ABSTRACT

BACKGROUND AND OBJECTIVE: Low Level Laser Therapy (LLLT) or photobiomodulation therapy is emerging as a promising new therapeutic option for fibrosis in different damaged and/or diseased organs. However, the anti-fibrotic potential of this treatment needs to be elucidated and the cellular and molecular targets of the laser clarified. Here we investigated the effects of a low intensity 635±5 nm diode laser irradiation on fibroblast-myofibroblast transition, a key event in the onset of fibrosis, and elucidated some of the underlying molecular mechanisms.

MATERIALS AND METHODS: NIH/3T3 fibroblasts were cultured in a low serum medium in the presence of Transforming Growth Factor (TGF)-β1, irradiated with a 635±5 nm diode laser (continuous wave, 89 mW, 0.3 J/cm²). Fibroblast-myofibroblast differentiation was assayed by morphological, biochemical and electrophysiological approaches. Expression of matrix metalloproteinase (MMP)-2 and MMP-9 and of Tissue inhibitor of MMPs, namely TIMP-1 and TIMP-2, after laser exposure were also evaluated by confocal immunofluorescence analyses. Moreover, the effect of the diode laser on Transient Receptor Potential Canonical Channel (TRPC)1/Stretch Activated Channel (SAC) expression and activity and on TGF-β1/Smad3 signaling was investigated.

RESULTS: Diode laser treatment inhibited TGF-β1-induced fibroblast-myofibroblast transition as judged by reduction of stress fibers formation, α-smooth muscle actin (sma) and type-1 collagen expression and by changes in electrophysiological properties such as resting membrane potential, cell capacitance and inwardly rectifying K⁺ currents. In addition, the irradiation up-regulated the expression of MMP-2 and MMP-9 and downregulated that of TIMP-1 and TIMP-2 in TGF-β1-treated cells. This laser effect was shown to involve TRPC1/SAC channel functionality. Finally, diode laser stimulation and TRPC1 functionality negatively affected fibroblast-myofibroblast transition by interfering with TGF-β1 signaling, namely reducing the expression of Smad3, the TGF-β1 downstream signaling molecule.

CONCLUSION: Low intensity irradiation with 635±5 nm diode laser inhibited TGF-β1/Smad3-mediated fibroblast-myofibroblast transition and this effect involved the modulation of TRPC1 ion channels. These data contribute to support the potential anti-fibrotic effect of LLLT and may offer further informations for considering this therapy as a promising therapeutic tool for the treatment of tissue fibrosis.

INTRODUCTION

Fibrosis represents a process influencing both progression and outcome of several diseases and it is estimated that, in developed countries, 45% of deaths can be attributed to pathologies where fibrosis plays a major aetiological role [1,2]. **Fibrosis** frequently occurs as aberrant response to an injury or chronic diseases, leading to the impairment of the functionality of multiple organs including heart, skeletal muscle, liver, kidney, lung and skin [3-8]. Also reactive stroma of solid tumors can be considered as a fibrotic tissue [9] and, in addition, the oral sub-mucosal layer may be affected by fibrosis as well, for instance after direct exposure of the buccal mucosa to noxious chemicals and additives with severe consequences for periodontal tissue [10].

In all cases, fibrosis consists of an excessive extracellular matrix (ECM) deposition attributable to the imbalance between collagen synthesis and degradation, in turn depending on the expression of collagen-related genes and activity of matrix metalloproteinases (MMPs) and their inhibitors (Tissue inhibitor of MMPs - TIMPs) [11]. The main cell type implicated in the onset and progression of fibrosis is the myofibroblast resulting from the activation and differentiation of fibroblasts [12]. Although myofibroblasts are required for the wound healing process and the reparative response to organ/tissue damage, their persistence in the damage site contributes to the excessive accumulation of ECM components, which ultimately replaces the necrotic or damaged tissue with a fibrotic scar. The current therapeutic options for fibrosis are very limited and at present, organ transplantation, when possible, is the only effective treatment for end-stage disease. Therefore, the development of alternative and effective therapies aimed to limit fibrotic response or even reverse the fibrotic pattern represents an urgent need with a potentially high impact on social wealth.

Along this line, much attention has been given in the recent years to molecules with anti-fibrotic effects [13-15]. In this context, studies conducted by our group and others have shown that the hormone relaxin can contribute to counteract fibrosis, inhibiting myofibroblast differentiation and modulating the expression of MMPs [16-19]. Moreover, emerging evidence suggests that cell-based therapy, utilizing mesenchymal stromal cells and other cell types, could attenuate the fibrogenic response in different tissues [19-22]. However, both the pharmacological and the cell-based approach present several criticisms and side effects which limit their clinical application. Indeed, soluble factors are typically short-lived, thus requiring more effective methods of delivery. On the other hand, the limitations of cell therapy are mainly related with the route of cell delivery in the host tissue which is still an issue of debate, the transient survival of the majority of transplanted cells within the recipient tissue and to the fact that long-term studies are required to elucidate the real outcome, side-effects and to validate the safety of transplanted cells.

1
2
3 A promising alternative therapeutic tool for the treatment of fibrosis could be represented by the
4 Low Level Laser Therapy (LLLT) or photobiomodulation therapy. This approach consists in the
5 direct application of a non ionizing light, usually delivered via a low power coherent light (laser) or
6 non-coherent light sources such as filtered lamps or light-emitting diode (LED), typically emitting
7 in the 600–1000 nm spectrum range (red to near infrared), with an energy density < 100 J/cm².
8
9 Given the low energy density and wavelengths used in this therapy, light is able to easily enter the
10 tissues in a non destructive and non thermal mode resulting in the biomodulation of various cellular
11 processes [23-27].
12

13
14
15
16 LLLT is considered a safe technology and is widely applied in different branches of medicine and
17 dentistry for pain management, to promote coagulation and reduce inflammation with satisfactory
18 outcomes [27-29]. Moreover, many studies show the beneficial effects of the photobiomodulation
19 therapy on healing and repair/regeneration processes at different tissues [30-37]. Along this line, we
20 have recently demonstrated that therapy with different types of diode lasers is able to improve
21 healing in chronic periodontitis patients [38]. More recently, photobiomodulation therapy is
22 reported to have beneficial effects in reducing fibrosis in different damaged and/or diseased organs
23 [27,28,33,39-45]. However despite these promising data, the anti-fibrotic potential of this kind of
24 laser therapy needs to be further investigated and confirmed prior to clinical use as new treatment
25 option for fibrosis. Indeed, the complexity of medical lasers in terms of different wavelengths,
26 energy output modes and setting parameters has produced a multiplicity of protocols with different
27 outcomes, thus sometimes hampering comparison of the results and identification of univocal
28 guidelines for their use; moreover, although the remarkable increase of data concerning the
29 mechanisms underlying the anti-fibrotic effect of photobiomodulation in recent years, the cellular
30 and molecular targets of the laser treatment are far from being elucidated.

35
36
37
38
39
40
41 On the basis of these considerations, the aim of the present study was to further extend the
42 knowledge on the anti-fibrotic action of photobiomodulation by examining the effect of low energy
43 diode laser (635±5 nm) irradiation on the *in vitro* transition of NIH/3T3 fibroblasts into
44 myofibroblasts and investigating the underlying molecular mechanisms.

2
3 atmosphere of 5% CO₂. The cells were induced to differentiate into myofibroblasts by culturing in
4 DMEM containing FBS 2% for 24 h, 48 h and 72 h in the presence of human Transforming Growth
5 Factor (TGF)-β1 (2 ng/ml; PeproTech, Inc., Rocky Hill, NJ, USA) according to our previous work
6 [16] and irradiated or not with diode laser. In some experiments the cells were also treated with
7 Gadolinium Chloride (GdCl₃; 50 μM; Sigma) a commonly used pharmacological Stretch Activated
8 Channel (SAC) blocker [24], prior laser irradiation.

