season on all parameters considered, and the different trends observed for the *A. hypochondriacus* accessions, especially with regard to the time of harvest and grain yield. Regarding the former, the two genotypes of this species reached maturity in a period exceeding 110 DAT in comparison to the average 70 DAT of the *A. cruentus* accessions. Some genotypes of the latter species showed a more rapid maturity up to 20 DAT in 2012 compared to 2011, a phenomenon easily attributable to the aforementioned climatic conditions. Similarly, stem diameter, plant height and seed yield were significantly reduced. In particular, for yield production, three groups could be distinguished. Group *A* with an average yield reduction of 60% in 2012, compared to 2011, a *B* group composed exclusively of *A. cruentus* genotypes of Mexican origin (PI 576481, PI 643053, PI 549507) with an average yield reduction of 43%

and, finally, a group *C* composed of the two accessions of *A. hypochondriacus* with low and practically negligible yields both in 2011 and 2012.

The results are the first to be obtained for these accessions in Central Italy over two growing season and confirm previous field trials conducted in the South of Italy (Alba *et al.*, 1997; Rivelli *et al.*, 2008). Moreover, it was shown that *A. cruentus* demonstrated the best adaptability to Tuscan environments in comparison to *A. hypochondriacus* in terms related to the period of major growth phases such as those of budstage and ripening. Rapid maturity and improved grain yield better

characterise *A. cruentus*, although production was significantly influenced by the agro-environmental conditions. *A hypochondriacus* was photoperiod sensitive. This was evident from both poor flowering and fruit development, as well as from the significant lengthening of the vegetative phase. This feature was even more apparent in the second year of the trial, during which the accessions were subjected to a strong climatic stress, resulting in a significant reduction in the diameter of the main panicle with inevitable negative effects on seed yield.

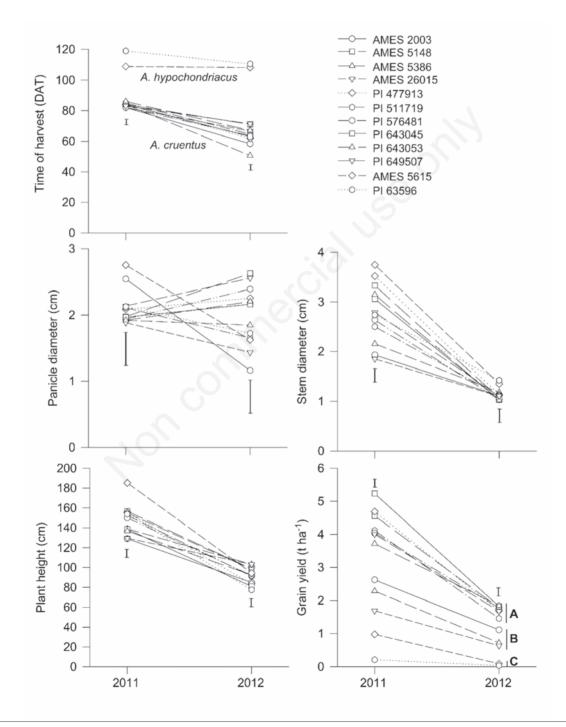

Figure 2. Experiment 1. Mean effect of the year on some morphological traits and on grain yield.

Experiment 2: plant density

The ANOVA results for various characteristics are shown in Table 6. The first observation was related to the non-significance of the interaction *Plant density* × *Accession* (PD × A) for all parameters. In contrast, *plant density* significantly affected most of the characters. Levels of significance at $P \le 0.01$ were observed for the following traits: time of harvest, relative increase in ground cover, branch number per plant and plant height as well as other morphological characteristics and seed yield.

The most significant parameters were represented in Figure 3. Ground cover increased with the increase in plant density from 7.5 to 30 plants m⁻², but with a concomitant decrease in ramification. Although statistically significant, the effect of density on the maturation period showed small variations around the average 75 DAT. Conversely, the increase in density lead to a significant decrease of the emission of branches per plant. At the lowest density, amaranth plants were characterised by 5 side branches that tended to decrease to an average of 2 at a density of 15 plants m⁻². At the highest density, no ramification occurred and there was a single main stem with apical panicles. Parallel to the reduction of side branches, there was a reduction in the length of the main panicle, which decreased from 22 cm to 13 cm at a density of 60 plants m⁻². A significant positive correlation between panicle length and ramification was evident, $r=0.385^*$. This, in turn, also led to a 23% reduction in the diameter of the main panicle which was significantly correlated to ramification, r=0.764**.

