The heme-containing indoleamine 2,3-dioxygenase 1 (IDO1) catalyses the O2-dependent oxidation of L-tryptophan (Trp) to the immunosuppressive metabolite L-kynurenine (Kyn). This reaction is the rate-limiting step in the kynurenine pathway, which leads to the formation of NAD^+ and regulates the immune response in host-pathogen interactions.[1] Dendritic cells (DCs) exploit IDO1 activity to create an immuno-tolerogenic microenvironment and to maintain tolerance to self-antigens. These functions occur in tissues and organs that may feature variations in metabolic factors such as nutrients and growth factors, as well as chemical factors such as pH and redox conditions. Early studies highlighted altering redox conditions, independent of oxygen levels, controls the expression and catalytic activity of IDO1 in DCs.[2] At the protein level, this may occur through redox conditions that regulate the oxidative turnover of the heme cofactor and/or disulfide bridge formation of cysteine residues in IDO1.

Several types of inhibitors have been developed to modulate IDO1 catalytic activity, with different binding modes that may engage or not the heme group through a coordination bond to the iron atom.[3]

In this study, we have tested the hypothesis that redox conditions may affect the binding properties of inhibitors to the enzyme. At this aim, we have investigated the effect of reducing agents on the interaction between IDO1 and its inhibitors in clinical trials, using MicroScale Thermophoresis (MST) and nano Differential Scanning Fluorimetry (nanoDSF) techniques. Our results show that redox conditions have different effects on the dissociation constant (K_d) of distinct types of inhibitors to the enzyme and suggest how redox imbalances in the tumour microenvironment may contribute to drug resistance mechanisms against specific classes of IDO1 inhibitors, making them ineffective for clinical benefits.

Structural simplification of imipridones to speed up the knowledge on the nature of the interactions with the human ClpP, a mitochondrial protease strictly linked to DIPG

M. Miciaccia,[a] D. Armenise,[a] O. M. Baldelli,[a] G. Cavallaro,[b] F. Rizzo,[c] S. Ferorelli,[a] C.G. Fortuna,[b] P. Loguercio Polosa,[c] M.G. Perrone,[a] A. Scilimati[a]

morena.miciaccia@uniba.it

The human ClpP (*h*ClpP), a mitochondrial matrix caseinolytic protease, is responsible for the mitochondria proteostasis by degradation of misfolded and damaged proteins under the physiological regulation of the AAA+ ATPase chaperone ClpX. By consuming ATP, ClpX recognizes, unfolds, and translocates the tagged proteins into the *h*ClpP tetradecamer proteolytic cylindrical chamber to be degraded. High *h*ClpP expression levels were found in multiple tumor tissues in which may play an oncogenic role. Given that *h*ClpP inhibition by small molecule inhibitors has shown therapeutic effects in several tumour types, the chemo-activation of mitochondrial *h*ClpP can also exhibits promising anticancer properties[1]. The most successful ClpP activators belong to the class of imipridones and ONC201, also named dordaviprone, is the first-in-class of the series (Figure 1). Currently ONC201 is worldwide evaluated in a Phase 3 study in H3K27-altered glioma, including Diffuse Intrinsic Pontine Glioma (DIPG)[2]. Through *a rational drug design approach*, the tetrahydropyridopyrimidinone (THPPD) was identified as a new scaffold for *h*ClpP potent activators development (e.g. TR57). Structure optimization led to a novel series of piperazine derivatives as putative *h*ClpP activators. A structure-activity relationship study aimed at deeply knowing the nature of the interactions with the *h*ClpP to identify a better *h*ClpP activator will be presented.

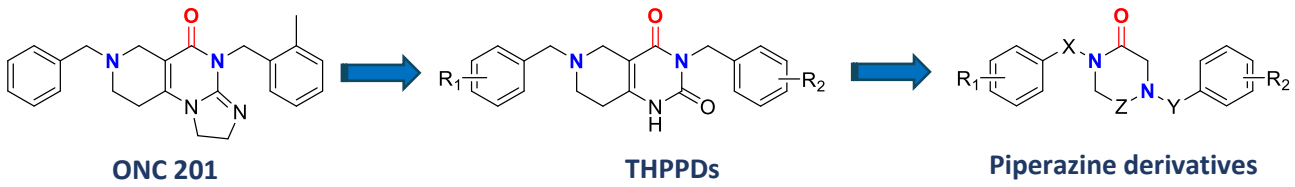

Figure 1: From ONC201 to novel piperazine derivatives as *h*ClpP activators.

Antibiotic Resistance is a global clinical issue caused by the widespread and incorrect use of antibiotics.[1] In this perspective, antimicrobial peptides (AMPs) are an emerging class of chemotypes that could represent new agents against resistant bacterial infections with a broad spectrum of activity. Unfortunately, AMPs have several pharmacokinetics limitations. To address these issues, several chemical modifications have been investigated. Among them, the reduction of the AMPs size and the conjugation of lipid moieties are emerging as promising strategies to improve antimicrobial activity and metabolic stability, minimizing the host cells toxicity[2]. Herein, a library of short lipopeptides was de novo designed and synthesized. These are endowed with a common peptide core consisting of Arg-Pro-Arg, wherein the Arg residues interact with the negatively charged bacterial counterpart, while the Pro, a well-known structuring amino acid, reduces the freedom degree of a spacer or a cationic amino acid bearing the fatty acid. The so-obtained lipopeptidomimetics were preliminary tested in vitro and a structure-guided design was employed to improve their activity and reduce their toxicity. Among all the synthesized tested lipo-peptidomimetics we identified some promising results, which displayed MIC values in the low-μM range against gram (-) and gram (+) bacteria and low-to-moderate toxicity versus host cells, favourable stability in human serum and a considerable ability to inhibit and destroy a biofilm of Staphylococcus aureus. Finally, this candidate is now under investigation for its potential capability to serve as the potential adjuvant in combination with conventional antibiotics.

Isocyanide: A Paradigm Shift in Medicinal Chemistry

F. Brunelli,[a] S. Aprile,[a] G. C. Tron[a]

[a]*Dipartimento di Scienze del Farmaco, Università del Piemonte Orientale, Largo Donegani 2, 28100 Novara, Italy*
francesca.brunelli@uniupo.it

The **isocyanide** stands out as an intriguing entity, owing to its **chameleonic reactivity** that has made it a widely utilized reactant in organic synthesis, especially in multicomponent reactions (MCRs). Despite its pivotal role in the biological activity of natural compounds, isocyanides have historically been overlooked by medicinal chemists due to misconceptions about their toxicity, reactivity, and metabolic instability. Additionally, the structural complexity and limited availability of natural isocyanides have contributed to this neglect. However, our recent investigations have revealed that, under specific molecular contexts, the isocyanide group can **resist human metabolism** and show promise as a pharmacophoric group in medicinal chemistry.[1] Notably, its unique attributes, such as its ability to act as a hydrogen bond acceptor with a high dipole moment, to serve as a π hole acceptor, and to function as a metal coordinating agent, coupled with its chemical inertness to major nucleophiles present in the organism at room temperature, render it an **aggressive pharmacophore**.

Therefore, our aim is to systematically utilize the isocyanide as a pharmacophoric group, integrating it into chemically straightforward and expeditiously synthesized structures, with the goal of deploy them in medicinal chemistry screening campaigns, particularly within the domains of **antimicrobial and oncological research**.

As a demonstration of the potential of the isocyanide group in drug discovery, we have developed a **one-pot synthetic strategy** to generate molecules containing an isocyanide warhead group using either a Ugi or Passerini MCR. Many of these isocyanides demonstrated **potent antibacterial activity** against the **multidrug-resistant strain *Staphylococcus aureus* MU50**, which is resistant to vancomycin, the antibiotic of last resort. These compounds do not exhibit **any cytotoxicity on human cell lines** at concentrations up to 100 times their MICs values and **preliminary *in vivo* studies** on a *C. elegans* model have confirmed their efficacy and safety.

In the oncological field, we are employing isocyanides to hit various targets important for tumors. For instance, by harnessing their significant ability to coordinate heme iron, we have developed isocyanides capable of **inhibiting cytochrome CYP4A11**, implicated in different types of **cancer**. Some of these compounds, besides demonstrating potent inhibitory capacity (IC_{50} = 57 nM), have also shown excellent selectivity towards other cytochrome isoforms.

Therefore, the use of the neglected isocyanide as a pharmacophoric group could potentially determine a **paradigm shift in the treatment of multidrug-resistant infections** and it can provide **new treatment opportunities for oncological pathologies.**

NR2F2 and NR2F6 as targets for drug repurposing: an insight by means of computational analysis

G. Culletta,[a] M. Tutone,[a] E. Garattini,[b] A.M. Almerico[a]

[a]*Dipartimento di Scienze e Tecnologie Biologiche Chimiche e Farmaceutiche (STEBICEF) Università di Palermo, Via Archirafi 32, 90123 Palermo (I)*

e-mail annamaria.almerico@unipa.it

Within the framework of the PNRR project "HEAL ITALIA", we focussed our interest on a small group of orphan nuclear receptors (ORFs), a small family of ligand-dependent transcriptional factors (15 members) controlling the expression of various target genes. In this context, we performed structural analyses aimed at identifying small organic molecules capable of interacting with the selected sub-group of ORFs. The ultimate goal of the study is to identify compounds available in public drug databases, which may be ready to be tested against target ORFs in view of rapid translational medicinal chemistry applications "from the bench to the bed".

Like all ORFS, NR2Fs constitute a sub-group of three receptors lacking endogenous ligands, i.e. NR2F1 (COUP-TFI, EAR-3), NR2F2 (COUP-TFII, ARP-1) and NR2F6 (COUP-TFIII, EAR-2). Structurally, the two most important regions of NR2Fs are the DBD (DNA binding domain) and the LBD (ligand binding domain), which act independently from each other. The overall structures of DBDs and LBDs are very similar in the three NR2F family members. In contrast, the structures of the N-terminal and the C-terminal regions of ORFs are variable. Indeed, the C-terminal region is missing in some ORFs and the knowledge on its functional significance is limited. Because of their central role in cell growth, NR2Fs are promising candidates as novel therapeutic targets in the treatment of cancer[1]. In the present study, we conducted a computational analysis on the X-ray crystal structures of the human NR2F2 ligand binding domain (PDB ID: 3CJW) and the human NR2F6 ligand binding domain (PDB ID: 8C5L). The initial aim of these analyses was to identify potential hotspot binding sites and to predict their druggability. Subsequently, we used the identified binding sites to perform a virtual screening protocol, involving pharmacophore models and docking studies, on large libraries such as Drugbank, FDA and commercial libraries for drug repurposing.

We identified a number of drug hits as possible ligands/inhibitors of the target ORFs. Currently, we are in the process of verifying the ability of these compounds to interact with and modulate the activity of NR2Fs with the use of suitable biological tests.

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal malignancies, with an average 5-year survival rate of 11%, mainly due to the lack of early diagnosis and limited response to treatments. Prostate cancer is the second most frequent cause of cancer death in men, with around 1.2 million of new cases diagnosed each year. Chemoresistance is a key impediment for treating both diseases, and drugs with innovative mechanisms of action could allow to overcome resistance to therapies. The 1,2,4-oxadiazole ring is considered a privileged scaffold in drug discovery, and it constitutes the pharmacophore moiety of several anticancer agents. Starting from an in-house library of 1,2,4-oxadiazole derivatives, we evaluated the antiproliferative activity towards two different human prostate cancer cell lines, DU-145 and LNCaP. In addition, we investigated the ability of the two most active compounds (**11** and **16**) to inhibit cell migration using wound healing assays in DU-145. Compounds **11** and **16** were also tested in two different pancreatic cancer cell lines (PANC-1 and MIA PaCa-2) and they showed low micromolar IC_{50}s. Early ADME-Tox investigation were performed to exclude drug-drug interaction, cardiotoxicity and cytotoxicity. In addition to the 1,2,4-oxadiazole ring, compounds **11** and **16** contain a 3-Br-4,5-dihydroisoxazole (BDHI)[1] nucleus, which is known to behave as a moderately reactive warhead. Thus, these compounds are expected to act as covalent inhibitors. Target(s) identification via mass spectrometry under denaturing conditions is currently ongoing, using PDAC cell lysates exposed to compound **16** under conditions mirroring those inducing antiproliferative effects. Overall, we identified novel agents for the treatment of pancreatic and prostate cancers, and their novel mode of action is currently being elucidated.

larissa.dellavedova@unimi.it

The interest for 5-(3',4'-dihydroxyphenyl)-γ-valerolactone (VL) has increased as it is one of the major metabolites derived from the catabolism of flavonoids by gut microbiota and is a well-known compound with health-promoting effects. However, the pre-ADMET properties have not yet been clarified due to the lack of a commercially available standard. Therefore, the purpose of this study is to understand and demonstrate the mechanism of absorption, efflux, metabolic stability, cytotoxicity, and druglike properties of synthetized VL, to fully comprehend the correlation between PACs and VL biological activities[1].

To evaluate the absorption, Caco2 and Wt-MDCK monolayer models were chosen and a UPLC-QqQ platform was used to quantify VL and to calculate its apparent permeability and efflux ratio. VL is rapidly metabolized into its phase II metabolite, 5-(hydroxyphenyl)-γ-valerolactone sulfate (VLS), which was confirmed by LC-HRMS. Although VLS showed in both models an apparent permeability acceptable for the oral route of administration the efflux ratio values found are discrepant in the two models: in Caco2 it is >2 but lower in Wt-MDCK, indicating that VLS is a substrate of an efflux transporter more expressed in Caco2 cell line (BCRP)[2]. Phase II and I metabolism of VL was evaluated with human liver S9 and microsome fraction (HLM). VL was found to be rapidly degraded in the S9 fraction (t ½ 8.72 minutes) but degraded at a slower rate in HLM (t ½ 23.08 minutes). Most importantly, in the S9 fraction, VL forms two different phase II metabolites over time, both glucuronic adducts, on the two possible sites of the molecule; moreover, the sum of glucuronic conjugates accounts for 49% of the metabolized VL. VL has been tested for its modulation of major CYPs, demonstrating its metabolic safety.

In conclusion, VL is widely absorbed as sulfate conjugate in the intestine and reaches systemic circulation. The sulfation pathway is reversible, and reversal is presumed to be mediated by arylsulfatase[3], hence the active form VL can circulate and reach the liver, where VL can be further metabolized into its glucuronide adducts. Finally, it neither induces nor blocks major CYPs and gene receptors that can alter its expression, nor efflux systems, causing no herb-drug interaction.

daniele.esposito6@unibo.it

Among innovative targets for cancer research, non-canonical structures of nucleic acids like G-quadruplex (G4), have represented an interesting focus in Medicinal Chemistry with the design of new G4-ligands able stabilize them, leading to the blocking of the catalytic activity of key and eventually to cell death.[1] A first diimidazopyrimidine core[2] was studied as a starting point for the development of new ligands, and the use of SAR together with techniques like FRET and CD spectroscopy, were helpful to optimize the design, the activity and selectivity of the analogues affording to FG (**Figure 1**),[3] a well-studied hit compound. Previous modification paved the way to a para-functionalization of the ring, making the synthesis of new potential molecular tools possible, where the FG scaffold could be enriched by other useful moieties for a later functionalization. Throughout the synthetic process we did not focus on the formation of the desired products only: mass and NMR analyses were used to characterize the byproducts formed throughout the synthesis, with the main aim of improving the yields of the reactions, optimizing the product formation. Moreover, our work will proceed with the synthesis of these candidates and with new one as well.

Second generation pyridobenzothiazolone analogues as potent anti-flavivirus agents: beyond NS5 polymerase inhibition

T. Felicetti,[a] C.P. Gwee,[b] K.W.K. Chan,[b] V. Cecchetti,[a] S. Vasudevan,[b] G. Manfroni.[a]

[a]*Dipartimento di Scienze Farmaceutiche, Università degli Studi di Perugia, Via del Liceo, 1 -06123, Perugia, Italy*

tommaso.felicetti@unipg.it

The mosquito-borne viruses belonging to the Flavivirus genus, such as Dengue (DENV), Zika (ZIKV), and West Nile (WNV) viruses, are responsible for a high number of infections in humans. These infections can range from mild flu-like symptoms to severe conditions like hemorrhagic fevers, hepatitis, and neuropathies.[1] Unfortunately, there are currently no effective and specific treatments available for flavivirus diseases and new anti-flavivirus drugs are urgently needed.[1]

For years, we have been researching pyridobenzothiazolone (PBTZ) analogues as anti-flavivirus agents targeting the NS5 RNA polymerase.[2] Recently, we also developed a sustainable three-component reaction for synthesizing the PBTZ scaffold, which allowed us to efficiently create a wide range of PBTZ analogues[3]. Building on our previous findings, this study reports the design, synthesis, and biological evaluation of a new series of PBTZ analogues. Although these new compounds lost their ability to inhibit the NS5 polymerase, they still showed potent anti-flavivirus activity. This lack of viral RNA polymerase inhibition is likely due to the absence of the carboxylic function at the C-4 portion of the molecule. Despite this, the new compounds still exhibited valuable anti-flavivirus activity in cell-based assays, with EC_{50} values against DENV-2 in the low µM range, albeit with sub-optimal selectivity indexes (SIs). Further medicinal chemistry efforts were undertaken to replace the liable ester functionality present at the C-4 position and explore the chemical space around the PBTZ core. These efforts led to the identification of a new set of C-2 modified PBTZ amide analogues with nanomolar EC_{50} values and SIs greater than 1000. Additional studies have provided insights into the new mechanism of action of this series of PBTZ derivatives that lack the carboxylic function. These studies indicated that the derivatives acted during the viral entry phase, highlighting the difference between them and PBTZ analogues from the first series. Additionally, investigations have shown that these compounds have a broad-spectrum antiviral activity against various RNA viruses. Furthermore, PBTZ derivatives demonstrated potent anti-DENV activity in an antibody-dependent enhancement (ADE) infection model. In summary, our findings highlight the potential of PBTZ derivatives as a promising class of anti-flavivirus agents, warranting further investigation and development.

Expanding the Toolbox for the Synthesis of Protein Degraders: Spotlight on BRD4-Targeting Hydrophobic-Tags

L. Gioiello,[a] G. Goutsiou,[a] FC. Balestrero,[a] A. Grolla,[a] R. M. C. di Martino,[a] F. Condorelli,[a] T. Pirali[a]

[a]*Department of Pharmaceutical Sciences, Università degli Studi del Piemonte Orientale, Largo Donegani 2, 28100 Novara, Italy*
laura.gioiello@uniupo.it

To address the challenge posed by undruggable proteins, researchers have developed various approaches based on the use of small molecules to induce targeted protein degradation, including the growing success of Proteolysis Targeting Chimeras (PROTACs)[1]. Another promising technology is the Hydrophobic tag (HyTag)-based protein degradation, wherein ligands containing highly hydrophobic groups bind to the protein of interest (POI), mimicking a damaged or misfolded protein state. This represents the stimulus that eventually triggers the degradation of the POI through the Ubiquitin Proteasome System or the Lysosomal Autophagy Pathway[2]. In detail, HyTags consist of a ligand for the target protein, a linker, and a hydrophobic moiety such as adamantane, fluorene, and norbornene[3-5]. Compared to PROTACs, HyTags are not subject to the so-called "hook effect" and, due to their simpler chemical structure, they are endowed with a lower molecular weight and improved drug-like properties. Despite these advantages, synthesizing new HyTags is still a considerable challenge. The linker needs to be asymmetrically diversified, which leads to a long multistep synthesis. In our recent work, we conceived a multicomponent platform based on Ugi and Passerini reactions to synthesize PROTAC degraders in a single step[6]. To further study the scope of this methodology, we applied the platform to the *one-pot* synthesis of novel BRD4-targeting HyTags. In a short period, we successfully synthesized a library of HyTag-based degraders, among which a compound stands out for its effective degradation of BRD4 in MDA-B-231 cells. This finding further corroborates the potential of Hy-tags as a new approach for targeted protein degradation and points out our multicomponent platform as an efficient and versatile tool for the synthesis of new protein degraders, regardless of the technology to which they belong.

Casein Kinase 1δ is a serine/threonine kinase involved in several biological processes, including mitotic checkpoint signaling, DNA repair, circadian rhythm, Wnt signaling, endocytosis and neurodegenerative disease progression.[1] Thus, the importance in finding new inhibitors towards this enzyme. The base of the project comes from an in-house screening of some pyrazine-derivatives that showed interesting activity towards CK1δ, in particular compound **1** that displayed an IC_{50} of 1.86 μM and represented the starting point for the structure optimization. In this work we explored the chemical space around pyrazine scaffold by introducing different substituents, considering aromatic groups, alkyl chains and both linear and cyclic amines (**Figure 1**). The obtained results allow to define a structure activity relationship and, supported by both docking studies and X-ray structure analysis of molecules-target co-crystals, a strong structural optimization has been carried out, leading to active compounds in the nanomolar range. Most promising compounds have been preliminary assayed for their neuroprotective effect on a neuronal cell model, giving encouraging results.

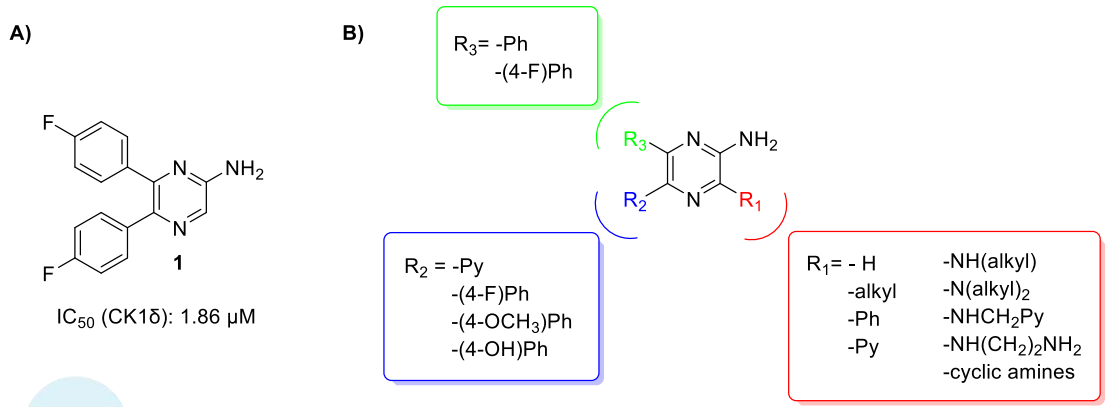

Figure 1: Panel A: Structure of compound **1**, starting point of this work, and its inhibitory activity towards the enzyme. Panel B: schematic representation of the investigation on the pyrazine scaffold.

giovanniadriano.bassan@phd.units.it

Casein Kinase (CK) 1δ is a protein that belongs to the class of serine-threonine kinases. A dysregulation in the activity of CK1δ can bring to hyperphosphorylation of substrates potentially related to the development and progress of pathological conditions including cancer and neurodegenerative diseases.[1] Among pharmacological tools useful to investigate the potential therapeutic role of CK1δ inhibition, covalent inhibitors, which could have some advantages respect to reversible inhibitors, are still missing. To bridge the gap, a series of covalent CK1δ inhibitors were designed, starting from the already known inhibitor reported in **Figure 1a**,[2] with the aim to target the catalytic Lys38 residue (**Figure 1b**).

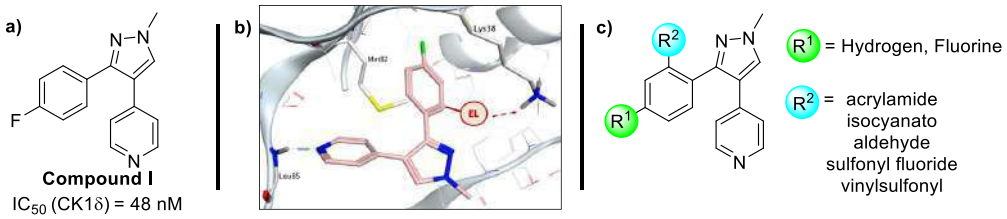

Figure 1: (**a**) Known reversible inhibitor used for the synthesis of CK1δ covalent inhibitors; (**b**) Representation of the hypothetical covalent bond formation in CK1δ; (**c**) Designed CK1δ covalent inhibitors.

Different electrophiles, chosen among the most common used to covalently bond a lysine residue, were introduced at the 2 position of the phenyl ring of compound I (**Figure 1c**).[3] Obtained results allow to point out a strict steric control at the 2 position, with most of the common electrophiles giving clashes in the CK1δ binding cleft. This has been confirmed both from enzyme activity assays and from computational studies. On the most promising compounds further characterization have been performed to prove the covalent nature of the binding between the molecule and the target enzyme.

francesca.gado@unimi.it

The circular economy is a model of production and consumption, which involves sharing, leasing, reusing, repairing, refurbishing and recycling existing materials as long as possible aiming to extend the life cycle of products. In this case our goal is the valorization, from the perspective of circular economy, of distillation subproducts, to produce nutraceuticals for the consumer care. This project is conducted in collaboration with Bonollo Distillery which gave us raw material, more specifically white grape skin (WGS) as by product of grappa process. Firstly, WGS was pulverized in liquid nitrogen and the resulting matrix was extracted setting up different methods either with water and with a hydro-alcoholic solution [1]. The hydro-alcoholic extract (HAE) was further treated with a resin (Sepabeads SP207) in order to enrich its polyphenol content. The polyphenolic profile have been characterized for both the extracts with hyphenated techniques. A qualitative analysis with LC-HRMS identified 51 compounds in HAE and a total of 39 compounds in the aqueous extract (AE). A subsequent quantitative analysis and the determination of the total polyphenol content by HPLC-PDA confirmed a richer profile in HAE compared to AE. Also spectroscopic analysis have been performed to furtherly characterized the two extracts. Moreover, HAE and AE have been tested on two different cell lines with gene reporter for the transcriptional factors Nrf2 e NfkB in order to evaluate their anti-oxidant and anti-inflammatory activity, respectively. Interestingly results showed that AE, despite its less abundant polyphenolic composition, present a stronger anti-inflammatory effect (from 1 μg/ml) in respect to HAE, totally independent from the NRF2 pathway since AE resulted unable to modulate the NRF2 activity. The scale up was made from the AE since it presents an easier and greener method of extraction with a strong anti-inflammatory activity. This industrial extract is called VITUVA® and was subjected again to all the analysis and tests of the parent extract AE in order to evaluate if AE properties have been mantained after the scale up process. Further studies will focus on the polyphenolic composition of HAE and AE in order to identify the compounds responsible of AE activity.

Concluding, we demonstrated that WGS may be effectively considered as a valuable source of polyphenols to be use as nutraceuticals to prevent / treat various inflammatory conditions highlighting the importance of the circular economy and the valorization of natural by products.

We report here the first dual inhibitors of brain carbonic anhydrases (CAs) and monoamine oxidase-B (MAO-B) for the management of Alzheimer's disease.[1] Classical CA inhibitors (CAIs) such as methazolamide prevent amyloid-β-peptide (Aβ)-induced overproduction of reactive oxygen species (ROS) and mitochondrial dysfunction.[2] MAO-B is also implicated in ROS production, cholinergic system disruption, and amyloid plaque formation.[3] In this work, we combined a reversible MAO-B inhibitor of the coumarin and chromone type with benzenesulfonamide fragments as highly effective CAIs. A hit-to-lead optimization led to a significant set of derivatives showing potent low nanomolar inhibition of the target brain CAs (KIs in the range of 0.1-90.0 nM) and MAO-B (IC50 in the range of 6.7-32.6 nM). Computational studies were conducted to elucidate the structure–activity relationship and predict ADMET properties. The most effective multitarget compounds totally prevented Aβ-related toxicity, reverted ROS formation, and restored the mitochondrial functionality in an SH-SY5Y cell model surpassing the efficacy of single-target drugs.

federica.borghi@unimore.it

Prostate cancer (PC) is the second common tumor diagnosed in men. Although current treatments are effective at the early stage of the disease, they lack efficacy in advanced stage and metastatic castrate-resistant prostate cancer (CRPC). HDAC6 and Hsp90 play a significant role in cellular processes and are involved in tumor genesis, metastasis and drug resistance.[1-2] Therefore, the possibility to simultaneous inhibit HDAC6 and Hsp90 would represent a promising strategy to treat CRPC. Recently, we identified potent pyrrolo-pyrimidine/purine HDAC inhibitors with excellent antiproliferative activity and anti-migration properties on PC.[3-4]

The 2-amino-pyrrolopyrimidine scaffold is also present in potent Hsp90 inhibitors. Thus, in the search of Hsp90/HDAC6 dual inhibitors we designed two series of 2-amino-pyrrolopyrimidine and purine derivatives carrying an hydroxamate or 3-hydroxyisoxazole as Zinc Binding Group required to coordinate the catalytic zinc ion present in the small hydrophobic pocket of HDAC6, and a benzyl linker of variable length with different decorations (**Figure 1**).

Two efficient synthetic routes were identified, allowing the obtainment of the desired products. The compounds were tested *in vitro* to assess their ability to inhibit recombinant HDAC6 and Hsp90. The results of the *in silico* design, chemical synthesis, and biological evaluation of the two series of compounds will be presented.

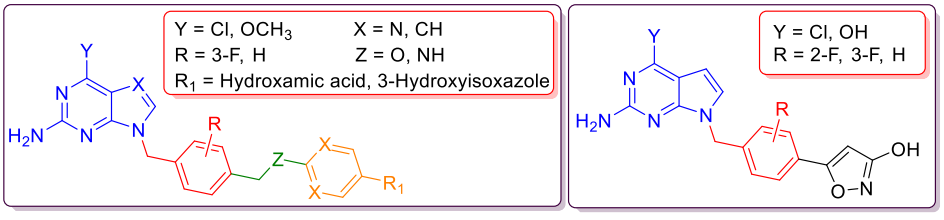

Figure 1: General structures of the dual HDAC6/Hsp90 inhibitors.

leonardo.bernal@unimore.it

Prostate cancer (PC) is often associated with poor outcomes in advanced stages, primarily due to the emergence of drug resistance which limits current therapies efficacy, emphasizing the need for novel treatments.[1] Drug repurposing (DR) is a viable strategy to leveraging existing drugs with known safety profiles for new applications and bypassing traditional issues of drug development (*i.e.*, timelines, costs and failures).[2] Notably, integrating synergic techniques like chemoinformatics and machine learning (ML) offers advantages in DR processes.[3] To identify potential DR candidates, we performed in depth similarity screenings on DrugBank, identifying 138 ligands significantly similar to compounds with potent antiproliferative activity of PC cell lines. Interestingly, some of the identified ligands resulted to be previously tested against PC cells with favourable outcomes, but had never been considered for therapeutic repositioning.[4] More importantly, 90 ligands have not been evaluated against PC cells, thus representing new repurposing possibilities. These candidates have been tested on *in-house* developed ML classifiers to predict their antiproliferative activity of PC-3 cell lines.[5] The performed analyses allowed the selection of 11 drug candidates, that were tested *in vitro* on PC cells with different aggressiveness. Remarkably, several of the selected candidates showed marked antiproliferative activity, and represent valuable candidates for further experimental testing.

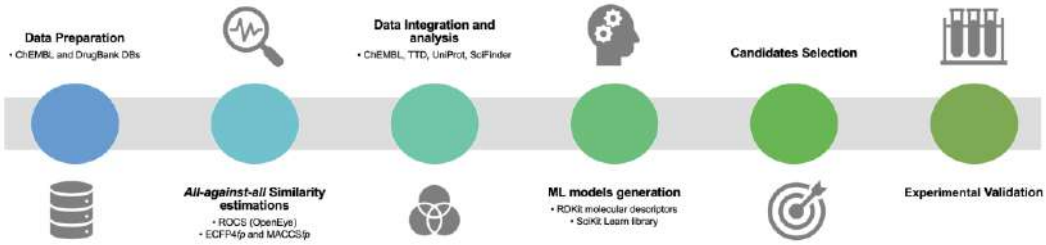

Figure 1: Workflow of the PC drug repurposing process.

Deciphering HSP90 Interaction Dynamics: An AI-Guided Approach Towards Targeted Prostate Cancer Therapies

A. Laus,[a] L. Pinzi[a], G. Rastelli [a*]

[a]*Department of Life Sciences, University of Modena and Reggio Emilia, Via G. Campi 103, 41125, Modena*
antolaus@unimore.it

The quest for effective and targeted prostate cancer therapies continues to pose significant challenges in the oncological research community. The chaperone protein Heat Shock Protein 90 (HSP90) has been identified as a critical facilitator of cancer cell survival and proliferation, making it a promising therapeutic target in prostate cancer.[1] This study introduces a novel methodology for identifying potent HSP90 inhibitors, utilizing precision in thermodynamic and kinetic calculations to elucidate the complex binding/unbinding dynamics of protein-ligand interactions. This study exploits AI's potential to drive enhanced dynamic sampling techniques,[2] using multidimensional collective variables through artificial neural networks optimized with supplementary AI systems.[3,4] This innovative method enables a thorough investigation of protein-ligand complex dynamics, accentuating critical elements like solvation dynamics, and the conformational changes of ligands, amino acids, and protein segments. Significantly, the research has achieved accurate predictions of experimentally evaluated residence times and binding free energies, alongside exploring binding conformations and providing insights into the mechanisms and modes of binding. The primary goal is to achieve a better understanding of the key molecular events occurring upon ligand binding/unbinding processes in HSP90, as a way to design inhibitors characterized by higher residence times, potency, and specificity.[5]

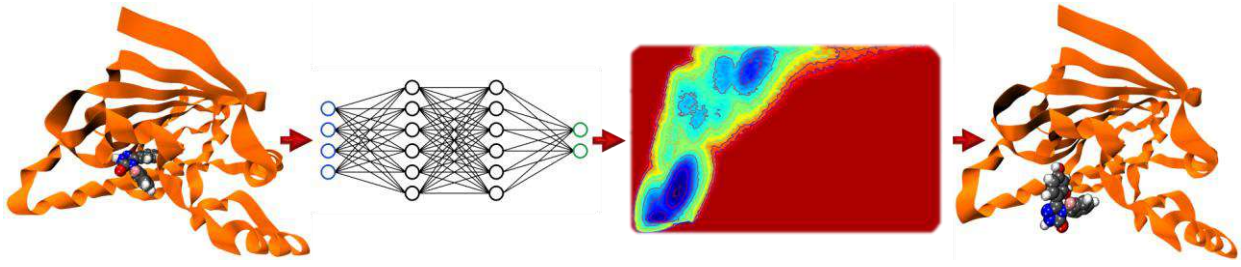

Figure 1: Summary representation of the kinetic and thermodynamic exploration process with visualisation of the binding/unbinding states of interest.

giuliana.costanzo@phd.unict.it

Tau is an intrinsically disordered protein mainly expressed in neuronal cells and has a crucial role in a group of neurodegenerative disorders, including Alzheimer's disease (AD). Targeting nuclear Tau or its cofactors might prevent nuclear accumulation and subsequent chromatin remodeling, which could lead to neuronal toxicity. TRIM28 is the only deeply investigated nuclear factor interacting with Tau, mediating its nuclear translocation. Moreover, the TRIM28 complex interacts with several enzyme families, such as histone deacetylases, and specific drugs can target this interaction. Specifically, Tau interacts with TRIM28, displacing HDAC1 from the complex, and consequently, HDAC1's nuclear function on chromatin remodeling is impaired.[1] Our research aims to reveal the nuclear Tau molecular mechanisms mediating gene expression alteration during AD disease's onset and progression. To address this goal, the design and functionalization of small molecules as modulators of the pathological Tau-dependent chromatin remodeling mechanisms are ongoing. A potent activator of HDAC1-mediated deacetylation, Exifone, with neuroprotective activity, was recently identified.[2] So, the work initially focused on identifying the allosteric binding site of Exifone in HDAC1 (**Figure 1**).

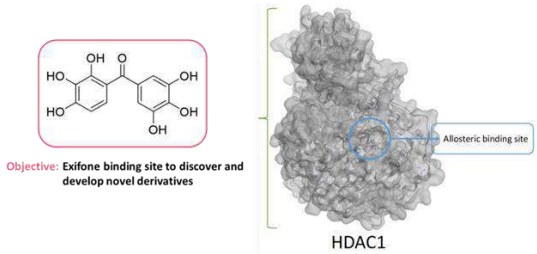

Figure 1: Identification of the allosteric binding site of Exifone in HDAC1.

The protein was studied using molecular dynamics (MD) simulations and docking calculations, and the allosteric binding site was identified. *In-silico* selection of candidate molecules and designed derivatives was performed. The novel-identified molecules will be screened to confirm their HDAC1 activation activity and, more generally, their neuroprotection activity.

Selective targeting of the bulge region in the (3+1) hybrid G-quadruplex of the PARP1 promoter through a Structure-Based Virtual Screening

A. Curcio,[a] R. Rocca,[a,b] A. Artese,[a,b] S. Alcaro[a,b]

antonio.curcio@unicz.it

Poly(ADP-ribose) polymerase-1 (PARP1) has a key role in catalysing the polymerization of ADP-ribose units, connecting PAR polymers to itself or other proteins. Its structure comprises three domains that collectively manage PARP1's response to DNA damage. DNA lesions stemming from spontaneous single-strand breaks (SSBs) and base modifications can lead to alterations in base pairing and subsequent casual mutations associated with cancer. PARP1 binds to SSBs, starting the addition of PAR onto itself and the PARylation of other proteins, promoting mechanisms such as single-strand break repair (SSBR)[1]. Thus, in homologous recombination deficient (HRD) cancer cells, inhibiting PARP1 activity causes the increase of unrepaired single-strand DNA breaks that converge to double-stranded DNA breaks, inducing selective cell death. Consequently, several PARP1 inhibitors have been developed, showing promising outcomes in cancer treatment. However, acquired resistance to these inhibitors is a significant limitation, and alternative strategies need to be explored. A non-canonical G-quadruplex (G4) with a unique adenine bulge has been found in the promoter region of the PARP1 gene. This presents a highly selective target to disrupt PARP1 expression in cancer cells[2]. Therefore, through virtual screening of various databases, several compounds with a higher theoretical binding affinity to the non-canonical G4 compared to the G-quadruplex ligand RHPS4 have been identified. Further *in silico* analysis aimed to select compounds capable of binding to the G4 bulge region with high selectivity. Experimental studies are currently underway to validate their ability to bind to this form of G4 with this novel binding mode. If successful, these compounds could offer a promising and selective avenue for disrupting PARP1 expression in cancer cells.

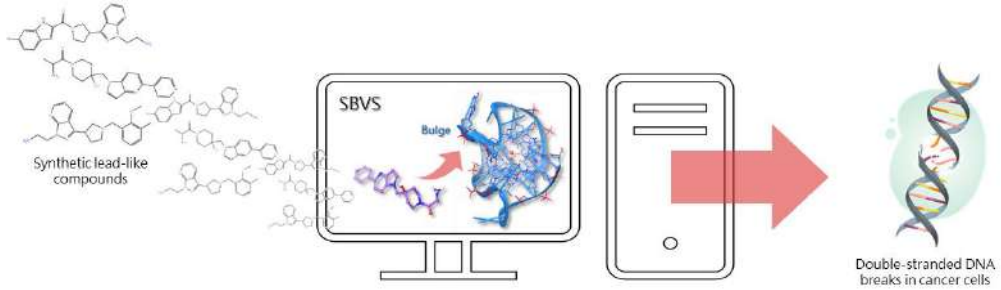

Figure 1: *In silico* identification of bulge selective binders towards non-canonical G4 in the PARP1 promoter.

giorgia.brosio@iit.it

Rational drug design is facilitated by computational tools that enable precise predictions of interactions between small molecules and biological targets, including proteins, DNA, and RNA. In this context, a particular challenge is the modelling of metal ions, among which magnesium ions are of particular interest due to their essential role in numerous biological processes such as RNA folding and enzymatic catalysis. Molecular mechanics (MM) force fields often fall short in correctly representing the interactions of magnesium ions with their ligands, while quantum mechanics (QM and QM/MM) methods remain computationally demanding[1,2]. In recent years, machine learning demonstrated to be a powerful approach to constructing various forms of atomistic potentials. However, the extension of this approach to include metal ions is challenging, due to the highly diverse nature of the ligands and coordination geometries. To address this gap, we assembled a comprehensive dataset of magnesium organometallic complexes collected from the Protein Data Bank and the Cambridge Structural Database. Quantum chemical calculations at the wb97x/6-31g* DFT level of theory allowed to complement publicly available datasets of molecules built from second row elements. This data is used to run a first transfer learning experiment on a new network, dubbed OBIWAN[3], that we recently developed.

simone.manzi@unimi.it

To date, analytical approaches to measure hyaluronic acid (HA) are based on the following steps: 1) protein removal and purification of HA; 2) enzymatic digestion of polysaccharides to the dimeric unit (*2-mer*, composed of D-glucuronic acid and N-acetylglucosamine); and 3) derivatization of the 2-*mer* unit and analysis of the adducts by LC-ESI-MS/MS. Most of the proposed methods do not include an internal standard (IS) to normalize HA extraction yield, hyaluronidase enzymatic efficiency and analyte response to MS analyzer. The innovation of the proposed method is the use of two isotope-labelled HA derivatives produced by recombinant technologies to meet these limitations. The method is based on direct enzymatic conversion of HA to the 4-*mer* oligomer by recombinant bacterial hyaluronidase from *Streptomyces koganeiensis* and its direct analysis without any derivatization and purification step by LC-ESI/MS-MS using a HILIC column. The yield of HA isolation and its enzymatic conversion to the 4-*mer* analyte was normalized by adding 100% ^{13}C-labeled HA to the sample before enzymatic conversion. Normalization of the MS response of the analyte was achieved by adding to the samples before mass analysis, a ^{13}C-4-*mer* isotope analogue obtained by enzymatic conversion of ^{13}C-HA enriched with 50% ^{13}C, followed by purification of the oligomers. HA enriched with 100% and 50% ^{13}C was bio-synthetically prepared using *Streptococcus equi* subsp. *equi* and D-glucose (U-$^{13}C_6$, 99%) as a carbon source in an animal-free minimal growth medium. Before precipitation, the HA produced was purified by active carbon filtration and ultrafiltration. Quantitative analysis of 4-*mer* was then carried out by multiple reaction monitoring (MRM) profiling, using *m/z* 757→554, *m/z* 785→574 and *m/z* 771→568 transitions for *4-mer* and its derivatives labelled 100% and 50% with ^{13}C, respectively. As expected, the use of the IS, normalizing the differences in extraction yield, enzyme efficiency and MS response of the analytes, greatly improved the precision and accuracy of the method. The R^2 value of the equation improved from 0.9312 to 0.9914 when constructed in the absence and presence of the double IS, respectively. Once validated, the method was then applied to measure HA in biological matrices and particularly in bovine vitreous humour and synovial fluid of healthy donors. In conclusion, the developed analytical method enabled the precise and accurate determination of HA in a complex biological matrix through the use of a double isotopic standard that can normalize the variation in enzyme efficiency and MS response of the analyte and can be easily adapted for HA determination in other biological and even pharmaceutical matrices.

Translational control is the selective and regulated translation of specific mRNAs from the pool of the transcribed mRNAs. According to several studies, it is the major regulator of gene expression. eIF6 is a translation initiation factor that acts downstream the insulin pathway. Seminal work from Biffo's group has shown that mice heterozygous for eIF6 fail to upregulate protein synthesis in postprandial conditions, and simultaneously show a reduction in the accumulation of white fat. Subsequent studies have shown that translation factors amplify lipid accumulation by acting at the translational level. Increased lipid accumulation in the liver is known as non-alcoholic fatty liver disease (NAFLD), a prevalent condition in Western countries. Notably, fatty liver is the fastest growing cause of liver failure and hepatocellular carcinoma (HCC), the second leading cause of cancer-related death worldwide. Recently, it was observed that genetic eIF6 inhibition reduces lipid metabolism and the progression of NAFLD to HCC.

We hypothesize that eIF6 inhibition is an effective strategy for impairing the pathological evolution from a fatty liver (NAFLD) to non-alcoholic steatohepatitis (NASH) and then HCC, and the progression of HCC. To challenge this hypothesis, we aim to generate a set of small molecules able to selectively degrade eIF6, based on the emerging proteolysis targeting chimera (PROTAC) technology. Docking, molecular dynamics simulations and ligand binding free energy (by MM-GBSA approach) have been accomplished on compounds displaying promising in vitro activity on eIF6. The top scoring candidates are currently under development. The design strategy, chemical synthesis, and pharmacological investigation of this novel class of targeted protein degraders will be presented and discussed.

Alzheimer disease (AD) represents a significant challenge in contemporary healthcare, and the urgency of finding effective treatments is underlined by the progressive increase in life expectancies and the resulting higher incidence of neurodegenerative diseases in aging population. Beyond the urgency of discovering a treatment for AD, there is the need to identify valid therapeutic targets that can combine the different pathological pathway of the disease.

GSK-3β is a serine/threonine kinase, ubiquitously expressed and widely found in central nervous system, where its dysregulation has been related to tau phosphorylation, Aβ deposition, reduced synaptic plasticity and inflammation. Since the primary function of kinases is to transfer a phosphate group from ATP to the substrate, targeting the ATP binding site proved to be a promising strategy to interfere with the activity of these enzymes. In this respect, designing drug candidates able to establish a network of hydrogen bonds with the hinge region is indeed a widely accepted strategy. The aminopyrazole can be considered a privileged scaffold, with a donor-acceptor-donor hydrogen bond pattern that could complementarily bind the hinge region of GSK-3β. Indeed, the acetamido derivative **A** (figure 1) emerged from a virtual screening as able to engage GSK-3β (IC_{50} = 39 μM).[1] Starting from this molecule, new derivatives were designed and in a first series a further amido-terminal group was introduced and different linkers were selected to connect the two functions. Moreover, the *N*-methylbenzyl terminal moiety was functionalized with *p*-H, *p*-OCH_3 and *p*-Cl. This series led to the hit compound **1c** (IC_{50} = 2.2 μM). In a second series of derivatives the maleic linker, which gave the best results, was maintained and substituents with different electronic and steric properties were introduced on the terminal benzyl ring. The compounds were tested for their GSK-3β inhibitory activity and for their ability to counteract Aβ aggregation. Moreover, due to their peculiar structure, the best compounds were also tested for their potential chelating properties towards some biometals overloaded in AD conditions.

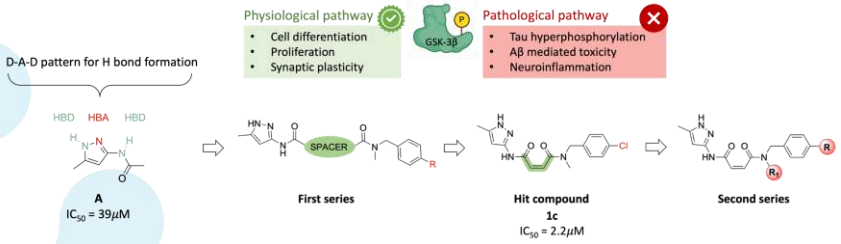

Figure 1. Design of the studied compounds

wendy.mensah2@unibo.it

Glutaminyl cyclase (QC) is a zinc-dependent enzyme that converts N-terminal glutamine or glutamic acid residues into N-terminal pyroglutamate (pGlu or pE) residues through deamidation or dehydration. This conversion is important for enhancing protein stability against aminopeptidase activity and increasing protein hydrophobicity. QC is involved in stabilizing hormones, peptides, and proteins, but it has also been linked to neurodegenerative disorders such as Huntington's and Alzheimer's diseases. In Alzheimer's disease (AD), truncated and N-terminal modified Aβ species, particularly Aβ3pE and Aβ11pE, have recently gained significant attention due to their relevant presence in neuritic plaques. Additionally, the N-terminal pyroglutamate offers protection against in vivo proteolysis, increasing their potential as seeds for aggregate formation. Finally, compared to full-length Aβ, Aβ3pE was shown to be more toxic. This finding underscores that reducing the levels of pE-Aβ by inhibiting QC could be an effective strategy for treating AD[1]. Currently, available methods for in vitro evaluating QC activity and its inhibition are quite limited. *In vitro* QC activity bioassays available on the market are based on tandem reactions, which imply the use of an auxiliary enzyme, such as pyroglutamyl peptidase, to produce a measurable chromogenic product [2]. The direct evaluation of enzyme activity without the need for auxiliary enzymes would offer advantages in medicinal chemistry campaigns by reducing false positive outputs which may arise from a downstream interference with the report enzyme. In the search for a direct bioassay, our work builds upon a previously proposed method[3], that was set for ex-vivo quantification of QC activity. It involves the use of L-glutamine 7-amido-4-methylcoumarin hydrobromide as a substrate and quantification of product formation (per unit of time) by reverse phase chromatography (RP-HPLC) using a PATfix® HPLC system coupled with a UV-vis detection. The use of a C4 column with a 300A pore size ensures the separation of the enzyme from the substrate and product. Assay conditions were optimized in terms of protocol for reaction termination, substrate concentration, reaction time, assay buffer composition, and post-reaction stability prior to analysis. Finally, the optimized method was validated by assessing the inhibitory potency of PBD150, a well-known human QC inhibitor.