13 **Laser treatment**

14
15
16 Irradiation was carried out with a diode laser (4x4™ Dental Laser System, General Project,
17 Montespertoli, Florence, Italy) operating at a wavelength of 635±5 nm in continuous irradiation
18 mode. The beam power was set at 89 mW and a 600 nm diameter optic fiber was used. The detailed
19 laser specification and irradiation parameters were reported in Table 1. During the treatment, the
20 temperature of the diode laser-irradiated cells was monitored by a thermal probe included in the
21 console of the 4x4™ Dental Laser System and a thermal camera (Ti9, Fluke Corp., Everett, USA)
22 able to show a thermal map of the treated area. This information allowed to finely tune the diode
23 laser irradiation and keep the temperature below the cell damage threshold. To avoid overlapping or
24 scattered irradiation, the cells of each cell preparation and experiment were seeded in wells or
25 dishes spaced apart. A black background in the irradiation area was used to minimize light
26 reflection. During the period of diode laser irradiation, the cover plate was removed and all the
27 procedures were performed under “clean bench” conditions to prevent bacterial contamination.
28 Eye protection of the operator and assistant was assured by wearing safety glasses.

39 **MTS cell viability assay**

40
41 Cell viability was determined by 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-
42 sulfophenyl)-2Htetrazolium (MTS) assay (Promega Corp., Madison, WI, USA), **essentially as**
43 **previously reported** [25]. Briefly, the cells were cultured in 96-well plates (6 x 10³ cells/well) in
44 DMEM supplemented with FBS 10% (control) and, after 24 h, were **transferred** in low serum (FBS
45 2%) phenol red-free culture medium in the presence of 2 ng/ml human TGF-β1, **diode laser**
46 **irradiated for 10 s as indicated in Table 1 (treated surface diameter: 18 mm) or not, and cultured for**
47 **24 h**. Then the cells were **transferred** in 100 μl of fresh medium and 20 μl of MTS test solution was
48 added to each well. After 4 h of incubation, the optical density (OD) of soluble formazan was
49 measured using a multi-well scanning spectrophotometer (ELISA reader; Amersham, Pharmacia
50 Biotech, Cambridge, UK) at a wavelength of 492 nm.

Silencing of TRPC1 by siRNA

1
2
3 To inhibit the expression of TRPC1, a mix of short interfering RNA duplexes (siRNA) (Santa Cruz
4 Biotechnology, Santa Cruz, CA, USA) corresponding to three distinct regions of the DNA sequence
5 of mouse TRPC1 gene (NM_011643) was used essentially as previously reported [46]. A non-
6 specific scrambled (SCR)-siRNA (Santa Cruz Biotechnology) was used as control. NIH/3T3
7 fibroblasts at 80% confluence were transfected using siRNA Transfection Reagent according to
8 manufacturer's instructions (Santa Cruz Biotechnology) with TRPC1-siRNA duplexes or with SCR-
9 siRNA (20 nM) for 24 h and then transferred in fresh medium for additional 5 h. After that the cells
10 were cultured for further 24 h in low serum culture medium (FBS 2%) in the presence of 2 ng/ml
11 TGF- β 1 and irradiated with diode laser for 26 sec as indicated in the Table 1 (*treated surface*
12 *diameter: 30 mm*) or not before being collected and processed for Western blotting analysis or fixed
13 for confocal immunofluorescence staining. The specific knock-down of TRPC1 was evaluated by
14 Western blotting (data not shown) and confocal immunofluorescence analysis. The efficiency of
15 transfection was estimated to range from 70 to 80%.

26 Confocal Immunofluorescence

27
28 The cells grown on glass coverslips, were fixed with 0.5% buffered paraformaldehyde (PFA) for 10
29 min at room temperature (RT). After permeabilization with cold acetone for 3 min, the fixed cells
30 were blocked with 0.5% bovine serum albumin (BSA; Sigma) and 3% glycerol in PBS for 20 min
31 and then incubated overnight at 4°C, with the following primary antibodies: rabbit polyclonal anti-
32 Ki67 (1:100; Santa Cruz Biotechnology), rabbit polyclonal anti-MMP-2 (1:200; Abcam,
33 Cambridge, UK), rabbit polyclonal anti-MMP-9 (1:100; Abcam), rabbit polyclonal anti-TIMP-1
34 (1:50; Bioss Inc, Woburn, MA, USA), mouse monoclonal anti-TIMP-2 (1:20; Abcam), rabbit
35 polyclonal anti-type-1 collagen (1:50; Santa Cruz Biotechnology), mouse monoclonal anti- α -
36 smooth muscle actin (α -sma, 1:100; Abcam), rabbit polyclonal anti-TRPC1 (1:80; Santa Cruz
37 Biotechnology). The immunoreactions were revealed by incubation with specific anti-rabbit or anti-
38 mouse Alexa Fluor 488- or 568-conjugated IgG (1:200; Molecular Probes, Eugene, OR, USA) for 1
39 h at RT. In some experiments, the cells were stained with Tetramethylrhodamine isothiocyanate
40 (TRITC)-labeled phalloidin (1:100; Sigma) to reveal actin filament organization. In others
41 experiments counterstaining was performed with propidium iodide (PI, 1:30; Molecular Probes) to
42 reveal nuclei. Negative controls were carried out by replacing the primary antibodies with non
43 immune serum; cross-reactivity of the secondary antibodies was tested in control experiments in
44 which primary antibodies were omitted. After washing, the coverslips containing the
45 immunolabelled cells were mounted with an antifade mounting medium (Biomedica Gel mount,
46 Electron Microscopy Sciences, Foster City, CA, USA) and observed under a confocal Leica TCS

3 SP5 microscope (Leica Microsystems, Mannheim, Germany) equipped with a HeNe/Ar laser source
4 for fluorescence measurements. Observations were performed using a Leica Plan Apo 63X/1.43NA
5 oil immersion objective. Series of optical sections (1024 x 1024 pixels each; pixel size 204.3 nm)
6 0.4 μm in thickness were taken through the depth of the cells at intervals of 0.4 μm . Images were
7 then projected onto a single 'extended focus' image. Densitometric analyses of the intensity of
8 MMP-2, MMP-9, TIMP-1, TIMP-2, type-1 collagen, α -sma, TRPC1 fluorescent signals were
9 performed on digitized images using ImageJ software (<http://rsbweb.nih.gov/ij>) in 20 regions of
10 interest (ROI) of 100 μm^2 for each confocal stacks (at least 10).

11
12
13
14
15
16 The number of NIH/3T3 cells with Ki67 positive nuclei was evaluated in 10 random 200 x 200 μm
17 square microscopic fields (63X ocular) in each cell preparation and expressed as percentage of the
18 total cell number.
19
20

21 22 23 **Western Blotting**

24
25 Cells were resuspended in appropriate volume of cold Cell Extraction Buffer (10 mM Tris/HCl, pH
26 7.4, 100 mM NaCl, 1 mM EDTA, 1 mM EGTA, 1 mM NaF, 20 mM Na₄P₂O₇, 2 mM Na₃VO₄,
27 1% Triton X-100, 10% glycerol, 0.1% SDS, 0.5% deoxycholate; Invitrogen Life Technologies,
28 Grand Island, NY, USA;) supplemented with 50 $\mu\text{l/ml}$ Protease Inhibitor Cocktail and 1 mM
29 Phenylmethanesulfonyl fluoride (PMSF; Sigma).
30
31