Amaranth is considered a species showing elasticity in morphology according to the different agro-environmental conditions (Häuptli, 1977; Henderson *et al.*, 2000). This study confirmed such elasticity showing that increased density decreased ramification, which is accompanied by a reduction in the stem diameter, plant height and panicle size. Higher plant densities were related to a higher concentration of panicles on the apex of the single stem of each plant. As a consequence, flowering and ripening of the panicles occurred at the same time, and was not graduated over time as occurs with ramification. Hence, there was less risk of seed dispersal or humidity differences at harvest. Additionally, the reduction in stem diameter has positive effects on both manual and mechanical harvesting, facilitating the cutting of plants (Henderson *et al.*, 2000). Increased plant density per unit area resulted in an increase in seed yield from 1.0 t ha⁻¹ at a density of 7.5 plants m^{-2} to 1.30 t ha⁻¹ at the highest densities.

Literature on the effect of density on seed yield has revealed contrasting results (Gimplinger et al., 2007). Some authors have reported an increase in production with increasing plant density (Guille-Portal et al., 1999; Apaza-Gutierrez et al., 2002; Garcia-Perevra et al., 2009), whilst others have reported the opposite effect (Weber et al., 1989; Peiretti and Gesumaria, 1998; Yarnia et al., 2010). These discrepancies can be attributed, not only to differences between the species of Amaranthus that were taken into consideration, but also the cultivation environment (Haas and Kauffman, 1984; Putnam, 1990). In addition, as suggested by Apaza-Gutierrez (2002), the effect on yield with increasing density may partly be attributable to different distances in row spacing, besides either the use or absence of double rows, which affords a better utilisation of available space. In that study, yield reduction was mainly attributed to the simultaneous increase of the number of inflorescences per plant at the highest densities that, in turn, lead to a reduction in the number of seeds per plant as the consequence of the highest plant competition. These results, however, were obtained with hybrid between A. hypochondriacus x A. hybridus (Yarnia et al., 2010).

Studies on results in seed yield corroborate findings of the present research in terms of the reduction of the stem diameter (Gimplinger *et al.*, 2007) and seed production per plant (Apaza-Gutierrez *et al.*, 2002). Similar to that found in the present study (Pearson correlation $r=-0.618^{**}$), the latter authors reported a negative correlation between density and diameter of the stem. Increased plant density resulted in increased intraspecific competition, manifested by decreased plant height and length and diameter of the main panicle. In the present study, the increase in yield observed with increased density, can be attributed at least in part to an increase of other yield components such as the number of panicles. Yarnia *et al.* (2010) reported that as plant density increased, there was a reduction in the oil content of the seeds due to a reduction in fatty acid metabolic activity. In contrast, the present results indicated an increase in oil content from 4.9% to 5.9%.

The success of a crop, sown in spring-summer, largely depends on a rapid growth during the vegetative phase, thereby increasing ground cover, which helps to reduce weed development. Figure 4 highlighted the trend of ground cover in relation to density and accession. It was shown that different densities leading to increased cover are very different in the first 28 DAT. The best mean increase of 37% for all accessions, was observed with the lowest density. This was reduced to 10%

at a density of 15 plants m⁻². The increase in initial coverage is positively and significantly correlated with the coverage at 40 DAT (r=0.660**). From Figure 4, the accessions AMES 5148 and PI 643035 showed mean coverage that was equal to 70%, 60% and 70% at a density of 7.5, 30 and 60 plants m⁻², respectively.

Figure 4 shows useful information on the behaviour of the accessions, especially in relation to their tolerance to drought. The graphs in the figure show how, during the protracted dry period until the end of July, three accessions reacted with a partial loss of leaves or with a vegetative stasis, which was then resumed with the slight rains in late July. This type of response was readily noticeable at the lowest density. However, all other densities clearly show the differences that are genotype dependent. PI 511719 showed a constant increase in ground cover up to 77 DAT. In contrast, the other two genotypes reduced coverage by

approximately 5-8%, coinciding with the dry period and high temperatures. Hence, PI 511719 was characterised by a better tolerance to aridity that, unlike the other accessions, resulted in a slight yield increase of 16%, over the dry period and with increasing plant density, from 30 to 60 plants m^{-2} .