Carbonic anhydrase (CA) was first discovered in 1933 by Meldrum and Roughton, who described its efficient catalysis for the reversible hydration of blood CO_2 to bicarbonate and protons.[1] This enzyme is so crucial for life that in over ninety years of studies it was found to be expressed in most if not all organisms. Eight families (α-ι) are known to date, among which the α family is the one expressed in human tissues. Many fundamental physiological processes have been correlated with the 15 human isoforms, such as electrolyte secretion, respiration, CO_2 transportation, gluconeogenesis, adipogenesis, ureagenesis, and more. Accordingly, altered activity or expression of these isoforms are correlated with numerous pathologies,[2] even if the role of some isoforms remains unclear. Several molecules behave as CA inhibitors (CAIs) by chelating the Zn^{2+} ion necessary for the catalytic activity, or as CA activators (CAAs) by increasing the catalytic rate of the enzyme. CAA are basic compounds that behave as proton shuttles, being part of a network formed of H-bonded water molecules and residues. Several X-ray structures of CA-activator complexes are available, including those of histamine (HST) and D- or *L*-histidine (HIS) with CA II.[3] Based on this information and on our group's effort in producing new piperazine scaffolds which already proved to generate some interesting selectivity,[4,5] we synthesized a series of rigid analogues of histidine (**figure 1**) as activator and then introduced a well known zinc-binding group to switch to inhibitors. The CA modulating properties and the isoform selectivity of the new compounds will be discussed in this presentation.

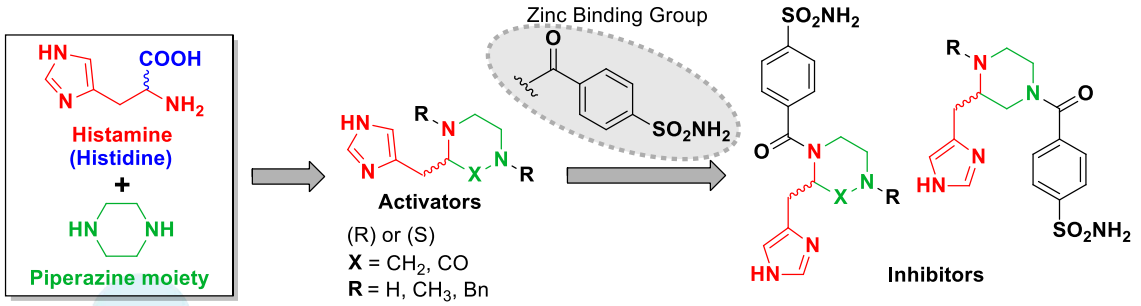

Figure 1: scheme of the work made. Merging the two structural moieties (box, left) allowed the obtaining of both CA activators and inhibitors.

It is well known that many pathways leading to cancer involve the overexpression of numerous epigenetic targets and/or depend mechanistically on their functions. Consequently, the epi-polypharmacological approach emerges as an effective tool to counteract cancer[1]. An interesting approach in this context is represented by the simultaneous inhibition of two or more targets involved in cancer pathogenesis, using hybrid molecules that possess different moieties and the ability to hit at the same time different targets. Epigenetic regulators like histone deacetylase inhibitors (HDACi) and EZH2 inhibitors have surfaced as potent instruments in cancer investigation, also in combination[2]. We based our work on Tazemetostat, a clinically approved EZH2 inhibitor, to develop new dual hybrids by incorporating HDAC enzyme inhibiting groups (EIG) such as *ortho*-aminoanilides and hydroxamic acids in its structure, and obtaining respectively the two lead compounds **MC4343** and **MC4355**. These compounds showed promising IC_{50} values in biochemical evaluation on both targets and were tested for their inhibition of proliferation in various B-cell lymphoma lines, including KARPAS422, Pfeiffer, SUDHL4, Toledo, and WSDL CL2. In particular, they showed a greater antiproliferative effect than Tazemetostat on SU-DHL-4 and Toledo, while maintaining comparable activity on other B-cell lymphoma lines. We also investigated the effect of such compounds on cell cycle using B-cell lymphoma lines and both compounds led to concentration-dependent increase in the pre-G1 phase, indicating potential apoptosis induction. Thus, we decided to merge the Tazemetostat scaffold with various both aromatic and aliphatic linkers, and then decorate them with hydroxamic acid and *ortho*-aminoanilide groups obtaining derivatives **1c-h** and **2c-f**. We also attempted to confer selectivity towards HDAC1-3 isoforms with two *o*-aminoanilides enriched with a fluorine atom in the *meta* position of the 2'-amino group and with a thiophene which, in the pharmacophoric model of HDACs inhibition, is able to confer selectivity for HDAC1/2[3], obtaining respectively **2a** and **2b**. Regarding EZH2, the new compounds showed inhibitory potency in the low nanomolar to single-digit picomolar range. Regarding HDAC isoforms, compound **2e** exhibited IC_{50} values in the low micromolar range for HDAC1-2, whereas **2c** demonstrated efficacy in specifically inhibiting HDAC6 at the nanomolar level. The most powerful compound was found to be **1e**, displaying selective inhibition against HDAC6 and 8 with IC_{50} values in the nanomolar range. Our new most potent inhibitors will be tested on various tumor lines to evaluate their antitumor potential.

Development of dual PD-L1 and epigenetic-target based inhibitors as novel potential molecules for anticancer immunotherapy

A. Raucci,[a] C. Castiello,[a] C. Zwergel,[a] I. Pacella,[b] T. Priamo,[b] S. Piconese,[b] S. Valente,[a] A. Mai[a]

Research on cancer immunotherapy is recently making many strides, and the PD-1/PD-L1 signaling pathway is increasingly highlighted as a target to be inhibited to enhance the function of immune cells in cancer[1]. Interaction between PD-1 and its ligand PD-L1 leads to immunosuppression and blockade of T-cells' functionality, playing an important role in various malignancies where it can attenuate the host immune response to tumor cells[2]. Of note, impairments in the immune cycle, which are crucial for PD-1/PD-L1 immunotherapy resistance, could be restored by epigenetic modifications[3]. In particular, there is much scientific evidence about the efficacy given by the synergistic combination of PD-L1 antibodies and epigenetic drug inhibitors4. As an immune checkpoint in combination with epigenetic therapeutic agents, PD-L1 is able to improve immune recognition and tumor growth, leading to increased response rates in preclinical and clinical studies, recently summarized in[4]. Considering our experience in polypharmacology to overcome the main limitations of the single target therapy thus aiming at superior therapeutic effects, decreased adverse reactions, and a reduction of potential mechanism(s) of drug resistance caused by robustness and redundancy of biological pathways[5], we developed a series of dual inhibitor molecules which presented both PD-1/PD-L1 and various epi-target inhibiting properties. The developed compounds showed promising inhibiting activities in biochemical assays against the targets of interest, exhibiting balanced IC_{50} values against the PD-1/PD-L1 axis inhibition as well as against the chosen epigenetic targets (i.e., HDACs or LSD1). Currently, the most promising compounds are under evaluation in in vivo tumour xenograft mouse models.

NOD1 and NOD2 are the best characterized members of the NOD-like Receptor (NLR) family of proteins, a group including more than twenty pattern recognition receptors involved in the innate immune response to cellular injury and stress.[1] Overactivation of these proteins is implied in a wide range of human inflammatory disorders, and it has been related to the onset and progression of several human cancer types.[1] NOD antagonists would therefore represent valuable pharmacological tools to gain new insight into the role of these proteins, potentially leading to novel therapeutic strategies. Based on the chemical structure of Noditinib-1 (a potent and selective NOD1 antagonist),[2] herein we report the expansion of the chemical space of NOD1 antagonism via a multicomponent synthetic approach affording a novel chemotype, namely, 2,3-diaminoindoles.[3] This led to the identification of a new *hit compound* endowed with low micromolar affinity and moderate selectivity towards NOD1 *versus* NOD2. Importantly, both Noditinib-1 and our *hit compound* were studied through protein-based NMR experiments and fluoresce titration assays which provided, for the first time, proof-of-evidence of their direct binding to NOD1. Moreover, a combination of molecular modelling studies and ligand-based NMR competition experiments led to identify NOD1 nucleotide-binding domain (NBD) as its putative binding-site for these small molecule inhibitors, thus providing unprecedented knowledge for the future structure-based design of new potent and selective NOD1 antagonists.

L-Tryptophan, an essential amino acid, is metabolized *via* the kynurenine pathway (KP) with hIDO1 as a key enzyme. In cancer management, targeting the KP with hIDO1 inhibitors shows promise.[1] Bioanalytical chemistry, particularly quantitative liquid chromatography with tandem mass spectrometry (qLC-MS/MS), is vital for understanding the KP and exploring therapeutics. Profiling kynurenines is challenging due to their diverse properties, but qLC-MS/MS offers reliable and selective analysis.[2] Plasma, serum, and urine are commonly used to measure hIDO1 activity by evaluating the kynurenine/tryptophan ratio.[3] While cell culture supernatants provide a physiological environment for *in vitro* cancer research, there's a scarcity of LC-MS methods for quantifying kynurenines in these media, necessitating further development. This abstract introduces a validated LC-MS/MS method for quantifying multiple kynurenines in cell culture media (Figure 1). The method, validated per EMA, ICH, and FDA guidelines, was applied to study selective hIDO1 inhibition effects on the kynurenine pathway in melanoma, breast cancer, and glioblastoma cell lines, as well as to determine the *in vitro* efficacy of hIDO1 inhibitors (Figure 2). The proposed LC-MS/MS method is reliable, robust, and versatile, suitable for preclinical drug research and *in vitro* assays.

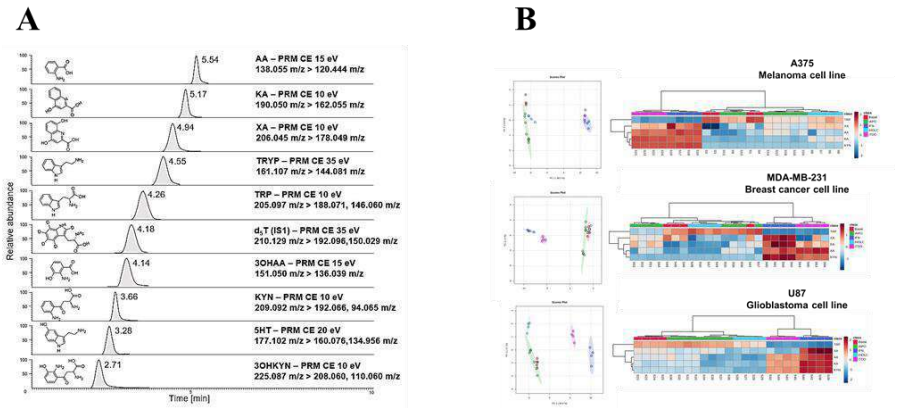

Figure 1: A - Mass chromatograms of KP catabolites. B - hIDO1 inhibition effects on the KP in cancer cell lines (A375 – melanoma, MDA-MB-231 – breast cancer, U87 – glioblastoma).

carmin.volpe@studenti.unina.it

Glioblastoma Multiforme (GBM) is the most common primary brain tumour in the European Countries and USA. Its remarkably poor prognosis, with a 5-year survival rate of 4-5%, makes it an urgent unmet medical need for pharmaceutical R&D. The standard-of-care for the treatment of GBM is Temozolomide (TMZ): an imidazotetrazine derivative that acts as an alkylating agent, after its activation at physiological pH. The principal reason for the weakness of this treatment is the emergence of resistance phenomena.[1] Accordingly, our present project aims to the design, synthesis, and biological evaluation of TMZ-conjugates to overcome these current limitations. Our design is so focused on the merging of TMZ with other compounds with activity on well-known drug resistance pathways, such as: senescence-associated secretory phenotypes, escape from immune surveillance, and deregulation of epigenetic mechanisms. To this end, the application of advanced synthetic methodologies in late-stage approaches[2] enables access to libraries of MultiTarget Chemical Entities (MTCEs) as pharmacological tools to further study resistance phenomena in brain tumours.

The agronomical and the food industries produce massive amounts of wastes, usually discarded although rich in bioactive and potentially used for nutraceutical and cosmeceutical purposes[1]. Leaves especially, one of the most abundant waste generated in this sector, are characterized by the presence of health-promoting functional components granting them antioxidant, antihypertensive, antiatherogenic, anti-inflammatory, hypoglycemic, and hypocholesterolemic properties[2].

Thus, leaves from *Olea europea* L. and *Curcubita moschata* have been selected to further evaluate the possibility to selectively extract some biologically active secondary metabolites. To this regard, an aqueous microwave assisted extraction of the olive leaves led us to obtain an oleuropein enriched extract, which was selectively isolated through solid phase adsorbtion (SPA) thanks to the use of lamellar solids. Finally, an eco-friendly, readily available, and reusable catalyst for the hydrolysis of Oleuropein in its two main components, hydroxytyrosol and elenolic acid (Fig.1). An extract enriched in the monoaldehydic dihydropyran form of elenolic acid was obtained by an acid-base work up and later characterized by GC-MS and NMR.

Different pumpkin leaf extracts of *Curcubita moschata* were tested *in vitro* for their pro-osteogenic properties and for their effects on intervertebral disc (IVD) degenerated cells. The acetone extract showed the most promising results, and after fractionation, the three most active subfraction were identified through GC-MS and NMR as 13-OH-9Z,11E,15E-octadecatrienoic acid, ferulic acid and p-coumaric acid (Fig.1).

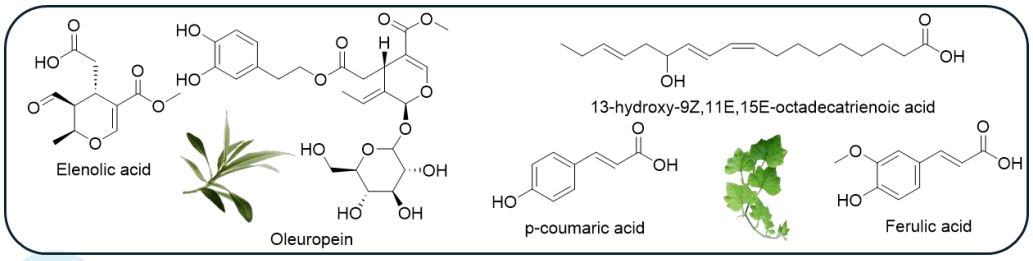

Figure 1: Main bioactive components found in the leaves of *Olea europea* L. and *Curcubita moschata*.

roberta.listro@unipv.it

Lichen secondary metabolites are well-studied medicinal compounds with diverse pharmacological properties. One of the lichen secondary metabolites is Usnic Acid (UA), a dibenzofuran characterized by the presence of a stereogenic center. Both enantiomers occur in nature, depending on the producing organism. The most abundant in nature is (*R*)-UA[1]. It has a broad spectrum of biological activity: antimicrobial, antitumor, anti-inflammatory, and antiviral. However, UA is characterized by low solubility and hepatotoxicity issues[2].

In this work, we focused on the generation of a small series of novel semisynthetic compounds of both (*R*)- and (*S*)-UA derivatives and their potential antifungal activity against topical fungal infections such as *Candida albicans*, *Candida tropicalis*, and *Trichophyton rubrum*. In detail, (*S*)-UA was extracted from *Caldonia foliacea*[1], while the (*R*)-enantiomer was purchased and successively a small series of both enantiomers was synthesized. All compounds were characterized in terms of water solubility, cytocompatibility, and antifungal activity. The (*S*)-configured derivatives resulted to be the most potent compounds, showing antifungal activity in the µM to nM range, while maintaining good cytocompatibility. The mechanism of action is under investigation.

Although the majority of the human DNA codifies for non-coding RNAs (ncRNAs), biomolecules exerting important biological functions, the field of RNA targeting for therapeutic application is still at an early stage.[1] The recent approval of RNA-targeting small molecules by regulatory agencies, such as Risdiplam® and Ataluren®, has opened the way to small molecule RNA therapeutics. Among the variety of ncRNAs, micro-RNAs, consisting of 20-25 nucleotides, mediate post-transcriptional gene regulation as they bind to messenger RNAs inducing their degradation or translation inhibition.[2] Micro-RNA-21 (miR-21) is a potential interesting pharmacological target, being an essential element for cancer cell proliferation and survival.[3] Micro-RNA-21 is overexpressed in several cancer types,[3] and decreasing its cellular levels has been reported to sensitize cancer cells to chemotherapy.[4] Several small molecules targeting miR-21 have been reported in the literature;[5] however, there is still ample space to discover new compounds capable to decrease miR-21 levels in cells.
One of the approaches to reduce miR-21 in cells consists in finding compounds that bind to its precursor (pre-miR-21) thus preventing the cleavage by the ribonuclease Dicer.[6] With this idea in mind, we performed a medium-throughput screening campaign to assess the affinity to pre-miR-21 of *circa* 600 fluorinated fragments by ^{19}F-NMR technique.[7] The primary hits were subsequently tested in a biochemical assay to measure their Kd [8] From this screening campaign, several hit compounds emerged for their promising affinity to pre-miR-21. Among them, a compound bearing a pyrazolopyrimidine scaffold showed Kd in the low micromolar range: this compound was selected for further investigation. A ligand-based approach was applied to improve the affinity to pre-miR-21. Several derivatives were synthesized, leading to a few compounds with submicromolar affinity to pre-miR-21 and capable of inhibiting the Dicer-mediated processing.

Development of an Analytical Method for assessing Pharmaceutical Contaminants of Emerging Concern in agricultural water

R. Spagnuolo,[a] M. Naldi,[a] W. Appiagyei Mensah,[a] M. Bartolini[a]

[a]*Department of Pharmacy and Biotechnology, via Belmeloro 6, Bologna*
rosaria.spagnuolo2@unibo.it

Water reuse is becoming increasingly important due to limitations in freshwater availability. Treated wastewater can be a reliable water supply, independent of seasonal droughts and weather changes. However, health and environmental protection must be considered when reusing wastewater. The EU Regulation 2020/741, effective June 2023, sets minimum monitoring and quality requirements for safe wastewater reuse in agricultural irrigation as part of the Circular Economy Action Plan[1]. Contaminants of emerging concern (CECs) are a pressing issue, encompassing various chemical compounds with potential ecological and health impacts. These CECs, including pharmaceuticals and personal care products, are not yet regulated under current environmental laws. Their global presence in aquatic systems is a cause for concern, exacerbated by the low efficiency of conventional wastewater treatment plants in removing these pollutants.[2] Proper identification and quantitation and the development of efficient removal procedures are crucial to reduce the threat to humans and ecosystems. In a collaborative project with the Department of Agriculture and Food Science (DISTAL) of the University of Bologna, we established an analytical protocol to monitor the presence of ten pharmaceutical CECs (Ph-CECs) which were selected based on previously published reports and literature. These selected Ph-CECs have varying physicochemical properties, with AlogP values ranging from -1.03 to 4.36 and pKa from 0.07 to 10.1. Although the concentration of Ph-CECs is anticipated to be low, ranging from ng/L to µg/L, their allowed limits are not yet regulated. Therefore, we optimized an isolation method using hyper-crosslinked hydroxylated polystyrene-divinylbenzene copolymer-based SPE cartridges to enhance analysis sensitivity. The optimized protocol allowed complete retention of all selected analytes despite their differences in hydrophilicity and ionization state. Elution with 100% organic solvent followed by solvent evaporation further contributed to the implementation of the method's sensitivity. Finally, for analyte quantitation, a high-performance liquid chromatography-electrospray ionization/mass spectrometry (HPLC-ESI/MS) method was developed and validated. This method will be applied to monitor the presence of the selected Ph-CECs in treated wastewater used for agricultural irrigation.

Acknowledgments: We acknowledge EU - NextGenerationEU with funds made available by the National Recovery and Resilience Plan (NRRP) Mission 4, Component 1, Investment 4.1 (M.D. 118/2023).

Adenosine A_{2A} receptor (AR) antagonists and antioxidant derivatives showed neuroprotective activity in animal models of cerebral ischemia.[1,2] Thus, to obtain new neuroprotective agents endowed with potentiated effect, a set of 8-amino-1,2,4-triazolo[4,3-a]pyrazine-3-ones were designed as hybrid compounds of our previously reported human (h)A_{2A} AR antagonist **A**[3] (K_i= 13 nM) and antioxidants, such as edaravone (EDA), a drug clinically used after ischemic stroke, and lipoic acid (LA). On the whole, the new derivatives proved to be potent hA_{2A} AR antagonists (K_i= 2.4-91 nM), and selective versus A_1, A_{2B} and A_3 ARs. The EDA-hybridized compounds showed antioxidant activity comparable to EDA (DPPH test). Selected triazolopyrazines proved to be effective in preventing irreversible blockade of neurotransmission and in decreasing neuronal damage induced by oxygen and glucose deprivation in the CA1 region of rat hippocampal slices. Molecular docking studies showed the best binding pose of these derivatives with the 2-phenyl ring positioned in the depth of the receptor cavity and the 6-substituent at the entrance, and oriented toward the extracellular environment.

The stress-inducible enzyme, named HO-1, exerts an essential role in maintaining cellular homeostasis in response to oxidative stress in normal cells. On the other hand, overexpression of this isoform in cancer cells has been linked to tumor aggressiveness and drug resistance phenomena. Therefore, the association of non-competitive HO-1 inhibitors, such as imidazole derivatives, with FDA-approved drugs showed *in vitro* efficacy in enhancing antiproliferative effects.[1] Unfortunately, the clinical application as adjuvant chemotherapy of this class of compounds might be limited by their lack of selectivity towards other heme-dependent enzymes (i.e., cytochromes P450),[2] likely, due to the presence of an imidazole nucleus. Based on this premise, we selected any of our most potent HO-1 inhibitors among three different series reported so far,[3] that served as reference compounds for lead-optimization. Specifically, to keep potent enzyme inhibition activity and reduce potential off-target effects (i.e., CYP3A4, and CYP2D6 inhibition) we replaced the imidazole ring with a 1,2,4-triazole one (Figure 1, left). Thus, new derivatives were synthesized, characterized, and tested for their *in vitro* activity towards the selected target; while molecular modeling studies allowed us to analyze their binding modalities (Figure 1, right). Finally, the *in vitro* antiproliferative properties of the most potent compound and its co-administration (combo) with 5-FU have been tested in selected cancer cell lines (i.e., DU-145 and MCF-7) using the MTT assay.

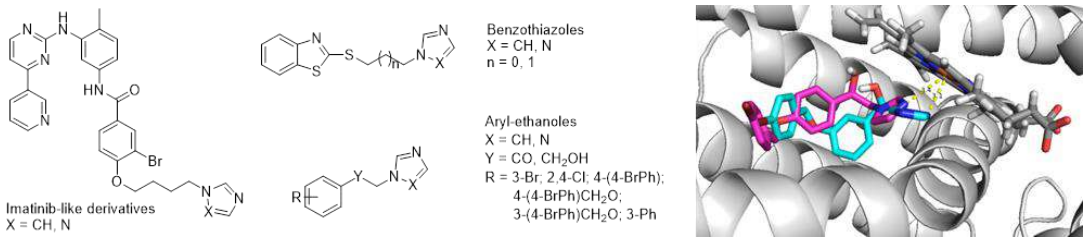

Figure 1: General structures and selected binding pose of 1,2,4-triazole-based derivatives.

beatrice.noce@uniroma1.it

NADPH oxidases (NOXs) are enzymes responsible for only generating reactive oxygen species (ROS). The seven NOX isoforms share the same catalytic core; despite this, each isoform presents peculiar items (tissue distribution, activation mechanism, and specific activities).[1] In cancers, dysregulation of NOX enzymes affects ROS production, leading to redox unbalance and tumor progression.[2] Our project focused on the molecular simplification of M41, a promising lead compound discovered through two ultra-large *in silico* screens of 350 million compounds, carried out by our collaborators. As the cocrystal structure of M41 with the NOX5 DH domain from *C. Stagnale* shows high adaptability of M41 for binding, we investigated the contributions of its various chemical groups, obtaining a first series of simplified derivatives. The reduction of the complexity of spiroamine has allowed us to obtain MC4876 and MC4854, which show potency and selectivity on NOX2 and NOX5, respectively, (**MC4876**: IC_{50} *h*NOX1 = 71.2 µM; IC_{50} *h*NOX2=7.7 µM; K_i (NOX2) = 7.3 µM; IC_{50} *h*NOX4 = 81.2 µM; IC_{50} *h*NOX5 = 63.5 µM; **MC4854**: IC_{50} *h*NOX1>100; IC_{50} *h*NOX2>100; IC_{50} *h*NOX4>100; IC_{50} *h*NOX5=1.6 µM). Given the good results obtained in vitro, we decided to better study MC4876 in cellulo (EC_{50} NOX2 = 5.7 µM; CETSA *h*NOX2 = + 1.1 °C).[3] Considering good results of MC4854 and MC4876, we designed and synthesized a second series of derivatives based on the two lead-compounds just mentioned. All the compounds synthesized have been tested against the full length of the various isoforms at Mattevi's laboratories at the University of Pavia. For some compounds, good isoform selectivity is maintained. Additionally, during the synthesis of the azetidine derivative MC4923 via Buchwald-Hartwig cross coupling reaction, we also obtained the bisquinoline derivative MC4921, that we decided to test. Surprisingly, this is, until now, our most potent compound (IC_{50} *h*NOX1>100, IC_{50} *h*NOX2 = 1.4 µM; IC_{50} *h*NOX4>100; IC_{50} *h*NOX5>100; K_i *h*NOX2 =2.1 µM; EC_{50} = *h*NOX2 = 0.77 µM; CETSA *h*NOX2: +6.0 °C). Additional biological studies are currently ongoing.

Design of novel nucleic acid-based therapeutics targeting a long non-coding RNA for the treatment of melanoma

B. Moras,[a] M. Ghezzo,[a] R. Rigo,[a] C. Sissi[a]

[a]*Department of Pharmaceutical and Pharmacological Sciences, University of Padova, via F. Marzolo 5, Padova*
beatrice.moras@studenti.unipd.it

Metastatic melanoma is a highly aggressive tumour with a high mortality rate. Recent findings have been proven that long noncoding RNAs (lncRNAs) are involved in the regulation of different cellular processes fundamental for the development/survival in several cancers including melanoma[1]. A common strategy to elicit the cellular activity of lncRNAs is to target them with chemically modified antisense oligonucleotides (ASOs)[2].

To identify the most suitable lncRNAs to be exploited for melanoma treatment with ASOs, we set up a systematic approach starting from the Lnc2Cancer v.3.0 database[3], integrated with GENCODE annotations[4]. Upon this search we selected BRAF-activated non-protein coding RNA (BANCR), a lncRNA whose expression is upregulated in melanoma[5]. The second step of our study was to verify the efficacy of DNA and RNA ASOs designed against BANCR lncRNA in melanoma cell lines.

First, the expression of BANCR was analysed in the A375 cell line using Quantitative Real-time PCR. Overall, our results demonstrated the presence of our lncRNA within the nucleus in the selected cell line.

Subsequently, the selection of accessible regions within BANCR to be targeted by ASOs was performed by using the structural predictions tool RNAfold (ViennaRNA Package)[6]. Additionally, BANCR's potential to sponge microRNAs was explored employing starBase[7] tool. We identified miR-205-5p as an attractive partner of BANCR for our goal. Therefore, we targeted the region of BANCR responsible for the binding to miR-205-5p with tailored DNA and RNA ASOs starting from the fully complementary sequences.

Hence, the interaction of BANCR with miR-205-5p, DNA and RNA ASOs were evaluated by circular dichroism (CD) and differential scanning calorimetry (DSC). Both the CD and DSC data confirmed the formation of the duplex complexes according to a fully reversible process. The efficiency capacity of the fully complementary DNA and RNA ASOs to displace the miR-205-5p from BANCR was confirmed.

These findings can provide proof-of-concept that the targeting of miR-205-5p binding region could be a new option for melanoma treatment through BANCR inhibition.

martina.pacetti26@gmail.com

The availability of novel and broad-spectrum anti-influenza virus (IV) drugs is a crucial weapon in the fight against future pandemic outbreaks, especially since drug resistance is a major concern for the limited number of approved anti-IV drugs. A promising target for the discovery of next-generation antivirals is RNA-dependent RNA polymerase (RdRP), which is essential for viral replication and evolution. It is a heterotrimeric complex that is highly conserved across IV strains and consists of PA, PB1 and PB2 subunits. Therefore, interfering with the formation of protein-protein interactions (PPIs) involved by RdRP subunits during the IV life cycle offers an innovative approach to identify anti-IV agents that reduce the ability of IV to develop drug resistance.[1] Starting from previously identified compound **1**, in this work I reported the structural exploration of the cycloheptathiophene-3-carboxamide (cHTC) core as well as the moieties at the C-2 and C-3 positions.[2-4] The investigation led to analogues capable of potent inhibition of IV replication in the nanomolar range against a panel of IV strains. (**Figure 1**) With the aim of clarifying the mechanism of action, in-depth studies were performed for the best compound **2**, which showed the ability to prevent PA-PB1 heterodimerization by binding PA_C. Finally, a more efficient and scalable chemical procedure was developed for the synthesis of these promising anti-IV agents.

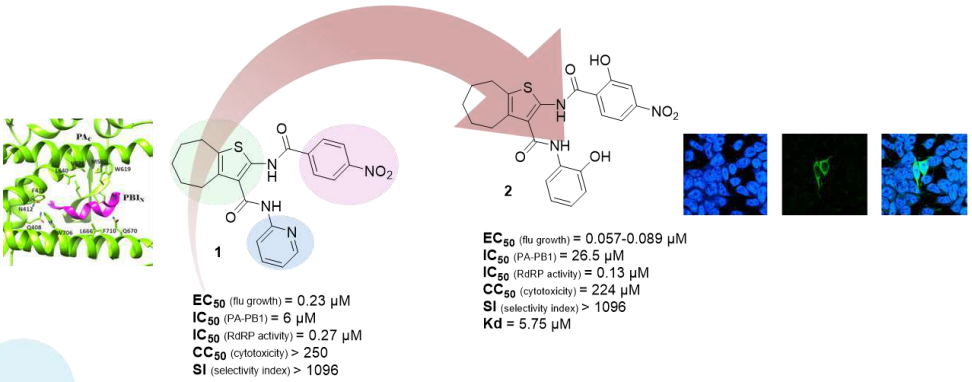

Figure 1: Schematic representation of the work herein reported.

Lipids are the major constituents of cell membranes, very efficient energy sources, and key pathophysiological mediators of several intercellular and intracellular processes. Lipids are increasingly recognized as valuable markers for the early detection and assessment of various inflammatory diseases[1,2]. Investigating lipid profiles offers insights into cellular phenomena such as low-grade inflammation, which is prevalent in numerous conditions including cancer, neurodegenerative disorders, diabetes, and obesity. This study aimed to identify lipid signatures within an inflammatory cell model by employing sophisticated bioanalytical methods and Machine Learning techniques. The analysis utilized high-resolution mass spectrometry to compare the lipidome from TNF-α inflamed cells (R3/1 NF-κB reporter cells) against non-inflamed control cells, identifying 469 lipids. Notably, 20% were phosphatidylcholines (PCs) and phosphatidylethanolamines (PE), 10% were sphingomyelins (SM), and smaller percentages were other lipid types such as phosphatidylinositols (PI), ceramides (Cer), phosphatidylglycerols (PG), and phosphatidylserine (PS). The TNF-α inducer altered 88 lipids with a fold change greater than 1.5, with 71 upregulated and 17 downregulated, impacting several cellular pathways as shown by network analysis. To assess the model's validity, TNF-α inflamed cells were treated with polyphenols from thinned young apples (TAP), known for their anti-inflammatory effects. This treatment reversed the dysregulation observed in specific ceramides in the inflamed cells. Network analysis further revealed the modulation of arachidonic acid and TNF signaling pathways by these polyphenols. The findings underscore the utility of this inflammatory model and bioanalytical approach in characterizing lipid profiles within complex biological contexts. Furthermore, the lipids were analyzed using an artificial intelligence framework to pinpoint significant signatures and clusters that influence cellular conditions. Ultimately, this research demonstrates the potential of lipidomics paired with machine learning and illustrates how to develop and validate machine learning models for predicting inflammation based on lipid patterns.

Inhibition of SARS-CoV-2 Replication by 2-Phenylquinoline Derivatives Targeting nsp13 Helicase

M.G. Nizi,[a] G. Cernicchi,[a] A. Corona,[b] S. Sabatini,[a] S. Massari,[a] F. Esposito,[b] E. Tramontano,[b] O. Tabarrini[a]

Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) emerged at the end of 2019 as a new deadly human betacoronavirus, responsible for COVID-19, a highly infectious and pathogenic disease. The RNA vaccines, approved in the early 2020, have represented the main weapon to successfully reduce the devastating impact of the outbreak, while the discovery of efficacious antivirals have lagged behind, with only three drugs that have approved to date. As a results, the development of SARS-CoV-2 antivirals is still a priority to address the limitations of the existing drugs and to effectively manage the future pandemics.

Due to its high conservation across coronaviruses, and being a crucial component of the replication transcription complex, the nsp13 helicase, which catalyses the RNA unwinding and ATP hydrolysis, could represent an alternative drug target.[1]

By screening a selection of small molecules from our in-house library, we have recently identified the 2-phenylquinoline (2-PhQ) as a promising scaffold to obtain new anti-SARS-CoV-2 agents. Indeed, the proper substitution pattern around the 2-PhQ nucleus furnished some compounds endowed with: broad anti-coronaviruses inhibition, being active in the low µM range against SARS-CoV-2 and two other human coronaviruses, HCoV-229E and HCoV-OC43; absence of toxicity up 100 µM concentration; µM inhibition of the helicase unwinding activity.[2]

Thus, guided by the preliminary SAR, a new series of 2-PhQ derivatives was synthesised by maintaining the 6,7-dimethoxytetrahydroisoquinoline at the C-4 position to guarantee the helicase recognition, while extensively modifying the C-2 substituent.

As an alternative approach to hit nsp13 helicase, the best 2-PhQs were also handled into hydrophobically tagged degraders.

The design, synthesis and biological evaluation of the new set of compounds will be object of the presentation.

Over the past few years, there has been a rapid expansion in the development of new chemical modalities and innovative approaches for modulating cellular pathways and addressing biological targets previously deemed undruggable.[1] One of the most significant advancements in this field has been the emergence of targeted protein degradation technologies, which have catalysed a paradigm shift in therapeutic strategies and opened up new avenues for drug design. Among them, proteolysis targeting chimeras (PROTACs) have resulted in promising clinical candidates, unlocking opportunities for biopharmaceutical innovation.[2] In parallel, hydrophobic tags (HyTs) have emerged as a promising platform in drug discovery, leveraging their lower molecular weight and reduced number of hydrogen bond donors/acceptors compared to PROTACs.[3] Despite the advances achieved to date, PROTACs synthesis remains complex, often involving multi-step approaches and orthogonal protection strategies. These challenges pose a bottleneck in PROTAC development, hindering synthetic throughput and efficiency. To address this limitation, we have devised an innovative synthetic platform that capitalizes on multicomponent reactions (MCRs) to accelerate PROTAC drug discovery, leveraging the modular nature of both PROTACs and MCRs.[4] To broaden the applicability of this platform and unlock its full potential in advancing drug discovery efforts, we have successfully applied the platform to the one-pot synthesis of novel BRD4-targeting HyTs, as well as to PROTACs targeting indoleamine 2,3-dioxygenase 1 (IDO1), a moonlighting protein that play a pivotal role in cancer immunotherapy,[5] and against transient receptor potential vanilloid 1 (TRPV1), also known as capsaicin receptor, involved in pain and itch.[6]

Neuroinflammation has been identified as a precursor to the onset of several neurodegenerative diseases, including Alzheimer's disease (AD). Understanding and managing the intricate interplay between the central nervous system (CNS) and the immune system is crucial from a physiological standpoint, as well as from pharmacological point of view. In an attempt to develop therapeutic approaches to prevent/delay disease's progression,[1] in the framework of the Italian National Recovery and Resilience Plan (PNRR) extended partnership (PE) 12 titled "A multiscale integrated approach to the study of the nervous system in health and disease" (MNESYS), a small molecule hit as been identified. It shows an intriguing inhibitory activity toward a neutrophil-specific enzyme implicated in AD neuroinflammation. (Patent Pending) This molecule has become the starting point for the development of innovative heterobifunctional small molecules exhibiting degrading behavior, that exploit the cellular proteasome machinery to degrade the identified target enzyme.[2] In these heterobifunctional molecules, the hit compound is connected, through different linker, to a recruiter of CRBN E3 ubiquitin ligase, i.e., thalidomide. (Figure 1) We develop a library of heterobifunctional molecules modifying the linker's characteristics: length, composition, and rigidity. An *in vitro* bioassay on the isolated target to perform SAR studies has been selected for a preliminary evaluation of the impact of the structural modifications on the binding/activity towards the target enzyme. The therapeutic potential of these heterobifunctional small molecules is currently under evaluation in neuroinflammatory cell models.

Funding: this research was supported by EU funding within the NextGenerationEU-MIUR PNRR Extended Partnership 12 (Project no. PE00000006, MNESYS – SPOKEN7)

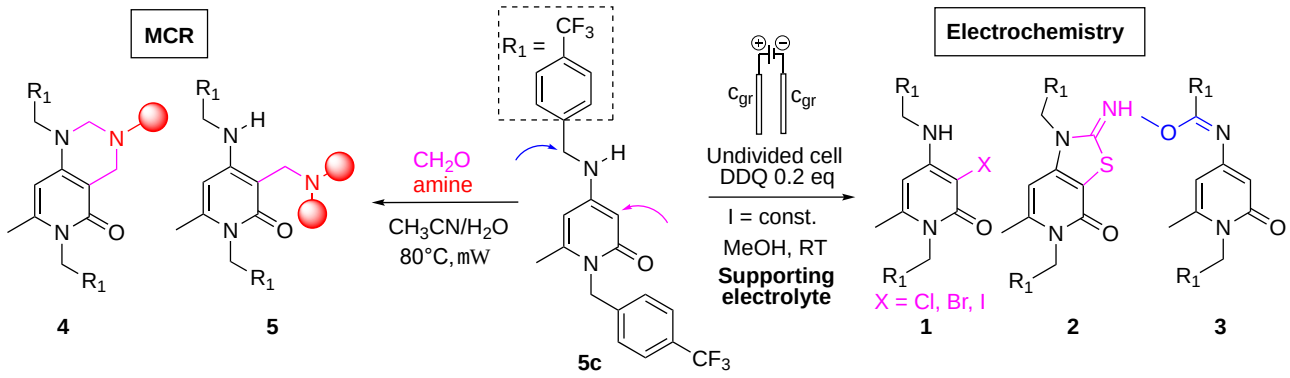
Late-stage functionalization (LSF) allows the chemo- and site-selective diversification of already complex and polyfunctionalized compounds, often exploiting green chemistry tools.[1] We recently identified the 4-amino-2-pyridone **5c** as promising lead compound for the development of novel small molecule PCSK9 inhibitors.[2] Aiming to both study the under-investigated reactivity of such 4-amino-2-pyridone scaffold and improve the pharmacokinetic profile of **5c**, LSF represents the best option for achieving these two goals concomitantly. The combination of the LSF strategy with other intrinsically green synthetic tools, as electrochemistry and multi-component reaction (MCR) allowed the set-up of innovative and green procedures for the obtainment of a small collection of derivatives. Exocyclic N, aromatic C3 and benzylic C11, as likely metabolic soft spots, were selected as sites of functionalization. On one hand, electrochemically driven modifications led to the synthesis of halogenated derivatives **1**, the novel bicyclic compound **2**, and the Shono-type product **3**. On the other hand, μW-assisted MCR allowed the synthesis of two different classes of products (**4** and **5**).[3] Biological studies on the newly synthesized analogue of **5c** are currently ongoing.



Scheme 1: LSF of compound **5c**.

Innovative Approaches to Combat Tuberculosis: Exploring Dual-Acting Inhibitors Targeting *Mt*MetAP1c and MbtI

A. Tresoldi,[a] M. Mori,[a] G. Cazzaniga,[a] A. Gelain,[a] G. Stellitano,[b] L. R. Chiarelli,[b] F. Meneghetti,[a] S. Villa[a]

andrea.tresoldi@unimi.it

Tuberculosis (TB) is the world's second-leading cause of death from a single infectious agent, remaining a significant global issue. Approximately 10 million new cases and 1.4 million deaths are reported annually by the World Health Organization (WHO). Moreover, the spread of multi-drug-resistant strains of *Mycobacterium tuberculosis* (*Mtb*) requires the urgent development of new therapeutic approaches.[1]

The mycobacterial methionine aminopeptidase family (*Mt*MetAP) has recently emerged as a promising target for the development of anti-TB agents due to its essential role in the protein synthesis pathway. Considering that recent studies identified *Mt*MetAP1c as essential for *Mtb* survival, our focus was primarily on this isoform.[2,3]

Hence, we prepared different substrates and known inhibitors to assess the functionality of *Mt*MetAP1c and develop an assay for the evaluation of new candidates.[4] In a literature survey, we observed that a 5-phenylfuran-2-carboxylic acid derivative had been identified as a *Mt*MetAP inhibitor.[2] Considering that this scaffold was also the core of a class of inhibitors of the salicylate synthase (MbtI) from *Mtb*, identified by our research group,[5] we envisaged that we could develop a series of potential dual inhibitors, maximizing their antimycobacterial effect by blocking two distinct pathways. Our preliminary data will be discussed, laying the foundation for the discovery of dual-acting enzymatic inhibitors for the treatment of *Mtb* infections.

Exploring the Inhibition of Iron Acquisition in *M. abscessus* as a Potential Anti-Virulence Strategy in People with Cystic Fibrosis

M. Mori,[a] A. Tresoldi,[a] G. Cazzaniga,[a] A. Gelain,[a] G. Stelitano,[b] M. Cocorullo,[b] L. R. Chiarelli,[b] P. Delre,[c] G. F. Mangiatordi,[c] A. Cassetta,[d] S. Covaceuszach,[d] S. Villa,[a] F. Meneghetti[a]

matteo.mori@unimi.it

M. abscessus (*Mab*), an opportunistic pathogen belonging to the class of non-tuberculous mycobacteria (NTM), causes chronic pulmonary infections in sensitive individuals, especially cystic fibrosis (CF) patients. Despite its incidence is on the rise, the available therapeutic strategies have only a limited efficacy and are very burdensome for the patients. Hence, due to the intrinsic resilience of NTM to treatments and the dramatic spread of resistant strains, new pharmacological approaches are urgently needed.[1]

In this context, iron acquisition has been recently proposed as an interesting target in the phylogenetically close *M. tuberculosis* (*Mtb*), due to the involvement of this metal in the pathogenesis and survival of the microorganism in the host.[2] Therefore, we decided to investigate the targeting of mycobacterium-specific iron chelators as a possible anti-virulence approach against *Mab*. In detail, we focused on the first enzyme involved in the siderophore biosynthetic pathway, a salicylate synthase (SaS) that has been successfully studied to identify antitubercular agents against *Mtb*. Due to the structural conservation of the active site in the two congeners, we approached this study by screening an in-house library of *Mtb*-SaS inhibitors. This initial investigation led to the identification of the first hit compounds against *Mab*-SaS.[3] Moreover, considering the high plasticity of the active site, we performed crystallization studies to solve the structure of *Mab*-SaS, providing a solid base to structure-based drug design efforts. The obtaining of the first 3D-model of this enzyme allowed us to characterize its orthosteric site and study the peculiar area around it.[4] Our promising results will be presented, along with preliminary data on the use of the new structure for the development of optimized inhibitors.

This research explores new possibilities for antimalarial drugs by focusing on the *Plasmodium falciparum* Dihydroorotate Dehydrogenase (*Pf*DHODH) enzyme, a critical enzyme in the parasite's pyrimidine biosynthesis pathway. Unlike humans, the malaria parasite cannot salvage pyrimidines, making *Pf*DHODH an ideal target[1]. The study combines various techniques, including 3D-QSAR, molecular docking, molecular dynamics (MD) simulations. A dataset of 99 triazolopyrimidine derivatives was examined using CoMFA and CoMSIA models, and the best ranked molecules were evaluated through molecular docking and MD simulations, confirming the stability of these inhibitors within *Pf*DHODH bindng site and reinforcing their potential as effective inhibitors. The best 25 triazolopyrimidine analogues derived from *in silico* studies has been synthetized, and their *in vitro* enzymatic activity will be here discussed. In summary, this research provides a robust approach for the design and of *Pf*DHODH inhibitors as novel leads for the treatment of malaria, offering hope in the fight against this deadly disease.

A sustainable one-pot three-step approach for the synthesis of 3,5-disubstituted 1,2,4-triazines as versatile pharmacological tools

D. Rubini, M.G. Martina, M. Incerti, F. Barbieri, M. Radi

Università degli Studi di Parma, Viale delle Scienze 27/A 43124, Parma (Italy)
daniele.rubini@unipr.it

1,2,4-Triazines are an important class of six-membered aromatic heterocycles which have demonstrated a wide range of pharmacological applications, showcasing properties that extend to anticonvulsant, antithrombotic, antibacterial, antimalarial, antiviral, anti-inflammatory, and anticancer activities.[1,2] While various strategies for synthesizing 1,2,4-triazines have been reported, they often require multiple steps/purifications, harsh reaction conditions, activation by toxic metals/oxidants, longer reaction times, use of complex synthetic precursors, and sometime lead to the formation of multiple regioisomers.[2] We report herein the first microwave-assisted one-pot three-step metal-free [4+2] procedure for the synthesis of 3-hydrazinyl-1,2,4-triazine directly from commercially available aromatic and heteroaromatic ketones (**1**). The optimized protocol allowed us to quickly generate substituted 5-aryl/heteroaryl-3-hydrazineyl-1,2,4-triazines (**5**) in good overall yields which were further elaborated by a μW-assisted condensation with a wide range of aldehydes/ketones to provide a collection of hydrazone-derivatives (**7**). The developed synthetic approach proceeds under mild conditions, with good functional group compatibility and represent a versatile, rapid, and efficient tool for the generation of new highly functionalized 1,2,4-triazines derivatives of potential biological interest.[3]

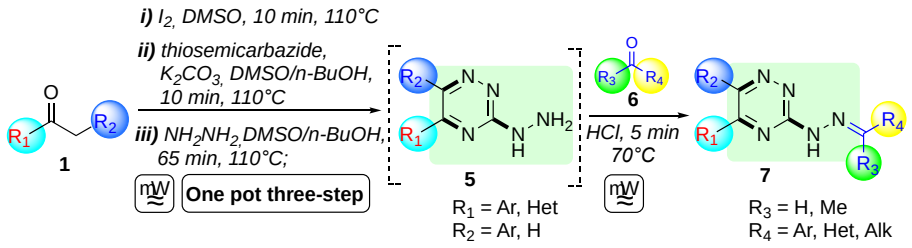

Figure 1: Synthetic route to obtain 1,2,4-triazine based derivatives.

Staphylococcus aureus uses the Iron-regulated surface determinant (Isd) system, including the IsdB receptor, to extract heme from hemoglobin in human hosts and obtain iron for its growth. This process involves hemolysins to release hemoglobin, IsdB receptor to extract heme, and other Isd proteins to transfer and oxidize heme to release iron for the bacteria's needs. Given its key role in heme scavenging, IsdB could represent the basis for the development of new biotechnological approaches to scavenge free and toxic hemoglobin in the blood, however the specific mechanism and the pathway of heme extraction at the IsdB-hemoglobin interface has not been reported yet.

In this work we simulated, for the first time to Authors' knowledge, the heme transfer in the IsdB-hemoglobin complex, an event that cannot be trapped by structural biology, nor clarified at the atomistic level by spectroscopy. Taking advantage of a protocol we previously devised for protein-ligand binding[1], we employed enhanced sampling molecular dynamics (MD) simulations to identify key residues involved in this process as well as interdomain motions and hotspots at the protein-protein interface. Furthermore, wild-type and deficient IsdB variant were expressed and purified, and spectroscopical assays were carried out to confirm simulations outcomes. In particular, our results highlight the importance of Tyr444 residue for heme extraction from human hemoglobin, laying the bases for a molecular understanding of the staphylococcal IsdB-human hemoglobin interaction.