32
33 Upon centrifugation at 13.000 g for 10 min at 4°C, the supernatants were collected and the total
34 protein content was quantified by Bio-Rad protein assay (Bio-Rad Laboratories S.r.l., Milan, Italy)
35 following the manufacturer's instructions. Forty micrograms of total proteins were electrophoresed
36 on NuPAGE[®] 4-12% Bis-Tris Gel (Invitrogen Life Technologies, 200V, 40 min) and blotted onto
37 polyvinylidene difluoride (PVDF) membranes (Invitrogen Life Technologies; 30V, 1 h). The
38 membranes were blocked with Blocking Solution included in the Western Breeze[®] Chromogenic
39 Western Blot Immunodetection Kit (Invitrogen Life Technologies) for 30 min at RT on rotary
40 shaker and incubated overnight at 4°C with mouse monoclonal anti- α -sma antibody (1:1000;
41 Abcam), rabbit polyclonal anti-Smad3 (1:1000; Cell Signaling Technology, Danvers, MA, USA)
42 rabbit polyclonal anti-TRPC1 (1:1000; Santa Cruz Biotechnology) rabbit polyclonal anti- α -tubulin
43 (1:1000; Cell Signaling Technology) and mouse monoclonal anti- β -actin (1:10000; Sigma)
44 antibodies, assuming α -tubulin or β -actin as control invariant protein. Immunodetection was
45 performed as described in the Western Breeze[®] Chromogenic Immunodetection protocol (Invitrogen
46 Life Technologies). Densitometric analysis of the bands was performed using ImageJ software
47 (<http://rsbweb.nih.gov/ij>) and the values normalized to α -tubulin or β -actin.

Electrophysiological recordings

Whole-cell patch-clamp

Electrophysiological analyses were conducted by the whole-cell patch-clamp technique both in current- and voltage-clamp mode. The experiments were performed and recorded with an Axopatch200B amplifier (Axon Instruments, Union City, CA, USA) interfaced to a Digidata 1200 data-acquisition system controlled by Clampex version 6 software (Axon Instruments) as reported previously [17]. In particular fibroblasts adherent to glass coverslips were put in the 35 mm recording chamber and superfused at 20-22 °C at a rate of 1.8 ml/min by a Pump 33 (Harvard Apparatus) with the following physiological bath solution: 140 mM NaCl, 5.4 mM KCl, 1.5 mM CaCl₂, 1.2 mM MgCl₂, 5.5 mM glucose and 5 mM HEPES/NaOH (pH 7.35). Different channel blockers were used to test the presence of specific ion currents: to record inwardly rectifier K⁺ currents (I_{Kir}), 4 mM Cs⁺ was applied to the bath solution and 0.5 mM BaCl₂ was used to block its occurrence. Stretch Activated Current (I_{SAC}) was blocked by GdCl₃ (50 μM; Sigma). The patch pipettes was filled with the following solution: 130 mM KCl, 10 mM NaH₂PO₄, 0.2 mM CaCl₂, 1 mM EGTA, 5 mM MgATP and 10 mM HEPES. For bath and pipette solution, pH was set to 7.4 with NaOH and to 7.2 with KOH, respectively. The resistance of the filled pipettes was approximately 6-8 MΩ.

The resting membrane potential (RMP) was recorded by switching to the current clamp mode of the 200B amplifier. **In order to record its precise value, we first estimated the junction potential of the electrode prior membrane patch formation; this junction potential value was then subtracted from the recorded membrane potential.** The cell linear capacitance (C_m) was evaluated as previously described [17]. C_m value was considered as an index of the cell surface area, assuming that membrane-specific capacitance is constant at 1 μF/cm². The current amplitude (I) was normalized to C_m to appropriately compare the test currents recorded in cells of different size; accordingly, I/C_m value is proposed as current density (pA/pF). Linear leak and capacitance currents were cancelled on-line by the P/4 procedure.

Pulse protocols of stimulation

The ionic currents were recorded in voltage clamp mode. The currents flowing through the voltage independent stretch activated channels (I_{SAC}) were estimated by a mathematical procedure. We first evoked the total membrane current I_m, by a voltage ramp pulse protocol ranging from -120 to +40 mV at a rate of 100 mV/second, applied from a holding potential (HP) of -40 mV. At the end of any experimental session a commonly used pharmacological Stretch Activated Channel (SAC)

1
2
3 blocker GdCl_3 (50 μM ; Sigma) was added to the bath solution and the pulse protocol was applied
4 again to record the leak current ($I_{m,\text{leak}}$). The Gd^{3+} -sensitive I_{SAC} was thus determined by the point-
5 by-point subtraction of $I_{m,\text{leak}}$ from the total current I_m , recorded at the beginning of the experiment.
6 This isolated the not voltage-dependent I_{SAC} currents, that were normalized for C_m , to allow the
7 comparison of size different cells. Similarly, we used ramp pulses from -120 to +50 mV (HP = 0
8 mV), at a rate of 100 mV/sec to evoke I_{Kir} , as previously published [17]. The experiments were
9 repeated in the presence of the blocker Ba^{2+} in the recording solution and the resulting current trace
10 was then subtracted from the one obtained in the absence of Ba^{2+} . The resulting I_{Kir} was then
11 normalized for C_m .

32 RESULTS

33 *Diode laser irradiation inhibited TGF- β 1-induced fibroblast-myofibroblast transition*

34
35 We evaluated the effects of a low level irradiation with a diode laser at a wavelength of 635 ± 5 nm
36 on fibroblast-myofibroblast transition. To this aim, NIH/3T3 fibroblasts were cultured in a low
37 serum medium (FBS 2%) for different times (24 h, 48 h or 72 h) in the presence of 2 ng/ml TGF-
38 β 1, the well known pro-fibrotic agent [47], in order to promote cell differentiation towards
39 myofibroblasts, irradiated or not with the diode laser using the parameters as reported in Table 1.
40 Cells cultured in the medium supplemented with FBS 10%, not treated with TGF- β 1 and not
41 irradiated were used as controls. We found that diode laser did not affect cell viability as judged by
42 MTS assay performed after 24 h from treatment (Fig. 1A). Simultaneously, diode laser irradiation
43 was able to induce a significant increase in proliferation of TGF- β 1 treated fibroblasts counteracting
44 the anti-proliferative action of the pro-fibrotic factor, as showed by the increase in the number of
45 the cells positive for Ki67, a nuclear protein marker for cell proliferation (Fig. 1B).

55

56 To evaluate the differentiation of fibroblasts into myofibroblasts in our experimental model, we
57 searched for well known myofibroblastic markers such as the presence of stress fibers and the
58
59
60

1
2
3 expression of α -sma and type-1 collagen. The morphological analysis showed that the cells treated
4 with TGF- β 1 already after 24 h, exhibited a more organized cytoskeleton as compared to that of
5 control cells, consisting in the presence of robust stress fibres associated with a significant increase
6 in the expression of α -sma, mainly localized along their course (Fig. 2A). As shown by Western
7 blotting analysis and as expected, TGF- β 1 induced a further increase in α -sma expression levels
8 after 48 h and 72 h of treatment (Fig. 2B). Moreover the cells exposed for 72 h to TGF- β 1 presented
9 an increase in the expression of type-1 collagen at the cytoplasmic level (Fig. 2A) further
10 confirming the capability of TGF- β 1 to induce fibroblast-myofibroblast transition. Of note, diode
11 laser irradiation was able to inhibit TGF- β 1-induced effect, by reducing the assembly of stress
12 fibers and down-regulating both α -sma and type-1 collagen expression (Fig. 2).