The results of the Pearson's correlations (Figure 5) showed interesting trends. Seed yield was shown to be negatively and significantly correlated with the number of branches per plant both at harvest (r= -0.530^{**}), as well as during the vegetative growth of plants. This finding is also confirmed by the negative correlation found between the number of ramifications at harvest, and the dry matter content of the whole plant (r= -0.536^{**}). An inverse relationship between ramification and protein and oil in the seeds was also evident with r values, respectively, equal to -0.453^{**} and -0.474^{**} .

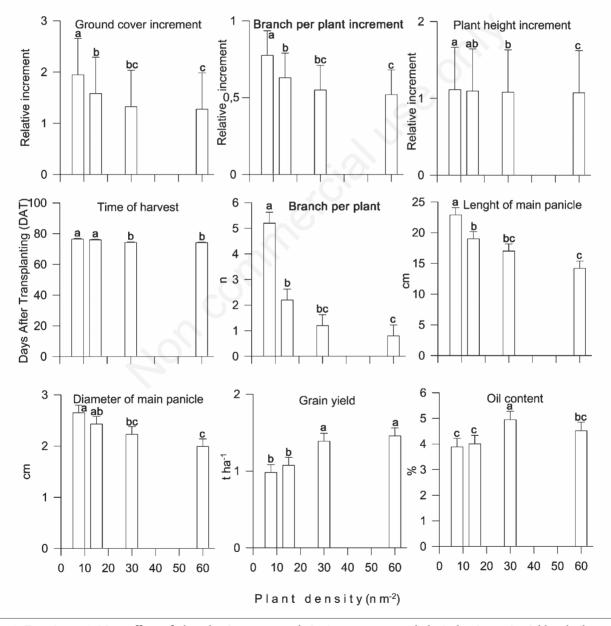

Figure 3. Experiment 2. Mean effects of plant density on some relative increments, morphological traits, grain yield and oil content of seeds. Means followed by the same letter(s) are not different for $P \le 0.05$ according to Tukey's test.

Discussion and conclusions

A. cruentus may be cultivated in Central Italy with satisfactory seed yields, and with a very short cycle in arid spring-summer period conditions. The genotypes of Mexican origin, in addition to those of Guatemala and Puerto Rico, are the most productive and/or demonstrate a better yield stability between years (2.8-3.2 t ha⁻¹). A. hypochondriacus, most likely for reasons attributable to photoperiod, was poorly adapted to Tuscany, displaying an extended growth cycle, and with negligible yields, especially in conditions of marked aridity and high average temperatures. Field trials also permitted us to determine the optimal plant density per unit area. The results have clearly shown that densities of 30 and 60 plants m⁻² resulted in the best yields for all considered genotypes. The phenotypic plasticity of this species

permitted the plants grown at the higher densities to drastically reduce ramification, evident at lower plant densities. As a consequence, the panicles were developed on the apices of the single main stem, which in turn resulted in both a spatial concentration of seed production and a lower degree of scaling with maturation. Such behaviour, together with the reduced stem diameter, and in the case of AMES 5148, the 20 cm reduction in plant height, could facilitate improved mechanical harvesting. Given that panicles on the main stem matured uniformly, this is an additional important aspect in terms of reducing seed loss through natural dispersal. In fact, removal of the stem would be easier and less traumatic for the plant, and seed maturation would occur with a lower degree of staggered ripening and differences in seed humidity. Of note is that particular attention should be given to the mechanisms adopted by the harvesting machines, taking into consideration the small size of the seed, which is at high risk of damage.

The Italian market for amaranth, as for other pseudo-cereals, is currently in the early stages, hence it is very difficult to draw conclusions about the profitability of the crop. In view of its many uses, amaranth could gain market ground where the demand for oil seeds is currently fulfilled exclusively from import. The quality of the base product (seed under the organic or biodynamic agriculture) and derivatives (*e.g.* oil) along with that of national origin may constitute a *key entry* into markets currently dominated by importation. In summary, given the possibility to cultivate this species in the Tuscan environment, a market should be created on the basis of compliance by industry (food and nonfood) to include amaranth products in their respective supply chains. Without this possibility, the utilisation and expansion of this pseudocereal crop will be very difficult.