The 83% of the chemical scaffolds found in nature are unique, due to the lack of commercially available synthons or prohibitive synthetic procedures.[1] This data prompted many researchers to consider libraries of secondary metabolites as the starting point of the drug discovery process. As a result, more than one hundred databases of NPs have been developed, among which 85% focus on data concerning terrestrial plants. Among this 85%, only 1% reports on plants from Europe, making clear how Europe's biodiversity is largely under-considered in the Nature-Aided Drug Discovery scenario.[2]

In this work we built a library containing almost 6000 secondary metabolites produced by plants growing in Pavia countryside and linked them to their SMILES code and producing organism. Thus, one of our purposes was to promote biodiversity conservation in Lombardy, particularly in Pavia countryside, being it a very underestimated hotspot of biodiversity. Next, we set up a pharmacophoric model exploiting Ligand Scout software to identify potential proteasome inhibitors and so potential anti-cancer agents. This target was selected being already available proteasome inhibitors associated with several side effects, which can cause a dose limitation or a complete suspension of the therapy. The following virtual screening allowed us to identify seven new potential proteasome inhibitors, which were next purchased or extracted to validate their activity via in vitro assays. These metabolites can be considered hit compounds in the fight against cancer and further research is ongoing to improve their pharmacokinetic and pharmacodynamic profiles. Of note, the herein presented approach allows merging the conservation of biodiversity and the identification of new active metabolites. This is due to the preliminary computational studies that avoid concerns related to harvesting high amounts of natural matrices for preliminary screening.

Carbonic anhydrases (CAs) are ubiquitous enzymes that catalyze the reversible hydration of carbon dioxide to produce monohydrogen carbonate and H^+ ions. The CA isoforms play key roles in many physiological processes: signal transduction, cell differentiation and proliferation, and onco-genesis[1]. The project starts from the relevance of the sulfonamide group as inhibitor of several isoforms of carbonic anhydrase. We decided to start from different derivatives, active as tubulin polymerization inhibitors, introducing a sulfonamide group, to selectively inhibit CA IX and CA XII isoforms, which are triggered by hypoxia-inducible factor 1 in many types of cancer. Novel pyrrole and indole derivatives have been synthesized as human carbonic anhydrase (hCA) inhibitors. The presence of both N1-(4-sulfonamidophenyl) and 3-(3,4,5-trimethoxyphenyl) substituents was essential for strong hCA inhibitors. Notably, compound 15, the most potent hCA XII inhibitor (Ki = 6.8 nM), demonstrated a dual target inhibition by effectively suppressing the Wnt/β-catenin signaling pathway as well, which is found to be dysregulated in some solid tumors, its target genes MYC, Fgf20, and Sall4 and exhibited the typical markers of apoptosis[2]. Docking experiments were performed to gain insights into the molecular details of the binding modes of the reported compounds. Several compounds exhibited promising activity against different tumor cell lines, including colorectal cancer and triple-negative breast cancer, highlighting their potential as therapeutic agents.

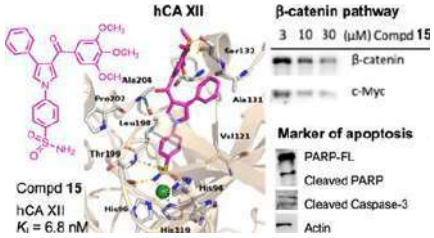

Figure 1: Compound 15 showed strong inhibition of viability in a panel of cancer cells.

serena.vittorio@unimi.it

The in silico prediction of drug metabolism is gaining a growing interest due to the possibility to process large datasets allowing the stability and safety of new drug candidates to be evaluated in the early stages of drug discovery process. To date, in silico models for metabolism prediction mainly exploits the physicochemical and stereo-electronic properties of the training molecules in order to predict the occurrence of a given metabolic reaction and/or the reactive site involved in the predicted biotransformation.[1] However, recent reports suggested that structure-based methods, such as docking simulations, can be conveniently integrated with ligand-based (LB) approaches for drug metabolism prediction purpose, with the advantages to predict if a given molecule can fit the enzyme active site and which moiety approaches the catalytic residues.[2] On this ground, this work aimed at developing ML predictive models for UDP-glucuronosyltransferase (UGT)-mediated metabolism by combining both ligand- and structure-based (SB) approaches. UGT enzymes catalyse a phase II metabolism reaction consisting of the glucuronidation of nucleophilic sites of the substrate. Specifically, our study was focused on UGT2B7 and UGT2B15 isoforms as they are widely implicated in the clearance of many drugs as well as in clinically relevant drug-drug and drug-xenobiotics interactions. First, a computational study, including docking and molecular dynamics (MD) simulations, was performed to investigate the binding order of cofactor and substrate to UGT2B7 and UGT2B15, exploiting their three-dimensional models available on AlphaFold repository. The analysis of MD trajectories allowed an appropriate conformation of both UGT isoforms to be identified for the development of ML classification models. For this purpose, a set of UGT substrates and non-substrates was collected from the manually curated MetaQSAR database[3] and split into training and test sets. SB models were trained on a set of scoring functions computed by docking and rescoring calculations and protein-ligand fingerprints. Instead, the LB classifiers were generated using a set of physicochemical and constitutional descriptors. All models were internally validated by ten-fold cross validation and evaluated on the test set. In addition, a further validation was carried out on an external test set containing molecules retrieved from GOSTAR database. Overall, the generated models displayed a good ability to correctly identify UGT substrates, with the SB classifiers outperforming the LB models when evaluated on the GOSTAR external dataset. Moreover, inspection of docking poses provided useful hints about the structural motifs that are most likely to undergo glucuronidation.

Protein disulfide isomerases (PDIs) are redox chaperone proteins that belong to the thioredoxin oxidoreductase superfamily and are able to catalyze dithiol-disulphide exchange reactions.[1] In the last years, the scientific community paid much attention to PDIA3 isoform, because altered expression and activity of this protein has been associated with several human diseases, such as cancer, neurodegenerative diseases, and also viral infection.[2] Indeed, the presence of PDIA3 on the cell surface has been related with the entry of different viruses in human cells. During influenza A virus (IAV) infection, PDIA3 is involved in the hemagglutinin protein maturation and IAV replication, suggesting a potential role as target to counteract IAV infection. Moreover, in human coronaviruses (HCoVs), PDIA3 is associated with the effective oxidative folding and trimerization of HCoV Spike (S) protein by catalyzing the formation of disulphide bonds that could mediate the interaction between the envelope and S protein. Therefore, PDIA3 may be viewed as an interesting pharmacological target with a huge potential for the development of innovative antiviral agents. Also considering its presence in human cells and not in the viruses, PDIA3 offers the opportunity to discovery new drugs as putative broad-spectrum antiviral agents, overcoming problems such as drug resistance.

In previous studies, 16F16 was reported as a covalent inhibitor of PDIA1 and PDIA3 proteins due to the presence of a chloroacetyl group that irreversibly binds to free cysteine thiols.[3] Starting from the chemical structure of 16F16, we designed and synthesized a small set of structural analogues, characterized by a tetrahydro-β-carbolines core endowed with a chloroacetyl group in 2-position as PDIA3 inhibitors, to further explore the structure activity relationship. The data coming from the biochemical assays will be shown and discussed.

Assessing Persistence, Bioaccumulation, and Toxicity (PBT) is crucial for understanding the potential risk associated to the release of chemicals in the environment. Screening for PBT is still a challenging process due to the scarcity and poor quality of available data. This highlights the need for accurate and readily available methods to better predict the environmental impact of chemicals. PBT can be concisely expressed by the PBT index, defined thanks to a traditional QSPR model based on four structural molecular descriptors.[1] However, the accuracy of traditional QSP(A)R models tend to decrease when applied to large and heterogeneous datasets. The aim of this project is to apply advanced machine learning (ML) algorithms to predict the PBT index of pharmaceutically relevant molecules, overcoming the limitations of more traditional approaches. Chemprop, a message passing neural network (MPNN) was employed for this purpose.[2] First, we assembled a comprehensive dataset of compounds already annotated by public agencies. After removing ambiguous and duplicated compounds, our final dataset encompassed 5129 molecules univocally labelled as PBT or non-PBT. Part of this collection (training set) was used to train a binary classification model that assigns each compound a PBT or non-PBT label based on features extracted from its structure. Once trained, the model was used to make predictions on the remaining molecules (test set). We further enhanced the robustness and stability of our PBT prediction model by increasing structural dissimilarity between training set and test set molecules by means of a clustering strategy. When applied to the test set, the figures of merit show how the model achieved an accuracy (g) of 0.90, and a recall rate (r) of 0.92. Overall, this study highlights the potential of ML models for predicting PBT properties, thereby focusing on enhancing model's generalizability. Moreover, using Chemprop's built-in 'interpret' function,[2] we are able to extract PBT-related significant substructures that are responsible for the PBT prediction in order to provide guarantees of model explainability for the PBT assessment. Lastly, a dataset of compounds of pharmaceutical interest (619 cmpds) extracted from DrugBank database will be tested to the proposed Chemprop model in order to identify potential PBTs among pharmaceuticals defined as contaminants of emerging concern.[3]

Given the large extent of information on ligands and targets involved in diseases available in public databases, increasing efforts have been made over the last decades on the application of in silico strategies. Among these, inverse screening approaches are attracting increasing great interest due to its many applications in the drug discovery process. For example, it allows the identification of both the mechanism of action of a new molecule and of secondary targets for investigated drugs or natural compounds, enabling the prediction of possible side effects and toxicity but also suggesting new potential therapeutic uses[1,2]. Different strategies to perform inverse screening have been developed in the last decades[3,4], they however present significant limitations due to an unsuitable number of target structures, which can result in an inefficient screening or in a too high computational and time requirement.

On these grounds, we developed a dataset of therapeutically relevant targets, consisting in 485 proteins associated with specific diseases and for which either an approved drug or a drug under clinical trial is available. For each target, we also collected a dataset of ligands with experimentally determined activity on the targets, including an equal number of active and inactive compounds depending on a defined activity threshold, reasonably covering all the involved chemical space. Both targets and ligands structures have been refined and optimized. The major applications of these datasets include the possibility to perform reverse screening campaigns and develop predictive models to identify targets for a specific query molecule. Some examples of relevant applications will be presented.

Despite all the efforts in recent decades cancer remains one of the leading causes of death. Among different treatments, chemotherapy is still the method of choice, however, the emergence of drug resistance could seriously undermine its effectiveness.[1] Indeed, cancer cells can develop resistance to several drugs with a different mechanism of action (MultiDrug Resistance) that represents a serious obstacle to the use of chemotherapeutics. In the past, we have found that gaseous signalling molecules, such as nitrogen monoxide (NO) and hydrogen sulfide (H_2S), could help overcoming the resistance of cancer cell to chemotherapeutics. Here we present the use of another gaseous messenger – CO, as a sensitizer of cancer cells.

The controlled delivery of CO to target tissue remains a challenge in medicinal chemistry. Several CO-releasing molecules (CORMs) have been proposed as alternatives to direct CO administration.[2] Here we decided to use non-metallic CORM (**1**) that release carbon monoxide after hydrolytic activation (**Scheme 1**).

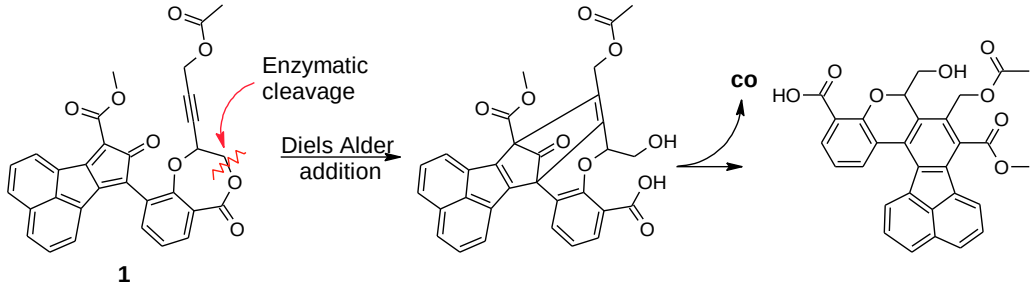

Figure 1: Mechanism of carbon monoxide release from **1**.

The toxicity of **1** alone and in combination with chemotherapeutic was evaluated in tumour cell lines known for their intrinsic resistance to chemotherapy. We have found the **1** itself reduced the viability of tumour cells at 0.1 – 1 μM concentration, while its toxicity in corresponding non-transformed cells was significantly lower. When **1** was co-incubated with increasing concentrations of cisplatin, doxorubicin, docetaxel or gemcitabine, i.e., the first line-treatments for corresponding tumour types a pronounced decrease in cell viability was observed. It seems that the mechanism responsible for sensitizing of resistant tumour cells include the mitochondrial damaged with a high level of mitochondrial ROS production due to CO production.

Myocardial infarction (MI) is the leading cause of morbidity and mortality worldwide. Its pathomechanism includes the oxygen/nutrients deprivation of the myocardium, leading to cardiac damage[1]. Timely restoration of coronary flow is necessary to decrease the infarct size (IS) and to rescue the hypoxic myocardium. Paradoxically, reperfusion leads to additional cardiac injury leading to cardiomyocyte dysfunction, referred to as "reperfusion injury"[2,3]. Sirtuins are epigenetic enzymes that catalyze the removal of acetyl groups from both histones' tails and non-histone proteins via a NAD^+-dependent mechanism[4]. Several studies reported the implication of sirtuins in ischemia/reperfusion injury (IRI)[5,6,7]. However, their cardioprotective potential is elusive and is based primarily on studies exploiting non-specific SIRT agonists. Therefore, we chose to test three novel SIRT agonists that we previously synthesized, namely MC2606, MC2789 and MC3215, exhibiting SIRT1, SIRT3 and SIRT5 agonism respectively, as confirmed by the Mass Spectrometry (MS)-based assay[8]. We tested the compounds *in vitro*, in cardiomyoblasts (H9c2 cells) and human endothelial cells (EA.hy-926 cells), in order to identify the cytoprotective effect of our compounds in hypoxia/reoxigenation conditions and to assess their target engagement in the selected cell lines with western blot analysis. Furthermore, we assessed the cardioprotective potential of SIRT agonists in an *in vivo* model of IRI (30min Ischemia/2h and 24h reperfusion) in C57BL6/J male mice and assessed the IS. Among the three compounds, the SIRT5 agonist exhibited the greater cardioprotective potential, by reducing IS compared to controls both at 2 and 24h of reperfusion. Therefore, SIRT5 agonist was selected for further molecular experiments in order to identify its underlying cardioprotective mechanism, providing useful and novel insights on the role of SIRT5 in IRI.

Insulin resistance is a pathological condition characterized by attenuated tissue response to normal or elevated insulin production. Type 2 diabetes mellitus (T2DM) and Metabolic Syndrome are the most common clinical pathologies associated with IR [1]. Most of glitazones, the traditional anti-diabetic drugs, which act as Peroxisome Proliferator-Activated Receptor γ (PPARγ) agonist, have been withdrawn from the market. To avoid the serious adverse effects related to the PPARγ agonism profile, a new opportunity is represented by the development of inhibitors of the PPARγ phosphorylation by the cyclin-dependent kinase 5 (Cdk5). Their mechanism of action is mediated by the stabilization of the PPARγ β-sheet containing Ser245 [2].

Recently, we disclosed the PPARγ non-agonist activity of 4-(4-bromophenyl)-3-hydroxy-5-(3-hydroxyphenyl)furan-2(5H)-one (**1**), which is able to block the phosphorylation of the enzyme without direct inhibition effect of both CDK5 and PPARγ [2]. We combined computational strategies and crystallographic experiments to deeply investigate the interaction of **1** with PPARγ and design innovative candidates, endowed with higher affinity for the target. The new derivatives, characterized by K_D values in the nanomolar range, improved the affinity for PPARγ of more than ten times compared to that of **1**. Furthermore, we successfully employed a bioisostere strategy to effectively improve the biostability of our compounds, thereby optimizing their pharmacokinetic profiles and therapeutic potential.

Of note, an innovative green synthetic approach was tackled in several steps, where the traditional organic solvents were replaced with bio-based solvents derived from biowaste, or from very cheap and easily accessible natural sources [3].

Overall, these outcomes, obtained combining computational, crystallographic, and innovative synthetic approaches, proved that the γ-hydroxy-lactone scaffold may provide a promising template for the development of novel anti-diabetic agents targeting PPARγ, without any transactivation potential or agonist activity. This innovative strategy could transform the treatment landscape for millions of individuals suffering from metabolic disorders, allowing the development of a safe treatment of insulin resistance.

Exploring Substituent Effects on π-π Stacking Interactions: Investigation of Benzene Dimers

A. Artasensi,[a] A. Macorano,[a] A. Pedretti,[a] L. Fumagalli,[a] G. Vistoli,[a]

[a] *Department of Pharmaceutical Sciences, Università degli Studi di Milano, 20133, Milan, Italy.*
angelica.artasensi@unimi.it

Noncovalent interactions are pivotal factors in controlling structural and energetical aspects of molecular recognition/sensing and self-assembling/engineering[1,2]. Particularly, π-π stacking stands out in the biological context, where these interactions commonly occur among the nucleobases and the aromatic amino acid residues. Despite their biological significance, our knowledge of these fundamental nonbonded interactions is still far from being complete, and our ability to predict their strength is limited. In this context, we are yet unable to correctly parametrize the role of aromatic substituents although they can influence the energy interaction and may provide a way to tune π-π interactions. Such insights may also help the design of new bioactive molecules and materials with desired physical and chemical properties. Thus, we decided to analyze these intramolecular interactions with high-level theoretical methods in order to determine the contribution of each substituent to the energy landscape. In this study, we used *ab initio* and density functional theory (DFT) to study π-π stacking interaction energies of benzene dimers. Specifically, we assessed substituent effects by introducing various electron-donating and -accepting groups on one benzene ring, examining the dimer across three configurations (T-shaped, sandwich, and parallel display) throughout its potential energy curves. The energies of the π-π interactions were compared with those of couple cluster (CC) one, widely considered the "gold standard" in quantum chemistry. Concomitantly, the influence of aromatic substituent on π–π interactions was also experimentally investigated. For this purpose, we performed HPLC analyses of the analytes on different chromatographic stationary phases.

Tumour metastases are still the leading cause of cancer-related death, being often responsible for the failure of current therapies.[1] In our previous work, we have developed a compound, AA6, that proved able to counteract the metastatic spread in a mouse model of breast cancer.[2] To identify the essential structural elements and the cellular target involved in the activity of our lead compound, a new series of AA6-derivatives was designed and synthesised. New compounds were tested for the inhibitory activity on tumour cell invasion, migration and adhesion in B16-F10 melanoma cells. From the *in vitro* results, compound CM365 was selected as the most promising derivative, showing good efficacy and most likely able to interact with the target through covalent binding. To pinpoint the cellular target, a proteomic analysis was carried out and this allowed to select septin-4 as the most likely protein involved. Septins are GTP-binding proteins, able to assemble into large filaments on the plasma membrane, modifying its rigidity in migrating cells and promoting tumour metastasis.[3] To study and compare the binding modes of the two derivatives, AA6 and CM365, with the molecular target, computational analyses were performed. Finally, the anti-metastatic properties of CM365 were evaluated *in vivo* in a murine model of metastatic melanoma. This compound proved capable of reducing metastases dissemination at different times of administration and of enhancing the antitumour effect of a known anticancer drug, paclitaxel, when administered in combination. The discovery of septin-4 as a new molecular target for the prevention of metastatic spread may encourage the future development of more specific inhibitors.

Cancer is the second global cause of mortality, accounting for nearly 10 million deaths in 2022.[1] Despite significant advancements in oncological treatments, poor outcomes are still associated with chemoresistance, metastasis, and the rise of cancer stem cells (CSCs). Targeting these latter represents a promising approach for overcoming the limits of the traditional cancer treatments. In this context, the Aldehyde Dehydrogenase (ALDH, EC: 1.2.1.3) family recently garnered significant attention from the scientific community, with the isoform1A3 being identified as a CSC marker[2] and overexpressed in several tumors, *e.g.,* glioblastoma multiforme. Our research group developed a library of diphenyl imidazo[1,2-*a*]pyridines as potent ALDH1A3 inhibitors and **NR6**, showing a 2,6-substitution pattern, emerged with a subnanomolar EC_{50} on ALDH1A3-overexpressing cell lines and an IC_{50} value of 5.3 µM in enzymatic inhibition assays.[3] Noteworthy, the presence of 3-cyanophenyl substitution in position 6 in **NR6** seems to play a key role in interacting with the enzyme, as suggested by crystallographic studies.[4] Aiming to improve solubility and enhance the inhibitory potency of such compounds, we explored the effect of different substitutions on the phenyl ring at position 2 of the heterocyclic core, thereby generating a novel series of **NR6** derivatives which allowed the construction of structure-activity relationships and address the synthetic efforts in the lead optimization process.

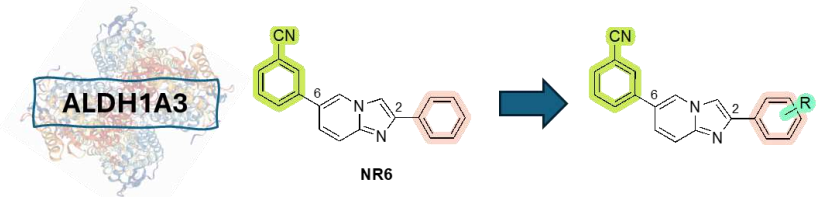

Figure 1: Chemical structure of NR6 and its derivatives series herein investigated.

caterina.deruvo@uniba.it

Human serum albumin (HSA) is the most abundant protein in plasma, playing an important role in drug transport and pharmacokinetics. Many nutrients and food bioactive compounds are strong HSA binders, affecting by competition the HSA binding of drugs.[1]

Although no significant interactions with foods, dietary supplements, and herbs by direct-acting oral anticoagulants (DOACs) have been shown, some recent clinical observations suggested that food ingredients can modulate bioavailability and activity of DOACs by affecting the plasma concentration of the drugs.[2]

Herein, applying surface plasmon resonance (SPR),[3] and fluorescence spectroscopy in competition experiments, we investigated how some nutrients, such as flavonoids (catechin, quercetin), caffeine and saturated fatty acids (myristic and palmitic acids) interfere with the HSA binding of DOACs, namely rivaroxaban, edoxaban, apixaban and dabigatran etexilate, as compared to the classical oral anticoagulant warfarin. The binding interactions were also investigated by molecular docking calculations.

Figure 1. 3-D Structures of edoxaban and human serum albumin (HSA), and SPR sensorgrams in affinity experimental determination.

Drug	HSA, K_D (μM)	
	SPR	*literature*
edoxaban	16.8 ± 1.3	10.1 ± 0.5
rivaroxaban	5.60 ± 0.51	7.5 ± 0.10
Warfarin	3.85 ± 0.30	3.30 ± 0.33

Targeting RNA for degradation with small molecules: design and synthesis of selective RNA binders and development of ribonuclease targeting chimeras (RIBOTACs)

F. Sdei,[a] G. Bagnolini,[a] F. Falchi,[a] M. Ghezzo,[b] A. Sosic,[b] C. Sissi,[b] M. Roberti,[a] M.L. Bolognesi[a]

federico.sdei2@unibo.it

RNA has been successfully targeted by small molecules for drug discovery purposes, by taking advantage of binding sites available upon rearrangement of RNA into secondary and tertiary structures.[1] A validated RNA target is pre-miR-21, a non-coding RNA, linked to various cancers and other pathologies.[2] This project aims to develop selective binders to target pre-miRNA21 and in turn decrease miRNA21 levels. To identify RNA ligands, we used a virtual screening, taking advantage of RNA binders reported in literature. Those compounds were docked against different possible conformations of pre-miRNA21. Here, the best compounds were selected for further synthesis. We identified two fragments, selected for a fragment growth campaign. Indeed, by following an optimized synthetic strategy, we obtained several derivatives that have been tested for their binding affinity to the short pre-miR-21 construct by high-resolution mass spectroscopy (MS) under native conditions. Binding data from native MS will guide ongoing structure–activity relationship (SAR) studies for the expansion of ligand library and the development of more potent and selective pre-miRNA21 ligands. Subsequently, pre-miRNA21 ligands will be employed as warheads to synthesize Ribonuclease Targeting Chimeras (RIBOTACs), a class of RNA-degraders.[3] RIBOTAC includes an RNA-binder conjugated by a linker to an RNase L recruiter, ultimately to induce enzymatic cleavage the RNA of Interest (ROI). (Figure 1).

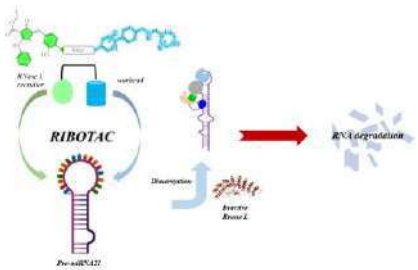

Figure 1: Formation of a ternary complex between RNA-RIBOTAC-RNase L which induces the consequent selective degradation of the ROI (RNA Of Interest).

New Biofilm Inhibitors to Fight Antibiotic Resistance

G. Marotta,[a] L. Braconi,[a] A.C. Conti,[b] E. Perrin[b], D. Manetti,[a] M.N. Romanelli,[a] E. Teodori.[a]

giambattista.marotta@unifi.it

Biofilms are aggregates of bacteria embedded in a self-produced matrix, that is composed of exopolysaccharides, proteins and nucleic acids.[1] Nowadays biofilm is considered a serious threat in infectious disease management, due to its ability to confer the bacterial cells a higher degree of resistance to antibiotics: indeed, its structure works as a barrier impeding the penetration of the drug or other xenobiotics into the cell.[2]

There are many mechanisms involved in the formation of biofilm, one of which is the Quorum Sensing (QS), a complex machinery governing the assembly of the structural components of biofilms, via the secretion of signalling molecules called autoinducers.[3] Based on these premises, as a continuation of a previous research, we designed new compounds acting as QS antagonists to prevent biofilm formation or to disrupt already formed biofilm in different strains of Gram-negative bacteria (figure 1).

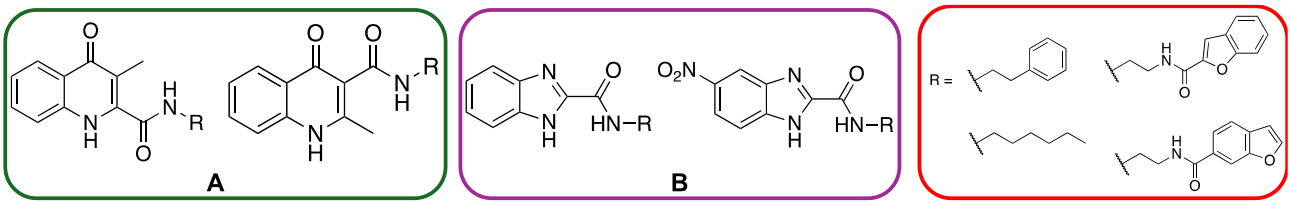

Figure 1: New molecules acting as biofilm inhibitors.

Compounds belonging to series A were based on the structure of 2-alkyl-4(1*H*)-quinolone derivatives, a group of potent autoinducers involved in QS signalling of *P. Aeruginosa*, while those in series B were conceived by drawing inspiration from some benzimidazole hybrids acting as anti-QS agents.[3] Both series of molecules have a common motif composed by a heterocyclic head, an amide spacer, and a side chain R carrying moieties with different steric and electronic features.

Early *in vitro* assays were performed on *B. Cenocepacia*, showing a promising ability of such compounds to reduce the biofilm formation up to 30%, while those on *P. Aeruginosa* and other Gram-negative bacteria are currently underway. These results enabled us shed lights on the structural features required for an anti-biofilm profile, thus constituting a starting point for a further optimization of the QS antagonist activity.

Design and synthesis of Rad51-BRCA2 protein-protein interaction disruptors to trigger synthetic lethality in pancreatic cancer cells

G. Ferrandi,[a] L. Poppi,[a] G. Bagnolini,[a] F. Falchi,[a] M. Roberti,[a] A. Cavalli[b]

[b]*CECAM, EPFL, Lausanne, Switzerland*
e-mail: giovanni.ferrandi2@unibo.it

Synthetic lethality (SL) is a phenotypic condition in which cells do not survive due to the combination of two genetic perturbations that, taken individually, do not induce cell death. A successful application is the use of PARP inhibitors in cancer patients with BRCA2 mutations. One of the key mechanisms of BRCA2 is to recruit the Rad51 to the site of double-strand breaks where it performs homologous recombination repair.[1] Our research project focuses on the development of Rad51-BRCA2 protein-protein interaction (PPI) disruptors that mimic the BRCA2 mutation to trigger fully small organic molecule SL in combination with Olaparib in BRCA2-functional pancreatic cancer cells.[2,3]

Through a virtual screening campaign on a PP critical "hotspot" on Rad51 surface, a quinoline-structured Rad51-BRCA2 disruptor (**ARN22142**, Scheme 1) has been identified. To discover more effective compounds and depict general structure-activity relationship studies, the chemical space around **ARN22142** has been explored by optimizing a general synthetic strategy and building a library of quinolinic analogues modified in two moieties of interest (red and blue residues, Scheme 1). Among the synthetized compounds, **ARN26912** (Scheme 1) has showed synergism on the antiproliferative efficacy with Olaparib in BRCA2-proficient pancreatic cancer cell lines. This supports the idea that small organic molecules can mimic genetic mutations. Further in vitro biological studies will be done with this promising compound.

Funding: This work is financially supported by the Italian Association for Cancer Research AIRC (IG 2018, id 21386).

Pseudomonas aeruginosa (*PA*) is a ubiquitous Gram-negative bacterium. Pulmonary infections caused by *PA* represent a serious threat, especially to patients with cystic fibrosis (CF). This risk is further exacerbated by the increasing spread of bacterial strains that show antibiotic resistance[1]. The ease with which *PA* can colonize the respiratory tract depends on its ability to proliferate even in environments where essential metals (such as Zn) are present in low concentration. In particular, zinc plays a fundamental role, as it is present in many bacterial proteins crucial for virulence. A peculiar tactic of *PA* to obtain zinc involves the secretion of pseudopaline (Fig. 1), that is a low molecular weight zinc chelating molecule, capable of binding zinc present in the external environment, extracting it also from proteins present in the host, and deliver it inside the bacterial cell[2]. The mechanism by which the zinc pseudopaline complex is transported into the bacterial cell has not yet been completely defined.

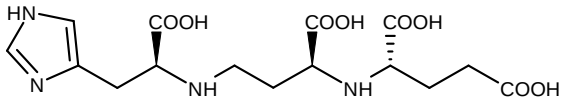

Figure 1: structure of pseudopaline.

The use of pseudopaline to chelate zinc represents a potential vulnerability of the pathogen, which can be exploited to allow antibiotics to enter the cell via the Trojan horse approach[3]. The aim of this study is to synthesize simplified analogs of pseudopaline, to evaluate the minimal structural requirements needed to participate in the zinc transport process of *PA*. These simplified zincophore compounds, simpler to synthesize than pseudopaline, can be more easily conjugated to various antibiotics that are still in use and active against these *PA* (such as aztreonam or ampicillin), to facilitate their entry into the bacterial cell through a preferential pathway. The antibacterial activity of these conjugates is evaluated against different *PA* strains to confirm the involvement of the zinc recovery pathway and demonstrate the proof of concept of the Trojan horse approach.

naomi.scarano@edu.unige.it

Sirtuin-2 (SIRT2) is a (NAD^+)-dependent enzyme with deacetylase activity[1]. Dysregulation in SIRT2 activity was shown to be related to a plethora of diseases, such as neurodegenerative disorders, cancer and metabolic syndromes[2]. Several conformationally diverse X-Ray structure of SIRT2 are available at the Protein Data Bank (PDB), both in the holo- and apo-states. With the aim to discover novel SIRT2 inhibitors (SIRT2Is) via structure-based virtual screening (SBVS), a preliminary study for the evaluation of the available SIRT2 PDB structures for the following VS was performed, scouting single- and multiple- protein conformation approaches. The structure ability to select SIRT2Is within a set of decoys was evaluated by Receiver Operating Characteristic AUC (ROC-AUC). The best system was chosen to screen the ChemDiv commercial library (>22,000 compounds), guiding the discovery of novel chemo-types endowed with modest SIRT2 inhibitory ability. This piece of information paved the way for the following SBVS of novel pyrazolo-pyrimidines and thiazole-based compounds exhibiting ameliorated SIRT2 inhibitory ability[3,4] (Figure 1).

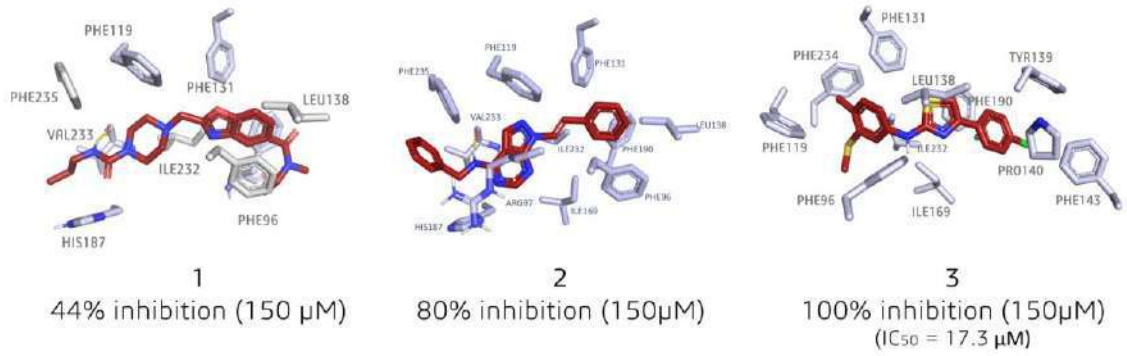

Figure 1: Hit compounds retrieved with the structure-based drug design approach.

A Computational Facility for Lead Identification integrated within VITALITY enabling Platform for Drug Discovery

G. M. Elisi,[a] M. Ymeraj,[a] V. Lembo,[a] G. Bottegoni[a]

[a]*Dipartimento di Scienze Biomolecolari, Università degli Studi di Urbino, Piazza Rinascimento 6, 61029 Urbino*
gianmarco.elisi@uniurb.it

After the challenges posed by the Covid-19 pandemic, and by leveraging funds from the National Recovery and Resilience Plan to stimulate growth and foster resilience, universities and other institutions from Central Italy capitalised on their expertise to establish a platform to devise innovative therapeutic approaches within the context of VITALITY project (Figure 1). As a key objective, our research group is setting up a computational facility accessible to third parties to speed up preclinical stages of drug discovery programs through virtuous iterative design-make-analyse cycles.

At the core of the initiative, an HPC platform at the University of Urbino has been set-up consisting of a small cluster endowed with GPUs, enabling the application of deep learning algorithms and the acceleration of molecular simulations. Workflows ready for virtual screening campaigns have been devised, including ultra-large library screening approaches and post-processing tools for rescoring.

Neural networks to prioritize compounds for physics-based scoring[1] and the integration of one-dimensional shape screening with structure-based techniques[2] have been included as capabilities effectively enabling large-scale campaigns. For this purpose, libraries in a format suitable for docking calculations are available to end-users, including diversity sets, biomimetics, covalent ligands classified by their reactive warhead, the entire Enamine REAL stored as binary fingerprints, and a curated academic library of pre-synthesized compounds.

Semi-automated pipelines, including fast rescoring of docking poses via free-energy methods[3] and a pharmacophore-based utility for covalent ligand identification, complement those assets. Finally, a series of scripts allowing for batch interrogation of online databases allow for library filtering and annotation, for target identification in phenotypic screening and for off-targets de-risking.

anastasia.ferraro@unina.it

In COVID-19 pandemic context, the scientific community mobilized extensive efforts to speed up the discovery of effective vaccines and potent antiviral drugs to counteract the rapid transmission and infection of SARS-CoV-2[1]. Particular attention has been devoted to SARS-CoV-2 essential targets in the viral life cycle, notably the main protease (M^{pro}) and polymerase, with small focus on the helicase[2]. Our research interest has been directed towards the helicase of SARS-CoV-2 (NSP13), the less explored target, but highly conserved across coronavirus family, indicating its potential as a target for pan-coronavirus antiviral therapies[3,4].

Previous studies have reported Pyridobenzothiazolones (PBTZS) as NS5 polymerase inhibitors of different Flavivirus in cell lines with potency ranging from low to sub-μM levels, and importantly, without toxicity[5]. The PBTZs' activity as "pan-Flaviviruses' inhibitors" induced us to explore their potential activity as Coronaviruses inhibitors. Therefore, we set up a screening cascade for SARS-CoV-2 that consisted in: i) antiviral phenotypic screening; ii) enzymatic assays M^{pro}, polymerase and helicase. Remarkably, all compounds demonstrated specific inhibition of the helicase and NTPase functionalities of NSP13 with an IC_{50} from 0.2 to 20 μM. One of the most identified hit showed IC_{50} = 0.32 ± 0.22 μM in helicase assay, and 4.4 ± 1.1 μM NTPase assay, with an antiviral potency EC_{50} = 10.37 ± 1.3 μM in VeroE6-GFP cells, and CC_{50}> 100 μM. We proceeded with the design of a small set of novel analogues to further investigate this new class of NSP13 helicase and NTPase inhibitors. In the absence of a co-crystal structure, our design strategy relied on a ligand-based structure-activity relationship (SAR) study. Two derivatives, namely F2F-2020406 and F2F-2020400, exhibited enhanced activity and selectivity.

Considering the current state of art of NSP13 inhibitors, this initial exploration identified a novel class of inhibitors with low μM antiviral activities of NSP13 helicase and NTPase enzymatic functionalities and importantly demonstrating activity against SARS-CoV-2 replication in cell-based assays.

chiarasarnari97@outlook.it

ADP-ribosylation, a reversible post-translational modification of proteins, is catalysed by a large family of enzymes (17 in humans) known as PARPs. While poly-ADP ribosylating enzymes (poly-ARTs) are well characterized with some approved anticancer compounds that represented an important step forward towards targeted therapy, mono-ADP ribosylating enzymes (mono-ARTs) still remain less understood. However, the interest toward these enzymes has grown due to their pivotal roles in various cellular processes such as cell replication, immune modulation, apoptosis, stress response, and neurodevelopment. Furthermore, targeting mono-ARTs shows promise in treating not only cancer but also inflammation and neurological disorders.[1] Despite the hot topic of this research field, the mono-ARTs inhibitors development is still at an early stage. Being the NAD pocket highly conserved among all the PARPs subfamilies and since most of the inhibitors work as NAD mimetics, the development of highly selective ARTs inhibitors still remains one of the major challenges to fight with.[1]

In this scenario, by exploring innovative heterocycles as new nicotinamide mimicking scaffolds, we have recently identified the most potent PARP10 and dual PARP10/PARP15 inhibitors described to date.[2,3] Based on these valid starting points and aiming to increase even more the selectivity and inhibit other specific enzymes within the mono-ARTs subfamily, a further SAR exploration has been performed. In particular, taking advantages of the available co-crystallographic structures, various modifications were made to reach some less conserved regions (*e.g.* D-loop or mono-ARTs hydrophobic cavity) of the PARPs catalytic domain for achieving specificity.

All of the synthesized compounds were tested against a wide panel of PARPs, from which interesting derivatives with new SAR insights emerged; the best derivatives were also characterized in cellular context and preliminarely studied for their ADMET properties. The results will be the object of the presentation.

gabriella.laspada@uniba.it

Neurodegenerative diseases (NDs) and cancer represent a global health problem. For NDs treatments, the current focus is on different targets including cholinesterase, monoamine oxidases (MAOs) and adenosine receptors (ARs). Due to their higher density in the brain, the most involved ARs are A_1R and $A_{2A}R$. Evidence indicates that $A_{2A}R$ plays a crucial role in the pathogenesis of Parkinson's disease (PD), linked to motor impairment managing and neuroprotection. Epidemiologic studies show an inverse correlation between the consumption of caffeine (a methylxanthine antagonist of AR) and the risk of developing PD [1][2]. The activity of A_1R and $A_{2A}R$, controlling the release of neurotransmitters (e.g. glutamate and acetylcholine) take part in modulating and integrating cognition and memory functions [3][4]. Studies suggest that in both Alzheimer's disease mouse models and humans, caffeine prevents the acute memory impairment [5][6]. For cancer monoamine oxidases, matrix metalloproteinases (MMPs) and ARs are attractive targets. It has been discovered that adenosine, which increases in hypoxic regions of solid tumours, can hinder the immune system's ability to recognize tumour cells by cytolytic effector cells [7][8]. We have selected compounds among an in-house chemical library with known activity as inhibitors of MMP 2 and 9, acetylcholinesterase, MAO A and B. The aim of this work is to identify additional activities targeting at ARs conferring to our molecules a multitarget activity profile. Thus, compounds bearing different scaffolds (coumarins, hydroxamic acids and barbituric acids) have been screened on the different adenosine receptors (A_1, A_{2A}, A_{2B}, A_3). The Bioluminescence Resonance Energy Transfer Assay using CHO cells expressing human adenosine receptors is being employed to assess the biological activity. Multitarget activity profile of previously disclosed inhibitors will be presented.

bianca.martinengo2@unibo.it

Selective oxyfunctionalisation of non-activated C-H, C-C and C=C bonds is a highly desirable transformation with broad implications in various product syntheses, including pharmaceuticals. However, the introduction of functionalities into the inert backbones of organic molecules is challenging. Biocatalysis is emerging as a powerful tool that exploits the substrate specificity, chemo-, enantio- and regioselectivity of enzymes under mild conditions.[1] Fungal unspecific peroxygenases (UPOs), a class of simple and robust haem thiolate-containing enzymes, catalyse a range of C-H oxyfunctionalisation reactions. When activated by H_2O_2, UPOs exhibit a kaleidoscope of oxyfunctionalisation reactions, positioning them as promising biocatalysts in synthetic chemistry.[2] The exploration of the biotransformation of food waste into high-value compounds via biocatalysis has attracted considerable interest, particularly in medicinal chemistry. Cashew nutshell liquid (CNSL), a by-product of cashew nut processing, is a natural source of phenolic compounds with a pentadecyl alkyl side chain with varying degrees of unsaturation.[3] While CNSL is a promising source of drug precursors, its biocatalytic functionalisation to drugs remains unexplored. As an alternative approach, we propose to functionalise the pentadecyl alkyl side chain of CNSL derivatives using biocatalytic oxidative systems, providing a sustainable alternative. Ongoing investigations aim to further elucidate the potential of this methodology in advancing drug discovery efforts for neglected tropical diseases (NTDs), highlighting the promising role of biocatalysis in sustainable synthetic pathways.

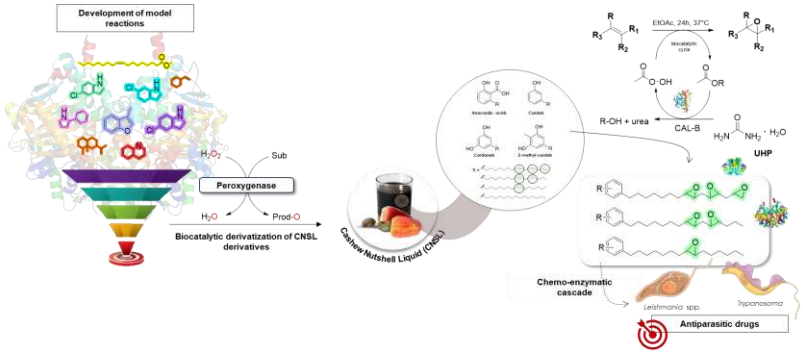

Figure 1: Biocatalytic derivatization of natural lipids, building blocks, and CNSL derivatives.

Focal adhesion kinase (FAK) is a nonreceptor tyrosine kinase overexpressed in numerous solid cancers playing a crucial role in regulation of cell adhesion, migration and invasion. Additionally, FAK modulates both cellular and molecular composition of the immunosuppressive tumour microenvironment. Recently, we described the synthesis and the antiproliferative activity of a series of 3-(imidazo[2,1-*b*][1,3,4]thiadiazol-2-yl)-1*H*-indole derivatives, which showed potent *in vitro* antiproliferative and antimigratory activity against numerous cancer cell lines belonging to the NCI full panel and PDAC panel, with GI_{50} values ranging from micromolar to sub-micromolar level.[1] Further studies identified the inhibition of phosphorylation of PTK2/FAK as the mechanism of action of this class of compounds. Based on the interesting antiproliferative activity observed for the imidazothiadiazole scaffold and the FAK inhibitory activity described in literature for pyridine compounds[2] we synthesized new derivatives bearing 3-pyridinyl and 4-pyridinyl nucleus at position 6 of the imidazothiadiazole nucleus, with the aim to obtain new anticancer agents targeting FAK.
Interestingly, some of the synthesized compounds exhibited an outstanding antiproliferative activity against several human cancer cell lines, being able to induce cancer immunogenic cell death (ICD).

Development of heterobifunctional small molecules for prion diseases

E. Uliassi,[a] G. De Leo,[b] L. Nikolic,[b] G. Legname,[b] M. L. Bolognesi[a*]

[a]*Department of Pharmacy and Biotechnology, Alma Mater Studiorum - University of Bologna, Via Belmeloro 6, 40126 Bologna, Italy*

elisa.uliassi3@unibo.it

Prion diseases are a group of lethal, infectious neurodegenerative diseases, involving a protein infectious agent that propagates the disease by transmitting protein conformational changes. The conversion of the cellular prion protein (PrP^{C}) into misfolded isoforms (PrP^{Sc}) is the main event in prion diseases. However, the mechanism by which this process results in brain damage and disease is largely unknown. Such unorthodox nature makes the search of effective anti-prion compounds highly challenging.[1] As a result, there is not a viable cure yet. Given the extensive validation of the PrP hypothesis, there have been several efforts to develop PrP-lowering therapies, but proximity-based modalities aimed to induce PrP degradation (and to lower its cellular level), have so far been never exploited. Thus, we sought to harness proteolysis-targeting chimeras (PROTACs, Figure 1), a leading proximity-based modality in drug discovery.[2] Thanks to their bifunctional nature, PROTACs may induce proximity between the PrP protein and a ubiquitin E3 ligase to trigger targeted PrP ubiquitination and subsequent degradation.

Following visual inspection of the available PrP-ligand complexes, an initial set of potential PrP-directed PROTACs was designed and synthesized by tethering a diphenylmethane-based PrP ligand with an E3 binder via different linkers. Preliminary investigation in noninfected neuronal N2a cells and RML strain scrapie-infected N2a (ScN2a-RML) cells to evaluate cytotoxicity and anti-prion activity is being performed.

Encouraged by their success with undruggable proteins, PROTACs hold enormous potential to unlock drug discovery efforts against this challenging target and to find an effective cure for prion diseases.

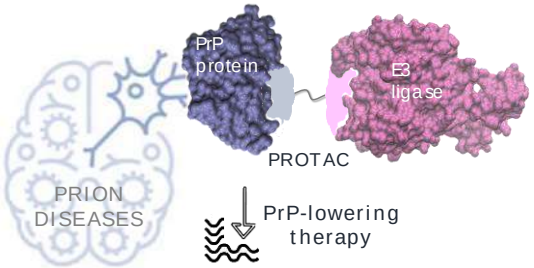

Figure 1: Bifunctional PROTACs directed to PrP.

Novel FtsZ inhibitors identified by virtual screening and Adaptive Steered Molecular Dynamics

P. Sciò,[a] S. Buroni,[b] A. Coluccia,[a] M. Bufano[a]

[a]*Laboratory Affiliated with the Institute Pasteur Italy-Cenci Bolognetti Foundation, Department of Drug Chemistry and Technologies, Sapienza University of Rome, Piazzale Aldo Moro 5, Roma*

pietro.scio@uniroma1.it

Filamentous temperature-sensitive Z (FtsZ) protein represents a promising antibacterial target owing to its essential role in bacterial cell division[1]. Serving as the prokaryotic functional homologue of tubulin, FtsZ polymerizes into protofilaments orchestrating the formation of the Z-ring during binary fission.

A molecular docking and pharmacophore based virtual screening campaign resulted in the discovery of a novel FtsZ polymerization inhibitor exhibiting an IC_{50} potency of 48 μM. The promising in-vivo MIC of 2 mg/mL was achieved in presence of a efflux pump inhibitor (PaβN[2]). To enhance potency and diminish affinity towards efflux pumps, an Adaptive Steered Molecular Dynamics (ASMD) based drug design approach was employed.

ASMD[3] presents a refinement of the Steered Molecular Dynamics (SMD) technique where the driving of a steered particle (i.e. the unbinding of a ligand) is performed by a time-dependent harmonic force in stages. Unlike SMD, which requires a large number of replicas to encompass all potential unbinding configurations and generate a reliable Potential of Mean Force (PMF) along the reaction coordinates using Jarzynski's Equality (JE), ASMD optimize this process by segmenting the unbinding pathway into stages and discarding trajectories that significantly deviate from the equilibrium path at the conclusion of each stage.