13
14 To further support these data, in parallel experiments we evaluated the electrophysiological
15 properties of the cells by whole-cell patch-clamp technique. We first recorded in current clamp
16 mode the resting membrane potential (RMP), a key physiological parameter whose small
17 modifications can substantially change cell excitability, contractility and other properties such as
18 cell migration [17]. RMP of fibroblasts cultured for different times in the presence of TGF- β 1,
19 showed that such condition induced a depolarization of RMP with respect to controls (Fig. 3A). By
20 contrast, diode laser stimulation was able to prevent the TGF- β 1-induced effect at any time point,
21 evoking a statistically significant hyperpolarization of RMP whose values returned to the ones
22 recorded in controls (Fig. 3A). We then analyzed in voltage clamp mode the cell capacitance (C_m),
23 usually assumed as index of cell surface. C_m increased with respect to control cells in both TGF- β 1
24 treated cells and TGF- β 1 and diode laser treated ones at any time, consistent with an increase of the
25 individual cell size during myofibroblast differentiation (Fig. 3B). However, diode laser stimulation
26 was not able to induce any significant change of C_m values respect to TGF- β 1 treatment alone.
27 According to our previously work [17] we also tested the effects of the cell treatments on the
28 inward rectifying K^+ current, I_{kir} , usually well expressed in myofibroblasts. We observed that in
29 response to voltage ramp pulse stimulation (as described in Methods), the cells treated with TGF- β 1
30 showed a consistent Ba^{2+} -sensitive I_{kir} for negative voltages, and that the amplitude of this current
31 was significantly reduced after diode laser stimulation (Fig. 4).

32 33 *Diode laser stimulation modulated the expression of MMPs and of TIMPs in TGF- β 1-treated* 34 *fibroblasts*

35
36 A fine coordination between a family of proteolytic enzymes that selectively digest individual
37 components of ECM, namely MMPs, and their specific tissue inhibitors (TIMPs) is crucial for

60

connective tissue remodelling after a tissue damage and for counteracting the excessive deposition of collagen by myofibroblasts [11]. On this basis, we investigated whether diode laser stimulation could modulate the expression and activity of MMP-2 /MMP-9 and TIMP-1/TIMP-2 **in fibroblasts**. As **determined** by confocal immunofluorescence analyses, we found that control NIH/3T3 cells expressed all these enzymes: in particular MMP-9 was concentrated along cytoskeletal filaments, MMP-2 was mainly distributed inside the cytoplasm as well as TIMP-1 and TIMP-2 (Fig. 5). The cells treated with TGF- β 1 for 24 h displayed a reduction of the expression of both MMP-2 and MMP-9 associated with an increase of TIMP-1 and TIMP-2 as compared to control cells (Fig. 5). Of note, diode laser irradiation was able to revert TGF- β 1 induced effect, by up-regulating MMP-2 and MMP-9 expression and down-regulating TIMP-1 and TIMP-2 (Fig. 5).

Diode laser-induced prevention of fibroblast-myofibroblast transition is mediated by the Transient Receptor Potential Canonical Channel 1 (TRPC1) functionality

It has been recently reported that TGF- β 1 affects the functionality of different ion channels including Transient Receptor Potential (TRP) channels and that TRP-mediated calcium influx is required to promote fibroblast–myofibroblast transition [48,49].

Based on these data, in order to investigate the mechanisms by which diode laser irradiation could influence fibroblast differentiation, we analyzed the expression and activity of TRPC1 in our experimental conditions. TRPC1 belongs to the superfamily of TRP protein, acting as Store-Operated Ca^{2+} entry Channel (SOC) in various cell types [50], and also as Stretch Activated Channel (SAC) [46].

Confocal immunofluorescence analysis showed a positive labeling of TRPC1 in the cytoplasm and plasmamembrane of control NIH/3T3 fibroblasts and a significant increase of the immunostaining in the cells treated with TGF- β 1 (Fig. 6A). In particular TRPC1 expression gradually increased with time reaching maximal levels after 48-72 h of treatment. The parallel electrophysiological recordings were in agreement with the morphological analyses; in fact TGF- β 1 treated fibroblasts regularly showed linear currents ascribable to non selective cation currents or TRPC1 fluxes through SACs (I_{SAC}) according to our previously reported data [46] (Fig. 6B).

These results suggested a role for TRPC1 channels in the fibroblast-myofibroblast transition. To support these data we then analyzed the expression of α -sma in cells in which TRPC1 gene expression was silenced with a specific TRPC1-siRNA, or the channel activity was pharmacologically blocked with 50 μM GdCl_3 . As judged by confocal immunofluorescence and Western blotting analyses the expression of the myofibroblast marker appeared significantly reduced when either the gene expression of TRPC1 was down-regulated or its activity blocked (Fig.

1
2
3 7). It was worth noting that diode laser irradiation was able to reduce the increase of TRPC1
4 expression and activity in TGF- β 1 treated cells at any time (Fig. 6) and to induce a further decrease
5 of α -sma expression in the cells silenced for TRPC1 or treated with GdCl₃ as compared to the laser
6 unstimulated ones (Fig. 7). All these data suggested that diode laser-induced inhibition of
7 fibroblast-myofibroblast transition could be, at least in part, mediated by the TRPC1 functionality.
8 Finally, we also demonstrated that diode laser irradiation and TRPC1 expression and activity could
9 exert their inhibitory effects on fibroblast differentiation by interfering with TGF- β 1 mediated
10 intracellular signaling pathway, since the diode laser treatment (Fig. 8A) as well as the inhibition of
11 TRPC1 (Fig. 8B) caused a significant decrease in the expression of Smad3, the TGF- β 1 downstream
12 signaling molecule, in TGF- β 1-treated cells.

20 21 DISCUSSION

22
23
24 The beneficial effect of LLLT or photobiomodulation therapy in ameliorating fibrosis has been
25 recently demonstrated in different damaged and diseased organs including kidney, skeletal muscle,
26 skin, heart and tendon, but little is known concerning the cellular and molecular mechanisms by
27 which the laser could exert this action [27,28,33,39-45].

28
29
30 Most of the studies in this field suggest that the cellular responses to laser therapy are mediated by
31 the classical mechanisms mainly involving changes in the activity of mitochondria. In fact,
32 mitochondria contain cytochromes and porphyrins of the respiratory chain which act as light
33 receptors and are therefore believed to be the primary phototargets during irradiation. In particular,
34 photon absorption results in the modulation of reactive oxygen species (ROS) production and in an
35 increase of ATP synthesis leading to regulation of the cell function, cytoprotection and, in turn,
36 attenuation of inflammation and fibrosis [26,39,40,45,51].

37
38
39 Data of the present study, beside supporting the anti-fibrotic effect of the photobiomodulation,
40 contribute to add new insights into the cellular and molecular targets of the laser. Indeed, we have
41 provided experimental evidence for the ability of photobiomodulation therapy with a 635 \pm 5 nm
42 diode laser, to inhibit TGF- β 1 induced fibroblast-myofibroblast transition *in vitro* by modulating the
43 expression and the activity of TRPC1 membrane channel and interfering with TGF- β 1 signaling.

44
45
46 It is well established that myofibroblasts are the major contributors to tissue scarring [12]. These
47 cells combine immunophenotypical and ultrastructural features of fibroblasts and smooth muscle
48 cells by exhibiting *de novo* formation and deployment of contractile actin/myosin-containing stress
49 fibers and expression of α -sma with the extensive endoplasmic reticulum of synthetically-active
50 fibroblasts. They respond to different stimuli including mechanical stress, hypoxia, paracrine factors
51
52
53
54
55
56
57
58
59
60

1
2
3 by increasing synthesis and deposition of ECM proteins and exerting traction forces on ECM
4 [2,12]. Fibroblast-myofibroblast transition is a key mechanism in the normal reparative response to
5 tissue damage and the myofibroblast activity is beneficial for restoring the tissue integrity through
6 the formation of a contractile scar. For example, scars stabilize the heart muscle after myocardial
7 infarction as well as tendon, bone, and cartilage after fracture or rupture. However, persistence of
8 myofibroblasts in the wound as well as deregulated and chronic activity of these cells, leads to
9 fibrosis and organ failure [12]. Given that myofibroblast generation is a crucial event shared by
10 fibrosis in all organs, its inhibition could represent an effective non-organ-specific tool, to
11 counteract fibrosis.
12