Structural analogues of the discovered inhibitor were purchased and tested to build preliminary structure-activity relationships (SAR) and the trends in inhibitory activities were retrospectively predicted by ASMD. The optimized parameters obtained from this analysis were utilized in the rational design a new derivative, featuring chemical moieties tailored towards mitigating bacterial efflux and enhancing potency.

ela.radosevic2@unibo.it

PROteolysis TArgeting Chimeras (PROTACs) are heterobifunctional small molecules which, by recruiting specific proteins of interest (POI) for ubiquitin-mediated degradation, control protein levels rather than modulating its function.[1] Alzheimer's disease (AD) is a complex neurodegenerative disorder characterized by the accumulation of misfolded proteins, synaptic dysfunction, and progressive cognitive decline and with no effective treatment up to date. Emerging evidence suggests a significant involvement of circadian rhythm dysregulation in the pathogenesis of AD, with protein kinases, such as CK1, playing a crucial role in modulating circadian processes.[2]

For that purpose, a small library of CK1-targeting PROTACs was designed based on benzothiazole derivatives originally developed for Amyotrophic Lateral Sclerosis (ALS), with promising potency, proven BBB permeability and already explored SAR.[3] Within this series, a combination of three different positions on POI ligand, two on cereblon recruiter, and two different linker lengths will be examined to determine optimal geometry for formation of effective ternary complexes. Currently, synthesis is in progress and, once obtained, compounds will be tested for in vitro potency and initial pharmacological and ADMET evaluation. Cell proof of concept studies will demonstrate effective degradation of the POI.

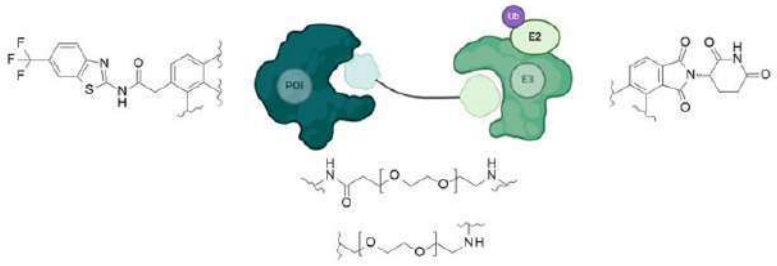

Figure 1: Design of first CK1-directed PROTACs analogues.

Metallo-β-Lactamases (MBLs) are enzymes able to catalyze the hydrolysis of a broad range of β-lactam antibiotics, including carbapenems.[1] Among these, the New Delhi Metallo-β-lactamase-1 (NDM-1) variant confers resistance to a wide variety of antibiotics, such as penicillins, cephalosporins, and carbapenems. The rapid global dissemination of NDM-1 is causing growing concern in the scientific community due to its wide spectrum of action, ability to select variants, and transferability, posing a significant risk of a new bacterial pandemic. Despite the availability of various Serine-β-lactamase mechanism-based inhibitors in therapy, there is currently a lack of specific and effective inhibitors against NDM-1 in clinical practice.[2] Consequently, there is an urgent need to identify clinically useful inhibitors of MBLs that can be co-administered with existing β-lactams to restore their antibacterial activity. To address this emerging challenge, we employed the Pharmacological Protein Inactivation by Folding Intermediate Targeting (PPI-FIT) technology to discover non-conventional degraders of NDM-1.[3] PPI-FIT represents a novel and advanced drug discovery approach based on the concept of regulating protein levels by targeting folding intermediates. Using this approach, we identify potential druggable pockets within a relevant folding intermediate of NDM-1, distinct from its native conformation and catalytic site. Subsequently, a structure-based virtual screening was exploited, leading to the identification of virtual hits. In this study, we outline our strategy, which integrates medicinal chemistry, structural biology, biochemical testing, and microbiological profiling, to identify novel non-conventional degraders of NDM-1.

Alzheimer's disease (AD) is an intricate neurodegenerative disorder with no effective cure, thus necessitating new therapeutic approaches. Recent research indicates a significant association between disturbances in the circadian rhythm and the development of AD, underscoring the circadian clock (CC), as a promising point of intervention[1]. In this context, we envisioned the development of Multi-target-Directed Ligands (MTDLs)[2] to modulate CC dysfunction in AD. We focused on the selective modulation of two kinases, glycogen synthase kinase-3 beta (GSK3-β) and casein kinase 1-delta (CK1-δ), which have been identified as pivotal regulators of CC. We designed a novel set of MTDLs starting from highly potent, BBB permeable, and GSK3-β and CK1-δ selective inhibitors reported in the literature. By identifying common structural requirements of each kinase and employing *in silico* calculations, we have identified the maleimide core as an optimal scaffold to generate dual GSK3-β/CKI-δ inhibitors. The optimization of the synthetic route is currently being performed to provide an initial set of potential maleimide-based MTDLs. These will be subsequently evaluated *in vitro* for their inhibitory profile against GSK3-β and CKI-δ, ADMET properties and cytotoxicity.

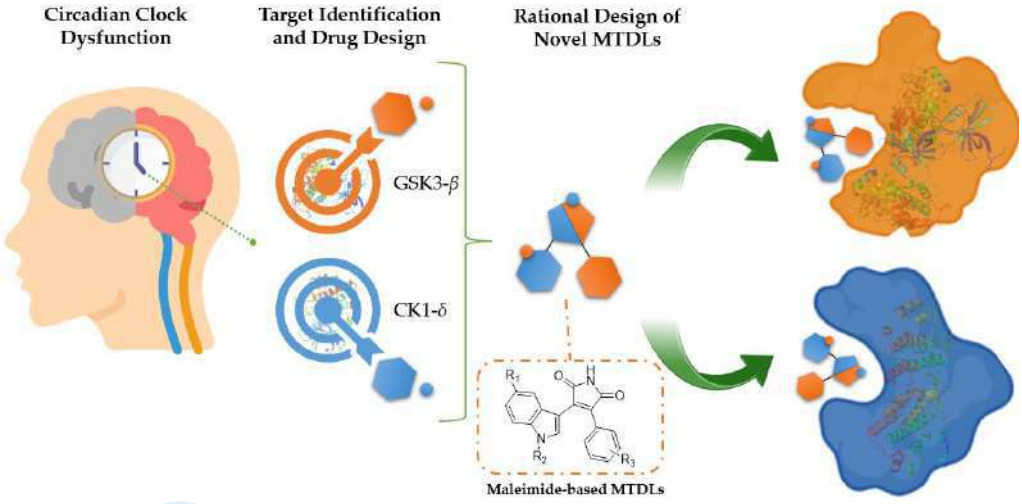

Figure 1: Design of the first set of potential MTDLs against GSK3-β and CK1$_\delta$

iole.mannella@unito.it

Tuberculosis (TB), caused by the bacillus Mycobacterium Tuberculosis (MTB), persists as one of the oldest diseases despite being curable. However, it remains the world's second leading cause of death from a single infectious agent, with 7.5 million new cases diagnosed globally in 2022[1], underscoring the urgent need for novel treatments, especially in the face of emerging drug-resistant MTB strains. Inhibition of crucial enzymes and pathways in MTB has been a focal point in the development of new drugs. Enzymes involved in nucleotide biosynthesis have emerged as promising targets due to their vital role in providing building blocks for DNA and RNA. Perturbations in cell metabolism can profoundly affect the proliferation of both infected cells and pathogens, rendering these enzymes pivotal targets for therapeutic interventions.

In the tuberculosis mycobacterium, dihydroorotate dehydrogenase (*mt*DHODH), a crucial enzyme of the *de novo* pyrimidine biosynthesis pathway, is indispensable for its replication. Our recent efforts have focused on characterizing the full-length *mt*DHODH, resulting in the successful determination of the crystal structure of the protein[2]. Through screening our *in-house* compound library, we have identified MEDS322 as the first inhibitor of *mt*DHODH known so far.

Here, we present the synthesis and biological evaluation of MEDS322 and its analogues based on a thiazolidinone ring scaffold as the first *mt*DHODH inhbitors.

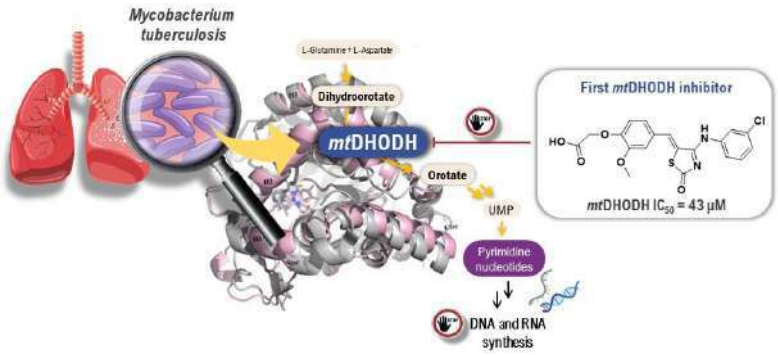

Figure 1: Representation of the *Mt*DHODH crystal structure and the first inhibitor of the series.

Vector-borne parasitic diseases (VBPDs) pose a significant threat to public health on a global scale. Collectively, Human African Trypanosomiasis (HAT), Leishmaniasis and Malaria threaten millions of people particularly in developing countries. Climate change might alter the transmission and spread of VBPDs, leading to a global burden of these diseases. Thus, novel agents are urgently needed to expand the therapeutic options and limit the spread of drug-resistance parasites.

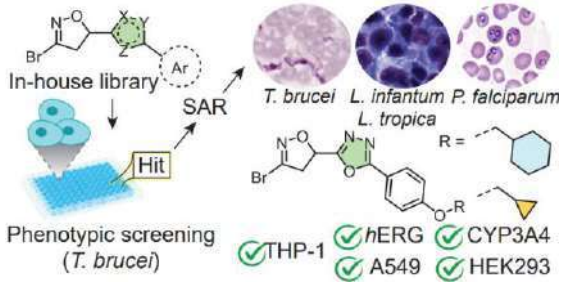

Figure 1: Strategy for the discovery of novel 1,3,4-oxadiazole derivatives

We screened an in-house library of antileishmanial and antimalarial compounds[1] towards *Trypanosoma brucei* (*T. brucei*) and we identified a 1,3,4-oxadiazole derivative as an anti-*T. brucei* hit compound, with predicted blood-brain-barrier permeability. Subsequently, extensive SAR studies around the lipophilic tail of our hit compound, led to a potent antitrypanosomal and antimalarial compound, with moderate potency also towards *Leishmania infantum* (*L. infantum*) and *L. tropica*. In addition, we discovered a pan-active antiparasitic molecule, showing low micromolar IC_{50}s towards *T. brucei* and *Leishmania* spp. promastigotes and amastigotes, and nanomolar IC_{50} against *Plasmodium falciparum*, together with high selectivity for the parasites over mammalian cells (THP-1). Early ADME-toxicity assays were used to assess the safety profile of the newly discovered compounds.

giorgia.giordano@studium.unict.it

Multi-Target-Directed ligands (MTDLs), with more than one pharmacological activity, are more efficient than single-target ligands, particularly for the treatment of multifactorial diseases such as cancer and neurodegenerative diseases. Sigma receptors (σRs) and histone deacetylase enzymes (HDACs) are under much attention due to their involvement in these diseases.[1,2] Therefore, the design and synthesis of multi-target σRs/HDACi ligands were conceived for their possible use in addressing these pathologies.[3]

The project uses computational tools to research molecules with hybrid activity for σRs and HDACs. First, the docking procedure was validated, ensuring that it reproduces the experimental K_i of known molecules, testing the method with decoys, and calculating the simulated K_i of other reported σRs and HDACs ligands.

Meanwhile, the Pharmacophore-Based Virtual Screening (PBVS) of many databases was accomplished using the Pharmit server; for all targets, the results were filtered through the Lipinski rule of five and ADMET properties and collected in a database for σRs and one for HDACs. The resulting databases were further analysed through PBVS to the other target. Molecules matching both σRs and HDACs PBVS were processed through docking simulation with YASARA. Results were carefully analyzed visually through BIOVIA Discovery Studio and selected for their fundamental interactions.

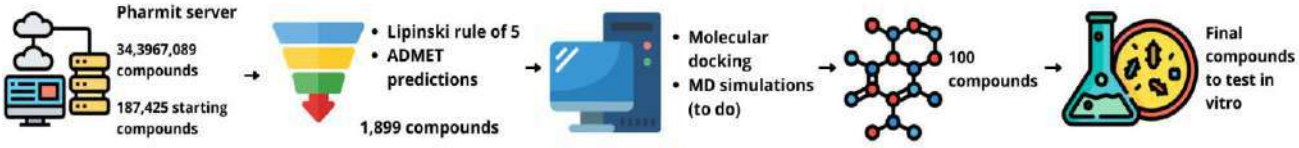

Figure 1: Virtual screening, compound filtration, and prospects workflow.

One hundred compounds were found with a high score for σRs and HDACs. From the literature some of the resulting molecules have already correlations with the σRs or HDACs, but none was studied for multi-target activity on both targets, and many of the resulting compounds are unrelated to these targets. These results will be further validated with molecular dynamic simulation, and best three compounds will be tested in vitro.

KLig Enumerator: a Tool for Library Creation Based on Kinase X-Ray Structures.

F. Ricci,[a] D. Sotillo,[a] G. Bottegoni[a]

[a] *University of Urbino, Dept. of Biomolecular Sciences, Piazza Rinascimento 6, Urbino*
Federico.ricci@uniurb.it

Kinases encompass one of the widest groups of proteins targeted in drug discovery campaigns. Not only due to their involvement in several diseases, kinases are often object of study in the context of multi – target drug discovery programs.[1]

Despite the different pockets and binding modes reported in literature for specific kinases or chemotypes, the so-called hinge region of the ATP binding site results is a conserved hot – spot for inhibitor design.[2] Furthermore, a plethora of co – crystal structures are available in the RCSB PDB and several information about ligand binding are now encoded in the KLIFS database.[3] Therefore, embedding moieties, whose binding mode in the proximity of the hinge is already known by means of crystallography, into another scaffold might be a strategy for increasing the chance of obtaining tailored kinase inhibitors and also for developing "fused" multi-target compounds.

Herein, KLig compound enumerator, a tool able to extract the fragments binding the hinge region from a list of kinase co-crystals and to connect them to a user defined scaffold, is presented.

The computational pipeline has been indeed employed to generate two libraries of potential dual inhibitors for the treatment of several multifactorial diseases, starting from a list of 4381 kinase complexes and two privileged cores. Nevertheless, further code implementations aimed at performing fully combinatorial library generation or at targeting different kinase regions are under evaluation.

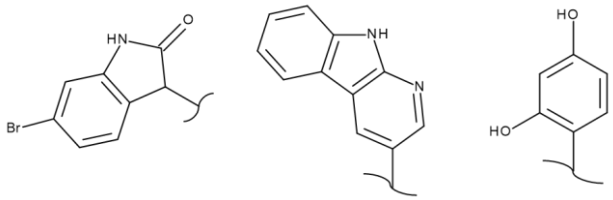

Figure 1: *Examples of hinge interacting fragments extracted by KLig.*

Structure-Based Virtual Screening targeting APSR to discover Covalent and Non-covalent Inhibitors.

M. Ymeraj,[a] G.M. Elisi,[a] G. Bottegoni[a]

[a] *Dipartimento di Scienze Biomolecolari, Università degli Studi di Urbino, Piazza Rinascimento 6, 61029 Urbino*

The discovery of inhibitors targeting adenosine 5′-phosphosulphate reductase (APSR), an essential enzyme involved in the reduction of inorganic sulphate to sulphite, crucial for synthesizing biomolecules,[1] offers a promising strategy for limiting *Pseudomonas aeruginosa* growth and antibiotic resistance. APSR enzymatic activity is attributed to its catalytic cysteine, located in the highly mobile *C*-terminal tail and executing a nucleophilic attack on the sulphur atom of the endogenous ligand adenosine phosphosulphate (APS), leading to the formation of the inactivated enzyme-thiosulphonate intermediate.[2]

To investigate the enzyme inhibition mechanism, two alternative approaches were considered to retrieve both non-covalent and covalent inhibitors. The first virtual screening workflow has been applied starting from an ultra-large library of over 6.5 billion compounds, relying on an initial shape screening protocol,[3] wherein the Enamine REAL compound collection was screened against the structure of the endogenous ligand (APS). Consequently, 100,000 compounds that displayed a higher degree of similarity, were submitted to a docking refinement procedure within the catalytic site, excluding compounds unable to fit within the protein environment. Moreover, the virtual screening workflow was complemented with short metadynamics simulations, assessing the ligand binding mode stability.

As an alternative strategy, a virtual screening campaign was set-up to discover covalent compounds targeting the catalytic cysteine. Since the crystallographic structure of APSR lacks the C-terminal tail, precluding the resolution of the Cys256, this region was built exploiting the AlphaFold model as a template for structural prediction. The obtained structure bound with different warheads was used to generate pharmacophore models able to screen and retain compounds forming reactive Michaelis complexes, to be processed with covalent docking calculations.

Our final selection of compounds, to be tested in enzymatic and cellular assays, explore alternative modalities to obtain enzymatic inhibition and an antiproliferative activity.

Huntington's disease (HD) is a hereditary condition caused by a mutation in the HTT gene, resulting in the progressive degeneration and death of neurons in certain areas of the brain. Unfortunately, there are currently no effective treatments capable of halting or preventing the onset of this debilitating disease. However, an increasing number of research suggests that the sigma-1 receptor (σ1R) may play a role in the management of various neurodegenerative disorders, including HD[1]. The σ1R is a relatively small and poorly understood membrane receptor found in the central nervous system. Its three-dimensional structure has recently been elucidated through X-ray crystallography, and it responds to various synthetic ligands, such as (+)-pentazocine (an agonist) and haloperidol (an antagonist). Studies have shown that agonists possess neuroprotective properties against neurodegenerative diseases. Nevertheless, the structural mechanisms underlying agonism or antagonism at the σ1R are not fully understood. Generally, the overall conformation of the receptor when bound to an agonist is similar to that when bound to an antagonist, except for a shift in the α4 helix by approximately 1.8Å[2]. This shift likely contributes to the agonists' ability to decrease the oligomeric state of the protein and may serves as a discriminative factor for agonist classification. Through structure-based computational methods, we designed new Iloperidone analogues as potential σ1R agonists. Indeed, very recently, a high binding affinity for σ1R of the antipsychotic Iloperidone has been demonstrated[3]. From our computational studies, including cross-docking procedures and molecular dynamics simulations, the pharmacophoric groups have emerged. In detail, the most stable interactions are established by the nitrogen atom of the piperidine ring of Iloperidone, which is positively charged at physiological pH. Starting to these data, the chemical structure of this antipsychotic drug has been modified applying a scaffold hopping approach, to obtain a pronounced and selective agonist of the σ1R. We synthesized new small molecules that retained the piperidine core and replacing the benzoisoxazole ring (responsible for a generic π-π interaction) with oximes. Additionally, we have functionalized the oxygen atom of the oxime group to enhance steric hindrance between the α5 and α4 helices, with shifts in the latter. Biological assay data will be presented and discussed.

aurora.albano@uniroma1.it

The coronavirus disease 19 (COVID-19) is a highly transmittable and pathogenic viral infection caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which spread around the world and caused the 2019–2020 pandemic. Even though successful vaccination programs to combat COVID-19 are available worldwide, little has been accomplished in the development of antivirals to treat the disease. The disparity in COVID-19 vaccination coverage, vaccine resistance, the emergence of several SARS-CoV-2 variants, and the increased transmission ability emphasize the importance of developing antiviral drugs to treat SARS-CoV-2 infections.[1] The development of new antiviral agents is, therefore, of utmost importance. The SARS-CoV-2 non-structural protein 13 (nsp13) has been identified as a promising drug target for the development of antivirals due to its crucial role in viral replication. The CoVs nsp13 is a multidomain enzyme that targets the natural nucleotides and deoxynucleotides as substrates when performing its adenosine triphosphatase (ATPase) activity, utilizing the energy of nucleotide triphosphate hydrolysis to unwind DNA or RNA. Moreover, nsp13 is the most conserved non-structural protein within the coronavirus family.[2] Several compounds have been reported to inhibit SARS-CoV-1 nsp13 and, very recently, also SARS-CoV-2 nsp13 has been actively explored as drug target, with some reports describing small molecules as inhibitors of SARS-CoV-2 nsp13. Among them, aryl diketo acids (DKAs), have been reported as inhibitors of SARS-CoV-2 nsp13.[3] On the other hand, the DKA chain suffers from several limits related to the pharmacokinetic and pharmacodynamic profiles. Therefore, to overcome the limits of the DKA moiety, a variety of compounds were developed by transferring the DKA chain to scaffolds characterized by improved druglike qualities. Therefore, we carried out a semi-random screening on our in-house library of non-DKA derivatives, identifying a promising hit compound as micromolar nsp13 inhibitor. We synthesized a set of derivatives structurally correlated with the hit, obtaining a new series of dual inhibitors of both the SARS-CoV-2 nsp13-associated activities. The data coming from the biological assays will be shown and discussed.

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is an RNA virus with a positive strand, responsible for the ongoing global pandemic of coronavirus disease 2019 (COVID-19). It is crucial to expedite the discovery of drugs to combat this pressing global health crisis. The interaction between the spike (S) protein of SARS-CoV-2 and the cell surface receptor angiotensin-converting enzyme 2 (ACE2) facilitates the virus's infectivity, enabling its entry into host cells. ACE2 functions as a ligand-receptor pair that initiates viral attachment and cellular entry. Specifically, the receptor-binding domain (RBD) of the S protein binds to the membrane-distal portion of the ACE2 proteine.[1] Notably, current vaccines stimulate antibody responses to the S protein, with most neutralizing antibodies targeting the RBD. Therefore, disrupting the binding between the S protein and the ACE2 receptor is promising as approach to impede virus entry. [2] Inhibitors targeting the protein-protein interaction between the S protein and human ACE2 are of significant interest as potential antiviral agents because this interaction initiates membrane fusion and virus entry, occurring at an accessible extracellular site. [3] While developing protein-protein interaction inhibitors with small molecules presents challenges compared to antibodies, small-molecule inhibitors could offer alternatives that are less susceptible to strain variations and mutations, suitable for oral or inhaled administration, and more controllable and less immunogenic. This strategy has already proven successful in inhibiting viral entry for other viruses, exemplified by two FDA-approved drugs, maraviroc and enfuvirtide. This study aimed to identify potent antiviral drugs against SARS-CoV-2 by targeting well-established proteins crucial to the viral cycle using high-throughput screening (HTS) techniques. A recombinant RBD of SARS-CoV-2 and ACE2 receptor, constructed with two different tags by collaborators at IP Paris, was utilized for HTS to identify molecules interfering with the interaction between the RBD and ACE2. Twenty-one candidates were selected from HTS based on a robust homogeneous time-resolved fluorescence (HTRF) assay. Among them, two hits were identified, demonstrating inhibitions of 51.4% and 25.6% and IC_{50} values of 1 and 2.42 µM against ACE2 and 0.44 and 3.58 µM against RBD, respectively. However, both hits exhibited cytotoxicity against SARS-CoV-2 infected cells. Therefore, to mitigate the cytotoxicity and enhance druggability, analogues of these compounds were designed. The data from the biological assays will be presented and discussed.

Development of first in class HDAC6-MAGL inhibitors

N. Tardiolo,[a] A. Lodola,[b] F. Galvani,[b] M. Mor,[b] F. Vincenzi,[c] S. Gemma,[a] G. Campiani,[a] S. Butini[a]

nicola.tardiolo@student.unisi.it

Monoacylglycerol lipase (MAGL) is a serine hydrolase responsible for catabolizing 2-arachidonoylglicerol (2-AG). Targeting the catalytic S122 residue of MAGL a robust impairment of enzymatic functionality is attained, thus indirectly activating cannabinoid receptors and prompting neuroprotective and anti-inflammatory outcomes.[1] Amongst the scientific efforts focused on the development of potent and selective MAGL inhibitors, beta-lactam-based irreversible MAGL inhibitors effectively reached the aimed goals.[2,3] Particularly, they harbour a branched aromatic motif, a N-containing linker and an electrophilic moiety embedding a good leaving group, detached by MAGL S122 thus leading to enzyme acylation, as demonstrated by the X-ray analysis.[3]

Histone deacetylase 6 (HDAC6) is a unique isoenzyme, being located in the cytoplasm and primarily interacting with non-histonic proteins. Lots of reports suggest that HDAC6 may play a pivotal role in triggering neurodegenerative and proinflammatory processes.[4] HDAC6 is a metalloenzyme, therefore a typical inhibitor embeds a Zn^{2+} binding group (ZBG) (commonly an hydroxamic acid), an aromatic or aliphatic linker, accommodated into a hydrophobic tunnel connecting the active site of the targeted protein to the outer region, and a bulky cap motif, responsible for isoform selectivity.[5]

We recently undertook the development of novel dual HDAC6-MAGL inhibitors. By merging the pharmacophoric elements useful for inhibiting the two targeted proteins, we designed two sets of compounds. The new molecules belonging to Set A bear the ZBG on a p-phenyl substituted feature and harbour several N-containing five member heterocycles. In Set B, an azole-based moiety was employed as a novel ZBG supporting motif; several potential ZBGs were installed on this heterocyclic nucleus. Notably, computational analysis underline that the presence of an EW group on position 4 of pyrazole ring allow to better delocalize the negative charge of TS intermediate, facilitating expulsion of the leaving group by S122. The new inhibitors may hold promise as in inflammatory and/or neurodegenerative-based diseases.

Enzymatic data displayed interesting SARs and selected analogues effectively inhibit both enzymes, thus representing promising hits to further develop novel pyrazole-based HDAC6-MAGL hybrid inhibitors.

In the current medical landscape, there is an urgent need to discover new effective drugs to enhance the therapeutic options for COVID-19. The SARS-CoV-2 non-structural protein 13 (NSP13) helicase enzyme has emerged as a promising target for the development of novel COVID-19 inhibitors. In this study, our objective was to identify potent natural products capable of inhibiting NSP13 through virtual screening of 96,402 compounds from the COCONUT Database. These compounds were docked into the NTPase active site, and Canvas similarity clustering was employed to categorize them into different scaffolds for further analysis. Subsequently, based on commercial availability, ten compounds were selected for in vitro testing. Among these, one compound exhibited significant NSP13 inhibitory activity with potency in a micromolar range (Figure 1). Building upon this finding, GBPM and ligand designer tools aided in the lead optimization process. The most promising chemical candidates will be synthesized and evaluated for their antiviral activity against SARS-CoV-2. This work is funded by the PANVIRIDE project[1].

Lubeluzole is an optically active benzothiazole derivative originally investigated as a neuroprotective agent for the treatment of ischemic stroke whose clinical trials were discontinued due to a lack of benefits in terms of survival. Moreover, a significant increase in heart conduction disorders was observed in some of the treated patients.[1] We demonstrated that lubeluzole is a potent inhibitor of skeletal muscle voltage-gated sodium channels hNav1.4, showing potent antimyotonic activity in an animal model of myotonia congenita.[2] Furthermore, we demonstrated that lubeluzole can inhibit the human ether-à-go-go-related gene (hERG) channel.[1] A series of lubeluzole congeners have been prepared and tested on hERG, Nav1.4, and Nav1.5 channels. The most promising compound has been evaluated in vivo in a rat model of myotonia.

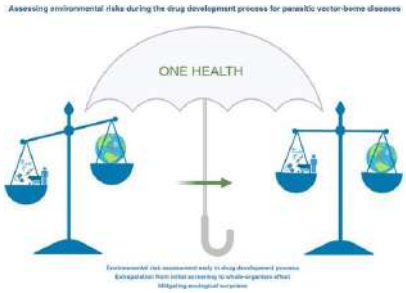
Nearly 75% of emerging human infections worldwide originate from animals. Current drugs for both human and animal (H&A) vector-borne diseases (VBD) are in short supply and have limited efficacy, potential toxicity, and limited resources. Emerging environmental issues in pharmaceutical use/manufacturing are increasing attention in this area. Currently, the two drug pipelines are being developed independently. Collaboration and research between different expertise is therefore essential to define how new drugs can be developed using a more sustainable approach. OneHealth*drugs*[1], a COST Action, is dedicated to the development of innovative strategies for the supply of drugs with a more environmentally friendly profile and low environmental impact[2]. The new drugs aim to combat H&A VBD while maintaining the principles of an optimal profile for both organisms, improving the quality of the drugs and associated delivery technologies. R&D experts from various fields, including chemical/biological/human/veterinary and earth sciences, are working together to propose guidelines and improve existing drug discovery tools in the field of NID discovery. The platform includes preclinical drug discovery, animal studies and drug delivery. Approaches such as compound and target database generation, bioinformatics and omics studies, medicinal chemistry strategies and nanotechnology tools will be implemented.



We expect the results of OneHealthdrugs to have a significant impact both in Europe and in disease-endemic countries. The latest advances in the compound database, including the greener principles derived properties[3] and the drug targets database managed by adopting reduced off-target species filtered with appropriate software, as well as the sustainable drug profiles in H&A health, will be presented together with the progress made within the OneHealthdrugs initiative.

leonardo.brunetti@uniba.it

Neurodegenerative diseases like Parkinson's Disease and Alzheimer's Disease involve several pathological phenomena that result in a diffuse neuroinflammatory state, exacerbating tissue damage via oxidative stress. Neuroinflammation is a multifaceted pathological factor involving several cell types, receptors, and mediators, and its resolution could help alter disease progression[1].

Formyl Peptide Receptor 2 (FPR2) is a G protein-coupled receptor (GPCR) expressed in microglia. It controls several aspects of the immune response and could thus be a key target for the resolution of neuroinflammation. Our research efforts have resulted in developing the ureidopropanamide class of FPR2 agonists[2].

We have set out to enhance the anti-inflammatory capabilities of these compounds by incorporating an H_2S-releasing moiety into their scaffold. H_2S is a gaseous neuromodulator and neuroprotector, regulating calcium influx and exerting anti-inflammatory and antioxidant effects at low doses[3]. Thus, the ureido and amide moieties of our compounds were converted into the corresponding thioureas or thioamides.

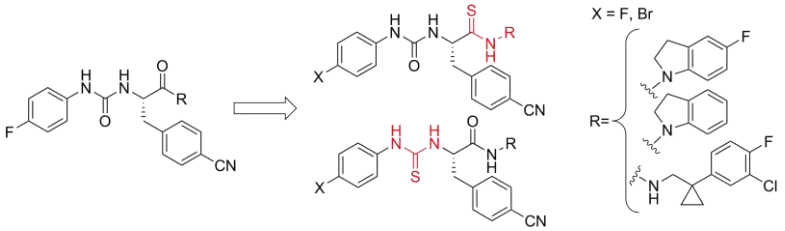

Figure 1: scaffolds of ureidopropanamide FPR2 agonists and their thioureido and thioamide counterparts.

These compounds were tested as FPR2 agonists, for their capacity as H_2S releasers, and their neuroprotective activity in models of neuroinflammation, showing a promising activity profile and demonstrating their potential as lead compounds for a new generation of anti-neuroinflammatory drugs.

lorenzo.raffellini@phd.unipi.it

Neurodegenerative diseases are one of the most significant health problems of the last decades, due to the absence of resolutive therapies. Over time, researchers turned their gaze toward natural substances with interesting biological activities in order to find new scaffolds to work on and synthesise new drugs[1]. Within this vast environment, ellagitannins (ETs) are a large group of bioactive compounds found in plant-source foods, such as pomegranates and berries. Ellagic acid is the aglycon portion of ETs, but the beneficial effects observed following the consumption of ET-containing foods are explained by their extensive metabolism to urolithins[2]. In particular, Urolithin A (UA) shows good antioxidant, anti-inflammatory and neuroprotective properties[2]. In this work, we describe the synthesis of a small library of urolithin analogues obtained through the decoration of the UA-scaffold, and the biological evaluation. *In vitro* preliminary results showed that new derivatives were able to promote autophagy using Urolithin A as a reference activity. The most active compounds were selected for further evaluation in a preclinical model for Alzheimer's diseases of *Caenorhabditis elegans*. In this poster I will discuss the results of these assays and the future perspectives that come with them.

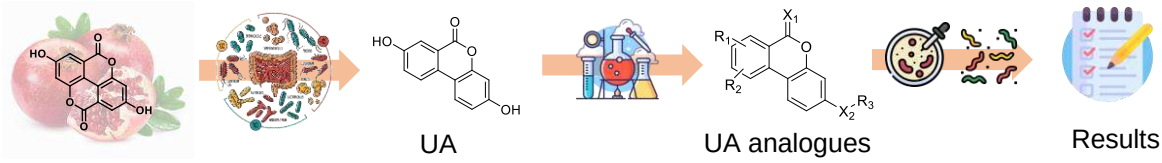

Figure 1: Workflow summary.

Targeting AKT1 in Cancer Therapy: Novel Inhibitors for Acute Myeloid Leukemia

M. Casciari,[a] M. Pacetti,[a] E. Primavera,[a] F. Milano,[b] A. Astolfi,[a] V. Cecchetti,[a] M.P. Martelli,[b] M.L. Barreca,[a] *and* S. Massari,[a]

marta.casciari@gmail.com

Acute myeloid leukemia (AML) is a heterogeneous hematopoietic cancer characterized by an abnormal proliferation of the progenitor cells of myeloid strains. In more than 60% of AML cases, the PI3K/AKT/mTOR signaling pathway becomes overactive, resulting in changes that are exacerbated by chemotherapy, leading to drug resistance.[1] Particularity, a pivotal role in this pathway is shown by the serine/threonine kinase (AKT or PKB), making it a particularly interesting drug target for precision cancer therapy. Against this backdrop, our research group has focused on the development of AKT1 inhibitors in AML treatment. In particular, compound 5,6,7,8-tetrahydrobenzo[4,5]thieno[2,3-d]pyrimidin-4(3H)-one (**T126**) has emerged as the most interesting compound with an IC_{50} = 1.99 ± 0.11 μM and a ligand efficiency (LE) of 0.35.[2] Further investigation of **T126** showed its ability to bind the AKT1 ATP-binding pocket preventing growth and inducing apoptosis in a panel of AML cells in the low micromolar range.[2]

In this work, we focused our attention on the identification of AKT1 allosteric inhibitors. In particular, the most potent AKT1 allosteric inhibitors reported in the literature were used to build a pharmacophore model. Then, the pharmacophore features and **T126** core were joined to generate a small set of AKT1 allosteric inhibitors (**Figure 1**). Among the synthesized compounds, one showed a very interesting profile, exhibiting an IC_{50} value in the low micromolar range and strong inhibitory activity against two mutated AML cell lines over wild-type.

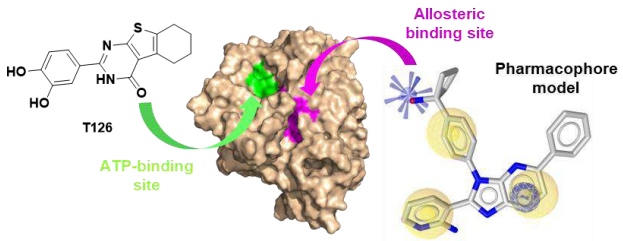

Figure 1: Schematic representation of rational design of AKT1 allosteric inhibitors reported in this work.

Malaria is an infectious disease caused mainly by *Plasmodium falciparum* that is responsible of millions of deaths every year. Although vaccines for the prevention of malaria have a suboptimal efficacy, chemotherapy approach represents the main treatment. However, drug resistance is very common and new chemoterapic approaches have been identified. One of the most promising discoveries is the targeting of the *Plasmodium falciparum* dihydroorotate dehydrogenase (*Pf*DHODH)[1]. DHODH, a ubiquitous flavin mononucleotide enzyme, acts as the pivotal rate-limiting step in *de novo* pyrimidine synthesis, facilitating the conversion of dihydroorotate (DHO) to orotate (ORO). This pathway is crucial for the survival of the parasite, as Plasmodium species lack the capability to utilize salvage pathway for pyrimidine acquisition, relying exclusively on *de novo* synthesis.

The Medsynth group, an academic research team of Turin University, previously published a work based on hydroxyazole scaffold-based *Pf*DHODH inhibitors[2]. Starting from the lead compound *1*, a new series of hydroxypyrazole inhibitors has been synthetized and investigated. Here we present the characterization of the inhibitor activity on the recombinant *Pf*DHODH of the new hydroxypyrazole inhibitors, their selectivity over the human isoform, their physical-chemical proprieties and their activity on *Plasmodium falciparum*-infected erythrocytes. Finally, co-crystallization studies of the most promising compounds are shown.

Human thymidylate synthase (hTS) catalyzes the reductive methylation of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP) which requires methylene tetrahydrofolate (mTHF) as a cofactor [1]. This enzyme has been targeted in cancer treatment because of its crucial role.
Drugs such as 5-fluorouracil (5-FU) and folate analogues like raltitrexed can bind covalently to the active site of hTS. However, this mechanism often leads to an increase in the expression of hTS within the cell, resulting in drug resistance. Over the years, it was shown that the hTS is a homodimer of 76 kDa consisting of two identical subunits, each weighing 37 kDa. Each subunit contributes to the formation of two active sites and can exist in different states. The dimer can switch between an active state and an inactive state, the dimer is in equilibrium with its monomeric form with a Kd around 6-8 nM. All these states can contribute to compose the broad interactome with different biomolecular targets within the cell and trigger eventually different specific mechanism. To overcome drug resistance, our research group has focused on finding new ways to switch the dimer to monomer equilibrium and reduce the enzyme catalytic activity causing its overexpression [2]. We aim to target the interface of the dimer to shift the equilibrium towards the inactive monomeric form of hTS. In order to characterize the dissociative character of these newly synthesized compounds to shift the equilibrium toward the monomeric form of the protein and inactivate it, different chemical-biological tools were set up: fluorescence-resonance energy tarnsfer (FRET) experiments, kinetic assays with dedicate algorithms, site specific mutagenesis and more recently dialysis experiments. The present work present the results from the different assays for some representative inhibitors and focus specifically on the recent results on the dialysis experiments. By conjugating the protein with a fluorescent probe we were able to monitor its movement in the dialysis device and detect some interesting events such as the dissociative effect of the dimer destabilizer. In conclusion, we succed in developing a new chemical biological tools to characterize the dissociative capacity of these newly shythesized inhibitor , which rapresent a promisimg Medicinal Chemistry strategy .

Having caused a great socioeconomical impact worldwide since 2019, SARS-CoV-2, is still a major public health issue. Despite benefits obtained with vaccination campaigns, SARS-CoV-2 has been still mutating for potential immune escape pathways. Among viral targets, the main protease (M^{pro}) represents a strong candidate due to various reasons: (1) the pivotal role of M^{pro} in the proteolytic cleveage of viral proteins, (2) the absence of human homolog of this protein,[1] (3) high conservation among Coronaviruses, especially in those domains crucial for its enzymatic activity – a potential for broad-spectrum activity.[2] One SARS-CoV-2 M^{pro} inhibitor has been approved so far by the FDA, namely Nirmatrelvir, but this drug has major issues.[3] Most recently, Petrou *et al*. also reported the antiviral activity of thiazolidine-4-one scaffold against SARS-CoV-2 M^{pro}.[4] All these facts rightfully highlight the pivotal importance of seeking out new M^{pro} inhibitors, more particularly deepening the SAR studies of thiazolidine-4-one class. Herein, we report the synthesis of new thiazolidine-4-one analogues as SARS-CoV-2 M^{pro} inhibitors. They were designed by derivatizing the thiazolidine-4-one scaffold with a 4-nitrophenyl ring and a variously substituted phenethyl moiety. Followingly, we assayed the enzymatic activity of the newly synthesized derivatives in *in vitro* assays against SARS-CoV-2 M^{pro}, showing inhibitory values within the low micromolar range. To deepen our understanding, we have further applied a molecular docking protocol to predict the possible binding mode of the compounds in complex with SARS-CoV-2 M^{pro}, shedding light on the main structural features involved in the enzymatic inhibition. An in-depth discussion of the data coming from the biological assays will be shown and described.

The inflammatory bowel disease (IBD), Chron's disease and ulcerative colitis are among the idiopathic colorectal inflammatory disorders. As in other inflammatory processes, neutrophils migrate into inflamed tissue in response to chemotactic signals, stimulating various antimicrobial functions including ROS production, phagocytosis, and degranulation. The interruption of this process or the excessive recruitment of neutrophils can cause a dysregulation of the inflammatory process which hinders its resolution.

The Formyl Peptide Receptors (FPRs) are human G protein-coupled receptors located on neutrophils capable of binding specialized pro-resolving mediators and participating in the resolution process. The human FPR family constitutes FPR1, FPR2/ALX and FPR3.

The synthetic hexapeptide WKYMVm, an agonist of the FPR1 and FPR 2 receptors, showed a therapeutic effect against ulcerative colitis by blocking the decrease in body weight, colon shortening and mucosal destruction induced by DSS (in a model mice). In contrast, the FPR2- receptor was inhibited by the WRWWWW peptide, indicating the crucial role of this receptor in inflammatory pathology.

The aim of this study is to design and synthesize WKYMVm agonist/antagonist analogues, testing their binding capacity to the FPR2 receptor and their anti-inflammatory activity at different concentrations in vitro. Future development comprises their encapsulation in different liposomal formulations, investigation of their absorption and possible anti-inflammatory effects in a 2D CaCo2/HT29 and CaCo2/HT29-MTX culture model used in Crohn's disease study.

The novel synthesized peptides may represent useful therapeutic agents against chronic intestinal inflammation.

marco.zupi01@universitadipavia.it

Triple Negative Breast Cancer (TNBC) poses a significant challenge within oncology due to its aggressive nature and the limited therapeutic option available[1]. To address these challenges, nano-based drug delivery systems have emerged as promising therapeutic tools[2].
In this study, we aimed to develop liposomes designed for targeted doxorubicin (DOX) delivery to TNBC cells overexpressing integrin receptors $\alpha_v\beta_3$ and $\alpha V\beta_5$. The liposomes underwent surface modification with cyclic pentapeptides containing the Arg-Gly-Asp sequence (cRGDs), which selectively bind to $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins with nanomolar IC50 values. Lipids modified with a dibenzocyclooctyne moiety were incorporated into the liposome's membrane and exploited for the surface functionalization, while the inclusion of rhodamine-tagged lipids allowed to monitor nanoparticle internalization. The cRGD derivatives, bearing a terminal azide group (N_3-3a-RGD), were linked to the liposome's surface through a strain-promoted azido-alkyne cycloaddition (SPAAC) reaction.
The analysis of the nanosystem's physicochemical properties confirmed the effective functionalization and the high efficiency in encapsulating doxorubicin. *In vitro* studies showed enhanced cellular uptake of cRGD-functionalized liposomes in TNBC cells, leading to increased cytotoxicity compared to free doxorubicin or non-functionalized liposomes. Overall, this study demonstrates that DOX-RGD-liposomes represent a promising theranostic nanocarrier for TNBC treatment.

The chemistry and possible therapeutic use of cannabinoids are at the forefront of current scientific research. Δ^9-tetrahydrocannabinol (THC) and cannabidiol (CBD) are the most abundant and pharmaceutically significant plant phytocannabinoids. Nonetheless, pre-clinical and clinical studies are still in progress to assess their detailed pharmacokinetic and pharmacodynamic features in new applications and in different formulations, products and conditions. Thus, techniques allowing the performance of studies with minimal invasiveness to humans, and with an acceptable approach to animals, are very welcome. Microsampling is one such approaches, with many supplemental advantages, including increased analyte stability, simplified shipping and storage protocols at room conditions.[1]

In this study we applied and compared two innovative, new-generation dried microsampling technologies, i.e., fabric-phase sorptive extraction (FPSE) and volumetric absorptive microsampling (VAMS). The former is based on cellulose-based, functionalised, calibrated fabric patches, allowing to choose different chemistries and affinity modes, thus providing increased versatility and enhanced selectivity. The latter is based on a calibrated, porous polymeric tip collecting volumetrically accurate samples, thus obviating to the volume variability and haematocrit-dependence of classical dried blood spots. Both microsampling approaches were followed by a feasible solvent extraction procedure and coupled to HPLC-ESI-MS/MS for the determination of THC, CBN and their main metabolites (namely, 11-OH-THC, 11-COOH-THC, 7-OH-CBD and 7-COOH-CBD) in peripheral blood. Deuterated analogues were used as the internal standards.

The results obtained have shown that both FPSE and VAMS are suitable for the purpose, with each one possessing unique strengths and challenges. In particular, both provide satisfactory extraction yields and accuracy, and almost negligible matrix effect. Thus, both dried microsampling approaches appear to be effective alternatives to classical venepuncture for the minimally invasive sampling of blood in pre-clinical and clinical studies involving cannabinoids.

Cannabidiol (CBD) is the main non-psychoactive phytocannabinoid derived from *Cannabis sativa* L. It is now an active pharmaceutical ingredient (API), given its usage in treating some types of paediatric epilepsy. For this reason, this compound requires a deep characterization in terms of purity and origin. Previous research work has shown two impurities, including cannabidivarin (CBDV) and cannabidibutol (CBDB), in CBD samples from hemp inflorescences, while abnormal-cannabidiol (abn-CBD) has been described as the primary by-product that generates in CBD synthesis. Both natural and synthetic CBD samples exhibit the presence of Δ^9-tetrahydrocannabinol (Δ^9-THC) and Δ^8-THC. In the light of all the above, this study is aimed to develop a new analytical method based on high-performance liquid chromatography (HPLC) with different detection systems to study the purity of CBD and define its origin based on the impurity profile. In addition to the above-mentioned cannabinoids, other compounds, such as cannabigerovarin (CBGV), cannabigerol (CBG), cannabichromenvarin (CBCV) and cannabichromene (CBC), were examined as potential discriminating impurities. Qualitative and quantitative analyses were carried out by UHPLC-HRMS and HPLC-UV/Vis, respectively. Principal Component Analysis was finally applied for statistical scrutiny. Natural CBD samples exhibited purity range between 97.5 and 99.7%, while synthetic samples were generally pure, except for three initially labeled as synthetic, revealing natural derived impurities. To further confirm the origin of CBD samples, the presence of other two minor impurities, namely cannabidihexol (CBDH) and cannabidiphorol (CBDP), was assessed as unequivocal for a natural origin. Finally, an enantioselective HPLC analysis was carried out and the results confirmed the exclusive presence of the (–)-*trans* enantiomer in all CBD samples. In conclusion, the HPLC method developed represents a reliable tool for detecting CBD impurities, thus providing a clear discrimination of the compound origin.

valerio.baia@unina.it

Antimicrobial resistance represents one of the major issues for the healthcare system. The β-lactam antibiotics including penicillins, cephalosporins and carbapenems are the cornerstones of antimicrobial chemotherapy.[1] ESKAPE pathogens (Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa, and Enterobacter spp) have become highly resistant to most available antibacterial drugs by exploiting different mechanism of resistance.[2] The COVID-19 pandemic has increased the antibiotic resistance, since COVID-19 patients were treated with broad-spectrum antibiotics, including extended-spectrum cephalosporins, quinolones, and carbapenems.[3] One of the main mechanism of resistance is due to the presence of metallo beta-lactamases (MBL), that are bacterial enzymes able to cleave the beta-lactam ring of the antibiotics. Since no clinically relevant MBL inhibitors have yet been approved, the quest for novel compound with a broad-spectrum activity against several MBL, represents a necessary although challenging task. Captopril, an angiotensin converting enzyme inhibitor used for the treatment of hypertension showed weak activity against some MBL isoforms. Therefore, our driving idea was to modify the structure of the captopril to improve potency and possibly extend the spectrum of inhibition towards MBL by increasing the hydrophobic features of the molecule generating an indoline system. We employed a Joullié-Ugi multicomponent reaction protocol for the synthesis of two indoline-based subseries generating a novel class of potent MBL inhibitors through a convenient continuous flow protocol for the rapid, efficient and diversity-oriented generation of analogues. Among the compounds tested against different MBL isoforms two derivatives stood out for their broad-spectrum inhibition profile against all the isoforms tested, namely NDM-1, VIM-1, and IMP-7. Furthermore, activity in clinical isolates in synergy with beta-lactam antibiotics was assessed for the best performing compounds, thus paving the way to further optimization for the newly disclosed inhibitors.

Lymphoma is a type of cancer that affects the lymphatic system, exist more than 70 cancer subtypes originating from both B- and T-cells. Beside the traditional chemotherapy and radiotherapy treatment options, recently have been developed kinase inhibitors targeting the Bruton's tyrosine kinase (BTK), BCL2 inhibitor Venetoclax and immunotherapeutics anti-PD1, affecting cell cancer growth and progression. However, the development of resistance to these inhibitors poses a significant challenge to successful treatment. Most Lymphomas are in need of new therapeutics and for this reason is constantly growing the interest in identifying alternative small synthetic molecules with targeted therapeutic potential. Starting from the oxindole scaffold widely used for the synthesis of kinase inhibitors[1,2], we synthesized new derivatives of general structure A. Then, following a phenotypic drug discovery (PDD) approach we screened a library of synthesized oxo-indole derivatives against a panel of lymphoma cell lines. Few molecules, across the library tested, showed nanomolar range antiproliferative activities in six lymphoma cell lines. To prioritize the identification of key targets, we set up a kinome profiling, DARTS (Drug Affinity Responsive Target Stability), CETSA (Cellular Theraml Shift Assay) and SPR (Surface Plasmon Resonance) experiments. Collected results led us to the discover of original modulators of 14-3-3 proteins.