13
14 In such a view, our data, demonstrating that the diode laser induced inhibition of fibroblast-
15 myofibroblast transition, appear intriguing and of potential clinical interest. In particular, our results
16 have shown that diode laser stimulation of TGF- β 1-treated NIH/3T3 fibroblasts, affects multiple
17 processes associated with fibroblast differentiation, namely *i*) inhibition of the assembly of stress
18 fibers; by these structures the myofibroblast is capable to remodel and contract the ECM and also
19 to adapt its activity to changes in the mechanical microenvironment as occur in fibrotic tissue
20 [12,52]; *ii*) reduction of α -sma and type-1 collagen expression; *iii*) modification of
21 plasmamembrane passive properties and ion currents typically expressed by myofibroblasts. In
22 particular, laser stimulation counteracted the tendency of TGF- β 1 to induce a depolarization of
23 RMP, strictly correlated with the proliferation and contractile properties of myofibroblasts [53],
24 causing an hyperpolarization of this parameter, and attenuated inwardly rectifying K⁺ currents (I_{Kir}),
25 which usually increase in the transition to myofibroblasts and are determinant of RMP and thus of
26 myofibroblast contractility [17,53].
27

28
29 It is well known that a fine coordination between MMPs and TIMPs is also essential to counteract
30 the excessive deposition of collagen by myofibroblasts and maintain the homeostasis of ECM [11]
31 Therefore our data, showing the capability of the laser to up-regulate the expression of MMP-2 and
32 MMP-9 while concomitantly down-regulating the expression of their specific tissue inhibitors
33 TIMP-1 and TIMP-2, add further evidence to the ability of photobiomodulation therapy to affect
34 ECM remodeling. This is in accordance with previous finding on the positive effect of LLLT on
35 MMP-2 gelatinolytic activity during the skeletal muscle regeneration process [44,54].
36

37
38 Although many cytokines and growth factors can stimulate fibroblast-myofibroblast
39 transition, TGF- β 1 is the most effective pro-fibrotic cytokine secreted by various cell types in the
40 lesion site, including epithelial cells, platelets, macrophages, fibroblasts and also myofibroblasts.
41 Indeed, autocrine TGF- β 1 secretion by myofibroblasts sustains a vicious cycle, which further
42 promotes their differentiation and the progression of fibrosis [13,47,55]. Moreover, there is
43

60

1
2
3 evidence supporting the concept that myofibroblasts could promote fibrogenic signaling also via a
4 contractile force-mediated activation of latent TGF- β 1 bound to the ECM. In this process,
5 contractility generated by stress fibers is transmitted from the cytoskeleton to the ECM through the
6 transmembrane integrins and this force transmission causes a conformational change of the ECM-
7 bound latent TGF- β 1 complex, thus leading to the release (or exposure) of active TGF- β 1 which is
8 **then able to bind to its receptor(s) [56].**

9
10
11
12
13 **TGF- β 1 promotes** fibroblast-myofibroblast differentiation and myofibroblast survival by
14 inducing a variety of signaling pathways, including the canonical TGF- β 1 signaling pathway
15 (Smad2/3-dependent) and non-canonical pathways, such as PI3K/AKT/mTOR pathway [47]. Our
16 data, showing a reduction of Smad3 expression in the fibroblast irradiated with the diode laser,
17 suggest that laser could exert its inhibitory effects on myofibroblast generation by interfering with
18 the canonical TGF- β 1 mediated intracellular signaling pathway. These data are in agreement with
19 previous studies demonstrating the contribution of **photobiomodulation therapy in preventing**
20 **fibrosis by decreasing TGF- β 1 mRNA expression [57,58] in an injured skeletal muscle and of**
21 **Smad3 expression in an animal model of renal interstitial fibrosis [41].**

22
23
24
25
26
27
28 **Moreover this study adds new insights into the molecular** targets of the laser suggesting, for
29 the first time, that diode laser could promote the inhibition of TGF- β 1 induced myofibroblast
30 generation by modulating TRPC1 ion channel functionality. In particular, we observed that the
31 expression and the activity of TRPC1 ion channel significantly augmented in TGF- β 1-treated
32 fibroblasts and that the pharmacological block of this channel as well as the silencing of TRPC1
33 gene expression reduced myofibroblast differentiation. Notably, the diode laser irradiation was able
34 to prevent the increase of TRPC1 ion channel expression and activity induced by TGF- β 1. In line
35 with this, previous data have shown the ability of LLLT to modulate TRP channel functionality in
36 other cell types; in particular it has been demonstrated a modulation of TRPC1 functionality by a
37 low pulse energy Nd:YAG laser irradiation in osteoblastic cells [24] and of Transient Receptor
38 Potential Vanilloid 4 (TRPV4) channels by a 405 nm laser in mast cell line [59]. Our data are also
39 consistent with the studies in the literature demonstrating that TGF- β 1 regulates different TRP
40 channels including TRPC1 in fibroblasts from different organs [48,60,61] and that TRPC-mediated
41 calcium signaling plays an important role in the differentiation of fibroblasts to myofibroblasts and
42 in fibrogenesis cascade [48,49,62-64].

43
44
45
46
47
48
49
50
51
52
53 Moreover, given that differentiation of fibroblastic cells towards the myofibroblastic phenotype is
54 also dependent on mechanical stimuli derived from ECM [12] and that TRPC1 has been
55 demonstrated to be a component of Stretch Activated Channels (SACs) acting as mechanotransducer
56 [46], it is worth to suggest that this channel could be involved in the myofibroblast generation for
57
58
59
60

1
2
3 its ability to integrate signals from TGF- β 1 and mechanical factors as reported for other classes of
4 TRP channels [65].

5
6 How laser irradiation could affect TRPC1 functionality **still** remains to be elucidated. Since TRP
7 proteins were first found in the eye of a Drosophila mutant and are required for maintaining the
8 light response [66], it can be hypothesized that TRPC1 can directly absorb photons to regulate its
9 activity, **but to our knowledge there are no studies in the literature on the effects of the light**
10 **stimulation on isolated mammalian TRPC proteins.** On the other hand, it can be supposed that the
11 laser-induced inhibition of TRPC1 expression and activity could be correlated to the reported ability
12 of the laser to prevent oxidative stress reducing the generation of reactive oxygen species (ROS)
13 [27,40] whose levels have been demonstrated to be regulated by TGF- β 1 [4,67] and involved in
14 TRPC1 activation [68,69]. Moreover, it can be also speculated that the mechanisms underlying the
15 laser-mediated channel functionality in fibroblast cells, may involve alterations of mechanical
16 properties of the cell surface followed by TRPC1 channel down-regulation, intracellular calcium
17 changes and inhibition of TGF- β 1/Smad3 signaling pathway. Further studies are required to define
18 the real mechanism of TRPC1 activation by laser irradiation.

19
20 **In conclusion, the results of this study provide novel insights into the cellular and molecular**
21 **mechanisms by which a LLLT with a 635 \pm 5 nm diode laser could exert an anti-fibrotic action and**
22 **may contribute to add information on the potentials of this therapy, as a new treatment option for**
23 **tissue fibrosis.**

FIGURE LEGEND

Fig. 1. Effect of diode laser irradiation on viability and proliferation of TGF- β 1 treated NIH/3T3 fibroblasts. The cells were cultured for 24 h in low serum (FBS 2%) in the presence of 2 ng/ml TGF- β 1, irradiated or not with diode laser for 10 s or 26 s as reported in Table 1. Control cells were cultured in growth medium (FBS 10%). A) MTS cell viability assay. Optical density of soluble colored formazan produced by MTS reduction, was evaluated using a multi-well scanning spectrophotometer at 492 nm. B) Evaluation of cell proliferation by confocal immunofluorescence analysis of Ki67 expression. The histogram shows the number of the cells with Ki67 positive nuclei expressed as percentage of the total nuclei number. Data shown are mean \pm SEM and represent the results of at five independent experiments performed in triplicate. Significance of difference evaluated by one-way ANOVA and Newman–Keuls multiple comparison test: * $p < 0.05$ vs CONTROL (FBS 10%); $^{\circ} p < 0.05$ vs FBS 2% + TGF- β 1.