This work presents the synthesis of new chemical entities endowed of potent anticancer activity and the campaign of drug target identification that highlighted their role as modulators of 14-3-3 proteins.

Can lipidomic alterations of neuroblastoma cells caused by amyloid peptide incubation be reverted by myricetin?

L. Davani,[a] A. De Simone,[b] E. Turrini,[c] S. Montanari,[c] M. Lämmerhofer,[d] V.Andrisano[c]

The investigation of brain lipid composition alterations observed in Alzheimer's disease (AD) can give insights into neurodegenerative mechanisms. Therefore, we wanted to validate and further explore the impact of β-amyloid ($A\beta_{1-42}$) self-aggregates on lipidome alterations, building upon our prior research.[1]
Specifically, differentiated human neuronal cells SH-SY5Y, were treated with $A\beta_{1-42}$ in the absence and in the presence of myricetin (Myr), a well-known $A\beta_{1-42}$ anti-aggregating agent.[2] The evaluation of *in vitro* toxicity confirmed that $A\beta_{1-42}$ (20 µM) significantly affects cell viability compared to control (83± 12 %). Meanwhile, Myr showed to not affect the cell viability at concentrations less than 40 µM. Conversely, it seems that there is an inverse dose-response relationship regarding Myr potential effect in counteracting the amyloid toxicity.
Then differentiated SH-SY5Y were treated in three different conditions.: i) $A\beta_{1-42}$ (20 µM); ii) $A\beta_{1-42}$ (20 µM) in the presence of Myr (40 µM); iii) Myr (40 µM). A protocol based on solvent direct cell scraping using a cold lipid extraction mixture (MeOH/MTBE/IPA (1.3:1:1, v/v/v)) was optimized for samples collection. Then, following a validated protocol lipids were extracted after cell cryo-lysis by homogenizer and the extracts analysed by a RP-UHPLC system coupled with a quadrupole-time-of-flight mass spectrometer in a comprehensive data-independent SWATH acquisition mode.[3] Data processing was achieved by MS-DIAL (version 4.24). After lipid identification we focused on the relative quantification of Glycerophospholipids and Sphingolipids classes and the results were compared with those obtained in our previous study.
By comparing lipid class profile in SH-SY5Y cells treated with $A\beta_{1-42}$ to untreated cells, we confirmed some alterations in PCs, LPCs profiles that might be related to cellular response mechanisms to the toxic stimuli of $A\beta_{1-42}$ aggregation species. According to the antiaggregating properties of Myr, in samples co-treated with this compound, changes in lipid levels seem to be restored, especially in case of O-PCs species that might be increased by the $A\beta_{1-42}$ oxidant effect.

alessandro.ajo@unimi.it

The RNA delivery is emerging in the last century as a new class of therapeutic for a wide range of diseases. Delivering RNA is a very interesting strategy for cancer therapy and rare diseases,[1] but remains a great challenge because of its low cell uptake, instability in blood.

For this reason, the use of lipidic nanoparticles has been recently witness as the solution for COVID 19 and the use of other type of nanocarriers is a promising approach for the RNA delivery and its controlled concentration over time. The problem is: what type of nanoparticles can be biocompatible, degradable and able to load enough RNA for therapeutic efficacy? Porous silicon nanostructures are of particular interest because of they fulfill all the requirements to allow *in vivo* applications, and they are easy to functionalize. The high porosity of these structure also allow a large amount of RNA entrapment and the structures prevent the degradation of the biomolecule and allow the specific drug release in a targeted area.[2] However, due to the fast degradability of the silicon, a coating with a polymeric layer is necessary to increase its stability and control the time of release.

Here, we report a strategy to load a high amount of RNA and, to avoid its early release, the use of hyaluronic acid (HA) wrapped around the particles. The presence of HA also helps to be selective towards the tumor environment due to the presence of overexpressed CD44 receptors specific for the polymer. Also the release of the RNA is achieved by the HA degradation promoted by an enzyme called hyaluronidase.[3]

In this work, is achieved a loading higher than 50% in weight thanks to the use of a calcium silicate reaction and we demonstrate the difference in the time release of RNA between nanoparticles coated and uncoated with HA.

Keywords: nanoparticles, drug delivery, silicon

The widespread formation of biofilms plays a significant role in human health, representing an important aspect in the development of infectious processes. To overcome the increasing antimicrobial resistance, the focus is to find new stategies to trigger the dispersal of biofilm or inhibit its initial formation.

To prevent biofilm development, we decided to consider novel antimicrobial-free strategies based on compounds acting at sub-lethal concentration, leading to biofilm inhibition while avoiding bactericidal effects. Starting from our previous studies[1,2], we explored the functionalization of inorganic nanoparticles with natural compound derivatives endowed with antifouling properties. The goal was to achieve novel nanoparticles suitable for surface coating, limiting the drawbacks of current anti-biofilm coverings, particularly the selection of resilient strains. Therefore we designed and synthesized two series of new silica nanoparticles (**1s**,**l** - **2s**,**l** and **3s**,**l** - **4s**,**l**). After their characterization, the sanples exhibiting the higher degree of functionalization (**1l** - **4l**) were used to coat glass coverslips by spin-coating. The coated surfaces (**A**-**D**, respectively) were tested against *P. aeruginosa* biofilm, and the results highlighted that surfaces **B** and **D** (Figure 1) showed promising anti-biofilm properties (percentage reduction of biofilm formation ranging from 59.2 ± 2.2 to 83.7 ± 3.4, respectively).

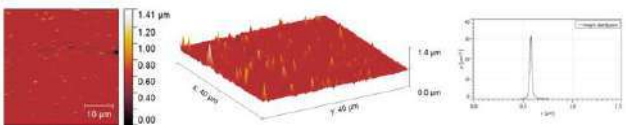

Figure 1: Atomic force microscopy (AFM) topographic image (40 × 40 µm), 3D rendering of the 40 µm image for perspective, and height histogram of surface **D**.

Photodynamic therapy (PDT) emerges as a promising alternative for cancer treatment [1]. However, PDT effectiveness is compromised by the attenuation of external light irradiation within tissues, thus reducing treatment efficacy. To overcome the need of an external light irradiation, an innovative approach involves generating light directly inside the cancer cells through a chemiluminescent reaction [2]. The emitted light can be absorbed by a photosensitizer to produce singlet oxygen or radicals, effectively inducing cell death. However, the proposed solution requires the efficient internalization of the components, ensuring non-toxicity, access to the target cells and close proximity with the photosensitizer. In this context, silica nanoparticles (NPs) emerge as a potential solution due to their ability to encapsulate and release components, offering advantageous properties such as biocompatibility, degradability, and a large surface area.

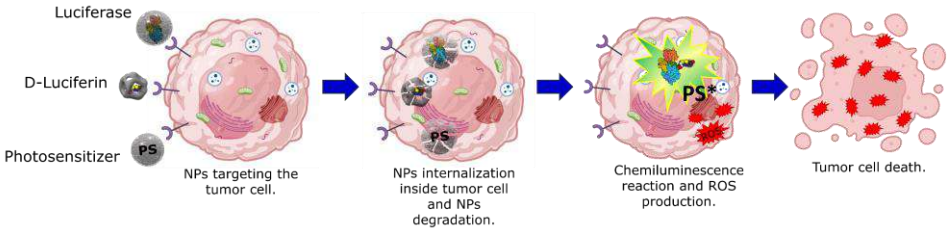

Figure 1: Concept of self-illuminating PDT.

This study explores a self-illuminating PDT approach, based on the encapsulation of chemiluminescent reagents and of a photosensitizer (PS) in silica NPs. Breakable organosilica nanocapsules, (ssNCPs), hollow structures with a unique hydrophilic cavity and breakable nanocages (ssOSCs) (exhibiting a cage-type morphology) were selected for the encapsulation of luciferase (enzyme) and D-luciferin (substrate). The silica network of these NPs contains disulfide bonds, allowing them to break within cells when exposed to a reducing environment like glutathione, abundant in cancer tissue. Figure 1 illustrates the concept of the study, demonstrating that upon the destruction and release of the components, the light generated by the chemiluminescent reaction can be absorbed by a photosensitizer (through energy transfer) to generate reactive species. Herein, preliminary experiments including the synthesis and characterization of organosilica nanoparticles are assessed using various methods (as electron microscopy, DLS, FTIR). Also, evidence of the encapsulation of luciferase and D-luciferin is presented.

In our efforts to combat the global spread of tuberculosis (TB),[1] we have focused on an innovative target, Salicylate Synthase I (MbtI), by combining traditional medicinal chemistry approaches with nanomedicine strategies. Over the past decades, anti-virulence therapy has emerged as an alternative to traditional antimicrobial treatments. Building on this, the impairment of iron acquisition through enzymatic inhibitors that block the production of siderophores has been identified as a viable strategy. Our group has devoted considerable efforts to developing inhibitors of MbtI, the first enzyme in the biosynthetic cascade, leading to several promising candidates. Among these, 5-(3-cyano-5-isobutoxyphenyl)furan-2-carboxylic acid (1) stands out as the most potent MbtI inhibitor discovered to date.[2] Furthermore, the unique challenges posed by TB, including the need for prolonged treatment regimens, underscore the urgent need for innovative approaches in drug delivery. Nanomedicine presents an unprecedented opportunity to address these challenges, ensuring more targeted, effective, and patient-friendly TB treatment strategies. The core innovation of our project lies in the development of specialized nanoparticles designed to deliver anti-TB drugs more effectively and safely.[3] We successfully loaded poly(2-(methacryloyloxy)ethyl phosphorylcholine)-co-poly(2-(diisopropylamino)ethyl methacrylate) (PMPC-PDPA) polymersomes (POs) with ethyl and propyl ester derivatives of 1, namely 1a and 1b. The POs, synthesized through a bottom-up approach, were fully characterized and MTT assays confirmed the absence of cytotoxicity for both the free drugs and the encapsulated POs. Additionally, we demonstrated that our pro-drugs (1a and 1b) can be converted into the active candidate by hydrolase enzymes once inside the macrophages. In vitro assays are ongoing to investigate the effects of our nanomaterials on innovative murine alveolar-like macrophage infection models of Mtb.

daria.diprisco@marionegri.it

The delivery of RNAs remains a challenge due to the fragility of the biomolecule as well as its difficult internalization on the desired cells. Nanostructures, e.g. liposomes, have been employed termed as carriers for different type of RNAs and have the limitation of large size, stability and eventually toxicity[1]. Alternative soft nanostructures are hydrogel particles, composed of polymers and mainly water are interesting carriers for a variety of biomolecules. In my contribution the use of gelatine based hydrogels is described as potential nanovectors for RNA delivery in different cell lines. The choice of the materials is dictated by their biocompatibility, lack of toxicity, ability to entrap large amount of the mRNA and siRNA. The chemical composition of the nanogels influence the charge, size (<100 nm) and degradation of the systems. To this aim, a Gelatin-based nanogels were prepared according to the literature by the two-step desolvation method [2-3] in order to obtain positive charges capable of interacting with RNA molecules for potential drug delivery (Figure 1). The use of nanogels with these characteristics should avoid fast clearance, improve easy cargo release.

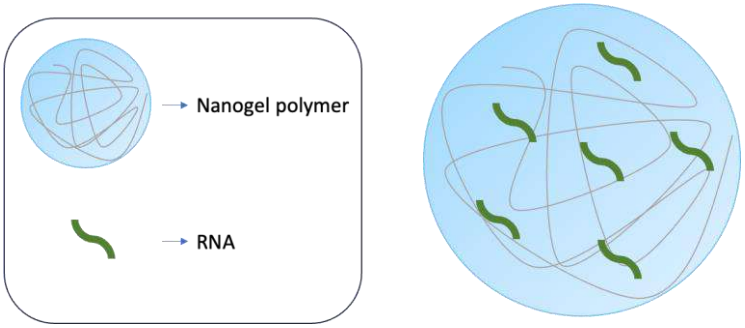

Figure 1: Nanogel-RNA complex

pietro.milesi@polimi.it

Melanoma treatment strategies have significantly improved patient survivability in the last decades, but there are still unresolved issues in current therapies. New drug combinations are gaining ground for the treatment of non-responsive or relapsing patients, and, for the purpose, kinases have been established as promising therapeutic targets in the design of novel drugs against cancer[1]. Recently, an *in vivo* screening performed at the European Institute of Oncology (IEO, Milan) demonstrated that the dual targeting of Aurora kinase A and MEK is highly effective against metastatic melanoma tumours derived from patients[2]. This synergy has already outperformed the standard-of-care therapy in *in vitro* and *in vivo* models.

This work aims to target clinical trials, and we propose to increase the outcome of melanoma treatments improving drug bioavailability, cellular uptake and tumour accumulation. In the nanomedicine field, pharmaceutical co-crystals and drug nanoencapsulation are among the more studied and promising strategies for the purpose.

For these reasons, in a first part of the work, we studied at the molecular level MEK and Aurora kinase A inhibitors, exploiting both protein databases[3] and experimental crystallographic techniques, with the aim of unravelling their internal interaction profile. This information is fundamental to design novel pharmaceutical co-crystals and salts, thus increasing their solubility in physiological conditions.

In parallel, novel dual-loaded nanoformulations of MEK and Aurora kinase A inhibitors have been developed with the aim of reducing toxicity and improving the efficacy of the therapy. First *in vitro* and *in vivo* results show increased cellular internalization and tumour accumulation of the encapsulated drugs with respect to the corresponding free drugs, reflecting in a more effective therapy.

luigi.zanovello@iit.it

The problem of how to dispose of the enormous amount of plastic waste is a pressing topic worldwide. In particular, new and sustainable approaches to plastic polymer degradation are required since the currently employed techniques are environmentally polluting. In the past few decades, the scientific community has invested considerable efforts to engineer naturally occurring enzymes capable of degrading plastic polymers to increase their catalytic efficiency and applicability on the industrial scale. In this framework, we apply machine learning models to the problem of mutating selected enzymes capable of degrading plastic polymers to increase their catalytic efficiency. In particular, provided the structural data of the enzyme and the polymer to degrade, the machine learning model will aim at predicting the kinetic parameters of the reaction (the binding affinity K_d and the turnover number k_{cat}). Such a pipeline would constitute the basis for a general framework to tackle the problem of enzyme optimization for plastic polymer degradation.

Astrochemistry & Solar System ancient history

C. Ceccarelli
Université Grenoble Alpes, IPAG, 414 Rue de la Piscine, Grenoble – FRANCE
e-mail: cecilia.ceccarelli@univ-grenoble-alpes.fr

Astrochemistry is the science that studies the chemistry in the Universe, namely the combination of two fields: astronomy and chemistry. It started about fifty years ago and it has progressed in leaps and bounds, often triggered by the advent of new telescopes. From the collection of new interstellar molecule detections, astrochemistry has evolved more and more in the quest to understand how they are formed and thrive in the harsh conditions of the interstellar space. The more we know the more we can use interstellar molecules as powerful diagnostic tools. In this presentation, I will briefly review some major aspects of astrochemistry connected with the earliest history of our Solar System and that helped to solve some basic puzzles, for example the origin of terrestrial water, or the possible contribution of the interstellar organic chemistry to kickstart life on Earth.

Opportunities and Challenges for the development of solar to fuels technologies: a photochemist's viewpoint

James R Durrant
Department of Chemistry, Centre for Processable Electronics, Imperial College London, London W12 0BZ, U.K. and SPECIFIC IKC, University of Swansea, Swansea
e-mail: j.durrant@imperial.ac.uk

There is increasing interest in harnessing sunlight to drive the synthesis of molecular fuels and chemicals, including in particular water photolysis to yield molecular oxygen and hydrogen. This can be achieved either through the coupling of photovoltaic cells and electrolysis, or through direct sunlight conversion by photoelectrodes or photocatalysts, the latter being the focus of this talk. In solar conversion, there is often a critical kinetic mismatch between the lifetimes of initially generated photoexcited states and the timescales of charge extraction / catalysis. I will start my talk by introducing solar driven fuel synthesis, and the charge carrier lifetime challenge in photoelectrochemical and photocatalytic systems. I will contrast this with the smaller lifetime challenges for photovoltaic solar energy conversion. I will then go on to discuss some of our recent studies employing transient optical spectroscopies measuring charge carrier dynamics in photoelectrodes and photocatalysts and how these impact upon the efficiency of solar driven water splitting, covering a range of metal oxide and polymer materials. I will consider the importance of d-orbital occupancy in metal oxide photocatalysts in determining charge carrier lifetimes. I will then go on to discuss carbon nitride and organic polymer photocatalysts, and the impact of charge trapping and heterojunctions in extending the lifetime of charge carriers. I will conclude by considering some of the kinetic challenges for photocatalysts and photoelectrodes materials based on conjugated polymers, and the role of materials design in impacting upon these kinetics.

Phosphorus assumes a paramount role in biology as phosphate (PO_4^{3-}), but its origin and transformation are uncertain. Most theories suggest meteorites brought phosphorus during the Archean, depositing iron-phosphide, like Schreibersite, on Earth. Recent experiments show these materials interact with wetting and corrosion to produce various oxygenated phosphorus compounds.

On the other hand, even if calcium phosphates, *i.e.* apatites, exhibit both low reactivity and insolubility, rendering the phosphate content inaccessible for phosphorylation reactions with specific prebiotic molecules, the role of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] as a catalyst in prebiotic chemistry for the formation of ribose from formaldehyde and glycolaldehyde has been proposed.

In this contribution, we studied the wetting process of schreibersite (Fe_2NiP) by means of density functional theory calculations.[1] The simulations explored various water coverages on the stable (110) [2] and (001) Fe_2NiP surfaces, providing insights into water binding energy values and predicting vibrational spectra. Furthermore, we examined water reactivity through multiple deprotonation reactions, progressively introducing more water molecules to facilitate the formation of phosphonic and phosphoric acids and their respective deprotonated forms.[3] Finally, we studied by means of very preliminary simulations the steps of the formose reaction on HA surfaces.

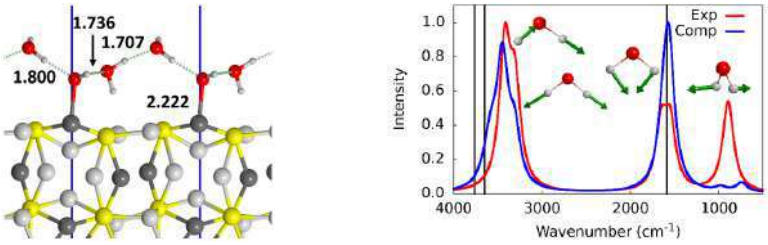

Figure: H_2O on (110) Fe_2NiP surface (left); experimental vs computed IR spectrum at 125 K (right). H in white, O in red, P in yellow, Fe in light grey, Ni in dark grey.

jessica.perrero@uab.cat

In the denser and colder regions of the interstellar medium (ISM), gas-phase sulphur is depleted by two or three orders of magnitude with respect to its cosmic abundance.[1] Thus, which species are the main carriers of sulphur is an open question. Recent studies have proposed S_n species as potential sulphur reservoirs.[2] Among the various sulphur allotropes, the most stable one is the S_8 ring, detected in asteroid Ryugu and Orgueil meteorite.[3] Shorter species, namely S_3 and S_4, have been found in comet 67P/C-G, but their presence in the ISM remains elusive.[4] In this study, we compute the binding energies (BEs) of S_n (n=1–8) species on an amorphous water ice surface model and analysed their infrared (IR) and Raman spectral features to provide data for their identification in the ISM. Our computations reveal that these species exhibit lower BEs than previously estimated in the literature[2], and their spectral features experience minimal shifts when adsorbed on water ice because of the weak S_n/ice interactions. Furthermore, these species display very weak IR band intensities, suggesting Raman spectroscopy as a promising technique for their identification in terrestrial laboratories.[5] Accurate instruments operating in the mid-infrared range are required for detecting the presence of these species in dense interstellar environments.

nadia.balucani@unipg.it

The detailed mechanism at the atomistic level of the reactions involving small aromatics has remained mostly unexplored because of the difficulty in studying multichannel reactions with the typical experimental methods available in the field of reaction dynamics. We have recently succeeded in doing that thanks to the versatility of the crossed molecular beam technique with mass spectrometric detection and time-of-flight analysis empowered by the soft ionization approach developed in our laboratory. We have investigated the reactions of atomic oxygen and atomic nitrogen with benzene, toluene and pyridine. The results have been surprising and interesting at the same time. Briefly, in the case of the atomic oxygen reactions, notable differences have been observed when comparing the reactions with benzene and pyridine (even though they are isoelectronic species for which a similar reaction mechanism was expected) or when comparing the reactions of benzene and toluene (even though the methyl substitution was not expected to affect the reaction mechanism).[1-3] A comparison with the predictions of state-of-the-art quantum calculations proved that those differences are due to the different extent of intersystem crossing to the underlying singlet potential energy surface (PES).[1] That, in turn, depends only on the coupling terms between the triplet and singlet PESs. In the case of the atomic nitrogen reactions, the reaction mechanisms for the three systems proceed via the insertion of N into the aromatic rings with the formation of 7-membered rings.[4,5] Ring contraction mechanisms are important in all cases, challenging the common notion that aromatic rings are resistant to chemical attack.

Our results help in clarifying the mechanism of chemical erosion of space-technology polymers in the Low Earth Orbit and the mechanism for the formation of N-doped graphene in N_2 plasmas.

The reliable simulation of molecular properties of complex systems requires an accurate description of all its components, including the interactions between the target molecule and its chemical environment. Multiscale modeling approaches have emerged as the most successful methodologies in this context, especially for computing spectroscopic properties of systems in solution.[1,2]

We have recently proposed a multilayer embedding approach, which divides the system into three portions. The first two portions are treated using density functional theory (DFT) and the frozen density embedding (FDE) approach.[3] The third part is described by using a classical atomistic polarizable embedding, based on the fluctuating charges (FQ) force field. The resulting QM/FDE/FQ method was challenged to calculate excitation energies of molecules in aqueous solution.[4]

In this contribution,[5] we extend the method to the calculation of NMR spectra of solvated systems, refining the outer FQ shell in terms of the fluctuating charges/fluctuating dipoles force field (FQFμ).[6] We demonstrate the effectiveness of the model by applying it to the simulation of NMR spectra of Brooker's merocyanine in aqueous and non-aqueous solutions, showing a good agreement with available experimental results and providing insight into solvent effects on NMR signals.

[b]*Department of Materials Science, University of Milano-Bicocca, 20125 Milano, Italy*
simone.perego@iit.it

Ammonia is considered a potential hydrogen vector due to its high hydrogen content and ease of transportation and storage. However, on-site carbon-free hydrogen production requires the development of efficient methods of hydrogen extraction from ammonia. To this end, iron-based catalysts are widely employed in ammonia cracking. Despite more than one century of studies, a microscopic characterization of the reaction is still lacking, hindered by extreme reaction conditions (700-800 K).[1] So far, studies based on density functional theory (DFT) calculations often neglect dynamic behaviours, which play a critical role in heterogenous catalysis, explaining the activity and long-term stability.[2-4] Leveraging state-of-the-art molecular dynamics, machine learning potentials, and enhanced sampling methods, we offer an atomistic view of the adsorption, diffusion, and dehydrogenation processes of NH_x (x=1,3) on two representative surfaces at *operando* temperature of 700 K. Dynamics pervasively affects all steps of decomposition, including on the stable (110) surface where the high mobility of reaction intermediates influences the reactivity. The role is even more dramatic on the (111) surface, where the mobility of Fe surface atoms introduces new adsorption sites and alters the dehydrogenation barriers. Our study establishes a correlation between diffusion and dehydrogenation free energy barriers, highlighting the intricate interplay between surface dynamics and catalytic activity. A detailed analysis of reactive events shows that there is never a single transition state, but it is always an ensemble composed of at least two pathways (Fig.1 left). Notwithstanding, a unified mechanism can be identified by following the charge transfer along the different reaction pathways (Fig.1 right).[5] The framework used is general and can be employed to study other heterogeneous catalysis processes with quantum mechanical-like accuracy.

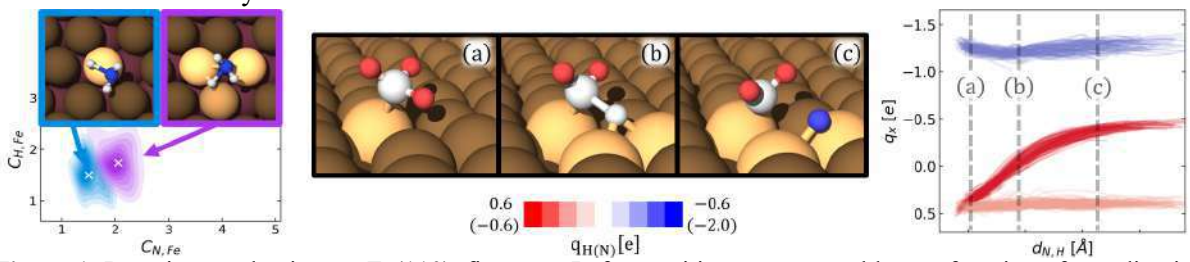

Figure 1: Reaction mechanism on Fe(110), first step. Left: transition state ensemble as a function of coordination numbers $C_{X,Fe}$. Two different channels are highlighted for each reaction. Right: charge evolution during reaction across 100 reactive events. Insets (a-c) show a reactive event with atoms coloured according to their net charges.

Exploring PET dissolution in monoterpenoid-based eutectic solvents: experimental insights and Molecular Dynamics simulations

E. Mangiacapre,[a] A. Czerska,[a] F. Lo Celso,[b] A. Triolo[c] and O. Russina[a]

Poly(ethylene terephthalate) (PET) is a widely used polyester plastic, accounting for 8% of global plastic production. Despite its versatility across industries, PET poses environmental challenges due to its non-biodegradable nature, raising concerns about its long-term persistence in landfills and potential harm to marine and human life. Chemical recycling methods facilitated by ionic liquids and eutectic solvents (ES), offer promising avenues for efficient PET breakdown. Notably, a natural ES comprised of carvacrol and thymol, two structural isomers, in a 1:1 molar ratio demonstrated effective PET solubilization, achieving a remarkable 10 wt% solubilization at 150°C without inducing plastic degradation.[1] This study presents a thorough characterization of various ES-PET mixtures at different plastic contents (ranging between 0 and 10 wt%). We investigated the temperature-dependent behavior of density (ρ) and dynamic viscosity (η) between 293.15 K and 333.15 K. Additionally, the aggregation of PET in these mixtures was examined through Dynamic Light Scattering and Small Angle X-ray Scattering experiments, elucidating the polymer status in solution. Furthermore, Molecular Dynamics simulations delve into PET oligomer solvation mechanisms, revealing the interplay between carvacrol and thymol in efficiently solvating the chain. This approach suggests that PET's high solubility is driven by thymol's hydrogen bonding interactions with PET oxygens and carvacrol's π-π interactions with the PET aromatic rings, underscoring its ring's propensity for such interactions [2]. This work represents a significant advancement in the comprehension of PET dissolution utilizing a natural ES based on monoterpenoids.

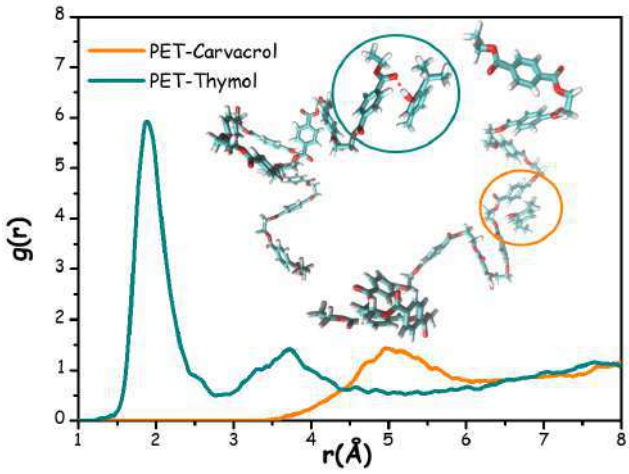

Figure 1: Radial Distribution Functions (RDFs) of the correlations between carbonyl oxygens of PET and thymol hydroxyl hydrogen (in green) and those between the centers of PET and carvacrol rings (in orange).

Thermodynamic study of urea/choline chloride deep eutectic solvent by vapor pressure measurements under effusion conditions

F. I. Travaglini, L. Romagnoli, M. Busato, G. Mannucci, P. D'Angelo, A. Ciccioli

Department of Chemistry, Sapienza University of Rome, Piazzale Aldo Moro 5, 00185 Rome, Italy
lorenza.romagnoli@uniroma1.it

Deep eutectic mixtures have received an ever-increasing attention in the last two decades as a novel class of eco-friendly solvents for a number of uses, thanks to their appealing and tunable properties such as low volatility, good thermal stability, low toxicity, and the possibility of being synthesized by safe, readily accessible and inexpensive precursors. Among the most useful applications proposed for deep eutectic solvents (DESs) there are batteries and other energy-related fields, catalysis and organic synthesis, separation processes, drug delivery and other aspects of pharmaceutical and biomedical research.

Starting from the work by Abbott et al.,[1] reporting unexpectedly low freezing points and interesting solvent properties for 2:1 mixtures of urea/choline chloride (reline) and other quaternary ammonium salts, the number of eutectic mixtures claimed as DESs has grown exponentially in the last years. Nevertheless, a rigorous methodology for the investigation of some of their fundamental physico-chemical properties has not been established yet, even for the most studied systems. In particular, it is frequently reported that DESs are characterized by low vapor pressures, in comparison with conventional solvents, although not as low as those of ionic liquids, which share with these mixtures several characteristics and prospective applications.

Despite their importance in deriving the mixing thermodynamic properties, studies reporting vapor pressure measurements of DESs are surprisingly scarce: as regards reline, only two thermogravimetric determinations, carried out under free evaporation conditions, are reported,[2,3] resulting in one order-of-magnitude disagreement. Apparently, no vapor pressure data based on effusion close-to-equilibrium conditions are available in the literature. In the effort to give a contribution to elucidate these contradictory results and to fill the gap on thermodynamic description of DESs, we have undertaken the measurement of equilibrium vapor pressures of reline using Knudsen effusion mass spectrometry. The vapor phase was proven to contain exclusively urea and, by integrating the mass spectrometric signal as a function of time, the change in the composition of the liquid mixture during the experiments was monitored. Urea vapor pressures were measured in the temperature range 320 – 360 K around the eutectic composition, aiming at determining the activity as a function of temperature and composition and the mixing properties.

Supported metal nanoparticles (NPs) may undergo adsorbate-induced phenomena, with evident consequences on their performance in catalytic applications. CO-induced surface phenomena involving Pd NPs have been documented mostly at high temperatures.[1,2] In this work, we report an unusual step-shaped CO adsorption isotherm at 30°C on Pd/Al_2O_3, associated with an unexpected increase in the heat of adsorption and with a modification in the relative abundance of the different Pd-carbonyl species. These three independent observations can be reconciled by considering a partially reversible CO-induced roughening of the Pd(100) facets entailing the creation of novel defective sites. The detailed knowledge of the interaction of CO with Pd NPs at mild temperature in terms of strength, coverage and adsorption mode/sites is a key to control reactivity and has analytical relevance for the correct interpretation of CO chemisorption measurements. Our experimental strategy has the potential to become a benchmark in the investigation of the adsorbate-induced dynamic behaviour of supported metal NPs.

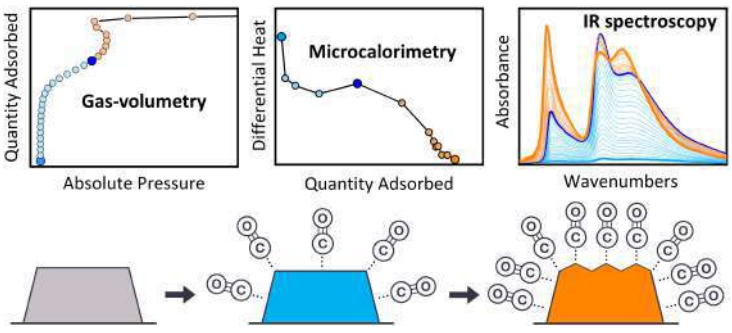

Figure 1: Combination of gas-volumetry, adsorption microcalorimetry and IR spectroscopy provided an unprecedent insight into a CO-induced surface reconstruction of Al_2O_3-supported Pd NPs involving the (100) surface and entailing the creation of new, defective, adsorption sites.

Ammonia (NH_3) has gained widespread use as a potent fertilizer in agricultural practices,[1] and has recently gained attention as a promising source of clean energy and fuel.[2,3] Although natural processes such as lightning and biological nitrogen fixation by nitrogenase contribute to nitrogen fixation, they are insufficient to satisfy the increasing demand driven by population growth. The introduction of the Haber–Bosch method in 1909 revolutionized ammonia industrial process. Due to the exceptional stability of nitrogen molecule (N_2) with a bond energy of 941.3 kJ mol^{-1}, the process of nitrogen fixation via the Haber-Bosch method requires the utilization of an Fe-based catalyst at elevated temperatures (400-450 °C) and pressures (150-200 atm).[4] This results in substantial energy consumption and elevated production costs for NH_3, along with significant environmental impacts.[1] Consequently, there is an urgent need for the advancement of novel nitrogen fixation technologies that are cost-effective, efficient, and environmentally sustainable.[5-7] In these last years, thanks to their unique and suitable energy band structure, high separation rate of photogenerated electrons-holes and response to visible light,[8] bismuth-based materials have emerged as a new kind of effective photocatalysts for nitrogen photofixation. We have then opted to direct our focus towards a more straightforward material such as Bismuth Oxide (Bi_2O_3). This material indeed has interesting properties,[8] notably its various phases (α, β, γ, δ, and ω), each with different property such as the band-gap, leading to distinct optical behaviours. Despite these intriguing properties, the literature regarding this material, particularly in nitrogen fixation, is rather limited. Therefore, we have synthesized various phases, including a mixture of these, to explore and elucidate their efficacy for the ammonia photoproduction. Additionally, we have focused on studying the luminescence properties of the obtained materials, in order to elucidate the dynamics of charge carriers and thus attempting to relate photocatalytic efficiencies to structural and electronic properties of the prepared materials.

marco.montalbano@unimi.it

Titanium dioxide nanosheets enthralled photocatalysis scientists worldwide due to their peculiar properties, such as the higher reactivity of the {001} facets compared to the {101} facets and an optimized charge separation resulting from the preferential migration of electrons and holes towards the {101} and {001} facets, respectively.[1] Nevertheless, the effects induced by the deposition of noble metal nanoparticles (NPs) on the photoactivity of differently shaped TiO_2 are still incompletely grasped. In this scenario, the present work aims at elucidating the interplay on TiO_2 photoactivity between particle morphology[2] and gold NPs deposition by evaluating the photoactivity of Au modified anatase nanocrystals with either a pseudo-spherical shape or a nanosheet structure.

We found that only in the case of pseudo-spherically shaped TiO_2 photocatalysts, mainly exposing {101} facets the deposition of noble metal NPs produces a significant photoactivity increase in both Rhodamine B photocatalytic oxidation under *in-situ* surface fluorination conditions and formic acid photocatalytic degradation.

Differently, we found that the deposition of Au NPs on the anatase surface only slightly affects its photocatalytic performance in Cr(VI) reduction, which is kinetically limited by the anodic half-reaction,[3] whereas a larger exposure of highly oxidant {001} facets result to be intrinsically beneficial for overcoming the rate-determining step of this photodegradation process. The obtained results are rationalized in the light of a novel mechanism based on the preferential migration of oppositely charged carriers towards different crystal facets. In fact, Au NPs deposited on {101} facets may cooperate with the preferential migration of electrons towards such facets by efficiently capturing them and improving charge separation. Instead, when Au NPs are mainly deposited on the more oxidant {001} facets, the electron capture ability of gold NPs and the preferential migration of the holes towards the same {001} facets may favour the extremely undesired recombination of photoproduced charge carriers.

Catalysts based on supported ruthenium (Ru) nanoparticles (NP) are widely employed for oxidation and hydrogenation reactions, owing to their performance and competitive price. Here we study the reducibility and the H_2-induced restructuring of a 5 wt% Ru/Al_2O_3 catalyst synthesized by deposition-precipitation from $RuCl_3$. Supported RuO_x species obtained with this method are easily reducible, at the expense of a higher complexity of the systems. Understanding the nature and the reducibility of supported RuO_x species is essential to optimize the catalyst activation step and/or obtain the best reaction conditions in hydrogenation reactions. By means of H_2-TPR, *operando* IR-MS spectroscopy and *operando* XRD/PDF-MS, we obtained deeper insights on thermodynamics and kinetics of Ru reduction, focusing on both surface and bulk phenomena. All measurements were carried out with the same protocol to allow direct comparison of complementary techniques. In H_2-TPR, two H_2 consumption events are assigned to the reduction of surface RuO_x and bulk RuO_2 (Fig.1A). Reduction occurs at notably lower temperature compared to similar catalysts previously reported[1,2] and a fraction of RuO_x reduces already at 25°C, as determined with quantitative analysis of H_2-TPR runs starting from -120 °C. In the *Operando* IR-MS experiment (Fig.1B), surface reduction is pinpointed by the decrease of the 2ν(Ru=O) band and the appearance of signals due to Ru hydrides concomitant to water evolution. *Operando* XRD/PDF-MS allowed to follow the kinetics of reduction of bulk rutile RuO_2 and the emergence of the *hcp* Ru phase (Fig.1C)[3,4]. The multi-technique approach undertaken allows to obtain a better definition of the reduction process of a complex catalyst composed of various Ru oxide entities and of the structural and chemical features of metal NP in their active state.

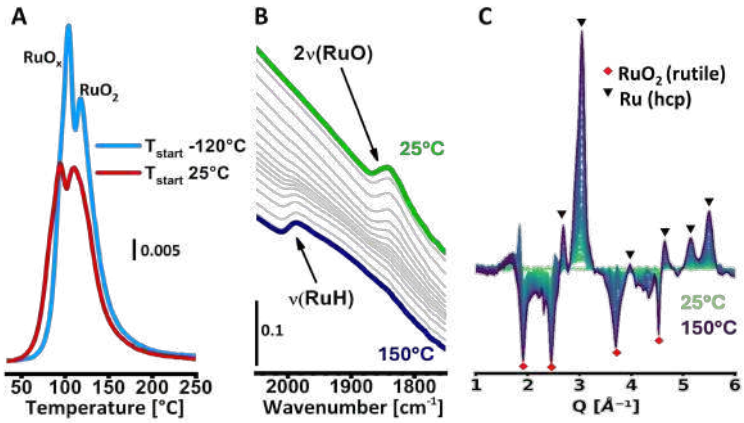

Figure 1(A) H_2-TPR performed starting, (B) IR spectra and (C) differential XRD patterns during reduction from 25°C.

francesca.rosso@unito.it

Titanium (Ti) doped zeolites are used as shape selective catalysts for partial oxidation reactions (e.g. epoxidations or hydroxylations), using hydrogen peroxide (H_2O_2) as oxidizing agent.[1] Titanium Silicalite-1 (TS-1)[2] with MFI framework is the most renowned among all Ti-zeolites. The Ti-zeolite with MWW framework and high TiO_2 loading (Ti-MWW, graphical representation of the framework shown in Figure 1, Ti atoms in cyan) recently showed very promising catalytic outcomes.[3-4] The Ti insertion in the purely siliceous MWW framework was discovered to occur mainly during the post treatment washing with HNO_3, when the double structure directing agent synthetic method is used.[5] When the framework is modified, the behaviour of the Ti-peroxo (Ti-OO^-) and Ti-hydroperoxo (Ti-OOH) active species[6] can be different. Here, a combination of infrared (IR) and ultraviolet-visible (UV-Vis) spectroscopies was adopted to unveil the reason of the catalytic behaviour of TS-1 and to provide direct means of comparison with TS-1.[5]

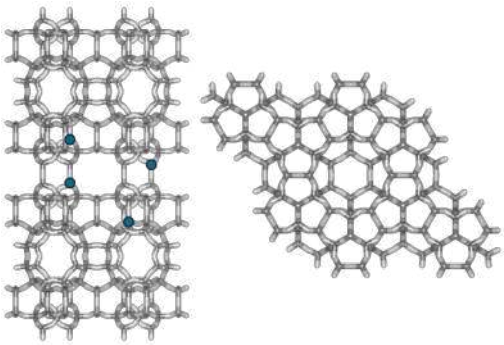

Figure 1: structure of MWW framework.

The acidic behaviour of the Ti sites and the interaction of the Ti sites with H_2O_2 were revealed by exploiting carbon monoxide, acetonitrile, pyridine and ammonia as probe molecules in infrared spectroscopy and diffuse reflectance ultraviolet spectroscopy. The Ti centres that behave as Lewis acid sites showed stronger acidity than those observed in TS-1. This is coherent with previously reported results,[4] suggesting that a significative fraction of the Ti sites in Ti-MWW are $TiOH(SiO)_3$ instead of $Ti(OSi)_4$. The Ti-peroxo and -hydroperoxo complexes formed with H_2O_2 were shown to be more labile than in TS-1 case and preliminary studies suggest that the formation of the active complexes is completely reversible.

The double life of kesterite nanoparticles: photovoltaics and photocatalysis

G. Tseberlidis,[a] A. H. Husien,[a] V. Trifiletti,[a] F. Gosetti,[b] S. Binetti[a]

[a]*Department of Materials Science and Solar Energy Research Center (MIB-SOLAR), University of Milano-Bicocca, Via Cozzi 55, 20125, Milan, Italy*

giorgio.tseberlidis@unimib.it

In the last decade, kesterite (Cu_2ZnSnS_4 – CZTS) thin films have been widely studied for photovoltaics (PV), due to their similarity to the well-known and well-performing $Cu(In,Ga)Se_2$ (CIGS). Its high absorption coefficient (> 10^4 cm^{-1}), its high stability and a tuneable direct band gap of 1.45 - 1.50 eV, promote kesterite as an ideal candidate for non-toxic, cheap, earth-abundant photovoltaic thin-film absorber.

Here we present our study on the properties and the possible use of CZTS in the form of nanoparticles (NPs) based on a straightforward hot-injection synthesis in an oxygen-free environment, starting from metal acetates and elemental sulphur in oleylamine. The impact of different injection temperatures on the crystalline size, crystal structure and formation of undesired secondary phases was investigated, along with a procedure to get rid of them. The resulting NPs were fully characterised by Raman spectroscopy, X-ray diffraction, energy-dispersive X-ray spectroscopy, transmission electron microscopy, and scanning electron microscopy. Additionally, the presence and removal of both organic traces and detrimental phases were confirmed by thermogravimetric analysis and FTIR-ATR analysis.

Our CZTS NPs were tested as potential inorganic hole transport material (HTM) to achieve cost-effectiveness, long-term operational stability and sustainability goals in perovskite solar cells (PSCs), especially if compared to the organic, expensive, not-sustainable but conventionally-used HTMs in PSCs (i.e. PTAA, 2PACz, PEDOT:PSS). The hole mobility and charge transport properties were investigated in plane and out of plane, to ensure the feasibility of the material to act as HTM. The resulting HTM film was used in p-i-n architecture with $[CH_3NH_3]PbI_3$ and compared to an organic-HTM-containing reference device. Under optimised conditions, the PSCs with CZTS NPs HTM remained stable, with PV performance improving by up to 80% of the initial value over time.

Parallelly, the photocatalytic activity of our CZTS NPs was tested, to address the environmental impact of industrial wastewater. To this purpose, the CZTS NPs were employed to degrade diclofenac (DCF) in water, being one of the most persistent and hazardous emerging micropollutants. Notably, the CZTS NPs show promising efficiency of 80-90% DCF degradation over 120 minutes in both UV-vis and Visible-light-only conditions, demonstrating its potential employment also in this field of application.

CO oxidation on $LaFe_{1-X}Co_XO_3$ perovskite: transient species analysis *via* Modulation Excitation DRIFT Spectroscopy with Phase Sensitive Detection (ME-DRIFTS-PSD)

P. Ticali,[a] N. Cosanne,[a] S. Najafishirtari,[a] M. Behrens[a]

[a] *Institute for Inorganic Chemistry, Christian-Albrechts University of Kiel, 24118 Kiel, Germany*
pticali@ac.uni-kiel.de

DRIFT Spectroscopy, under gas-phase and *operando* conditions, in combination with Modulation Excitation Spectroscopy (MES) could help provide new insights in heterogeneous catalysis and surface science to increase the signal-to-noise ratio and differentiate between the active vs. spectator species. Under a periodic modulation of the reaction environment, the catalyst's active species give different responses. By transforming the data into the phase domain and performing in-phase analysis, the Phase Sensitive Detection (PSD) can identify the sequence of the occurrence of these species in the phase domain and therefore, provide information about the reaction mechanism (Figure 1a).[1] A square wave stimulation was used.[1] To extract kinetic information from the system, the PSD analysis was applied at different *k* indices.

This work shows a transient species analysis regarding two LaFe-based perovskite catalysts with 0% and 25% of Co loading involved in CO oxidation. The focus is to clarify the role of Co in CO_2 formation. In this case, we performed the analysis after CO oxidation at both 100 and 200 °C (based on catalytic results). The analysis shows that carbonates are formed before any other species on the surface upon exposure to a mixture of $CO+O_2$. In the presence of Co, the catalyst shows a slower (more negative phase delays) saturation of the surface due to carbonates and faster (less negative phase delays) formation of CO_2, suggesting the active role of Co, compared to the 0%Co sample. On the other hand, the comparison of different *k* indices highlights that CO_2 formation is faster at k=1, suggesting the presence of two competing mechanisms: one carbonate-mediated route and one non-carbonate-mediated route. Our study unveils the potential of ME-DRIFTS as a powerful tool to unravel kinetic information from catalytic reactions by shedding light on the reaction mechanism. This study not only widens understanding but also influences future research and application of spectroscopy in the field of heterogeneous catalysis.

$$A_k\left(\phi_k^{psd}\right) = \frac{2}{T}\int_0^T A(t)\sin\left(k\omega t + \phi_k^{psd}\right)dt$$

Role of the nature, strength, and density of the acid sites in mesostructured aluminosilicate catalysts for CO_2 conversion to dimethyl ether

F. Secci,[a,b] V. Mameli,[a,b] E. Rombi,[a,b] S. Lai,[c] M. Sanna Angotzi,[a,b] P.A. Russo,[d] N. Pinna,[d] M. Mureddu,[c] C. Cannas[a,b]

fausto.secci@unica.it

Due to the increasing concern regarding global warming, research is currently focusing on green fuels obtained by the reduction of captured CO_2 (e-fuels). One of the most promising e-fuels is dimethyl ether (DME), a replacement for diesel fuel. DME is obtained from CO_2 through two subsequent reactions. The first one, promoted by Cu-based redox catalysts, is the reduction of CO_2 to methanol; the second one, promoted by solid acidic catalysts, is the dehydration of methanol to DME[1,2].

Three different mesostructured aluminosilicates (Al-MCM-41, Al-SBA-16, and Al-SBA-15) and a mesostructured alumina (γ-Al_2O_3) are here proposed as methanol dehydration catalysts to be used in physical mixture with a Cu-based redox catalyst (CZA) for the one-step DME synthesis from CO_2. All the systems were synthesized by different sol-gel approaches. All mesostructured catalysts were characterized with XRD, TEM and nitrogen physisorption to determine their structural, morphological, and textural properties. Some systems were characterized by ^{27}Al- and ^{29}Si-SS-NMR. A particular focus was put on the characterization of the acid sites with NH_3-microcalorimetry and pyridine-FTIR. The catalysts were finally tested for the CO_2-to-DME conversion in a bench-scale plant with a fixed-bed reactor, correlating their performances with their acidic properties. The structural, morphological, and textural characterization evidences a hexagonal (P6mm) mesopore arrangement for all samples with the exception of Al-SBA-16, that shows a cubic (Im3m) arrangement. The characterization of the acid sites indicates that γ-Al_2O_3 only features Lewis sites, while all the aluminosilicates show both Lewis and Brønsted sites; it also points out that Lewis sites are stronger than Brønsted sites. Another important observation is that γ-Al_2O_3 shows the highest surface density of acid sites (number of sites as a function of the surface area); among the three aluminosilicates, the one with higher surface density of sites is Al-SBA-16. The catalytic tests show that Al-SBA-16 is, among all catalysts, the one with the highest dehydration activity, followed by the other aluminosilicates and, last, by γ-Al_2O_3. These results evidence that Brønsted sites are more active towards methanol dehydration than Lewis sites, due to their nature and their moderate strength, and that the proximity of such sites (high surface density) promotes methanol dehydration.