Fig. 2. Effect of diode laser irradiation on fibroblast-myofibroblast transition. NIH/3T3 fibroblasts were cultured for 24 h, 48 h and 72 h in low serum (FBS 2%) in the presence of 2 ng/ml TGF- β 1, irradiated or not with diode laser for 26 s as reported in Table 1 (*treated surface diameter: 30 mm*). Control cells were cultured in growth medium (FBS 10%). A) Representative confocal fluorescence images of the cells in the indicated experimental conditions, stained with TRITC-conjugated phalloidin to reveal F-actin (red) or immunostained with antibodies against α -sma (green) or type-1 collagen (cyan). Nuclei are counterstained in red with propidium iodide (PI). The histograms show the densitometric analyses of the intensity of the fluorescence signals for each specific marker performed on digitized images. Scale bar = 25 μ m. B) Western blotting analysis of α -sma expression in fibroblasts in the indicated experimental conditions. The densitometric analysis of the bands normalized to α -tubulin is reported in the histogram. Data shown are mean \pm SEM and represent the results of at least three independent experiments performed in triplicate. TABLE 1. Laser specification

IRRADIATION PARAMETERS

Treated surface diameter (mm)	Modality	Distance from laser output (mm)	Irradiation time (s)
18	photoinductive	60	10
30	photoinductive	90	26

LASER BEAM PARAMETERS

Treated surface diameter (mm)	Laser type	Wavelength (nm)	Irradiation mode	Power output (mW)	Target power (mW)	Laser beam diameter (mm)
18	Diode 635	635±5	continuous wave	89	89	18
30	Diode 635	635±5	continuous wave	89	89	30

LASER SPOT PARAMETERS

Treated surface diameter (mm)	Spot diameter /area at target level (mm/mm ²)	Power density (mW/cm ²)
18	18.6 / 273	32.6
30	30 / 703	12.6

SURFACE TREATMENT DATA

Treated surface diameter (mm)	Treated area (mm ²)	Treatment mode	Total energy delivered (mJ)	Total energy density (mJ/cm ²)
18	273	without contact	890	326
30	703	without contact	2314	329

Figure 1

Effect of diode laser irradiation on viability and proliferation of TGF- β 1 treated NIH/3T3 fibroblasts. The cells were cultured for 24 h in low serum (FBS 2%) in the presence of 2 ng/ml TGF- β 1, irradiated or not with diode laser for 10 s or 26 s as reported in Table 1. Control cells were cultured in growth medium (FBS 10%).

A) MTS cell viability assay. Optical density of soluble colored formazan produced by MTS reduction, was evaluated using a multi-well scanning spectrophotometer at 492 nm. B) Evaluation of cell proliferation by confocal immunofluorescence analysis of Ki67 expression. The histogram shows the number of the cells with Ki67 positive nuclei expressed as percentage of the total nuclei number. Data shown are mean \pm SEM and represent the results of at five independent experiments performed in triplicate. Significance of difference evaluated by one-way ANOVA and Newman-Keuls multiple comparison test: * $p < 0.05$ vs CONTROL (FBS 10%); ° $p < 0.05$ vs FBS 2% + TGF- β 1.

241x325mm (300 x 300 DPI)

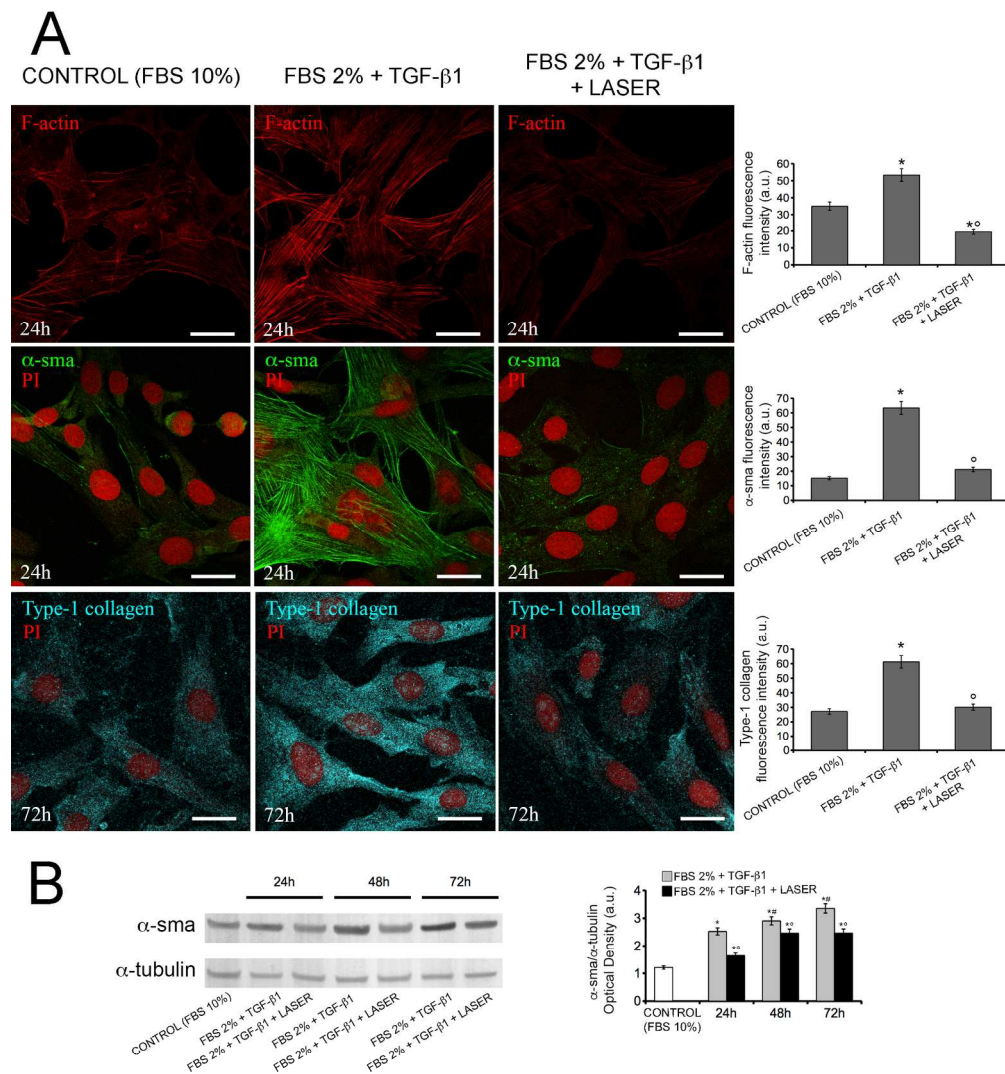

Figure 2

Effect of diode laser irradiation on fibroblast-myofibroblast transition. NIH/3T3 fibroblasts were cultured for 24 h, 48 h and 72 h in low serum (FBS 2%) in the presence of 2 ng/ml TGF- β 1, irradiated or not with diode laser for 26 s as reported in Table 1 (treated surface diameter: 30 mm). Control cells were cultured in growth medium (FBS 10%). A) Representative confocal fluorescence images of the cells in the indicated experimental conditions, stained with TRITC-conjugated phalloidin to reveal F-actin (red) or immunostained with antibodies against α -sma (green) or type-1 collagen (cyan). Nuclei are counterstained in red with propidium iodide (PI). The histograms show the densitometric analyses of the intensity of the fluorescence signals for each specific marker performed on digitized images. Scale bar = 25 μ m. B) Western blotting analysis of α -sma expression in fibroblasts in the indicated experimental conditions. The densitometric analysis of the bands normalized to α -tubulin is reported in the histogram. Data shown are mean \pm SEM and represent the results of at least three independent experiments performed in triplicate. Significance of difference evaluated by one-way ANOVA and Newman-Keuls multiple comparison test: * $p < 0.05$ vs CONTROL (FBS 10%); $^{\circ}$ $p < 0.05$ vs FBS 2% + TGF- β 1; # $p < 0.05$ vs previous time.