In this work, a catalytic system was investigated using halloysite nanotubes (HNTs) sourced from different deposits. Halloysite nanotubes find application in different fields including drug delivery, enzyme immobilization, polymer technology, catalysts design, removal of pollutants and cultural heritage.[1] HNTs are characterized by mineral impurities that influence the physical and chemical properties of this material.[2] Despite the possibility of using HNTs as support for catalytic purposes, HNTs could have an intrinsic catalytic activity that alter the final experimental results. The purpose of this research is to highlight this aspect through the degradation of ascorbic acid and the photocatalysis of ibuprofen employing four different types of halloysite, as shown in Figure 1. In particular, we observed a correlation between the presence of impurities in the chemical composition and the efficiency of a catalyst. Specifically, we examined how the presence of zinc and manganese in the composition could influence the degradation.

This investigation opens up new perspectives of research for accurately selecting halloysite over other nanoclays options.

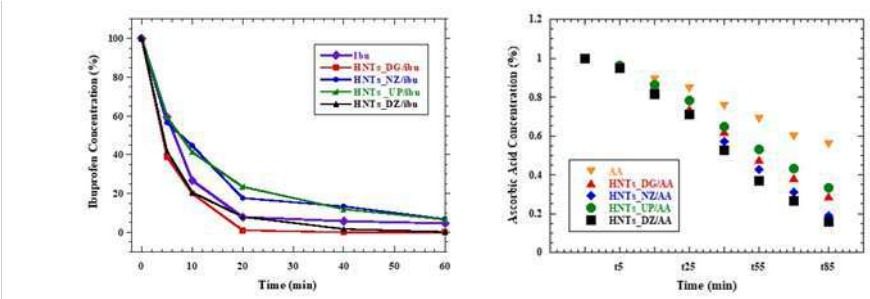

Figure 1: Photodegradation of ibuprofen (on the left), degradation of ascorbic acid (on the right).

$BiVO_4$-based Photoanodes for Solar Energy Conversion

M.V. Dozzi, A. Polo, C. Nomellini, I. Grigioni, E. Selli

Dipartimento di Chimica, Università degli Studi di Milano, Via Golgi 19, 20133 Milano, Italy
mariavittoria.dozzi@unimi.it

Solar water splitting in a photoelectrochemical (PEC) tandem cell is a leading candidate reaction to convert and store solar energy in high-value chemicals, such as green hydrogen, that could replace fossil sources.[1] Identifying light-absorbing materials that satisfy the requirements of stability and performance is a major challenge, especially when employing them as photoanodes in the demanding water oxidation reaction.

Bismuth vanadate, having a 2.4 eV band gap energy and thus being able to absorb ca. 8% of the solar spectrum, has emerged as a good transition metal semiconductor oxide to be employed as photoanode, though it has intrinsic limitations, i.e., poor charge transport, slow water oxidation kinetics and high rate of surface recombination.

Two main strategies have been pursued to increase the solar energy to fuel conversion efficiency of $BiVO_4$, consisting in either i) coupling it with another suitable semiconductor oxide in a heterojunction, in order to increase the separation of the photoproduced charges, or ii) doping it with higher valent metal ions, with respect to both Bi^{3+} and V^{5+}, such as Mo^{6+}, trying to alleviate its intrinsic poor electron transport properties.

Indeed, significantly higher values of Incident Photon to Current Efficiency (IPCE) have been attained at wavelengths shorter than 500 nm when $BiVO_4$ was coupled with WO_3 in a $WO_3/BiVO_4$ heterojunction, by exploiting the excellent visible light harvesting properties of $BiVO_4$ combined with the superior conductivity of photoexcited electrons, typical of WO_3. Due to the favourable band alignment between the two oxides, photopromoted electrons in $BiVO_4$ are expected to migrate into WO_3 and then rapidly to the external circuit, while photoproduced holes may accumulate in $BiVO_4$. Selected case studies dealing with the performances exhibited under different irradiation configurations by home-made thin coupled electrodes, prepared through variable deposition techniques, will be presented.[2-4] At the same time, the multifaceted role of Mo^{6+} doping onto both bulk and surface properties of $BiVO_4$ will be clarified by means of a unique combination of morphological and PEC analyses.[5-6]

Semi-Transparent Perovskite Solar Cells with Dielectric/Metal/Dielectric Electrodes

V. Ferrara, G. Arrabito, F. Principato, V. Vetri, M. Scopelliti, B. Pignataro

Department of Physics and Chemistry - Emilio Segrè, University of Palermo, viale delle Scienze, Palermo 90128, Italy.
vittorio.ferrara@unipa.it

Semi-transparent perovskite solar cells (ST-PSCs) are promising devices for applications including building-integrated photovoltaics and multi-junction tandem cells.[1,2] The performances of ST-PSCs are influenced by the electrical and optical characteristics of each cell component. In this context, dielectric/metal/dielectric (D/M/D) multilayers have emerged as one of the current preferred choices for semi-transparent electrodes, achieving an ideal balance between conductivity and transparency.[3,4] This study proposes a novel D/M/D multilayer with nickel as a thin metallic film in between MoO_x dielectric layers as the top anode electrode in ST-PSCs. The MoO_x/Ni/MoO_x multilayers were deposited by thermal evaporation and their optical and electrical properties were characterized by using UV-visible absorption spectroscopy and sheet resistance measurements. Also, the electrodes were studied using depth-profiling X-ray Photoelectron Spectroscopy (XPS) to investigate possible atom migration or interface physicochemical processes. The systems proposed can represent a more economical alternative to the common noble metal layer used as electrodes, thus improving the cost-effectiveness and commercial viability of ST-PSCs.

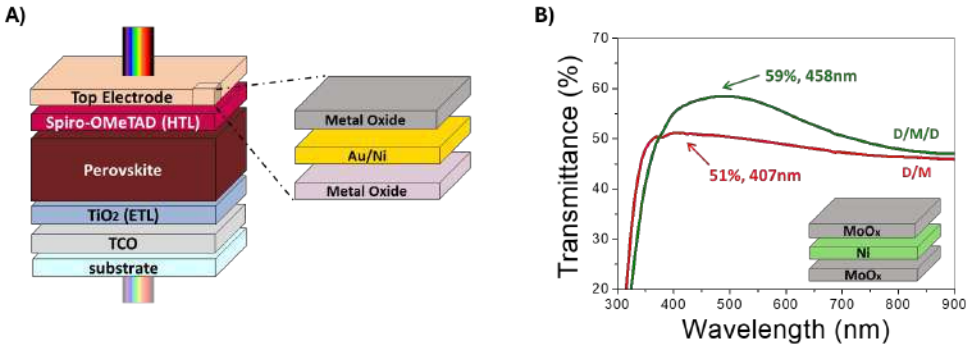

Figure 1: A) scheme of ST-PSC with a semi-transparent D/M/D electrode; B) transmittance changes at 300-900 nm.

In recent years, exploring sustainable energy sources has led to growing interest in hydrogen (H_2) as an energy carrier; in particular, many studies have been dedicated to H_2 storage, aiming to overcome its application limits [1]. Solid-state systems are considered the safest option to store H_2 and various classes of materials have been thoroughly investigated to assess their gravimetric capacity, distinguishing them according to the sorption mechanism that takes place. By the physical adsorption approach, porous carbon materials are the most suitable candidates because of their lightweight, high surface area, and microporous structure [2].

To enhance cost-effectiveness, activated carbon materials (ACs) derived from various renewable feedstock wastes have gained importance, owing to their abundance and the potential for tailoring their properties through simple chemical processing [3].

Our work is based on activated carbons (ACs) derived from pyrolysis and activation of agrifood wastes, ranging from the most common biomasses as cereals to more local wastes typical of the Lombardy region as asparagus stems and pumpkin peels, aiming to use them as solid-state H_2 storage systems. Biomass residues undergo a two-step synthesis: an initial pyrolysis process at moderate temperatures (450°C-650°C), yielding a carbonaceous material referred to as biochar, followed by a thermochemical activation with KOH leading to alterations in structural morphology, specifically in microporosity development, and giving as final product ACs. Analyses of specific surface area, pore characteristics, and H_2 adsorption/desorption behaviours provide insights into the impact of the thermochemical treatments on the H_2 storage efficiency of the various ACs. The results demonstrated a significant improvement in H_2 storage capacity through activation in all the analysed biochar, going from initial values on pyrolyzed biochar of less than 1 wt% to values of 5 wt% at 77K and 20 bar, substantially higher than the performance of graphitic based materials (up to 3 wt%). The forthcoming comparative analysis of various biochar materials derived from different agricultural wastes enables the identification of the most optimal biochar for enhanced H_2 storage and advancing clean energy technologies.

Even though $LiCrO_2$ and $NaCrO_2$ belong to the same family of O3-type layer oxides and share the same transition metal, they have significantly different electrochemical properties. The latter is one of the most popular active materials as positive electrodes in Na-based all-solid-state batteries, since its working voltage matches fairly well with the stability window of a series of solid electrolytes.[1,2] The former, however, has proven to be electrochemically inactive *vs.* Li. When Li is de-intercalated, the oxidized, relatively small Cr(VI) moves towards tetrahedral sites in the Van der Waals gap. [3] Such a migration is preferred in $LiCrO_2$, in which the O-O distance is shorter, allowing the Cr(VI) to sit in a more stable configuration. To prevent the Cr migration, it could be synthesized a mixed phase possessing both Li and Na as interslabs cations, with the Na increasing the O-O distance (*i.e.* less stable tetrahedral sites for Cr). Nonetheless, the large chemical stability of both $LiCrO_2$ and $NaCrO_2$ hampers the synthesis of such mixed phase following conventional, quasi equilibrium processes. Indeed, the synthesis of both $LiCrO_2$ and $NaCrO_2$ requires 5 hours of heat treatment at 900 °C in an inert atmosphere.[3] Conversely, solid-state microwave-assisted syntheses, provide a high heat transfer rate to the reacting powders, forming metastable phases.[4] This dramatically reduces the reaction time, making these processes more attractive from both economic and environmental point of view. In the present work, $LiCrO_2$ and $NaCrO_2$ have been obtained from fast microwave-assisted reactions, after 120 s of treatment at 500°C, in an open crucible. Moreover, a new mixed $Li_xNa_{1-x}CrO_2$ phase has been successfully synthesized, with different Li/Na ratios. P-XRD highlighted that the quaternary phase crystallizes in the *R*-3*m* space group, as the ternary oxides do, with an intermediate cell parameter along *c*-axis. No peaks owing to a superstructure demonstrate that Li and Na are mixed in each WdV gap and they do not form alternate layers. The formation reaction of $Li_{0.58}$-$Na_{0.42}CrO_2$ has been followed by *in situ* synchrotron P-XRD simulating the fast-heating rate with a tuned hot blower, revealing an intermediate formation of a eutectic between the two carbonates. Galvanostatic cycling tests show that microwave-assisted $NaCrO_2$ has the same electrochemical behaviour in both liquid- and solid-state cells of the same compound obtained via conventional synthesis, while the $Li_xNa_{1-x}CrO_2$ still shows poor to no activity *vs.* Li.

In the last decades in the field of energy storage, many research efforts have been devoted to the development of solid-state electrolytes (SSE), in order to eliminate the flammability issues related to the organic solvents and allow the manufacturing of compact, more durable and with higher energy density secondary batteries.[1]
In this context, we recently explored the development of novel SSE based on metal-organic frameworks (MOFs), to be employed as stand-alone or auxiliary electrolytes, taking advantage of the single-ion conducting features of these materials.
This can be either obtained by anchoring anionic pendants to the MOF structure in a post-synthetic fashion, leaving only the cations (e.g. Li^+, Na^+, Mg^{2+},) free to flow, or by synthetizing MOFs that feature themselves an anionic (or cationic) structure.[2]
An example of the first approach might involve MOF structures modified to conduct further reactions on them (e.g. couplings, click chemistry, condensations). We implemented this idea to develop a composite electrolyte in which a UiO-66 series MOF has been embedded into a polymeric membrane to improve mechanical properties while also participating in the ionic conduction.
The second approach mentioned above involves anionic or cationic MOFs. These structures have counter ions to stabilize the charge. Respectively, anionic MOFs are targeted to develop SSE for conventional batteries, while cationic ones aim to investigate SSE for halide-ion (e.g. F^-, Cl^-) batteries.
The latter are an emerging field in which the lack of solid-state electrolytes for ambient temperature applications is an issue to tackle. In fact, several of the cells developed so far suffer from degradation due to the liquid electrolytes which dissolve the metal halide electrodes.[3]
In this context, a cationic MOF is being studied as anion-conductor to assess the electrochemical properties of the material while changing the anions in the bulk.
In summary, our studies aim to explore the possibility of applying different MOFs as SSE, comparing the two different routes of post-synthetic modification and ion-exchange approach.

Green consolidants for cultural heritage: physico-chemical aspects of the new materials developed within GREENART

G. Poggi,[a] D. Chelazzi,[a] A. Casini,[a] P. Baglioni[a]

[a]*CSGI&DICUS – University of Florence, via della Lastruccia 3, Sesto Fiorentino (FI)*
giovanna.poggi@unifi.it

Cultural Heritage (CH) is a pivotal socioeconomic resource, yet its preservation confronts persistent threats from recurring degradation processes. Conservation methodologies nowadays available lack sustainability and cost-effectiveness, and are typically based on non-environmentally friendly materials. This contribution will report on the main results so-far achieved in the EU-funded project GREen ENdeavor in Art ResToration (GREENART). Coping with the imperatives of EU Green Deal, the project proposes new solutions based on green and sustainable materials and methods, to preserve, conserve and restore CH. Here we will tackle consolidants based on natural polymers from renewable sources, to mechanically strengthen weak artifacts. In the restoration practice, consolidation is typically carried out to re-introduce adhesion and cohesion of color binders with pigments, of surface layers in murals and stone, or of fibers in canvas paintings, textile, collagen-based and cellulose-based substrates. In this context, colloids and soft matter can provide invaluable contributions. For instance, we have recently demonstrated that the consolidation of decohesive pictorial layers can be achieved using amorphous starch nanoparticles (SNPs), which can be obtained by starch dissolution followed by nanoprecipitation in green non-solvents, that allows controlling the physicochemical properties of SNPs, by tuning the local ordering of polymeric chains[1]. In addition to that, we recently proposed the use of dispersions of self-regenerated silk fibroin (SRSF) for the consolidation of fragile silk, alone or in combination with cellulose nanocrystals (CNC). We have studied the response of gels formed by pure SRSF dispersions and by SRSF/CNC mixtures to shed light on the effect of nanocellulose on the physico-chemical behavior of hybrid systems. For instance, our findings show that the addition of CNC alters the gelation kinetics, leads to stronger gels and qualitatively modifies the yielding behavior[2]. Nanocellulose have been also used to strengthen degraded cellulosic fibers, by preparing hybrid systems with calcium hydroxide and calcium carbonate nanoparticles. In particular, we explored the impact of composition on the macro- and nano-scale properties of CNC-based systems through rheological analysis and small-angle X-ray scattering (SAXS), highlighting that the interactions between cellulose nanocrystals are the driving force behind the gelation of the systems[3]. Overall, the GREENART project is re-writing the current landscape of restoration tools by incorporating green metrics into the best state-of-the-art practices. It not only introduces innovative systems but also anticipates the establishment of novel green and sustainable standards in the preservation of CH.

gabriella.dicarlo@cnr.it

Nowadays, the corrosion of steel rebars represents one of the main degradation causes in concrete heritage. It is well known that the formation of corrosion products can induce mechanical stress into the concrete structure and those are typically responsible for cracks formation, spalling and detachment of the surface cover.

To preserve concrete monuments that are part of our heritage for their artistic, cultural or social value, it is necessary to develop novel solutions that are more effective than state-of-art materials and that are purposely designed for cultural heritage applications. It means that the conservation treatments should be not invasive and maintain the original aesthetical properties.

In the last decades, the search on new materials for the effective and long-term protection of steel rebars has received increasing interest. It is worth noting that new solutions should be safe for humans and the environment, preserving the surface appearance and ensuring protection from corrosion.

To face these issues, we have developed active protective materials based on stimuli responsive nanocarriers that can release a corrosion inhibitor only in a degrading environment. This approach, previously used for the protection of copper alloys,[1] was optimized for the conservation of concrete monuments within the EU H2020 InnovaConcrete project (G.A. n. 760858). Different corrosion inhibitors for steel rebars were validated in simulated concrete pore solutions and the most promising one was loaded into nanocarriers, as silica and layered double hydroxides, for a tailored release. The results showed that, by selecting an appropriate nanocarrier, it is possible to control the inhibitor release based on external stimuli and time of treatment.[3-4]

Efforts are now addressed to make these protective materials greener and to increase their protective efficacy. Specifically, safe and sustainable corrosion inhibitors have been selected and validated by comparing their protective properties with those of a benchmark. This activity is carried out within the "Smart and eco-sustainable materials for the long-term and safe protection of concrete heritage – ECOforCONCRETE" project (MUR PRIN2022 2022M4KCKP) which is kindly acknowledged for financial support.

"Twin-Chain" gels with tailored tortuosity and cleaning abilities

R. Mastrangelo[a], D. Bandelli[a], T. Guaragnone[b], A. Casini[b], P.Baglioni[b]

[a]*Department of Chemistry, University of Florence, Via della Lastruccia 3, 50019, Sesto Fiorentino, Florence, Italy*

rosangela.mastrangelo@unifi.it

Twin-Chain Networks (TCNs) are a class of hydrogels featuring enhanced cleaning ability on rough, delicate artistic surfaces.[1]

TCNs are obtained by mixing two poly-vinyl alcohols, with higher (H-PVA) and lower (L-PVA) hydrolysis degree.[1] H-PVA/L-PVA aqueous mixtures undergo a spontaneous liquid-liquid phase separation before gelation, that templates the final gel structure. After a freeze-thaw process, sponge-like gels are obtained.

We recently focused on the cleaning mechanism occurring at the gel-artwork interface: a multiplicity of factors influences the cleaning process, making its full understanding extremely complex. Nonetheless, gels cleaning abilities can be related to the networks apparent tortuosity at the nanoscale (i.e. to gels transport properties and the removal of soluble components) and gel surface roughness at the microscale (enabling the embedding of particulate matter)[2,3]. Counterintuitively, highly tortuous gels, i.e. gels in which diffusion is slower, show higher cleaning performances. Tortuosity affects the cleaning fluid residence time at the interface: a higher tortuosity results in longer residence times, improving dirt removal.

In this contribution, TCNs tortuosity was modulated by varying L-PVA molecular weight, degree of hydrolysis and hydrophilicity. As L-PVA acts as porogen during gels cryostructuration, the variation of L-PVA properties affects the polymers phase-behaviour in water, leading to different sponge-like networks (Confocal Microscopy and SEM data). The different pores morphology at the micron-scale affects both gels roughness and transport at the nanoscale: gels are characterized by a different apparent tortuosity, measured through Fluorescence Correlation Spectroscopy (FCS). Nanoscale features (crystallinity and mesh-size, from SAXS) are also affected. In general, gels featuring the largest pores at the micron-scale are the most tortuous and those showing the highest cleaning ability. The systems were tested on both model artistic surfaces and paintings from Pollock, Hélion and Tancredi Parmeggiani (Peggy Guggenheim Collection, Venice).

Carbon Capture and Storage (CCS) strategies play a central role in mitigating carbon dioxide (CO_2) emissions. Solid adsorbents for post-combustion carbon capture appear to be a promising solution due to their easier application into existing facilities.[1] Among the materials potentially able to overcome the state-of-the-art technology based on aqueous amines, Metal-Organic Frameworks (MOFs) attract an increasing attention due to the ease in tuning their structure toward a more selective CO_2 binding and a lower energy consumption process. Of special interest are the so-called "phase-change" MOFs that display steep CO_2 uptake when a threshold partial pressure is reached, because they can afford superior separation performance with a reduced energy penalty. In this work, new recently discovered flexible perfluorinated MOFs were synthesized and deeply studied: an ultramicroporous MOF based on Ce(IV) and tetrafluoroterephthalate (F_4BDC),[2] and a MOF based on Al(III) and F_4BDC.[3] The fluorinated linkers were chosen to possibly increase the hydrophobicity of the materials and the affinity towards CO_2.

An advanced multi-technique characterization approach was adopted to unveil the origin of their peculiar CO_2 adsorption mechanism, disclosing phase-change behaviours and breathing effects. To this purpose, we combined gas sorption analysis, in situ infrared spectroscopy, in situ powder X-ray diffraction, multinuclear solid state nuclear magnetic resonance spectroscopy and adsorption microcalorimetry with periodic density functional theory simulations. This fine experimental approach allowed us understanding the "phase-change" behaviour of these MOFs, associated with very specific interactions of the adsorbate with the surface of the sorbent that trigger a structural rearrangement.

annamaria.maurelli@isa.cnr.it

Agri-food matrices are known for their excellent nutritional value. They are rich in vitamins, carbohydrates, macro- and trace elements, secondary metabolites, and other bioactive compounds, both in the edible part and in the waste. By virtue of their anti-inflammatory, antioxidant and anti-cancer properties, natural products are increasingly included in food supplements and their use has been suggested for the treatment of various types of diseases. The major class of secondary metabolites is represented by polyphenols, occurring in fruits, cereals, spices, nuts, legumes, tea, coffee, olive oil, and herbaceous plants (e.g., Brassicaceae, Asteraceae)[1].

Thus, numerous studies have been carried out on the extraction of bioactive molecules from natural products for applications in a wide variety of fields. Traditional extraction processes include maceration, pressing, decoction, infusion, percolation and Soxhlet extraction[2]. However, these processes involve the use of huge amounts of organic solvents and/or energy-intensive conditions. In line with the "six principles of green extraction of natural products", efforts are currently directed towards environmentally friendly extraction processes. Examples of green extraction techniques are supercritical fluid or pressurized liquid extraction, microwave, ultrasound, enzyme, or cold plasma assisted techniques, or combined technologies[3].

In this work, we proposed the use of ultrasounds and bio-based surfactants in water-based solvents for the extraction of antioxidant compounds from Zingiberaceae and Brassicaceae derivatives. First, the effects of solvent composition, temperature, time, and ultrasound power on the extraction process have been investigated. Thus, obtained extracts were characterized in terms of antioxidant activity and biological properties. However, extracted compounds often show limited bioactive efficacy due to their poor absorption and low bioavailability. To improve their efficacy, hydrophobic and hydrophilic natural compound models were encapsulated in colloidal delivery systems and their activity was further investigated.

This study was carried out within the project AGRITECH National Research Centre for Agricultural Technologies – Spoke 8 and received funding from the European Union Next-GenerationEU (PIANO NAZIONALE DI RIPRESA E RESILIENZA (PNRR) – MISSIONE 4 COMPONENTE 2, INVESTIMENTO 1.4 – D.D. 1032 17/06/2022, CN00000022). This abstract reflects only the authors' views and opinions, neither the European Union nor the European Commission can be considered responsible for them.

Hybrid swellable silicas as adsorbent for the removal of organic dyes from water media

L. Maccarino[a], L. Marchese[a], C. Bisio[a,b]

[a] *Dept. of Sciences and Technological Innovation, Università del Piemonte Orientale, Viale T. Michel 11, 15121 Alessandria, Italy.*

lorenzo.maccarino@uniupo.it

Organic dyes are a class of compounds largely used for industrial applications, but they can have adverse effects for the environment and humans; for this reason, there is the needing to find convenient processes to remove these compounds from wastewaters. Due to its efficiency, low cost and versatility, adsorption on porous materials is considered a valuable solution for the decontamination of water from organic dyes[1]. Nevertheless, commercial adsorbents (i.e. carbons, clays) lack of affinity towards certain dyes or are characterised by low removal efficiency and/or are difficult to be regenerated and then reused. For these reasons, the research work devoted to the study of new and more performant solids deserved increasing interest[2].

Swellable Organically Modified Silicas (SOMS) are a class of hybrid silicas with peculiar adsorption properties for PFAS[3] and VOCs[4] species. SOMS are hybrid materials formed by polycondensation of a bis-silane that contains an aromatic ring linked to an ethyl group as binding unit between Si atoms. These materials possess the peculiar ability to swell when in contact with organic solvents thus resulting in an improvement of SOMS adsorption capacity[4].

In this work, SOMS silicas have been prepared by an optimised sol-gel approach and characterized from the physico-chemical point of view through a multi-technique approach. SOMS possess an irregular shape and distribution of particle dimensions, with a surface area of ca. 420 m^2/g and an irregular distribution of pores dimensions. SOMS have been functionalised using a quaternary amino group, thus conferring a positive surface charge to the material (QA-SOMS).

The adsorption performances have been tested against different dye molecules (i.e. Rhodamine B, Methyl Orange, Crystal Violet). In particular, the kinetics, and effect of pH have been studied. The materials can be regenerated with a simple sonication in ethanol and reused for 6 adsorption cycles, showing no losses in adsorption performances, which remain very rapid and high in terms of quantity removed for every cycle. Finally, mixtures of dyes have been also tested for the first time.

Mechanistic insights into C mineralization over Si-based materials driven by mechanical energy

G.Mulas,[a] F.Murgia,[a] S.Garroni,[a] S.Enzo,[a] M.Poddighe,[a] B.Vecciu,[a] M.D.Simula,[a] C.Cau,[a]

[a]*Department of Chemical, Physical, Mathematical and Natural Sciences, University of Sassari, Via Vienna 2, Sassari, Italy*
mulas@uniss.it

Among CCUS, Carbon Capture Utilisation and Storage, strategies, the C mineralisation represents a potentially versatile and downhill pathway for achieving safe and efficient reduction of CO_2 levels in the atmosphere.[1] In particular, the utilisation of poor or waste materials as substrates and the implementation of sustainable activation routes for those processes, may represent the key for unravelling the potential of C mineralization for large scale applications. Along this line, the use of various Si-based materials, arising from largely available minerals or from scraps of established industrial processes, as well as the exploitation of mechanical energy for triggering the process, fulfil the above-mentioned requirements. This latter is worth of interest since it can be, at least partially, recovered from the industrial process itself. In this framework our attention has been addressed to set up efficient mechanochemical pathways for CO_2 valorisation over different Si-based systems, including olivine, basalt, black steel slags and granites, continuously feeding moist CO_2 into the reactor, so mimicking industrial processes.[2] Elevated CO_2 conversion values with fast reaction kinetics characterise those processes, although ruled by complex mechanisms, including specific features typical of mechanochemically activated processes and gas-solid interactions. In this work our efforts are addressed to tentatively shed light on mechanistic inferences of such processes: to this, ex situ structural investigation through X Ray Diffraction and semi-quantitative phases analyses by Rietveld were paralleled by fitting the kinetics profiles of CO_2 conversion according to different reaction path models. Survey results suggest that mineral carbonation, and eventual CO_2 reduction to hydrocarbons, occur through a multi-step process with specific features depending on the chemical characteristics of the solid substrates and on the adopted mechanochemical experimental conditions.

duccio.tatini@unisi.it

Geographic origin assessment of food products involved in olive oil and wine production plays a crucial role in protecting the top-quality standards of these traditional excellences and in raising consumers and stakeholders awareness of product authenticity. Moreover, it represents an open challenge in the framework of the EU and international regulations, that require a precise labelling for products traceability.[1] In this work a set of extra virgin olive oils and *Sangiovese* monovarietal wines from the 2022 harvest in the Tuscany area, along with their corresponding vegetable matrices (*i.e.* drupes, grapes and plant leaves), were analyzed via ^{1}H NMR and Excitation-Emission Matrix (EEM) fluorescence spectroscopy. The spectral features were processed using different chemometric methods: Principal Component Analysis (PCA), Linear Discriminant Analysis (LDA), Partial Least Squares Discriminant Analysis (PLS-DA) for NMR data, and Parallel Factor Analysis (PARAFAC) for EEM maps.[2] The results show that the two combined spectroscopic-chemometrics approaches provide a sub-regional classification of the oil and wine samples according to their geographic origin. The performance of the classification procedure is confirmed by the results obtained for the drupes, grapes and leaves samples. In addition, a novel multi-block analysis strategy integrating the data from NMR and fluorescence spectroscopy is proposed.

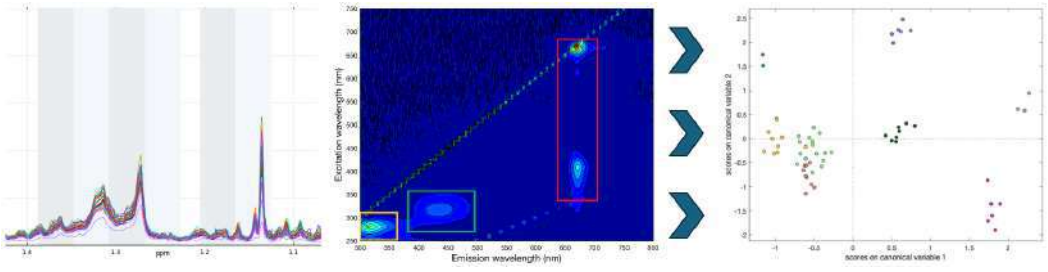

Figure 1: Scheme of combined spectroscopic-chemometric approaches for geographic origin discrimination.

This study was carried out within the Agritech National Research Center (Spoke 9) and supported by the European Union Next-Generation EU (D.D. 1032 17/06/2022, CN00000022).

Liquid crystalline elastomers are well known smart materials with interesting actuation properties. In the recent years, these partially ordered materials were used to prepare soft-soft composites called 'Polymer Dispersed Liquid Crystalline Elastomers' (PDLCEs).[1] 3D shape reprogrammable objects (see **Figure 1**) showing highly reproducible actuation properties and different geometries[2] have been prepared based on PDLCEs made of main-chain liquid crystalline elastomers.[3]

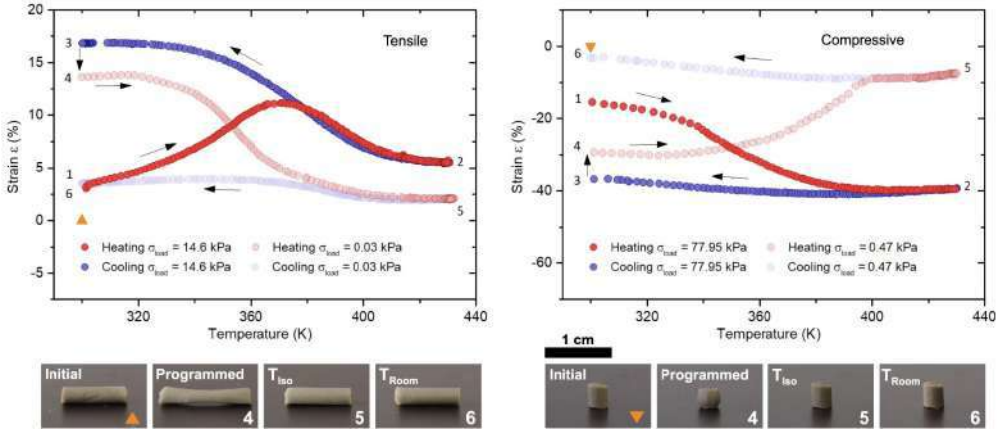

Figure 1: Tensile (left) and (compressive) strain behaviour versus temperature of PDLCEs during actuation and reprogrammed shape steps are shown.

Several key parameters concerning the preparation of PDLCEs aimed to tune several chemical-physical and physical properties, such as the mesomorphic behaviour, the thermo-mechanical and thermo-elastic response, were object of investigation and the main results will be presented and discussed.

Permanent magnets (PM) play a pivotal role in energy-related applications[1], and the quest for sustainable materials has refocused attention on ferrites, with $SrFe_{12}O_{19}$ (SFO) standing out. This study explores synthetic strategies, including cation substitution and superexchange-coupling of magnetic phases, to enhance ferrite magnetic properties[2]. Employing a scalable bottom-up sol-gel self-combustion process, we designed superexchange-coupled nanocomposites ($SrFe_{12-x}Al_xO_{19}/CoFe_{2-y}Al_yO_4$ 90/10 wt%).

Monte Carlo simulations unveiled insights into the magnetic behavior, aligning with experimental findings. Structural analysis, including synchrotron X-ray powder diffraction and electron microscopy, highlighted controlled size, morphology, and composition of the nanocomposites. This integrated approach showcased the success of the sol-gel process in tailoring properties. Spark plasma sintering (SPS) was employed to fabricate highly dense bulk magnets (SPS_NC and SPS_NC_SM). The SPS process, known for its efficiency[3], demonstrated the preservation of desired properties and improved alignment. Hysteresis loops, studied for randomly and parallel-oriented anisotropy axes, unravelled the intricate interplay of factors influencing magnetic properties. Importantly, the interface differences in NC and NC_SM nanocomposites were explored, shedding light on their unique characteristics. Calculations of $(BH)_{max}$, the energy product, were conducted, further emphasizing the tailored magnetic properties achieved in this study. The exploration of interface variations, alongside the calculated $(BH)_{max}$ values, provides comprehensive insights into the design, synthesis, and processing of advanced permanent magnets, offering potential for sustainable energy applications.

Bacterial infections cause numerous risks to human health. Gram (-) is a major source of infection, due to the inside of their outer membrane of endotoxins, such as lipopolysaccharides (LPS) [1]. For this reason, it is important to develop a biosensor that can specifically detect and quantify Gram (-) pathogens [2]. Biosensors combine a biological recognition mechanism with physical transduction, leading to selective and sensitive recognition of analytes. The aim of this project is to develop a biosensor by optimizing the matrix, consisting of F-doped zinc oxide nanoparticles (F-ZnO NPs) [3,4], and choosing the appropriate biomolecule (the aptamer LA-27). In this way, the aptamer labeled with a fluorescence probe (i.e., FAM or ROX) should act as the energy donor and the NPs as the energy acceptor, analyzing the optical response of the aptasensor will be able to detect the presence of LPS and their quantification. Therefore, we have synthesized and characterized F-ZnO at different F-concentration NPs in solution to choose the best sample, in terms of size, morphology, and optical properties, to create the matrix. On the NPs matrix surface was linked an LPS sensible aptamer for the detection and quantification of LPS of Gram (-) pathogens. Here the development of the system and the preliminary results will be discussed.

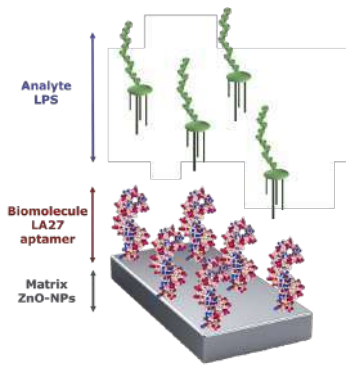

Figure 1: Schematic representation of the aptasensor.

Concurrent control over packing, morphology and spectroscopic response of crystals is desirable for designing materials with targeted functionalities. Yet, achieving such combination of properties via direct synthetic approaches is extremely challenging.

We show that an initial metal–organic framework (Mn-AdDB) can be used as crystallographic and morphological template to generate a series of isomorphic and isostructural crystals having different bivalent metal ions of the first row of the transition elements (Fe, Co, Ni, Cu or Zn) by post-synthetic metal cation exchange.[1-3] The crystal-to-crystal conversion has been shown to be quantitative both at the single-crystal and ensemble level. We detail on the mechanistic aspects of the exchange process, and demonstrate how the metal cation controls the optical (absorption, fluorescence, cathodoluminescence) and magnetic properties. Our work is an intriguing example of crystal engineering spanning different hierarchical orders, from molecular packing, composition to morphology and properties thereof.

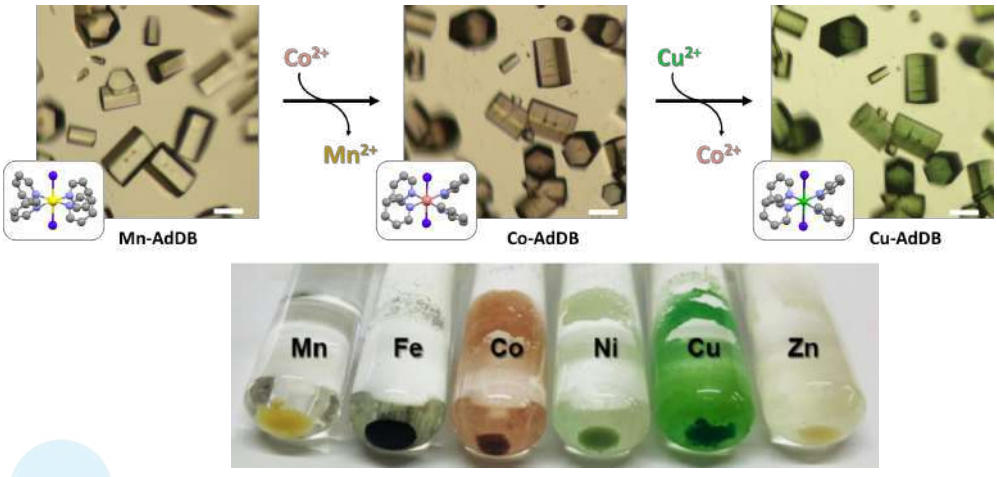

Figure 1: Optical microscopy images demonstrating the consecutive metal cation exchange. Bulk appearance of the sample before (tube Mn) and after metal cation exchange (from tubes Fe to Zn)

Strontium Aluminate Phosphors: a photochemical and environmental journey insight the most famous persistent luminescent materials

R.Bondi[a] and L.Latterini,[a]

[a] *Nano4Light Lab-Department of Chemistry, Biology and Biotechnology, University of Perugia, Perugia, 06123, Italy*

roberto.bondi@studenti.unipg.it

Thanks to the capability to produce light for seconds or even minutes after the excitation ceases, in recent times persistent luminescence (PersL) materials have become very popular with their application that spreads from civil uses (decoration, safety displays) to scientific application fields (energy and environmental engineering, biomedicine)[1,2]. The stunning properties of persistent luminescence materials mainly come from the emitter and the trap centers. While the emitter emit radiation after excitation, the trap centers, formed due to impurities or various co-dopants, store the excitation energy for some time and then gradually release it to the emitters by thermal or other physical activation. Their incredible success started from the 1996 breakthrough discovery of $SrAl_2O_4:Eu^{2+},Dy^{3+}$ by Mitsuzawa et al., which showed extremely bright and long phosphorescence. In this work, the strontium aluminate phosphor is synthesized by combustion method[4]. Then, different rare-earth (Tb^{3+}, Yb^{3+},Er^{3+}) or transition metals (Co^{3+}) elements are introduced as co-dopants to investigate the effect on the emission intensity and persistent luminescence time. Emission spectra, excitation spectra, PL Quantum Yield and persistent luminescence decay measurements will be recorded.

Figure 1: Persistent luminescence of $SrAl_2O_4:Eu^{2+},Dy^{3+}$ collected 1,10,20,30,40 and 50s (from left to right) after excitation at 390 nm. The excitation time was 30 s.

After having found the right balance between persistent luminescence time, emission intensity and PLQY, the sample with the optimized co-dopant will be dispersed into different polymer matrices (PMMA, PVA, PVP…) and later tested as possible indoor and outdoor environmental solutions thanks to a climatic chamber.

elisa.dellalatta@phd.unipi.it

Membrane-based gas separation technology has attracted considerable interest as an energy-efficient alternative to most common techniques. Swager et al. introduced the concept of including rigid molecular structures in polymers, leading to materials with intrinsic microporosity and high gas separation performances [1,2,3,4]. In this scenario, triptycene groups are rigid three-dimensional structures generating free volume and preventing the efficient packing of molecular chains [5]. In this work, we present a Solid-State NMR (SSNMR) study of a triptycene-containing fluorinated aryl ether (FLARE) polymer [1].

A polymer film prepared starting from a high molecular weight polymer was studied both before and after adsorption of $^{13}CO_2$. Indeed, SSNMR can provide information about host@guest interactions exploiting many different nuclear properties combined with the possibility to probe different nuclei [6].

The dynamics of the host was here investigated by measuring ^{1}H and ^{19}F spin-lattice relaxation times (T_1) and utilizing ^{19}F-^{13}C and ^{1}H-^{13}C DIPolar chemical SHIFT correlation experiments (DIPSHIFT).

CO_2 dynamics of the $^{13}CO_2$-loaded sample was studied by recording variable temperature ^{13}C Direct Excitation (DE) spectra both in static and high-resolution (*i.e.*, under Magic Angle Spinning (MAS)) conditions. A deeper understanding of CO_2 motions inside the porous structure of the membrane was also gained through the analysis of ^{19}F-^{13}C and ^{1}H-^{13}C Cross-Polarization/MAS (CP/MAS) spectra and ^{13}C spin-lattice relaxation times (T_1) of $^{13}CO_2$.

Small Angle X-ray Scattering (SAXS), when coupled with Wide X-ray Angle scattering (WAXS), offers a comprehensive understanding of a material's structure, ranging from supra-molecular (SAXS) to sub-molecular scales (WAXS)[1]. Here, we utilize SAXS/WAXS scanning microscopies to investigate the glycation process of type 1 collagen in bio-tissues derived from bovine pericardium, following incubation in glucose and ribose[2]. By identifying arginine and lysine/hydroxylysine amino acids as primary glycation sites and assuming that the topological polar surface area of sugar molecules influences glycation rates, we modelled glycation over time. This modelling allowed us to determine glycation rates, track the progression of glycation, and observe resulting volume increases. Research was supported by the PRIN2017 project entitled "A system approach for identifying connective tissue degeneration in diabetic analogues (SAPIENT)".

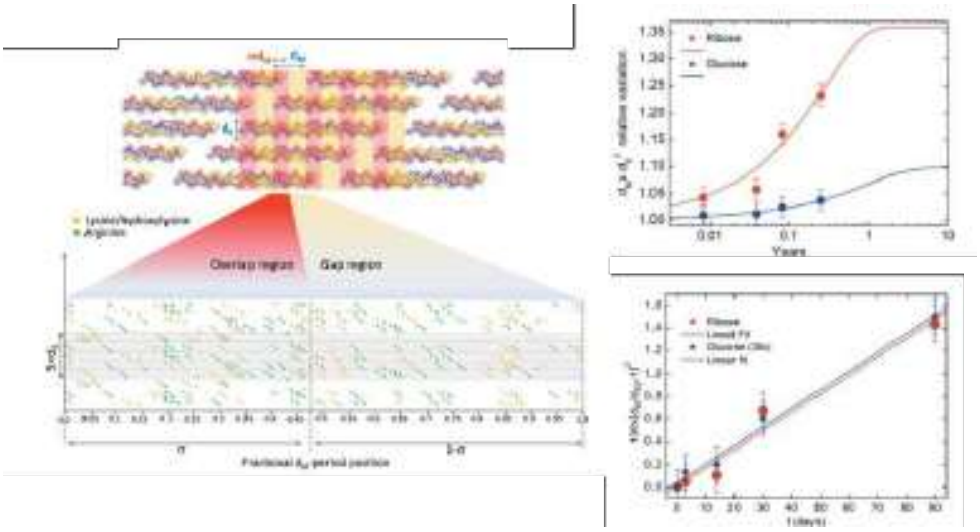

Figure 1: Top Left: Schematic rappresentation of the staggered repetition unit of the triple-helix collagen structure alternating σdM-wide overlapping regions and (1-σ)dM-wide gap regions. Bottom Left: linearized projection of the 3D triple-helix collagen residues, with the lysine/hydroxylysine (orange bullets) and arginine (green bullets) amino acid positions shown as a function of the fractional d_M-period coordinate. Top Right: Time variation of the volume occupied by glycated collagen with respect to the native molecule for a sugar concentration of 40 mg/ml. Bottom Right: measure for the variation of the equatorial in-plane areal density of collagen molecules as a function of the incubation time. Note that the glucose data have been multiplied by a constant factor of 38.

Phosphorene and graphene with their derivatives are novel supports that present a dimension in the nanoscale, and have attracted the attention of the scientific community in the last years owing to their unique physicochemical, optical, mechanical, thermal and conductive properties.[1] Two-dimensional sheets have been employed for the physical and chemical adsorption of molecules in a diverse range of applications such as drug delivery, catalysis, composites for electronics, nanophotonics and optoelectronics fields, sensors and energy related systems and their combination have been used for the preparation of gels.[2] But, to exploit these promising materials, it is critical to understand the molecular mechanisms that govern the adsorption of molecules onto its surface. To reach the goal, in this work,[4] many spectroscopic and microscopic methods have been utilized going to investigate the effects on proteins conformation after the interaction between Lysozyme and the 2D-nanomaterials, i.e. phosphorene, graphene and graphene oxide at different molar ratio and environmental conditions. In particular, UV-Vis absorption, reflectance and emission spectroscopy have proven to be fast, non-invasive and sensitive tools that represent a molecular fingerprint enclosing chemical, structural and conformational information on the biomolecules in contact with the nanosurface.[3] We have followed the changes of the profiles band of Amide I and Amide II signals through IR measurements to monitor the protein adsorption and denaturation processes. The size and the surface charge of the binary systems have been determined by Dynamic Light Scattering and Z-Potential measurements. Images of the different nanocomposites have been obtained through Transmission Electron and Confocal Microscopy to detect the modification of the protein structures after the absorption and the gelling processes. Through Raman spectra, we have evaluated the interactions at the interfaces, monitoring the conformation changes of Lysozyme.

The work represents a starting point for the development of controlled interfaces materials with different chemical-physical properties respect to the native proteins.

micaela.giannetti@uniroma2.it

The discovery of immune checkpoint inhibitors made a huge contribution to the research for cancer treatments. Particularly, programmed death ligand-1 (PD-L1) is a protein placed on the surface of some (regulatory) cells that, by binding to the PD-1, an immune checkpoint receptor expressed on the surface of killer T-cells, forms the PD-1/PD-L1 complex, which suppresses the immune response. The over-expression of PD-L1 is exploited by tumor cells as a strategy to escape the immune system. To inhibit this interaction, small molecules, such as peptide therapeutics, have been developed. Peptides have, particularly, numerous advantages such as low toxicity, absence of immunogenicity, high fidelity of synthesis, and low manufacturing costs. Moreover, to improve targeting affinity for the ligand and to avoid the degradation of the peptides due to enzymes present in a biological environment, peptides can be linked to AuNP plasmonic nanostructures (AuNP-NS), which are inert in a biological environment[1]. By addition of reporters, AuNP-NS also show strong surface-enhanced Raman scattering (SERS) signals, which are narrow and very intense signals, which represent a novel approach for imaging and diagnosis.[2]

In this work, a new generation of oligopeptides (Table 1) showing a high affinity for the PD-L1 region which interacts with PD-1, will be presented. They have been designed through Molecular dynamics (MD) simulation, synthesized, and bonded to the AuNS, through the S-Au covalent bond. The prepared nanostructures were incubated, at several concentrations, with tumoral cells which overexpress PD-L1. SERS measurements quantified the great affinity of the oligopeptides for PD-L1. MD simulations of NPs functionalized with peptides, interacting with PDL1, allow to explain, at molecular level, the different activity of the peptides under study.

Unfolding and refolding of Albumin induced by a time-programmable dissipative pH-jump

A. Del Giudice,[a] D. Del Giudice,[a] E. Spatola,[a] L. Galantini,[a] S. Di Stefano,[a]

[a]*Department of Chemistry, Sapienza University of Rome, P.le A. Moro 5 00185, Rome*
alessandra.delgiudice@uniroma1.it

Simple reagents can be employed to control the pH of a water solution as a function of time, generating dissipative pH jumps whose amplitude and duration can be tuned. This represents a strategy to control pH-dependent properties as a function of time without additional intervention. Nitroacetic acid (NAA), an activated carboxylic acid able to undergo base catalysed decarboxylation, can be used as a chemical fuel to achieve pH_{high} - pHl_{ow} - pH_{high} sequences, exploited to drive the operation of host-guest systems and DNA based molecular devices.[1,2] We show how this strategy works to induce and monitor with fluorescence and synchrotron small-angle X-ray scattering (SAXS) the pH-dependent conformational variations of Human Serum Albumin (HSA), in a complementary way to the time-dependent acidification obtained by slow hydrolysis of glucono-d-lactone.[3,4] Starting from the protein in its native form, we employed NAA to achieve a fast acidification of the solution with consequent denaturation of the protein, followed by a time-tunable slow raising of the pH without additional intervention, which enables a full protein refolding. This method allows a whole conformational cycle (from native form to acid partially unfolded forms, and then to native again) and a verification of the extent and reversibility of the protein structural transition in different conditions. It could be applied to formulate pH-dependent drug encapsulation and release protocols using albumin as a safe and versatile macromolecular carrier.