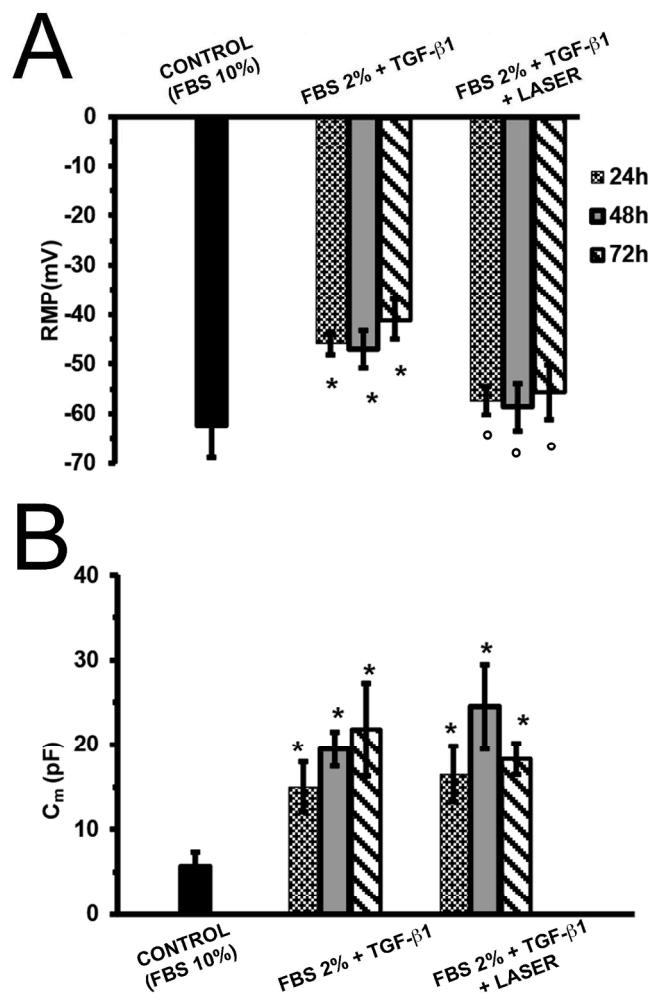

Figure 3

Effect of diode laser irradiation on electrophysiological plasmamembrane properties of TGF-β1 treated NIH/3T3 fibroblasts. NIH/3T3 fibroblasts were cultured for 24 h, 48 h and 72 h in low serum (FBS 2%) in the presence of 2 ng/ml TGF-β1, irradiated or not with diode laser for 26 s as reported in Table 1 (treated surface diameter: 30 mm). Control cells were cultured in growth medium (FBS 10%). A) Resting membrane potential (RMP) recorded by whole-cell patch-clamp technique in current clamp mode. B) Cell capacitance (C_m) commonly used as index of cell size, recorded by whole-cell patch-clamp technique in voltage clamp mode. Data are the mean ± SEM: CONTROL (FBS 10%), n = 20 cells; FBS 2% + TGF-β1, n = 30 cells; FBS 2% + TGF-β1 + LASER, n = 30 cells. Significance of difference evaluated by one-way ANOVA and Newman-Keuls multiple comparison test : * p < 0.05 vs CONTROL (FBS 10%); ° p < 0.05 vs FBS 2% + TGF-β1 treatment at the same time.

139x244mm (300 x 300 DPI)

Figure 4

Effect of diode laser irradiation on delayed rectifier total outward K^+ currents ($I_{K,DR}$) on TGF- β 1 treated NIH/3T3 fibroblasts.

I-V plot related to the inward rectifying K^+ currents (I_{Kir}), obtained in response to ramp voltage pulse stimulation ($HP = 0$ mV) applied to fibroblasts cultured for 72 h in low serum (FBS 2%) in the presence of 2 ng/ml TGF- β 1 (blue trace) and to TGF- β 1 treated fibroblasts irradiated with the diode laser (red trace) for 26 s as reported in Table 1 (treated surface diameter: 30 mm). Each trace was obtained by pharmacological dissection in the presence of Kir channel blocker (Barium Chloride), subtracting the current recorded in the bath recording solution from that recorded in control solution. Current amplitude values were normalized for cell capacitance (C_m). Data are expressed as mean \pm SEM (FBS 2% + TGF- β 1, $n = 22$ cells; FBS 2% + TGF- β 1 + LASER, $n = 22$ cells). Significance of difference evaluated by one-way ANOVA and Newman-Keuls multiple comparison test: * $p < 0.05$ vs FBS 2% + TGF- β 1 + LASER.

90x101mm (300 x 300 DPI)

Figure 5

Effect of diode laser irradiation on MMP-2, MMP-9, TIMP-1 and TIMP-2 expression in TGF-β1 treated NIH/3T3 fibroblasts. Representative immunofluorescence confocal images of NIH/3T3 fibroblasts cultured in growth medium (CONTROL, FBS 10%) or cultured for 24 h in low serum medium (FBS 2%) in the presence of 2 ng/ml TGF-β1, irradiated or not with diode laser for 26 s as reported in Table 1 (treated surface diameter: 30 mm) and immunostained with antibodies against MMP-9 (red), MMP-2 (green), TIMP-1 (cyan) and TIMP-2 (green). Scale bar = 25 μm. Densitometric analyses of the intensity of the specific fluorescence signals performed on digitized images are reported in the histograms. Data shown are mean ± SEM and represent the results of at least three independent experiments performed in duplicate. Significance of difference evaluated by one-way ANOVA and Newman-Keuls multiple comparison test: * $p < 0.05$ vs CONTROL (FBS 10%); ° $p < 0.05$ vs FBS 2% + TGF-β1.
203x229mm (300 x 300 DPI)

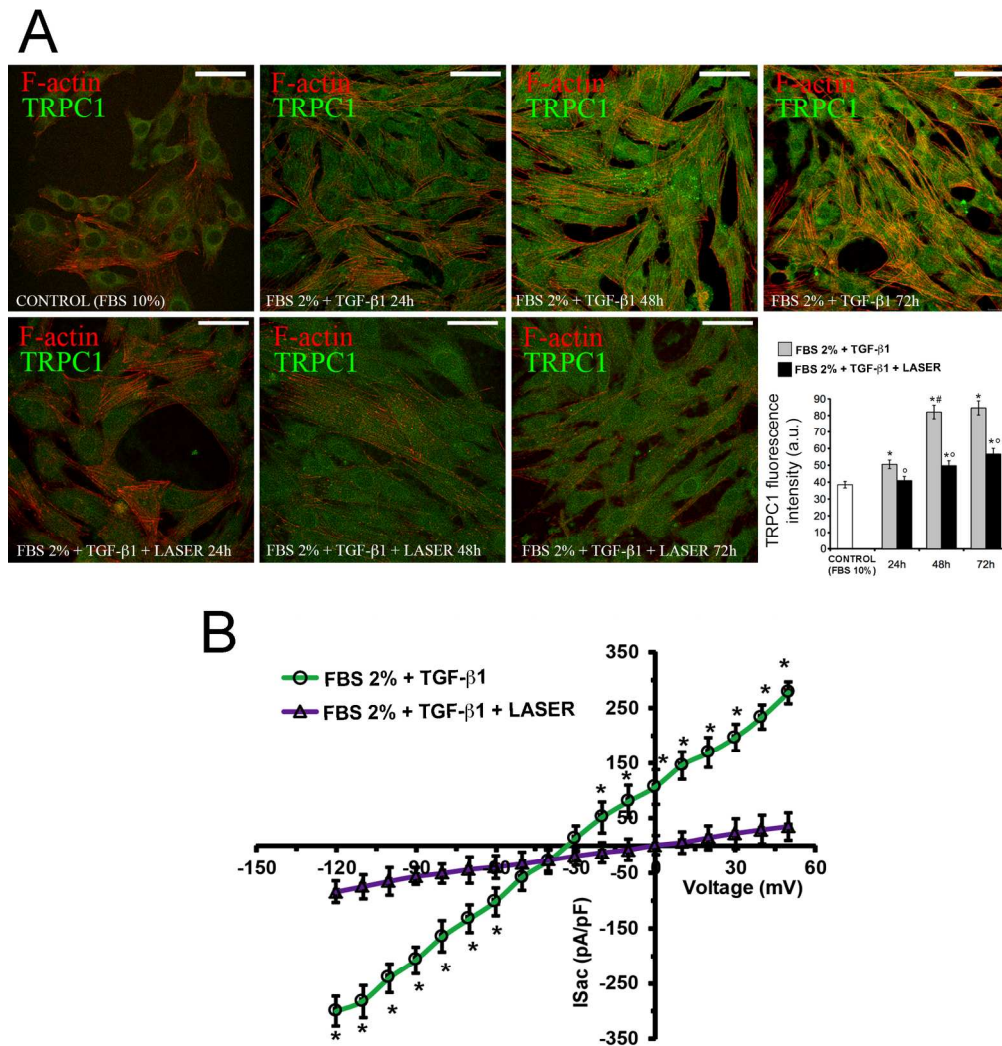

Figure 6

46 Effect of diode laser irradiation on TRPC1 expression and on currents through TRPC1 (ISAC) in TGF-β1
47 treated NIH/3T3 fibroblasts. NIH/3T3 fibroblasts were cultured for 24 h, 48 h and 72 h in low serum (FBS
48 2%) in the presence of 2 ng/ml TGF-β1, irradiated or not with diode laser for 26 s as reported in Table 1
49 (treated surface diameter: 30 mm). Control cells were cultured in growth medium (FBS 10%). A)

50 Representative confocal fluorescence images of the cells in the indicated experimental conditions stained
51 with TRITC-conjugated phalloidin to reveal F-actin (red) and immunostained with antibodies against TRPC1
52 (green). Scale bar = 50 μm. The histogram shows the densitometric analyses of the intensity of the TRPC1
53 fluorescence signal performed on digitized images. Data shown are mean ± SEM and represent the results of
54 at least three independent experiments performed in triplicate. B) I-V plot related to the non selective cation
55 currents fluxes through SACs (ISAC), obtained in response to ramp voltage pulse stimulation (HP = -40 mV)
56 applied to fibroblasts cultured for 72 h in low serum (FBS 2%) in the presence of 2 ng/ml TGF-β1 not
57 irradiated (green trace) or irradiated with diode laser (violet trace). Current amplitude is normalized for cell
58 capacitance (Cm). Data are mean ± SEM (FBS 2% + TGF-β1, n = 20 cells; FBS 2% + TGF-β1 + LASER, n =
59 20 cells). Significance of difference evaluated by one-way ANOVA and Newman-Keuls multiple comparison

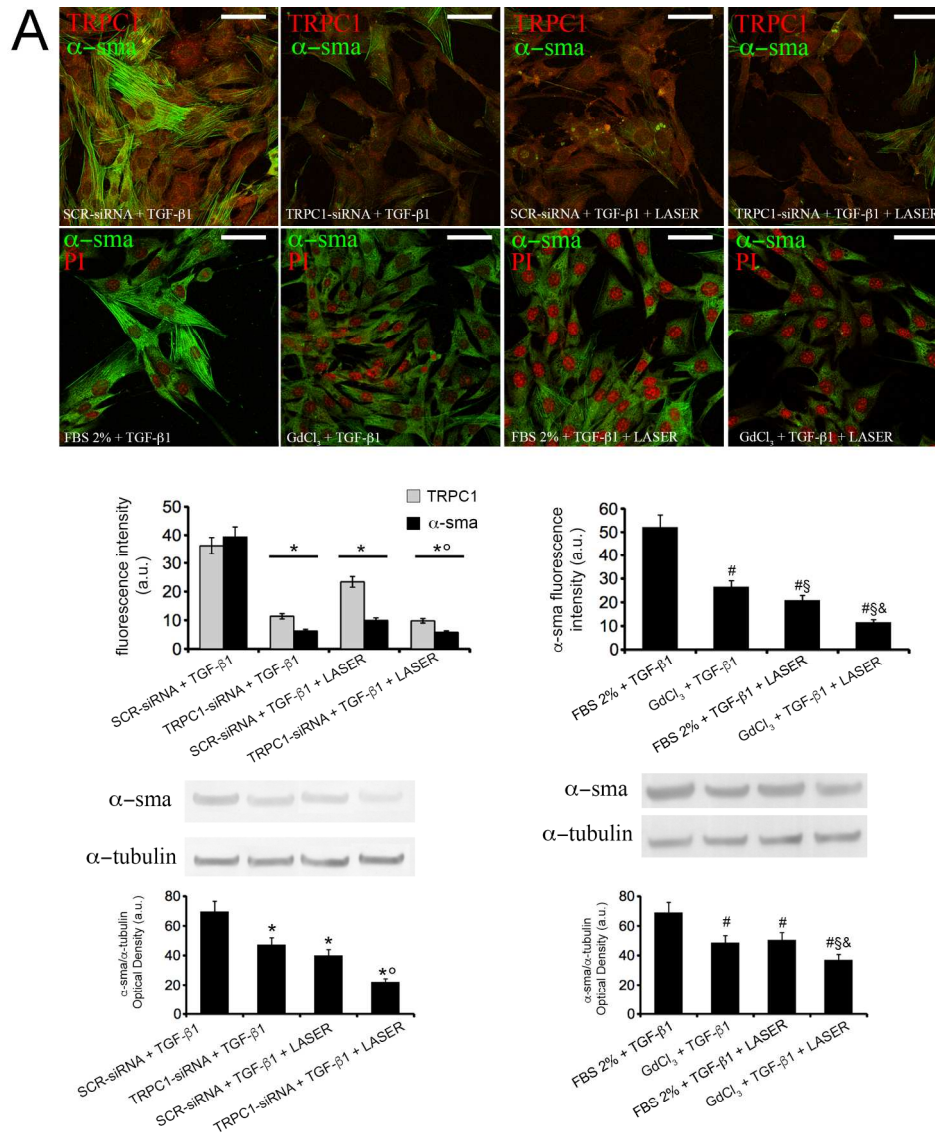

Figure 7

Effect of inhibition of TRPC1 expression and functionality on fibroblast-myofibroblast transition. To inhibit TRPC1 gene expression NIH/3T3 fibroblasts were silenced by specific TRPC1-siRNA cultured for 24 h in low serum (FBS 2%) in the presence of 2 ng/ml TGF- β 1, irradiated or not with diode laser for 26 s as reported in Table 1 (treated surface diameter: 30 mm), SCR-siRNA was used as control. In other experiments the cells in low serum medium were pre-treated with Gadolinium Chloride (50 μ M, GdCl₃) a specific SAC channel blocker, before TGF- β 1 addition and irradiation or not with diode laser. A) Representative confocal immunofluorescence images of the cells in the indicated experimental conditions immunostained with antibodies against TRPC1 (red, upper panel) and α -sma (green). Propidium iodide (PI, red) was used to counterstain nuclei. Scale bar = 50 μ m. The histograms show the densitometric analyses of the intensity of the fluorescence signal for specific markers performed on digitized images. B) Western blotting analysis of α -sma expression in fibroblasts in the indicated experimental conditions. The densitometric analysis of the bands normalized to α -tubulin is reported in the histograms. Data shown are mean \pm SEM and represent the results of at least three independent experiments performed in triplicate. Significance of difference