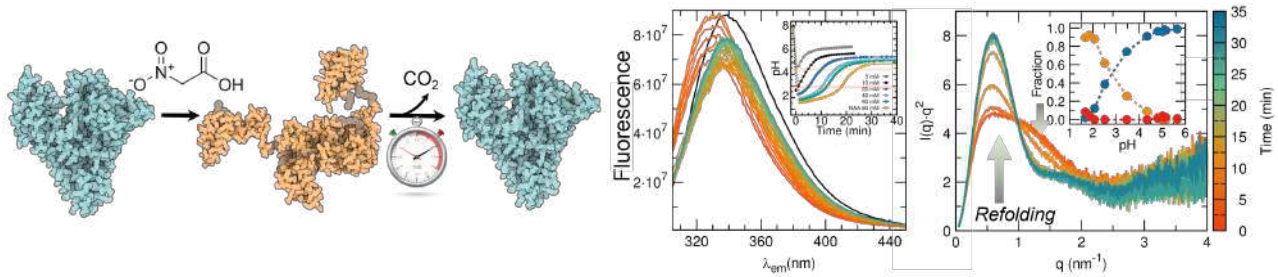

Figure 1: Pictorial view of an unfolding-refolding experiment triggered by NAA decarboxylation. Intrinsic fluorescence of HSA and SAXS data in the form of Kratky plot show time-dependent refolding to native state.

High-throughput screening and optimization of microfluidic-synthetized lipid-based nanocarriers

I. Clemente, [a,b,c] G. Gabbricci, [a,b,c] L. Talarico,[a,b,c] S. Pepi [a,b,c], C. Bonechi,[a,b,c] G. Leone,[a,b,c] A. Magnani[a,b,c]

ilaria.clemente2@unisi.it

In the past decade lipid-based nanocarriers have gained increasing popularity as the emergent technology for drug delivery, owing to the capability to protect the bioactive cargo and improve intracellular transport and release[1]. Since their approval for clinical usage both as vectors for anticancer drugs and gene therapy, several lipid nanocarrier formulations were investigated to obtain optimal physicochemical properties and enhanced therapeutic efficacy. Among the factors influencing structure, stability and intracellular uptake, the choice of lipid components plays a major role[2].

Generally, the main constituents are helper/structural lipids (i.e. phospholipids and cholesterol), that provide stability and membrane fusogenicity. Then, either ionizable lipids for lipid nanoparticles (LNPs) or solid lipids for solid LNPs (SLNs) respectively, are employed to improve cargo encapsulation and protection from leakage. Finally, surfactant or polyethylene glycol-lipids coatings are used to enhance *in vivo* circulation time. Thus, careful manipulation of composition and relative abundance results in dramatic modification of physicochemical properties and functionality. Microfluidic-assisted preparation of lipid-based nanocarriers allows to obtain monodisperse and stable formulations with high reproducibility, boosting screening and optimization potential for rapid clinical translation.[3]

In this work, high-throughput screening and optimization of three types of lipid nanocarriers, i.e. LNPs, SLNs and transethosomes as candidates for drug delivery is proposed. Microfluidic synthesis allowed to screen a large set of lipid components, surface coatings and relative compositions following an experimental design approach. Supramolecular characterization by means of Dynamic Light Scattering, Zeta potential, Small Angle X-ray Scattering, Nuclear Magnetic Resonance, and quantification of encapsulation efficiency of model drugs by High Performance Liquid Chromatography allowed to select the optimal carrier candidates.

Effect of proteins and stabilizing agents on the formation and stability of colloidal hybrid calciprotein-like particles

R. Gelli,[a] F. Ridi,[a]

rita.gelli@unifi.it

Calciprotein particles (CPPs) consist of hybrid protein-mineral nanoparticles made of calcium phosphate stabilized by a glycoprotein called Fetuin-A (Fet-A). CPPs circulate in serum and contribute to maintain calcium and phosphate homeostasis and prevent the formation of unwanted calcium phosphate deposits in soft tissues[1]. In pathological situations, the initially formed amorphous spherical nanoparticles (CPPI) may mature into crystalline hydroxyapatite (CPPII), eventually resulting in ectopic calcifications. In this context, the role of albumin is also important, given the abundance of this protein in serum and its ability to complex Ca^{2+} ions. Understanding from a physico-chemical perspective the ripening from CPPI to CPPII and the factors affecting the process is fundamental to prevent the surge of ectopic calcifications by developing strategies to delay the crystallization and precipitation of CaP in serum.

In this contribution we describe the effect of proteins (Fet-A and Albumin) and ions (Mg^{2+}, pyrophosphate and citrate) on the formation and crystallization of CPPs[2-3]. Synthetic CPPs were prepared at different concentrations of Fet-A and their formation and ripening were followed in situ by means of turbidimetry and scattering techniques. The morphology of the nanoparticles was analyzed by means of scanning and cryo-transmission electron microscopy whereas FT-IR spectroscopy and X-Rays diffraction allowed for the study of their crystallinity. Experiments were also conducted with different concentrations of albumin and Mg^{2+}, pyrophosphate and citrate. This multi-technique approach allowed us to identify the most effective conditions for preventing the crystallization of CPPI, suggesting novel strategies to inhibit and treat cardiovascular calcifications.

Huntington's Disease (HD) is a rare, progressive, autosomal dominant neurodegenerative disorder. HD hinges on the CAG triplet expansion within the first exon of the HTT gene, which then encodes for a mutant, polyglutamine-expanded (polyQ) protein (mHTT). Unfortunately, no effective therapy exists to date. Molecular approaches, as antibodies or intrabodies failed because of inadequate selectivity, toxicity, poor delivery, and system complexity[1]. Aptamers promise to override these limits thanks to their unmatched specificity, easy selection, very low immunogenicity, and broad stability. Four guanine-rich DNA aptamers able to selectively bind the mHTT protein have been recently identified, showing high efficacy in modulating the functions of the mutated protein in a variety of cell experiments[2]. Interestingly, these aptamers were proved to fold into G-quadruplex structures but no conclusive data on their conformation and/or structure-activity relationship were provided.

Here, we demonstrated that the best aptamer in the series and some of its derivatives adopt a very stable parallel G-quadruplex structure and show high resistance to nuclease digestion in pseudo-physiological solutions. Moreover, experiments on SH-SY5Y cells, as model of neuronal cells, have been also carried out, to verify the aptamers cell uptake and cytotoxicity. Finally, the *in vivo* activity of the aptamers has been studied using a well-established *Drosophila melanogaster* model for HD, which expresses the human mutated huntingtin[3,4].

With their ability to encapsulate therapeutics and release their content at the desired time, liposomes provide a valuable platform for the treatment of a variety of diseases. Notwithstanding their impressive advantages, the administration modality plays a not less important role in targeting efficiency and side effect reduction, as well as patient comfort. In this regard, a promising alternative to intravenous administration is represented by pulmonary administration by inhalation.[1,2] We developed liposomes using the main component of pulmonary surfactant (DPPC) as a major substituent to improve the biocompatibility of the entire system and ensure better interaction with the lung surfactant membrane, which is the main barrier that liposomes need to overcome while being pulmonary administrated. Liposomes with different compositions have been designed to understand how each lipid (DPPC, DOTAP, and cholesterol) affects the physicochemical properties of the system itself. This was done by combining several techniques, such as DSC, DLS and SAXS. The results obtained revealed that DOTAP and cholesterol addition affect liposome size, as well as lipid system transition temperature. Preliminary tests have been performed to encapsulate a CSC-targeting DNA aptamer (AP-9R) that suppresses tumorigenesis, cancer progression and angiogenesis in lung cancer.[3] Understanding how the different lipids affected the physicochemical properties of lipid nanocarriers, can benefit the development of new strategies for the delivery of oligonucleotide therapeutics, providing a scientific platform for future clinical approaches.

Silver nanoparticles (AgNPs) hold great promise for several different applications, from colorimetric sensors to antimicrobial agents. Despite their widespread incorporation in consumer products, limited understanding of the detrimental effects and cellular antioxidant responses associated with AgNPs at sublethal concentrations persists, raising concerns for human and ecological well-being.[1] To address this gap, we synthesized AgNPs of varying sizes and evaluated their cytotoxicity against human dermal fibroblasts (HDF). Our study revealed that AgNPs-toxicity is a time- and size-dependent process, even at low exposure levels. AgNPs exhibited low short-term cytotoxicity but high long-term impact, particularly for the smallest NPs tested. Raman microspectroscopy was employed for in-time investigations in the intracellular molecular variations, during the first 24 h of exposure to AgNPs of 35 nm. Subtle protein and lipid degradation were detected, but no discernable damage to DNA was observed. Signals associated with antioxidant proteins, such as superoxide dismutase (SOD), catalase (CAT) and metallothioneins (MTs), increased over time, reflecting heightened production of these defense agents.[2,3] Fluorescence microscopy further confirmed the efficacy of overexpressed antioxidant proteins in mitigating ROS formation during short-term AgNPs exposure. This work provides valuable insights into the molecular changes and remedial strategies within the cellular environment, utilizing Raman microspectroscopy as advanced analytical technique. These findings offer a novel perspective on the cytotoxicity mechanism of AgNPs, contributing to the development of safer materials and advising regulatory guidelines for their biomedical applications.

Cancer immunotherapy exploits the body's own immune system to fight against cancer. T cells play central roles in cell-mediated adaptive immunity. Crucial to advancing gene-modified cell therapies, especially T cell therapies, are lenti- or retroviral vectors. While effective, these approaches are costly and carry residual risks such as germline transmission, immunogenicity, and insertional mutagenesis. Therefore, there is a quest for efficient strategies for non-viral transduction of synthetic receptors into primary T cells[1]. Synthetic nanovectors, loaded with a specific plasmid (pSLCAR-CD19-28z), have been engineered to bypass chromosomal integration and reduce risks. Nanostructured lipid carriers (NLCs) and two kinds of mesoporous silica nanoparticles (MSNs), namely core@shell nanostructures (SiO_2@MSNs), with a non-porous silica core and dendritic mesoporous silica shell, and hollow MSNs (H-MSNs) were synthesized for their advantageous properties, including biocompatibility and efficient loading capacity. NLCs were produced through hot homogenization and loaded with the plasmid using a hydrophobic ion pairing approach. SiO_2@MSNs and H-MSNs were synthesized *via* dynamic soft-templating and single-step sol-gel processes, respectively[3] and were surface-functionalized with a cationic polymer polyethyleneimine (PEI) as initial step for plasmid loading. Physical-chemical characterization and *in vitro* studies were conducted on both types of nanostructures, that resulted characterized by an average hydrodynamic diameter lower than 200 nm, featuring all a considerable colloidal stability in physiological media, a high capacity of releasing the plasmid without degradation and a good biocompatibility. These conclusive results affirm the successful development of these nanoplatforms positioning them as promising candidates for potential applications the field of oncology.

Microbial electrochemical systems combine biological catalysts to abiotic electrodes to achieve sustainable devices (i.e. biosensing, electrochemical wastewater remediation, energy generation, and the production of chemical commodities)[1]. While considerable research has been directed towards the identification of suitable microorganisms, less studies have focused on the rational development of electrode materials for interaction with these biocomponents. Specifically, an efficient electrode would combine both desired surface and structural properties, with conductive and biodegradable materials being of interest to achieve high biocompatibility and electrochemical performance. In this context, the use of biobased polymers coupled with conductive material ensure efficient bacterial colonization and enhanced catalytic activity.[2] Our group previously reported the use of polydopamine (PDA) on polyhydroxybutyrate (PHB)-based electrodes for obtaining microbial electrodes.[3] PHB is a biopolymer produced by purple non sulphur bacteria (PNSB) as energy feedstock under specific environmental condition.

Herein, we report the possibility to employ the reported system to develop a biohybrid photocathode with anoxygenic photosynthetic bacteria. Specifically, we utilized a blend of PHB and carbon nanofibers (CF) with metabolically active cells of *Rhodobacter capsulatus* embedded in a biohybrid PDA matrix. The biohybrid photocathode was characterized by means of scanning electron microscopy, cyclic voltammetry, and chronoamperometry, revealing the role of PNSB in the obtained cathodic photocurrent. The system achieved enhanced catalytic activity under illumination, with a 30-35-fold increase in photocurrent production compared to biophotoelectrodes based on glassy carbon, and 10-fold increase compared to abiotic control electrodes. These results pave the way towards possible applications of such bio-based photocathode in water remediation and chemical energy conversion into a green energy vector, *i.e.* hydrogen.

Bio-electrochemical systems (BES) offer a promising avenue for sustainable energy production. Among the various biological catalysts reported in literature (i.e., enzymes, organelles, bacteria), intact photosynthetic bacteria are of particular interest as they allow developing biohybrid photoelectrochemical systems for the conversion of solar energy into electrical energy.[1] The combination of nanomaterials with bacterial cells has the potential to overcome some of the intrinsic limitations associated with living organisms-based electrochemical systems, such as limited solar light absorption, hindered extracellular electron transfer (EET), and low stability.[2,3,4] Accordingly, herein we explore the potential synergistic effects of gold (Au) and ceria oxide (CeO_2) nanoparticles on enhancing electron transfer kinetics and stability in purple photosynthetic bacterium *Rhodobacter capsulatus* (*R. capsulatus*)-based electrodes. This bacterium exhibits remarkable metabolic versatility, making it suitable for application in BES.[5,6] With the aim to facilitate the ET and solar light absorption, our group proposed the modification of *R. capsulatus* with cysteine-functionalized gold nanoparticles, which resulted in increased current generation. To tackle the stability limitations, CeO_2 nanoparticles have been proposed based on their reactive oxygen species scavenging capabilities to mitigate oxidative stress-induced degradation, thereby improving the overall performance and longevity of microbial-electrode interfaces. This work will discuss the potential of nanoparticle-mediated strategies for improving microbial-electrode interactions in BES and advancing the development of sustainable bioenergy technologies.

Beyond configurational entropy: understanding the phase stability of high entropy oxide $Mg_{0.2}Co_{0.2}Ni_{0.2}Cu_{0.2}Zn_{0.2}O$ by a chemometric approach

M. Fracchia,[a] M. Coduri,[a] L. R. Magnaghi,[b] P. Ghigna, R. Biesuz[b], U. Anselmi Tamburini

martinailaria.fracchia@unipv.it

High entropy oxides (HEOs) are a recently discovered class of materials where a particular crystal structure, which in general is different from that of the parent compounds, is stabilized in a multicomponent system, characterized by a large amount of configurational entropy[1]. In recent years, these materials are gathering increasing attention for many technologically relevant applications. In particular, they have been employed as electrodes for Li and Na-ion batteries, for catalysis, and they present interesting properties such as colossal dieletric constant and enhanced mechanical properties[2,3].

The main driver for the growing interest in HEOs is the potential to obtain novel properties by exploiting the enormous number of possible elemental combinations. However, most investigations on HEOs assume that these systems present their optimal characteristics in the proximity of an equimolar composition, where the configuration entropy is highest. Overall, the study of phase stability and of the optimization of the functional properties in HEOs present significant challenges. In fact, conducting a study using the traditional approach of uniformly sampling the compositional space is not feasible due to the high number of compositional parameters involved.

Here we present a chemometric approach based on the Design of Experiment (DoE), that we employed as a simple and time-saving strategy to predict the phase stability of the prototypical high entropy oxide (Cu,Zn,Mg,Ni,Co)O with a rock salt structure[4]. This approach allowed to extract a polynomial function able to predict, for every combination of the 5 elements, the fraction of the single rocksalt phase that could be obtained, allowing therefore to draw an isothermal phase diagram at 1000 °C for this multicomponent system. It was observed that the stability region of this HEO extends well beyond the equimolar composition $Cu_{0.2}Zn_{0.2}Mg_{0.2}Ni_{0.2}Co_{0.2}O$. In particular, significantly lower and higher fractions of Cu^{2+} and Zn^{2+} can be inserted and still lead to a single phase. By combining these thereotical findings with X-ray diffraction, we observed that a high content of Cu^{2+} induces a tetragonal distortion, associated to the strong Jahn-Teller effect of this cation. Moreover, it was clearly observed that the overall quantity of single-phase RS that can be formed is not strictly dependent on the configurational entropy of the resulting compositions, but rather on the type and content of the cations involved[5]. This points towards the fact that configurational entropy does not have a central role in the phase stability of this HEO.

We also note that this chemometric approach can be exploited for all multicomponent systems, allowing to draw isothermal phase diagram with a limited exprimental effort.

Besides pure performance, the development of new materials for electrochemical devices must satisfy mandatory requirements addressing costs and sustainability, issues that become increasingly more important day by day. In particular, the large use of cobalt poses ethical and political concerns, since cobalt commodities have reached limited availability, are expensive, and are harmful to human health and the environment.[1]

In this work, we analyzed the structural rearrangement occurring in the formation cycles of a cobalt-free lithium-rich layered oxide (LRLO) positive electrode with $Li_{1.28}Ni_{0.15}Mn_{0.57}O_2$ stoichiometry in a lithium cell.[2] After applying a tailored activation procedure, this LRLO formulation shows a remarkable reversible capacity of 240 mAh g^{-1} at a C/10 rate. The absence of this electrochemical formation protocol results in much worse performance in terms of specific capacity or reversibility. Our analysis of the compositional and structural rearrangements in the lattice of the LRLO phase provided a rationale for these phenomena. We combine electrochemical tests, on-line electrochemical mass spectrometry, *operando* X-ray diffraction and dual-edge X-ray absorption spectroscopy, and density functional theory modeling. The large capacity originates from the Ni^{2+}/Ni^{4+} as well as the O^{2-}/O^{-} redox couples. However, at potentials above 4.2 *vs*. Li^{+}/Li, the electron exchange is smeared over the entire anionic sublattice, rather than being localized on a specific oxygen atomic site. This redox mechanism is nicely reversible and takes place without detrimental evolution of molecular oxygen, thus avoiding the onset of the degradation of the LRLO crystal structure. However, in the activation cycles, the sequential nickel and oxygen redox trigger irreversible structural distortions in the coordination of the redox-inactive Mn^{4+} centers. We can ascribe this local structural evolution, mainly involving the MnO_6 octahedra, as the enabler for superior electrochemical performance in this LRLO phase.

Dimethyl carbonate (DMC) is a valuable eco-friendly compound, and its increasing demand is due to its various applications (polycarbonates, fuel and the lithium-ion battery industries). There are several synthetic pathways that are used for the production of DMC, but most of them involve toxic and dangerous substances, as reagents, catalysts, and by-products. For example, most of the industrial production of DMC still uses phosgene, a highly toxic chemical that can cause several health issues. In recent decades, research has been focused on developing more sustainable synthetic approaches that can replace the phosgene method. Currently the attention has been paid on the direct synthesis from methanol and CO_2, converting the latter from waste into fuel. However, this strategy still remains at laboratory level because of poor conversions and low yields of DMC, due to thermodynamic stability and kinetic inertness of CO_2. In order to overcome these drawbacks, new and efficient catalysts have been developed. Among all, Ce-based catalysts are particularly promising for their chemical stability, redox properties, and high catalytic activity. In this work, low porosity CeO_2 and Fe-doped CeO_2 were prepared through hydrothermal (nanorods) and sol-gel self-combustion (SC) synthesis, mesoporous CeO_2 was obtained with a surfactant-assisted precipitation method, and impregnation methods were used to obtain mesostructured nanocomposites (10%wt CeO_2@SBA-15). The as-obtained catalysts were characterized using PXRD, TEM, FTIR, Raman and N_2-physisorption. In some cases, XPS measurements were performed. The direct formation of DMC from methanol and CO_2 was carried out in a batch reactor by studying different parameters such as temperature, pressure, amount of catalyst, and volume of methanol. GC-FID was used to evaluate the DMC formation. The various synthetic strategies led to the obtainment of ceria-based systems with different microstructures and textures. CeO_2 and particularly Fe-doped CeO_2 nanorods are the most promising ones from the catalytic point of view, mainly due to the peculiar morphology. The superior performance of the Fe-doped nanorods could be ascribed to the co-presence of the hematite phase and the creation of the ceria/hematite interface. The worse catalytic performance is observed for the SC sample doped with iron where a complete insertion of iron into the ceria structure was achieved. Mesoporous CeO_2 shows intermediate performances. The homogeneous dispersion of ceria on SBA-15 through proper impregnation strategies (CeO_2@SBA-15) resulted to be a promising approach to design efficient catalysts. The effect of dehydrating agents is under study.

In recent years, nanotechnology has garnered significant attention as a pivotal tool for addressing critical challenges such as environmental remediation and clean energy production, aligning with initiatives like the European Agenda 2030 and the Green Deal program.[1] In this context, suitably engineered nanoparticles (NPs) have been found advantageous in the disinfection from pathogenic microorganisms, thus overcoming the antibiotic resistance problem.[2] In particular, Silver (Ag) NPs are promising for their disinfectant function in various sectors, including biomedical disinfection, water and air disinfection, the textile industry and food packaging. Ag has served as a disinfectant for centuries, utilized in various forms including salts and colloidal nanosystems.[3] However, only since 2004 extensive studies on the antibacterial activity of Ag NPs have emerged, and research in this field has grown considerably in recent years. Particularly, it has been demonstrated that Ag NPs have a high capacity to inhibit the growth of a wide range of pathogens, even at low doses.[4] The toxicity of Ag NPs depends on their physicochemical characteristics e.g., size, shape, chemical nature, reactivity, surface area and surface charge, the nature of surface coatings, the exposure concentration and release of Ag^+ ions.[5] The antimicrobial efficacy of Ag NPs is ascribed to several phenomena and reactions occurring both on the bacteria membrane and within the cytoplasm, altering cellular metabolism and leading to bacterial death.[6] NPs surface composition influence the kinetics of Ag^+ release as well as their interaction with the bacteria. Moreover, NPs size plays a crucial role, as smaller NPs exhibit a higher release rate of Ag^+ ions in various media, thereby significantly enhancing their antibacterial activity. On the other hand, small Ag NPs easily tend to aggregate and form larger particles, thus turning in a decreased antibacterial activity.

This study addresses this challenge by synthesizing heterostructures utilizing mesoporous silica nanoparticles (MSNs) as templates and/or supports for the in situ reduction of silver precursor salts, facilitating the formation of physically separated, anchored Ag NPs. Different growth mechanisms and final size of the metal domain result by using mild reducing agents as tetrakis(hydroxymethyl)phosphonium chloride (THPC) in water or, alternatively, butyl amine in ethanol. The two selected heterostructures are tested for inhibiting Escherichia coli in aqueous medium and their activity is compared with that of bare Ag NPs and MSN. The results reveal a reduction of the dose of heterostructures required for the inhibition process, that, remarkably, demonstrates to be structure-dependent.

brando.adranno@unimi.it

In the field of CO_2 reduction reaction (CO_2RR), there are multiple strategies to increase the process selectivity towards desired C-containing products. In particular, the use of additives with anchored ionic liquids, binding ionomers and N-based cationic species (i.e. ammonium, pyridinium, imidazolium) on metal electrocatalysts has been successfully exploited in order to limit the competitive and undesired hydrogen evolution reaction and modify the product selectivity.[1-3] Less attention has been devoted to the use of P-based cations, though these species positively affect the stabilization of reaction intermediates of CO_2RR and chemical fixation of CO_2 in solution.[4,5]

In this work, we prepared and characterized styrene-based copolymers containing phosphonium groups to be employed as functionalized binding additives mixed with Cu nanoparticles (NPs) to assemble gas diffusion electrodes (GDEs) for electrochemical CO_2RR in flow cells (**Figure 1**). We carefully compared the CO_2RR results attained by using commercial Cu NPs and Nafion® as binding agent with those achieved with our home-made GDEs with different substituents and amounts of phosphonium groups, seeking for selectivity changes. Preliminary results show the GDE's high hydrophobicity and higher selectivity towards C_1 gas products.

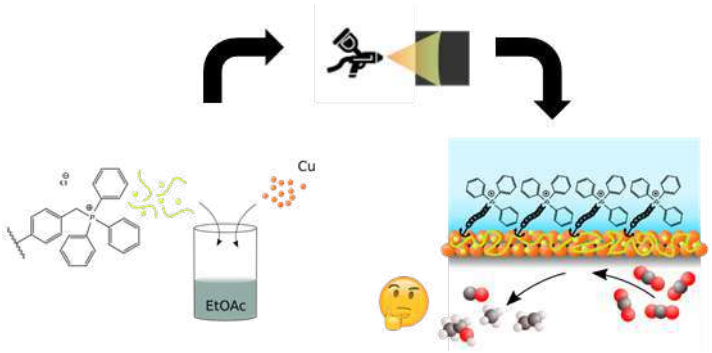

Figure 1: Home-made functionalization of Cu NPs with phosphonium loaded styrene-based copolymer to be used in electrochemical flow cells for CO_2RR.

Natural gas and petroleum gas (ethane, propane, buthane) are energy carriers more sustainable than coal. Moreover, natural gases like propane are seen as green refrigerants which will soon replace highly polluting hydrofluorocarbons (HFCs). Purification of fossil fuel gases may be accomplished with polymeric membranes. In this work, we investigated the sorption of binary gas mixtures constituted of carbon dioxide and either methane, ethane or propane in Poly(2,6-dimethyl-1,4-phenylene)oxide (PPO) endowed with nanoporous crystalline domains[1]. This material is a good candidate for fuel gas sweetening due to its peculiar pore morphology and distribution. The experiments were conducted at sub-atmospheric pressures and in the range [24, 35] °C to prevent any structural modification induced by the sorbates.

We resorted to a hyphenated technique coupling *in situ* FTIR Spectroscopy and Barometry[2]. First, we conducted pure gas sorption tests. At thermodynamic equilibrium, the IR signal of each low molecular weight species was isolated in the polymer phase and its absorptivity was calibrated with Barometry[1]. Then, binary sorption tests were conducted and the solubility of each species in PPO was measured at thermodynamic equilibrium and during diffusion with vibrational spectroscopy. Competitive sorption with ethane or propane produces a depletion of the solubility of carbon dioxide with respect to pure gas sorption at the same partial pressure. Moreover, at short times during co-diffusion, carbon dioxide reaches *supraequilibrium* loading. Such a phenomenon is described by an *overshoot* in the kinetics and is attributed to the solubility competition between the two penetrants. We effectively interpreted it with the Maxwell – Stefan theory of multicomponent diffusion coupled with the classical Langmuir's adsorption model and showed that the *overshoot* is a proof of *uphill* diffusion in PPO[3].

At the thermodynamic conditions investigated, the separation performances of PPO are analogous to DDR type zeolites despite the different chemical nature of the two adsorbents[4]. For the first time, the competitive diffusion of two gases in a polymer film is unveiled.

Enhanced Photocatalytic Methylene Blue Degradation by Mn_3O_4/HNT-based composite material

I. Kovinchuk,[a,b] P. Hluhova,[b] G. Lazzara,[a] G. Sokolsky,[b]

iryna.kovinchuk@unipa.it

Manganese oxide-based materials are extensively explored for their application in catalysis, photocatalysis, environmental cleanup, water splitting, and energy storage, owing to their polymorphism and composite formation capability[1]. It notably features the use of halloysite (HNT), with its distinct tubular structure and variably charged surfaces, to improve photocatalytic performance by increasing the active surface area.

In this work, the influence of excess ammonium ions (NH_4^+) on the phase composition of a composite material based on manganese oxides and halloysite nanotubes was studied. The composites' photocatalytic performance was evaluated based on their efficiency in degrading the model dye methylene blue. Their phase composition was determined by the Rietveld refinement procedure using Powder Cell for Windows software.

Analysis of the phase composition shows that the presence of NH_4^+ ions stabilises the hausmannite phase during chemical synthesis under relatively high pH = 10 with a stoichiometric amount of $MnSO_4$ and H_2O_2 as an oxidising agent. The observed phenomena could potentially arise from the stabilisation of manganese's anionic sulfate complexes and the preferential formation of a spinel phase, which exhibits a mixed oxidation state of manganese (II, III) compared to Mn_2O_3. Samples synthesised at the pH range 5–7 contain predominately $MnOOH/MnO_2$ components at other equal conditions. Therefore, higher pH and the presence of NH_4^+ ions change the phase composition and reduce the average oxidation state of manganese in the product.

Concerning photocatalytic activity, samples containing 28% of halloysite showed higher dye removal efficiency compared to those synthesized under similar conditions but without the addition of halloysite; 95% and 24% were removed in 60 minutes under UV light, respectively. Despite their insulating properties, HNTs enhance photocatalytic activity, probably due to the decoration effect of Mn_xO_y NPs onto HNTs. Moreover, similar behaviour of HNTs was described elsewhere[2,3].

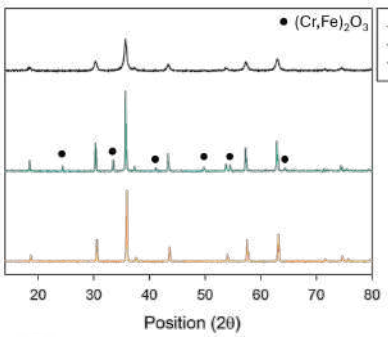
In our study, we optimized a commercial black pigment containing Cr, Mn, Fe, Ni, and high amounts of Co, targeting the environmentally demanding steps required for its industrial production. This includes the use of metals classified as critical raw materials by the EU Commission[1], solid state synthesis at 1300°C[2], and lengthy milling to decrease the pigment's particle size for better dispersion in the ink solvent. By employing the Design of Experiments[3], we obtained a composition containing only Cr, Fe and low Co content, eliminating the other critical metals while maintaining the desired black hue of original 5-metals formulation. Further improvements included reducing both calcination temperature to 1100°C, and milling time.

The life cycle assessment is underway to evaluate the environmental impact of our pigment.

Additionally, the optimized composition was prepared via spray pyrolysis, a more sustainable procedure that ensures product formation in nanometre dimensions, potentially eliminating the need for milling.

Assessment of colorimetric performance is currently under investigation.

Our research marks a significant stride towards designing ecological pigments, aiming to reduce the overall carbon footprint.



Optimized composition:
$Cr_{1.2}Fe_{1.05}Co_{0.75}O_4$

Synthesis	T(°C)	Spinel (%)	$(Cr,Fe)_2O_3$ (%)	ΔE
Solid State	1300°C	100		2.7 ± 0.2
	1100°C	79.3(3)	20.7(3)	0.69 ± 0.04
Spray Pyrolysis	1000°C	100		Expected <1

Figure 1: X-ray diffraction patterns of the synthesized black pigments; quantification of secondary phases via Rietveld Refinement and colorimetric performance of the pigments (evaluated via chromatic factor ΔE)

giuseppe.mastronardi@unito.it

Direct air capture (DAC) of has been recognized as a fundamental strategy to drastically reduce CO_2 levels in the atmosphere and mitigate the greenhouse effect.
However, CO_2 removal from ambient air is a difficult task, since its atmospheric concentration is only 420 ppm, which is roughly 350 times lower than its concentration in other sources of air, like coal-based flue gas (≈15% CO_2). In these conditions, sorbents that capture CO_2 through chemisorption exhibit stronger and more selective interaction sites than physisorbent materials.
Amine functionalities contribute to the chemical sorption of CO_2 by virtue of the reversible formation of carbamate moiety. The development of amino-functionalized solids sorbents (e.g., Metal-Organic Frameworks - MOFs) represents a benchmark strategy to create new possible DAC technologies.[1]
Many amino-based Ionic Liquids (ILs) possess high efficiency in CO_2 capture, in particular a class of ILs containing azoles and amines has shown interesting performances. For this reason, the IL composed of pyrazole and diethylenetriamine has been chosen as main target to design a novel amino-functionalized MOF for DAC.[2]
The synthetic procedure involves the anchoring of diamine molecules to the MOF by virtue of an acid-base interaction, rather similar to that involved in the formation of the ionic liquids previously mentioned ILs. The novel MOF-303 structure[3] appeared to be suitable for this scope thanks to the pyrazolic nature of the linkers and the presence of a strong H-bonding adsorption site which makes anchoring of the amine moieties possible. The employment of spectroscopic techniques (such as in *situ* IR and Solid State-NMR) and computational methods could elucidate the structure of the adsorption sites and the nature of the still unclear CO_2 capture mechanism involved. In the next future, further experiments will include the use of breakthrough set up, the evaluation of water effect on adsorption performances and how the presence of water in the gas streams could affect the performances of the adsorbent.

Successfully achieving methane-to-methanol selective oxidation present a significant catalytic challenge, one that nature efficiently masters through specific copper-histidine sites in lytic polysaccharide monooxygenases (LPMOs) enzymes[1]. Compared to enzymatic systems, Metal Organic Frameworks (MOFs) represent promising candidates because of their stability, high surface area and selectivity[2]. Inspired by LPMOs, two **Cu-UiO-66-his** MOFs samples with different Cu/his ratios (high and low histidine loading) were synthesized and characterized at the ESRF beamline BM23 by *in situ* X-Ray Absorption Spectroscopy (XAS). The experimental protocol consisted of an activation step in He up to 150 °C, isothermal reduction in H_2 and re-oxidation in O_2. Multivariate Curve Resolution (MCR) and Wavelet Transform (WT) EXAFS advanced analysis methods were applied, securing a thorough understanding of the experimental data in complex multi-component cases. MCR analysis was performed following a *Waterfall* systematic approach, guiding the method to yield chemically and physically meaningful outcomes. The results are reported in **Errore. L'origine riferimento non è stata trovata.**.

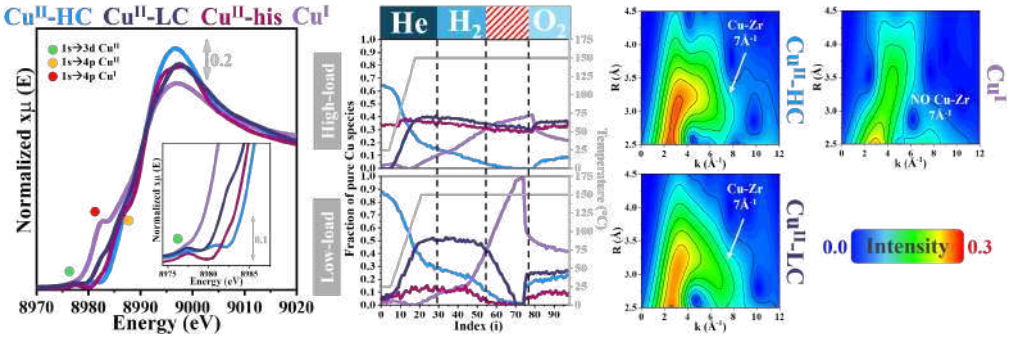

Figure 1 : (Left) MCR reconstruction, including XANES, FT-EXAFS spectra and concentration profiles of pure Cu species. (Right) Representation of WT maps magnified in the 2.5-4.5 Å range.

According to XANES fingerprints, four distinct pure Cu species were identified in both samples. Notably, the **Cu^{II}-his** pure species displayed partial inertness to the overall chemistry, while the **Cu^{II}-LC** species underwent preferential evolution at the expenses of the more-coordinated **Cu^{II}-HC**. The presence of pure **Cu^{I}** species suggests that both samples exhibit redox properties, albeit with preferential Cu^{II} reduction in the low-loading sample. This is attributed to the ca. 40% of **Cu^{II}-his** species present in the high-loading sample. WT analysis indicated that in **Cu^{II}-HC** and **Cu^{II}-LC** species, Cu-Zr contributions were detectable, leading us to describe these species as cluster-derived sites. Importantly, this Cu-Zr scattering contribution was completely lost for the identified Cu^{I} species. We're currently working on EXAFS fitting analysis using DFT-derived structures, obtaining promising results aimed at validating our structural hypothesis.

Agri-food wastes as new resource: Kiwi Peels as adsorbent material for water remediation

Domenico Cignolo [a], Vito Rizzi [a], Jennifer Gubitosa [a], Pinalysa Cosma [a,b], Paola Fini [b]
[a] *Dipartimento di Chimica, Università degli Studi di Bari Aldo Moro, 70126 Bari, Italy;*

domenicocignolo@hotmail.com

In recent years, population growth has caused the increase in supply demands, like water and food 1. That represents the source of the different global issues, particularly the management of water resources, including pollution, treatment, and protection concerns, and handling of agri-food wastes end-life 2. In contrast with linear economy approach, which enhances these problems, by following the principles of Circular Economy, the same agri-food wastes can represent a solution for water treatment 3,4. In this context, the use of Kiwi Peels, an agri-food waste, was proposed as an adsorbent material to remove various Concern Emerging Contaminants and textile dyes from water. The adsorbent substrate was characterized by adopting FTIR-ATR, TG and SEM analyses, before and after its use, proposing it as a recyclable material. UV-VIS spectroscopy analyses were performed for the purpose. Ciprofloxacin and Direct Blue 78 were selected model contaminants to infer information about the behaviour of Kiwi Peels during water treatments; so, the role of several parameters affecting the process was assessed. The study encompassed thermodynamics, adsorption isotherms, and kinetics.

To extend the lifetime of Kiwi Peels, desorption experiments were carried out by using hot water or salt solutions. 10 cycles of adsorption/desorption were studied, evidencing the recycling of both pollutants and Kiwi Peels. Moreover, the solid-state pollutant photodegradation was proposed as a possible alternative for the adsorbent regeneration.

Efficient removal of perfluorooctanoic acid (PFOA) from water with magnetic metal-organic frameworks (MOF)

D. Ceriotti[a], M. Pedrazzoli[a], L. Magagnin[a, b], M. Sansotera[a, b]

davide.ceriotti@polimi.it

Poly- and Per-fluoroalkyl substances (PFAS) are a class of hazardous and bio accumulative compounds that have an impact on both the environment and human health[1]. The safety threat posed by Perfluoroalkyl acids (PFAAs) in drinking water is a growing concern, in particular perfluorooctanoic acid (PFOA) is widely diffused in Northern Italy[2]. Many degradation techniques have been developed over the last decade to address this issue[3]; unfortunately, they have the downside of releasing further environmentally toxic molecules or short-PFAS[4]. Some adsorption methods have been studied, such as activated carbon[5] or ion exchange resin filters[6], however they are not selective, saturate fast or are expensive. Magnetic particles functionalized with metal-organic frameworks coatings represent an innovative solution that could adsorb PFOA selectively without the need for filtration steps or the production of undesired byproducts.
In this work, a zirconium-based (UiO-66) and an iron-based (Fe-MIL-100) metal–organic frameworks have been synthetized and employed to functionalize magnetic particles. The obtained magnetic powders have shown great adsorption capacity, capturing up to 99% of the PFOA dissolved in water, offering a sustainable and efficient solution to PFAS contamination.

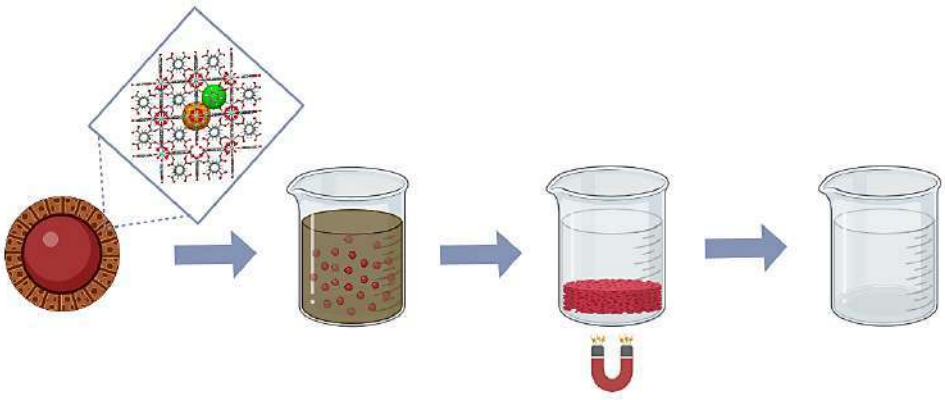

Figure 1: Magnetic particles with metal-organic frameworks functionalization and subsequent PFAS adsorption.

stefano.pezzoli@unimi.it

The mastery of metallurgy represented a transformative leap for mankind, enabling the production from the first revolutionary tools and weapons to today's hi-tech materials. Global aluminium production is reported to be second only to that of iron, with the smelting of 70.593 MT of Al in 2023 alone[1]. Endless recyclability, reduced production costs, and eco-compatibility, combined with metal's extreme versatility, make aluminium foundries sustainability-conscious and cutting-edge to the extent that future projections anticipate an 80% increase in demand by 2050[2]. Castable refractory ceramics play a crucial role in the aluminium production process, thus special features such as high-temperature, thermal shock, chemical and mechanical resistances as well as formability, durability and insulating properties are required.

In this work, BN-doped ternary SiO_2-Al_2O_3-CaO ceramics were manufactured and fully characterised. The well-known SiO_2-Al_2O_3-CaO system is able to meet many demands[3]. Nevertheless, a deep insight into the mechanisms at the base of their performance in the specific application is highly necessary. Inductively Coupled Plasma-Optical Emission Spectrometry (ICP-OES) analyses confirmed the theoretical values of the major elements, while Scanning Electron Microscopy (SEM) provided morphological and structural information showing the heterogeneity of the ceramic product which consisted of a calcium aluminosilicate matrix in which fragments of silica and BN were dispersed. Moreover, SEM technique revealed that sintering caused a decrease in macroporosity with a concomitant increase in microporosity. X-Ray Diffraction (XRD) showed that the microstructure of the ceramic was a result of both amorphous and crystalline phases. Interestingly, the microstructures before and after the heat treatment appeared very similar despite a slight increase in the crystalline/amorphous ratio and the loss of two water-related phases, *i.e.*, aluminium hydroxide (*nordstrandite*) and calcium aluminium hydroxide hydrate. This phenomenon has already been observed and ascribed to water loss with consequent modifications in the crystalline lattice[4]. Furthermore, XRD patterns of samples treated at different sintering temperatures, *i.e.*, 850 °C, 950 °C and 1050 °C, permitted to determine a significant increase in cristobalite content as the temperature increased, and the formation of corundum at 1050 °C. In addition to the physicochemical characterization, thermal analyses and mechanical testing were started with the aim to disclose specific correlation between product characteristics and its performance.

Finally, a MatLab-based calculation tool was developed to estimate the heat losses occurring during the transportation of molten Al from the holding furnace to the casting station. This met the need for improved product sustainability combined with the possibility of creating uniqueness, whose purpose is to lead to products and processes customization.

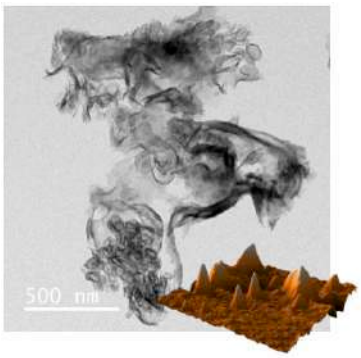
Designing g-C_3N_4/g-C_3N_4 nanoarchitectures by playing with urea/melamine precursor ratio

P. Negro,[a] F. Cesano,[a] D. Scarano[a]

[a]*Chemistry Department of Excellence and NIS (Nanomaterials for Industry and Sustainability) Interdipartmental Centre, University of Torino & INSTM-UdR Torino, Via P. Giuria 7, 10125 Torino, Italy*
pa.negro@unito.it

The metal-free polymeric graphitic carbon nitride (g-C_3N_4) is an emerging 2D layered graphene-like materials due to its exceptional properties *i.e.* thermal and chemical stability, non-toxicity, tunable band gap and visible light activity. For these reasons, nowadays, g-C_3N_4 finds applications in many fields like photodegradation of pollutants, photocatalysis for hydrogen production, carbon dioxide reduction, water splitting, solar light-driven photo-redox catalysis, photoelectric conversion[1]. Nevertheless, it's essential to highlight some g-C_3N_4 limitations, such as the high recombination rate of the photoinduced electron–hole pairs, the poor charge carrier mobility the chemical inertness itself and the low specific surface area[2]. For this reason, currently, considerable efforts are directed towards overcoming the aforementioned drawbacks[3], either by establishing g-C_3N_4/g-C_3N_4 or g-C_3N_4/graphene metal-free homo/hetero-junctions or g-C_3N_4/inorganic semiconductors and/or metals, etc.. hybrid materials. In this study, porous g-C_3N_4 nanoarchitectures are achieved through a facile and effective in-situ synthesis method involving the thermal treatment of different melamine (M) and urea (U) precursor mass ratios. The role of the precursors on morphology and structure, was analysed by means of many characterization techniques, including HRTEM, FESEM, X-ray diffraction, UV-visible, PL and FTIR spectroscopies. Some more, samples, obtained by mixing melamine (M) and urea (U) precursors, combine the advantage of high thermal stability and significant reaction yields, due to melamine action and greatly improved surface area, low dimensionality and short migration paths, due to urea action. Consequently, different "top-down" approaches have been optimized with the aim of further increasing the surface area and decreasing the dimensionality of the U-derived-g-C_3N_4 systems, thus exploiting the well-known "quantum confinement" effect typical of low-dimensional architectures.



Lastly, preliminary results also on the synthesis and characterization of low-dimensional-g-C_3N_4/oxides heterojunctions will be discussed, in order to highlight the role of morphology, structure, surface and bulk properties on the photocatalytic performance.

tbianconi@wisc.edu

The interest for symmetric multi-branched electron donor–acceptor dyes has considerably increased over the last decade. These compounds are usually characterized by a large two-photon absorption cross-section and have also been introduced as promising chromophores for thermally activated delayed fluorescence providing low singlet–triplet gap. Additionally, these multibranched dyes can be viewed as simple models of organic conjugated polymers and are particularly useful for understanding the electronic excited-state properties of these materials. Whereas, as expected for compounds that do not possess a permanent electric dipole moment, their absorption spectra show almost no solvent-dependence, their fluorescence spectra display a strong solvatochromism suggesting a dipolar S_1 state. This behavior was rationalized in terms of a break-up of the symmetry in the excited state driven by structural and solvent fluctuations.[1,2] In this regard, the aim of our research has been the investigation of three symmetric and multidonor-acceptor compounds bearing one or two C-C triple bonds per branch.[3]

Specifically, in this work, these compounds were investigated in a wide set of organic solvents, to evaluate the impact of the medium, the nature of the donor group and the presence of multiple C-C triple bonds on their excited state dynamics. The first part of this study was carried out by means of steady-state and advanced spectroscopic techniques, such as nanosecond and femtosecond UV-Vis transient absorption and femtosecond broadband fluorescence up-conversion as well as non-linear two-photon excited fluorescence. Despite useful information on the excited-state lifetime, the data collected by electronic spectroscopies do not present any clear feature that could be assigned to the transition from a symmetric and quadrupolar excited state to an asymmetric dipolar state. For this reason, we decided to employ, for the first time in this kind of multimodular push-pull compounds, the Time-Resolved Infrared Spectroscopy to resolve the spatial distribution of the excitation within the molecules and then to follow the occurrence of the Excited-State Symmetry Breaking.

r.labarile@ba.ipcf.cnr.it

Photosynthetic microorganisms and their molecular components represent attractive tools for harvesting and conversion of solar light. The new era of biohybrid devices relies on the exploitation of isolated structures from these microorganisms, or the entire living cells, as the active components for photoconversion in optoelectronic devices and photoelectrochemical cells [1]. The bacterial reaction center (RC) extracted from the purple non-sulphur bacterium *Rhodobacter (R.) sphaeroides* has been integrated into photoactive transistors [2]. Polydopamine (PDA), a biocompatible polymer produced *via* self-oxidative polymerization of the dopamine monomer, has been used to immobilize RC without altering the enzymatic photoactivity, and producing photocurrents in photoelectrochemical cells [3].

Finally, assessed PDA biocompatibility with *R. sphaeroides* cells [4], we have been investigated different approaches for interfacing intact photosynthetic microorganisms with electrodes, enabling photoconversion of whole living cells of *R. sphaeroides* and *R. capsulatus*, using PDA as the interface material either as a coating on the cells' surface, or as a film entrapping the cells on the electrode surface [5, 6].

New computer models for passive permeation through the lipid bilayer and protein channels

S. Boi[a], S. Milenkovic[b], M. Ceccarelli[b], M. A. Scorciapino[a]

[a]Department of Chemical and Geological Sciences and [b]Physics, University of Cagliari, Cittadella Universitaria di Monserrato - S.P. 8 km 0,700, I-09042 Monserrato, Italy
sara.boi95@unica.it

The transport of substances across lipid membranes, either passive or active, is of vital importance for any living organism.[1] The permeability of the membrane determines which substances can pass through it and depends on the physicochemical properties of both the membrane components and the permeating substance. Being able to predict permeability is fundamental in therapeutic agent design, because even the most active one becomes ineffective if it is unable to cross the membrane(s) and reach the target. Our work is focused on passive transport and aims at providing a mathematical model that explicitly considers all the main processes that are involved. Mathematical models presented in the literature[2] are either too simplistic, by focusing on a few physicochemical parameters, or too complex, by including so many parameters to result of low human interpretability. Others are too time and resource demanding making them unsuitable for screening campaigns. Despite the model, consistent experimental data are needed to check it. However, methods for permeability measurement are only a few, each one with its own limitations. Starting from previous studies of the research group,[3] we measured the permeability of antibiotics and other substrates (40 in total) through E. coli outer membrane porin OmpF. We used the liposome swelling assay,[4] which although dates back to the 80s, it provides direct evidence of permeation while being simple and focused on the channel translocation. The results have been used to build a machine learning model with the smallest possible number of descriptors to preserve interpretability. We have also investigated the direct passive transport across the lipid bilayer, by using the same experimental protocol but removing the protein channel. Both non-permeant and permeant species have been investigated, thus, obtaining water and substrates apparent permeability coefficients. Good repeatability was achieved even by reducing substrate concentration as much as possible. We observed that vesicle swelling offers too low sensitivity, whereas working in the direction of shrinkage gave the best results. We built a mathematical model able to reconstruct the experimental curves by including all the relevant processes, namely, partition, diffusion, and osmotic pressure, with the corresponding parameters. Simulated curves were fitted to the experimental data through a Monte Carlo scheme. This approach allows to compare different substrates more precisely. The model allows to investigate in-silico the effect of each parameter separately.

Photocross-linked gelatin methacryloyl microparticles prepared by double emulsion method for drug delivery

G. Mugnaini,[a] G. Moschini,[a] M. Bonini,[a]

[a] *CSGI & Department of Chemistry "Ugo Schiff", University of Florence, Via della Lastruccia 3, 50019, Sesto Fiorentino, Florence, Italy*
giulia.mugnaini@unifi.it

Despite the well-known versatility and biocompatibility of gelatin, this biopolymer has been underutilized due to the potential toxicity of traditional cross-linking agents, *e.g.*, glutaraldehyde, which are generally used to stabilize gelatin-based microparticles in aqueous environments at physiological temperature. Here we proposed a safer and more biocompatible alternative method which integrates a straightforward and effective double emulsion preparation protocol[1] with UV-activated cross-linking[2]. Photocross-linkable gelatin methacryloyl (GelMA), which has been proven to be suitable for tissue engineering[3] and drug delivery[4] applications, was selected as primary material for the preparation of porous microparticles. Photocross-linked GelMA porous microparticles with different degrees of substitution were comprehensively investigated using a variety of techniques, including optical and electron microscopy, as well as scattering methods, highlighting the significant impact of substitution degree, and photocross-linking on the microparticles' dimensions, surface morphology, nanoscale organization and swelling abilities. To demonstrate their potential application as delivery vehicles, the photocross-linked microparticles were loaded with a model drug (methylene blue) and the release in water was studied at two different temperatures (25°C and 37°C), resulting in a direct relationship between the release temperature and the drug quantity released. The release patterns, fitted with the empirical Weibull function, suggest a Fickian diffusion mechanism. Our results mark a substantial advancement towards the effective design and preparation of functional, porous gelatin-based cross-linked microparticles suitable for drug delivery applications.

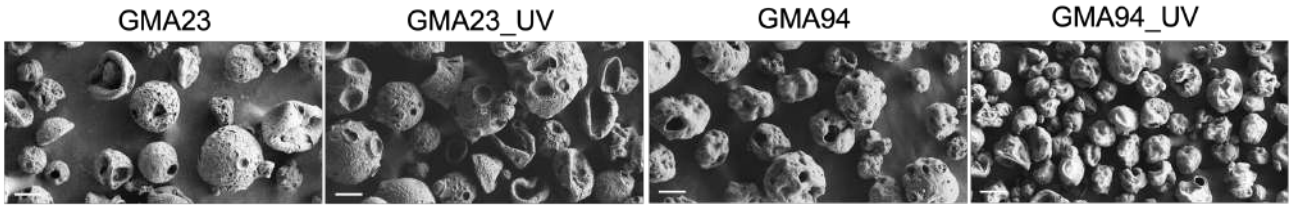

Figure 1: FE-SEM micrographs of GelMA porous microparticles. The scale bar is 100 µm.

Sugar fatty acid esters (SFAEs) are a class of non-ionic surfactants characterized by excellent interfacial tension reduction capability, low toxicity, and biodegradability. These properties make SFAEs extremely promising for cosmetic and food applications as emulsifiers, alongside to the fact that they can be obtained from renewable sources, thus answering the need for evermore sustainable and circular chemistry.[1] Herein, cheese whey permeate (CWP), the main waste stream of dairy industry, was used as starting material to produce bio-based surfactants. Specifically, CWP was enzymatically hydrolysed into a mixture of glucose and galactose which was then submitted to a two-step chemoenzymatic synthetic protocol.[2] The first step (Fischer glycosylation) was not straightforward since several parameter influenced both yield and isomeric ratio. Therefore, the reaction conditions were optimized by means of a chemometric study. In the second step an enzymatic esterification reaction was conducted to obtain an isomeric mixture of *n*-butyl 6-*O*-palmitoyl-D-glycosides and its surfactancy was deeply investigated in terms of static/dynamic interfacial tension and water-in-sunflower oil (W/O) emulsion stabilization capacity over time. Computational studies were conducted on isolated couples of anomers, namely pyranosides- and furanosides-based compounds, to study the role of the ring size on the final emulsifying properties of the isomeric mixture.

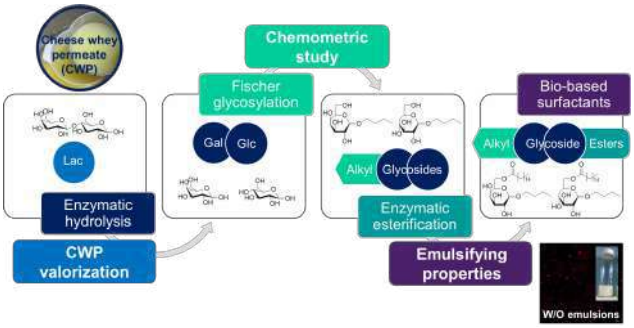

Figure 1: Chemoenzymatic synthesis of bio-based emulsifiers from cheese whey permeate.

valerio.lagambina@uniroma1.it

Self-assembly catanionic nanotubes are an odd architecture with relevant applicative interests. Their formation is very rare and there is currently no clear understanding of their chemistry. Here we report the intriguing assembly of mixtures formed by CTAB (flexible surfactant) and a thermoresponsive bile salt derivative[1] (rigid surfactant, Tb or TBAC). The pure bile salt derivative aggregates into tubules at a temperature above 37°C.When catanionic mixtures are prepared, a peculiar phenomenon was observed: nanotubes form at a specific critical ratio, requiring a minimum portion of CTAB, namely bile salt derivative : CTAB = 9:1. Slightly different variations in CTAB amount, both up or below the critical ratio, create unfavorable conditions for the tubules homogeneity and stability. UV, Circular dichroism, SAXS and microscopy data suggest a molecular packing where the bile acid derivative creates the scaffold of the tubule's bilayer whereas CTAB co-adjuvates in screening the charged heads. Moreover, this system enables for a temperature induced tubule-tubule interconversion: indeed, by increasing the temperature on the catanionic tubules, the catanionic tubules break up and the pure Tb tubules form. The data highlight an innovative case within the narrow umbrella of catanionic nanotubes and encourage further exploration of the possibility offered by the catanionic combination of rigid molecules and flexible surfactants.

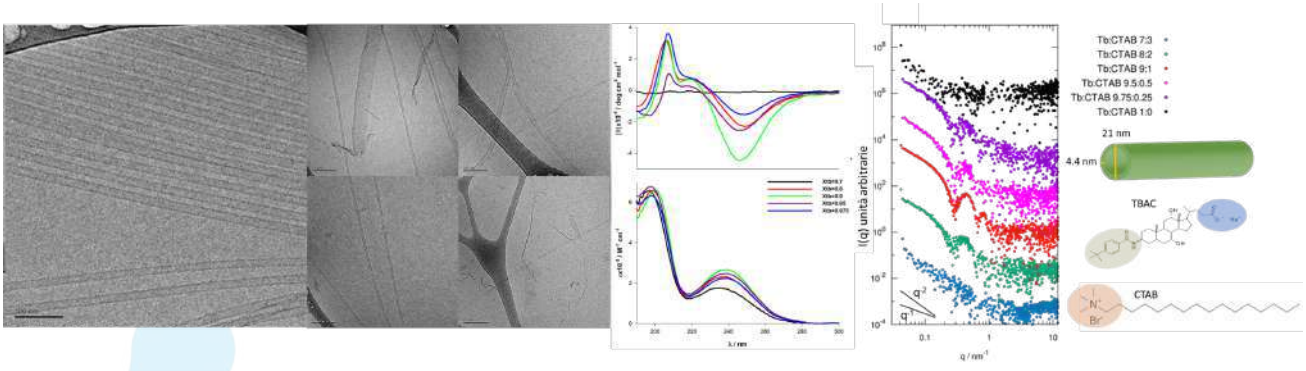

Figure 1: UV, Circular dichroism, SAXS and Cryo-TEM data.

erika.manicone@uniba.it

X-ray scattering techniques can provide a large amount of structural and morphological information, both at the atomic and nano-scale, and are thus particularly suited to study composite/nanostructured materials. The crystalline components are mainly studied by Wide Angle X-ray Scattering (WAXS), providing information on the crystallinity and crystalline phases, as well as on possible texture. The nanoscale structure/morphology can be assessed based on the Small Angle X-ray Scattering (SAXS) signal and related to the possible crystallinity through combined SAXS/WAXS mapping. SAXS/WAXS/Absorption Microscopy is particularly suited to study biological tissues (or any structured material) with nano and/or atomic scale periodicity. The availability of high brilliance X-ray micro-sources for laboratory equipment allows nowadays to perform the aforesaid advanced X-ray characterization, in both transmission and reflection geometries, in the home laboratory, being such X-ray sources considered as "synchrotron-class". The synchrotron-class micro-source combined with the SAXS/WAXS system installed at IC-Bari (XMI-L@b, https://www.ic.cnr.it/laboratorio/xmi-lb/) has been successfully applied to the study of free-standing nano/bio-materials. A in-house developed package (SUNBIM) for the collection and analysis of X-ray microscopies with absorption and/or diffraction contrast, as well as data reduction for transmission and reflection geometries is freely available at http://www.ba.ic.cnr.it/softwareic/sunbimweb/, and constantly updated. Moreover, it has been successfully applied in grazing incidence reflection geometry (GISAXS/GIWAXS) for the study of several nanostructured films for advanced electronic applications. New tools with their respective application examples will be showcased, aimed at enhancing the quality of extracted information, distinguishing variations in density from structural variations in materials.[1-2] This work was supported by the research project "Potentiating the Italian Capacity for Structural Biology Services in Instruct Eric" (Acronym: ITACA.SB, project n° IR0000009) within the call MUR D.D. 0003264 dated 28/12/2021 PNRR M4/C2/L3.1.1, funded by the European Union NextGenerationEU.

Development of mRNA nanovectors as non-viral tool to produce CAR-T cells: future prospectives and applications for CAR-T cell therapy of Glioblastoma

M. Zingarelli,[a,b] M. Beccalli,[b] S. Musio,[a] P. Metrangolo,[b] S. Pellegatta,[a] F. Baldelli Bombelli[b]

manuela.zingarelli@polimi.it

Biocompatible Nanoparticles (NPs) have been extensively investigated in the therapeutic field for their application as drug and gene delivery vectors. In particular, lipid nanoparticles (LNPs) have been used in clinical setting as mRNA-based vaccines. LNPs have also showed to be a promising tool to generate personalized therapies in cancer immunotherapy, for example in the production of CAR-T cells[1].

The tremendous success of CAR-T cells in the treatment of B cell malignancies has revolutionized the field of cancer immunotherapy, but they have not been yet effective in treating all solid tumors. Specifically, for glioblastoma, a rare but serious and untreatable primary brain cancer, phase I clinical studies demonstrated safety, but modest efficacy. Recently, a retroviral-based CAR targeting B7-H3 (a membrane protein overexpressed in more than 70% of GBM, as well as in other cancers, but absent in normal tissues) was developed. B7-H3.CAR-Ts recognize and kill GBM cell lines *in vitro* and increase survival in GBM xenograft models[2]. Although these encouraging preclinical results, developing engineered CAR-Ts at clinical levels by viral-based gene transfer is costly and logistically difficult since it requires cell factories specifically designed for producing clinical grade viral vectors and transduced CAR T cells[3].

We propose the use of T cells, in which B7-H3.CAR expression will be obtained through non-viral lipid-based mRNA nanovectors (NVs), to demonstrate the efficacy of mRNA-B7-H3.CAR-Ts in a preclinical model of glioblastoma. We show the synthesis and characterization of mRNA loaded lipid-based nanovectors and their transfection efficiency. Positive results will accelerate the use of CAR-T cells in the clinical setting of glioblastoma, thus addressing one of the most urgent unmet needs in oncology.

Physicochemical insights into peptide-based targeting of G-quadruplex DNA structures

S. Marzano, F. D'Aria, J. Amato, B. Pagano

Department of Pharmacy, University of Naples Federico II, via Domenico Montesano 49, 80131 Naples, Italy
simona.marzano@unina.it

Protein-DNA interactions are crucial for fundamental cellular processes, including transcription and replication. In addition to interacting with double-stranded DNA, proteins also recognize the noncanonical DNA secondary structures, such as G-quadruplexes (G4s).[1] G4s are polymorphic structures formed within guanine (G)-rich strands, characterized by the presence of at least two G-tetrads, i.e. cyclic planar arrays of four guanines.[2]

We have explored whether it is possible to exploit the DNA recognition motif of G4-binding proteins to obtain peptides that selectively target G4s. Many G4-binding proteins feature an arginine and glycine-rich motif known as the RGG or RG-rich motif. Although this motif plays a crucial role in the recognition of such non-canonical structures, their interaction is still poorly understood.[3]

Aiming to develop peptide-based molecules capable of targeting G4s, we have focused our attention on two peptides: one containing an RGG motif shared by numerous human G4-binding proteins (NIQI),[4] and another derived from the DNA-binding domain of the yeast protein Rap1 ($Myb^{397-415}$).[5] We have studied their interaction with biologically relevant DNA G4s with different topologies (parallel, antiparallel, or hybrid) using a combination of physicochemical techniques, including circular dichroism spectroscopy, microscale thermophoresis, and isothermal titration calorimetry (ITC). Both peptides exhibited the ability to selectively bind and stabilize some G4s. ITC experiments have allowed us to elucidate the thermodynamics of peptide-G4 interactions. We also shed light on the key amino acids involved in the binding process by introducing point mutations.

Our findings contribute to lay the basis for the development of a new class of peptide-based G4 ligands as an alternative to small molecules.

*These authors contributed equally to this work.

Proteins have surface active properties that make them able to adsorb at liquid interfaces [1] stabilizing emulsions and foams; moreover, with respect to synthetic surfactants, they are significantly more biodegradable and might also be obtained by waste materials, representing a promising eco-sustainable alternative to surfactants. However, given their large dimensions and complex multi-ordered structure, each characterized by its intrinsic flexibility and adaptability to environmental conditions, their adsorption properties dramatically depends on environmental conditions [2]. A possible strategy to stabilize protein films under dynamical conditions is based on the exploitation of nanoparticles (NPs), which when decorated by proper additives can adsorb irreversibly at interfaces thanks to their high desorption energy [3]. In this respect, protein-NP interactions and NP-induced protein structural changes in bulk solution are expected to play a crucial role in guiding adsorption at interface and determining interfacial film behaviour.

Here we present a comprehensive analysis, performed by a combination of spectroscopic and scattering techniques, of the interaction process in bulk conditions between model proteins such as Bovine Serum Albumin and negatively charged SiO_2 NPs as a function of different environmental parameters such as pH, ionic strength and salt nature, aimed at understanding and rationalizing the properties of mixed protein-NP interfacial films.

Quadruplex-forming oligonucleotides as tools in anticancer therapy: a physicochemical insight

F. D'Aria[a], C. Giancola[a]

[a]*Department of Pharmacy, University of Naples Federico II, 80131 Naples, Italy*

giancola@unina.it

G-quadruplexes (G4s) are peculiar DNA structures formed by guanine-rich sequences characterised by guanine tetrads stabilized by Hoogsteen hydrogen bonds and monovalent cations[1]. G4s have been found in many sequences of human genome, such as promoter regions of the genes, including many oncogenes, therefore representing promising anticancer drug targets[2]. Particularly, G4 formation in oncogene promoters and their stabilization with G4-ligands can downregulate the expression of the corresponding oncoproteins[3]. In this context, the deep understanding of the energetics of G4 structure stability and their interaction with ligands is of pivotal importance to design molecules with highest affinity for G4s and improved biological activity[4]. In this regard, we applied calorimetric and spectroscopic methodologies in combination with biochemical and biological assays.

The energetics of molecular interactions and dynamical behaviour of G4/helicase complexes in the absence and presence of well-known G4 ligands, which can significantly interfere with several biological processes involving G4s, have also been investigated[5]. To obtain information on G4/helicase and G4/drug/helicase interactions in vitro, complementary physicochemical and biochemical methodologies were used for this study as well.

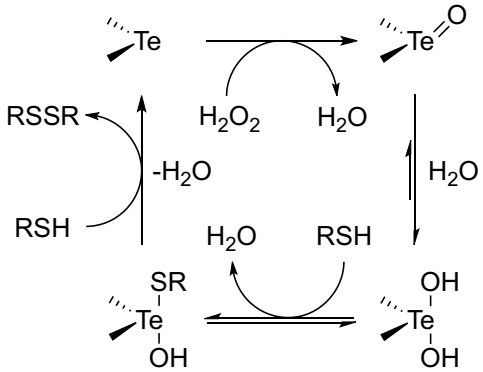
Glutathione peroxidases (GPxs) are a family of selenium-based enzymes that catalyze the reduction of hydroperoxides in living organisms, counteracting the formation of reactive oxygen species that may lead to cellular damage and degenerative pathologies.[1] Organotellurium compounds have been investigated as possible GPx mimics, since they often display a higher catalytic activity compared to the corresponding S and Se-equivalents (**Figure 1**). Recently, several novel β-substituted diorganotellurides were synthesized and evaluated as catalysts for the reduction of hydrogen peroxide.[2] The chemical nature of the substituent proved to have a crucial effect on the rate of oxidation of the thiol substrate. Specifically, the presence of a β-amino group on the telluride lead to a much higher catalytic activity, compared to other substituents.

In our study, an *in silico* approach was adopted to interpret experimental results and draw general conclusions on the reactivity of organochalcogenides with H_2O_2. The computational work has been conducted within the framework of Density Functional Theory, combined with the Activation Strain Analysis. The calculated activation energies for the reaction of the chalcogenides with H_2O_2 are consistent, both in gas-phase and in solvent, with the experimental evidence. We thereby conjecture a *low-barrier* alternative reaction mechanism, which is presumably involved when the β-amino moiety is found in its protonated form.



Scheme 1: GPx-like catalytic cycle of diorganotellurides. Two equivalents of a thiol substrate (RSH) per cycle are consumed to restore the initial oxidation state of the catalyst.

Lab-on-a-chip (LOC) devices have become widespread to study cellular processes and to implement disease modelling.[1] They merge microfluidic, microelectrodes and sensors, and make it possible to grow and monitor living cells. The core of the architecture is about the microelectrodes design. The established technique for thin film patterning is physical vapor deposition (PVD).[2] Despite being able to produce detailed microelectrodes, it is an expensive and time-consuming method. The spray coating technique, on the other hand, allows thin metallic layers to be produced easily and quickly. The advantages of this technique are manifold: a large area deposition can be achieved using less material and at the same time keeping the material properties unchanged.[2] Furthermore, by using appropriate shadow masks, it is possible to obtain microelectrodes with resolutions of a few µm.[3] It is herein presented the application of inkjet printing technology to produce water-soluble shadow masks, which will be used to produce thin nanostructured plasmonic films with a thickness of a few hundred nanometers. The presented approach is used for fabrication of metal microelectrodes with desired geometry, in an easy, fast, and greener way than traditional PVD techniques. In addition, spraying gold nanoparticles (AuNPs) produced by laser ablation in solution (LASiS) enables the formation of nanostructured films suitable for the occurrence of the SERS effect, allowing the detection of surface-adsorbed molecules. This would make it possible to exploit a further method - in addition to the established electrical and optical methods - to monitor the health and growth of living cells cultured on the surface of these devices.

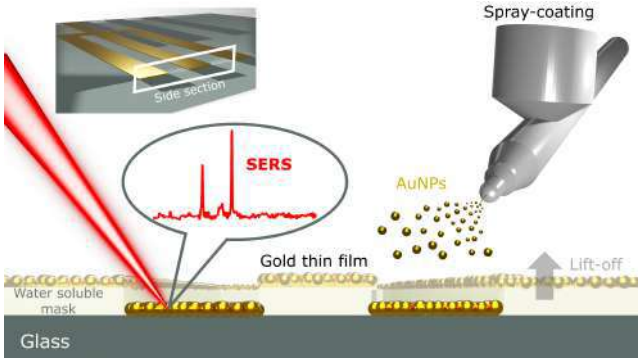

Figure 1: Schematics of the plasmonic microelectrode and the required fabrication steps.

Unveiling the impact of force fields and non-covalent interactions on the adsorption of (bio)molecules onto solvated metal nanosurfaces

Sveva Sodomaco,[a] Sara Gómez,[a] Tommaso Giovannini,[a] Chiara Cappelli[a]

[a]*Scuola Normale Superiore, Piazza dei Cavalieri, 7, 56126, Pisa*
sveva.sodomaco@sns.it

The computational investigation of (bio)molecule adsorption on metal surfaces at the atomistic level remains a challenging task. Within classical molecular dynamics (MD) simulations, selecting appropriate force fields (FFs) is crucial to accurately represent the complex interactions occurring at these interfaces.[1]

This contribution explores the influence of FFs on modeling the adsorption dynamics of selected biochemical molecules on an aqueous Au(111) surface by systematically comparing four combinations of molecule/gold/water FFs. Minimum distance, water coordination numbers, and Non-Covalent Interaction (NCI)[2] plots along the adsorption pathway are analyzed, and adsorption free energies are estimated.

Our findings, partly summarized in Figure 1, highlight how different FF combinations determine general trends in both structural and energetic features.[3] Also, the proposed protocol paves the way for a fruitful integration with multiscale QM/classical approaches for modeling surface-enhanced spectroscopies.[4]

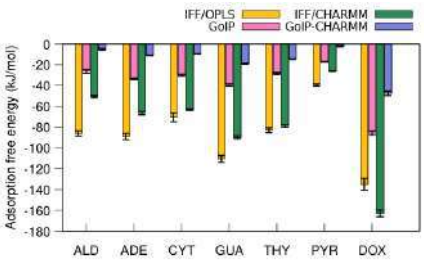

Figure 1: Adsorption free energies of the selected molecules - alanine dipeptide (ALD), adenine (ADE), guanine (GUA), cytosine (CYT), thymine (THY), pyridine (PYR) and doxorubicin (DOX) - obtained using the umbrella sampling method for all FFs.

Cu/TiO_2 based catalysts for electrocatalytic CO_2 reduction

L. Vigni, M. Sistilii, I. Grigioni, M.V. Dozzi

University of Milan, Department of Chemistry, Via Golgi 19, 20133 Milan, Italy.
laura.vigni@unimi.it

Catalyst design to modify the electronic and geometric properties of copper-based electrocatalysts for carbon dioxide reduction reaction (CO_2RR) is a promising strategy to improve the selectivity towards one peculiar reaction product, such as methane, ethylene, or ethanol.[1]

In this work, two series of Cu-TiO_2 samples have been prepared in order to modify both the active surface area and the electronic structure of the Cu material. The study was carefully extended by varying the nominal weight ratio of copper (1%, 5%, 10%, 15%, 25%) deposited on a commercial TiO_2 P25 powder, employed as the Cu support, by means of two different synthetic methods: *i*) grafting (G), and *ii*) freeze drying (FD). Their catalytic activity has been assessed by loading the catalysts onto gas diffusion electrodes (GDEs) and using a flow-cell device.

The most efficient catalyst resulted to be the FD-prepared one containing 15 wt.% of copper, labeled as Cu/P25_15_FD and exhibiting significant selectivity for the production of ethylene. At an industrially relevant current density of 400 mA·cm^{-2}, the FD series suppressed hydrogen evolution reaction (HER) compared to the G series and CO_2RR products (CH_4, C_2H_4, CO) were favored by increasing the Cu loading. The high selectivity for CO_2RR of the FD series is in line with the fact that the rapid sublimation of the solvent allows the growth of small nanoclusters, as further confirmed by High Resolution-TEM images. Theoretical calculations in the literature support that a proper Cu atomic dispersion provides an abundance of catalytic sites, which is extremely advantageous for promoting CO_2RR.[2]

Further optimization of the most performing Cu/P25_15%_FD catalyst was achieved by systematically investigating the effect of additives, *i.e.* Nafion, added to the ink formulation of the spray-coated GDE and acting as an essential binding agent, simultaneously facilitating the CO_2 diffusion through the catalyst.[3] We found a clear correlation between the Nafion content and the FE toward CO_2RR, resulting in a bell-shaped trend peaking for the catalyst with a 4.1 mg cm^{-2} Nafion content. In this way we were thus able to further improve the production of ethylene, reaching a ca. 50% Faradaic efficiency.

stefano.magliocco@unito.it

Catalysts based on Cu-CHA zeolites, broadly employed for reducing NO_x emissions from diesel vehicles through the NH_3-SCR reaction, undergo low temperature deactivation by exposure to SO_2. It has been shown that deactivation occurs through a reaction with a $Cu^{II}[(NH_3)_4O_2]_2^+$ complex, which is generated during the activation of O_2 in the NH_3-SCR reaction cycle and plays an important role as reaction intermediate[1]. In this investigation, this reaction is investigated by vibrational spectroscopy using two samples with identical Cu loading but differing Si/Al ratios, to monitor the evolution of the NH_3 ligands in the process.

In-situ IR spectra were measured using an operando IR reactor cell working in transmission mode. The measurement comprised several steps: (1) pre-treatment in O_2 at 300°C, (2) reduction in 500 ppm NO/600 ppm NH_3 to form $[Cu^I(NH_3)_2]^+$, and (3) oxidation in 10% O_2 to form $Cu^{II}[(NH_3)_4O_2]_2^+$, followed by exposure to 50 ppm SO_2 in N_2 at 200°C. Steps (2-4) were executed at 200°C.

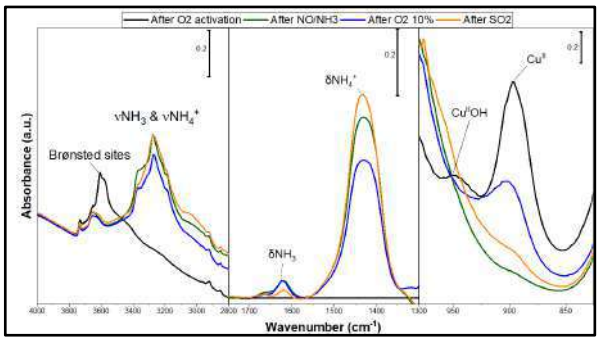

Figure 1- FTIR spectra of Cu-CHA with Cu=3.2 wt% and Si/Al=6.7 under different conditions at 200°C.

In-situ IR spectra show features related to a) Brønsted sites and νNH modes of NH_3 ligands and NH_4^+ formed by interaction with Brønsted sites; b) bending modes of NH_3 ligands and NH_4^+ (1622 cm^{-1} and 1430 cm^{-1}, respectively); c) fingerprints of framework coordinated Cu^{II} ions (fw-Cu^{II}) at 950 and 900 cm^{-1}, which disappear when the Cu ions are solvated by ligands. By following the changes during the different steps we observed an exchange between NH_4^+ and fw-Cu^{II} ions during the formation of the $Cu^{II}[(NH_3)_4O_2]_2^+$ complex, indicating that not all Cu ions are involved in its formation, with a dependence on the zeolite Si/Al ratio. During reaction with SO_2, some NH_3 ligands of the $Cu^{II}[(NH_3)_4O_2]_2^+$ are converted to NH_4^+ replacing fw-Cu^{II} sites, and some $(NH_4)_2SO_4$ is formed. [2] These results point out the mobility of Cu and NH_4^+ ions in catalytically relevant conditions and could help understand better the complex chemistry related to SO_2 poisoning.

The role of metal-support interactions on the red-ox properties of Pd-TiO_2 catalysts

Elizaveta Kozyr,[a], Oleg Usoltsev,[b] Paul Paciok,[c] Riccardo Pellegrini,[d] Elena Groppo,[a] Aram Bugaev.[e] and Lorenzo Mino[a]

[a]Department of Chemistry and NIS Centre, University of Torino, Italy;[b]Alba Synchrotron, Barcelona, Spain; [c]Forschungszentrum Jülich GmbH, Jülich, Germany;[d]Chimet SpA-Catalyst Division, Viciomaggio Arezzo, Italy; [e]Paul Scherrer Institut, Villigen, Switzerland
**elizaveta.kozyr@unito.it*

In situ X-ray absorption spectroscopy (XAS), high-resolution scanning transmission electron microscopy (HR-STEM), Fourier-transform infrared (FTIR) spectroscopy, and density-functional theory (DFT) calculations were combined to uncover the effect of metal-support interactions on the red-ox properties of Pd NPs immobilized on TiO_2 (P25) using deposition-precipitation (Pd_dep) and photodeposition (Pd_photo) methods. These systems are employed in several catalytic reactions, including H_2 photocatalytic production,

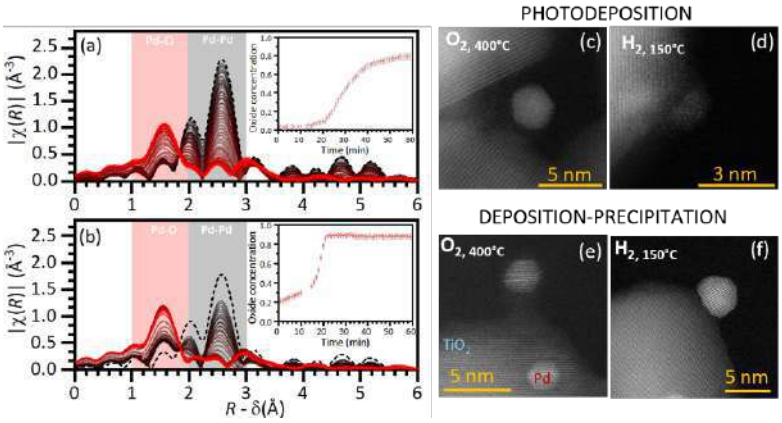

Figure 1. XAS data Pd_photo (a) and Pd_dep (b) samples during oxidation (from black to red); and HR-STEM for Pd_photo (c,d) and Pd_dep (e,f) under oxidizing and reducing conditions.

XAS data demonstrate that Pd_dep upon heating in O_2 experience surface oxidation already at room temperature (Figure 1b) and gets fully oxidized at ca. 200 °C. In contrast, the Pd_photo gets oxidized much slower, starting from ca. 250°C. According to *in situ* HR-STEM under oxidizing conditions, in Pd_dep a distinct PdO shell is formed around the NPs, that also reshape into a more spherical form with less contact with TiO_2. Pd_photo did not demonstrate any clear PdO shell formation. FTIR data reveal the presence of Pd^{2+} sites in Pd_photo, likely related to the presence of atomically dispersed Pd. Finally, DFT calculation predict a lattice contraction in Pd-particles upon oxidation, which was confirmed by XAS for Pd_dep, but was not observed for Pd_photo. Altogether, the observed data suggest a stronger metal-support interaction in Pd_photo sample, which strongly affects its red-ox properties compared to conventionally supported Pd. This work demonstrates the role of metal-support interactions on the red-ox properties of palladium NPs supported on TiO_2, which are crucial for the understanding their catalytic behavior, and suggests a strategy to tune these properties by varying the synthetic procedure.

Zeolites are microporous silicates with a large variety of applications as catalysts, adsorbents, molecular sieves, and cation exchangers. Stable silica-based zeolites with extra-large pores are actively studied because they allow adsorption and processing of large molecules. Still, their synthesis procedures are usually challenging. In this work, a novel highly stable pure silica zeolite called ZEO-3 (IZA code: JZT) is being investigated.[1] This material has a multidimensional, interconnected system of extra-large pores open through windows made by 16 and 14 silicate tetrahedra, and is the least dense crystalline polymorph of silica, with a specific surface area of more than 1000 m^2/g. In preliminary synthetic attempts, it was found that with higher amount of the organic structure directing agent (OSDA), namely tricyclohexyl-methyl-phosphine hydroxide, i.e. $OSDA/SiO_2 = 0.82$ compared to the reference molar ratio 0.5 as from ref. 1, the structure is obtained along with higher crystallinity, even though the amorphous fraction increases upon calcination. Based on these preliminary results, further studies to correlate the effect of different concentration of OSDA ($0.5 < OSDA/SiO_2 < 1$) with the quality of the final material are ongoing. Future investigations will involve the insertion of metals such as Ti in the framework, to be exploited as catalytic active centres for partial oxidation of bulky molecules along with H_2O_2, a better understanding of the crystallization process, and the advanced characterization of the synthesized materials.

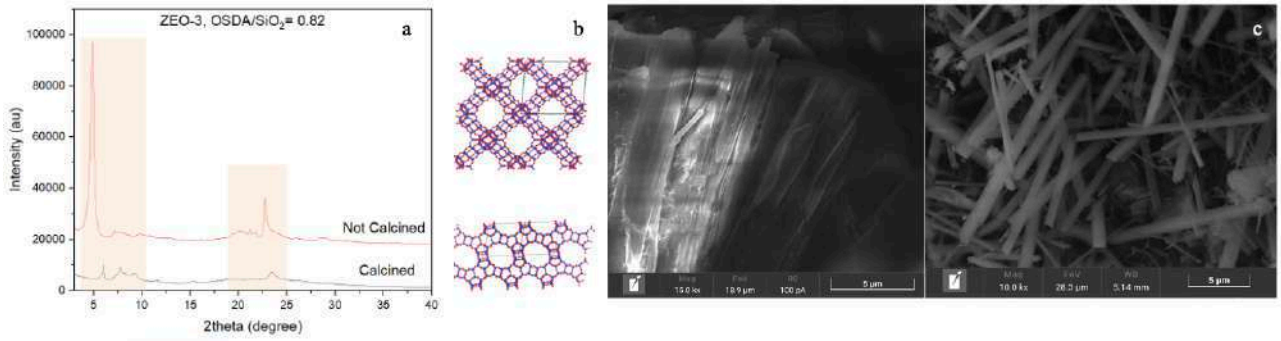

Figure 1: a) Effect of calcination on ZEO-3, $OSDA/SiO_2 = 0.82$, analysed by PXRD, b) Representation of (up)16- and (down)14-member ring windows of ZEO-3 framework. c) SEM images of the (left) not calcined ZEO-3 and (right) calcined ZEO-3.

Effect of Plasmonic Nanoparticles on the Photocatalytic Properties of Nanostructured Silica

R. Zema [a], G. Quaglia [a], R. D'Amato [a], L. Latterini [a]

[a] *Università di Perugia - Dipartimento di chimica, biologia e biotecnologie, Via dell'Elce di sotto, 8, Perugia*
riccardo.zema@studenti.unipg.it, riccardo.zema@dottorandi.unipg.it

Photocatalytic processes aim to use the energy of photons to drive reactions such as production of fuels and degradation of water contaminants. The most studied photocatalysts reported in the literature are nanostructured metal oxides, as TiO_2, ZnO, ZrO_2, etc. These are characterised by wide band gaps (3 – 5 eV) and absorption of the UV portion of the solar spectrum[1]. On the other hand, nanostructured silica has lower cost and restrained environmental impact, exhibiting, as well, photo-activation capacities in the UV region. Furthermore, thanks to its surface reactivity, silica represent an attractive substrate suitable for useful functionalisation aimed to improve the photocatalytic response[2,3]. In this perspective, particularly appealing strategies involve the exploitation of localised surface plasmon resonance (LSPR) effect of metal nanoparticles (MNPs) anchored on silica nanoparticles (SNPs). These materials have interesting synergistic effects when coupled[4], firstly endowing the composite material with enhanced absorption towards visible light, secondly assisting photocatalytic reactions by LSPR radiative and non-radiative decay processes (i.e scattering, energy transfer and heat conversion). In this work, a comprehensive study on the effect of both hydrophobic and hydrophilic MNPs on SNPs efficiency for the photo-degradation of organic pollutants is proposed. Thus, the evaluation of the parameters (i.e. MNPs size, stabilizer effect, aggregation) determining the photocatalytic properties of the composite materials is performed through a full characterization (Figure 1).

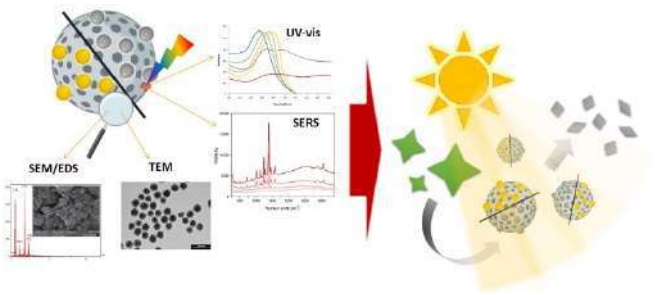

Figure 1: Graphical scheme of the scope of this research work. Some of the used techniques are reported.

Multiscale multiconfigurational self-consistent field/fluctuating charges approach to simulate electronic properties of solvated systems

C. Sepali,[a] L. Goletto,[a] P. Lafiosca,[a] M. Rinaldi,[a] T. Giovannini,[a] C. Cappelli[a]

chiara.sepali@sns.it

Multi-reference self-consistent field (MCSCF) methods are used to overcome the limitations of single-determinant quantum mechanical (QM) approaches[1,2,3]. These methods incorporate many electronic configurations into what are known as multiconfigurational wave functions, allowing for a more accurate description of multireference electronic structures. This is particularly relevant for highly conjugated systems such as carotenoids or transition-metal enzymes[4,5].

Another crucial aspect, in addition to the choice of the QM method, is how to account for the influence of the environment surrounding the target molecule[6]. Indeed, when a molecule is embedded in a solution or a biological matrix, its properties can change significantly. Multiscale focused models, such as QM/Molecular Mechanics approaches, are successful methods for studying such complex systems[6,7]. Specifically, these approaches involve partitioning the system into a primary region treated at the QM level and a secondary region that describes the solvent, usually with electrostatics.

This study introduces a novel approach that couples MCSCF theory (CASSCF) with the fluctuating charges model (FQ)[8,9] to investigate the electronic properties of solvated systems. The hybrid QM/FQ model[10] captures the complex multi-configuration nature of molecules and the effects of the external environment, making it a promising tool for future research in various fields.

Computational modeling of electronic excitations in solution

M. Rinaldi[a], M. Trinari[a], C.Sepali[a], P. Lafiosca[a] , T. Giovannini[a] ,C. Cappelli[a]

[a]*Scuola Normale Superiore, Piazza dei Cavalieri 7, 56126 Pisa, Italy*
matteo.rinaldi@sns.it

The investigation of electronic transitions in solution is a useful tool to gather information on relevant biological systems. To this extent, accurate ab initio methods based on Quantum Mechanics (QM) can aid in the interpretation and rationalization of experimental results. Solvated systems are usually characterized by a very large number of atoms, and the straightforward application of QM methods is unfeasible from the computational point of view. A possible solution is to resort to multiscale modeling,[1,2] in which the solute is described at the QM level, while the solvent is modeled employing simplified embedding potentials. Among these methods, hybrid QM/Molecular Mechanics (MM) methods have proven to be particularly successful in the simulation of solvated systems.[3,4] In particular, QM/MM methods are capable of describing specific solute-solvent interactions such as hydrogen bonding patterns, that can play a role in the shaping of spectroscopic signals.[5]

From the solute's point of view, one of the most popular approaches for the calculation of excitation energies is Time-Dependent Density Functional Theory (TDDFT) since it represents a good compromise between accuracy and computational cost.[6] However, one of the major intrinsic drawbacks of TDDFT is the lack of nondynamical correlation, which is crucial for the simulation of multireference systems, e.g. conjugated systems or transition metal complexes.[7,8]

To overcome this limitation, in this contribution we propose a QM/MM computational strategy based on the combination of multi-configurational methods, grounded in the Complete Active Space Self Consistent Field (CASSCF)[9] approach, and the Fluctuating Charges (FQ)[10] force field. The resulting CASSCF/FQ method[11] is then applied to the calculation of vertical excitation energies of a set of molecules in solution, which paves the way for future applications on biological systems. A detailed comparison with reference and experimental data is also proposed.

Binding energies (BEs) are crucial parameters to understand the evolution of molecular species in dense clouds, determining whether a species is frozen onto the grain surfaces or free in the gas phase. Nowadays, BEs are usually provided as single point values, however the predominant amorphousness of icy grains gives rise to a distribution of BE sites and values. Recently, ACO-FROST, an automatic procedure to simulate realistic icy grains has been released.[1] capable to build up models of amorphous ice up to 1000 molecules and to simulate a large variety of BE sites, see Figure 1 left panel.

In the present work, the aforementioned procedure was applied to compute BE distribution of S-bearing species, *i.e.,* H_2S, OCS, CH_3SH. S-species were selected in order to contribute to a long-standing issue in the field: the Sulphur depletion problem.[2] BEs were computed at DFT level (B97-3c) and then refined with one of the highest level of theory available (DLPNO-CCSD(T)). The previous reported BE values are overestimated with respect to our new BE distribution,[3] see Figure 1 central panel. Besides, frequencies distribution was calculated for OCS molecule and compared to the James Webb Space Telescope (JWST) observations[4] as reported in Figure 1 right panel. The computed distribution outstandingly reproduces JWST data indicating the robustness of the model studied and thus defining a novel computational tool to predict icy species vibrational features.

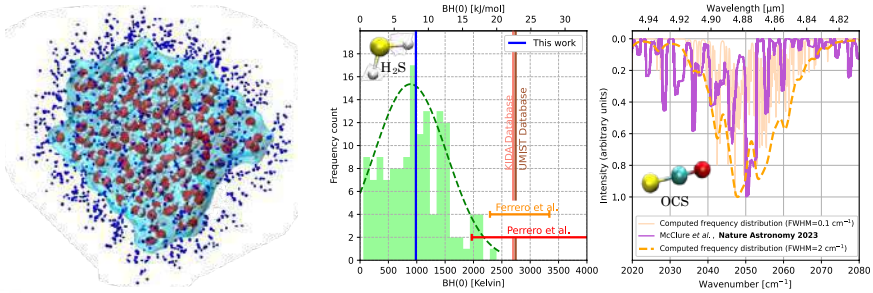

Figure 1: Left panel: 200-H_2O grain covered by a grid of 486 BE sampling sites. Central panel: BE distribution of H_2S compared with previous results. Right panel: Computed frequencies distribution for OCS molecule compared with JWST observations.

The extensive use of fossil fuels for energy production has brought about profound environmental changes. The aspiration to establish an energy transition based on natural and renewable sources clashes with the essential requirement for electrochemical energy storage devices to deliver high performance while relying on critical raw materials. Supercapacitors are fast gaining interest due to their intrinsic enhanced eco-friendliness, safety, long life-cycle, and high charge/discharge rates. Their major limitation, however, lies in the low energy densities in comparison to state-of-the-art metal-ion batteries. [1] To address this limitation and expand the applications of supercapacitors, a number of approaches have been explored, including the possibility of increasing the device energy density exploiting the Faradic current contribution of natural antioxidant molecules as redox additives in the electrolyte. [2] Waste generated from the coffee value chain has emerged as a promising solution. Despite being the third most consumed beverage globally, following water and tea, only approximately 1% by mass of the initial coffee cherry fruit is utilized, leaving over 10 million tons per year of by-products and waste that contain valuable chemicals, including antioxidant polyphenols, worth considering as resource. [3,4] We present a novel bio-based metal free supercapacitor developed from a carbon-based current collector, a water-based slurry and a bio-based binder formulation.

The symmetric supercapacitor exhibits a high specific capacitance of 105 F g^{-1} and an excellent cycle stability (capacitance retention after 10.000 cycles >95%). Preliminary findings indicate the feasibility of employing chlorogenic acid (extracted from coffee) as redox additive to aqueous electrolytes for advanced bio-based energy storage devices, enabling a new circular value chain based on waste from the coffee industry as possible sources for obtaining electrochemically active materials or molecules.

Amidst the increasing demand for green energy and the pressing necessity for decarbonization to counteract the detrimental effects of greenhouse gas emissions, hydrogen (H_2) emerges as a promising, sustainable, and environmentally friendly renewable carrier and energy storage medium. However, unlocking its full potential necessitates the development of efficient and cost-effective storage systems. The utilization of porous materials such as Activated Carbons (ACs) for hydrogen adsorption represents an optimal solution for this issue. This kind of material can be easily prepared through a first step of pyrolysis of the biomass, obtaining the so-called *biochar*, followed by a thermochemical activation step to achieve a microporous structure.

These carbon-based materials boast numerous advantages, including low mass density and high storage capacity. Noteworthy results have been achieved by our research group using ACs derived from agri-food wastes, demonstrating hydrogen adsorption values of 4.2 wt% and 3.9 wt% at 77K and 6 bar on materials derived from melon peels and asparagus stems, respectively. However, the requirement to maintain extremely low temperatures poses a significant challenge, particularly for automotive applications.

Consequently, there is a growing interest in exploring Metal-Doped ACs. Exploiting the interactions between hydrogen and metallic nanoparticles (NPs) offers the potential to push the storage mechanism towards chemisorption, enabling higher operating temperatures, closer to ambient conditions. The spillover effect, in particular, is based on the dissociation of H_2 molecule on metal NPs and the migration of H atoms in the material, enhancing storage performance. To deepen this behaviour, ACs can be decorated with metals using, for example, the impregnation method. This technique, commonly employed in catalyst preparation [1], consists in stirring the solution of the metal precursor (*e.g.* nitrates of transition metals) with the carbon material, followed by chemical reduction or thermal treatment, in order to obtain zero-valent metal NPs dispersed in the carbon matrix [2]. The effect of different metals and experimental conditions is deeply investigated.

Perovskite-based high-entropy materials by solid-state microwave-assisted synthesis

L. Caggiu,[a] F. Murgia,[a] C. Cau,[a] A. Locci[b], R. Orru,[b] A. Iacomini[c], G. Mulas,[a] S. Garroni[a]

lcaggiu@uniss.it

In the last decade the high-entropy materials (HEM) aroused hype in the scientific community[1] due to their versatility and properties tunability for a wide range of application, such as energy storage, catalysis, solar energy harvesting[2] among others. We refer to "high-entropy material" as a defined compound obtained by the combination of five or more elements (not as dopant), whose synergistic interaction, i.e. *cocktail effect* confers original properties respect to a pure metal or precursor[3]. However, the further addition of atoms in a crystalline structure causes a distortion of the lattice, due to the difference in the atomic radii. Therefore, the formation of HEM, should lie on crystalline structures that are more prone to perturbation, in order for new atoms to be host. Perovskites (general formula = ABO_3) come to the rescue, since they feature two cation sublattice sites, which make the structure more flexible and therefore they could be employed as building block for the HEM.

HEM are usually prepared by solid-state reactions, through mechanical treatment, sintering or a combination of both[4]. Especially for high-entropy oxides, the sintering step is necessary, which is indeed the most energy-consuming process. Alternatively, the heat treatment could be replaced by the microwave-assisted heating that dramatically decreases the amount of required power, given the reduced processing time[5]. In addition, such a high-heating-rate process provided by solid-state microwave syntheses (MWS) promotes non-equilibrium reactions, effectively achieving metastable phases such as the HEM.

In this work, the MWS is employed to obtain various perovskite-based HEM. The reference structure is $BaTiO_3$, where the perovskite B site (Ti) was partially substituted from three different elements in the same ratio: $Ba(Ti_{0.25}Zr_{0.25}Y_{0.25}Hf_{0.25})O_3$. To get to this phase, a crucial role is played by the tuning of the MWS parameters, such as heating rate, dwelling time, and final temperature, which could also provide multiple formation pathways, through intermediate phase as $Ba_{1.08}Y_{0.11}Hf_{0.91}O_3$, as confirmed by *ex situ* X-ray powder diffraction (PXRD). The effects of syntheses conditions are also investigated by scanning electron microscope (SEM) and Energy Dispersive X-ray Analysis (EDX), to evaluate both morphology and homogeneity of the final products, which are key parameters for the overall performance of the HEM.

Aprotic lithium−oxygen batteries (aLOBs) are considered as one of the most interesting high density secondary batteries[1]. Therefore, overcoming the limits that hinder their employment is a key target in order to fulfil the increasing demand for energy storage systems. A significant drawback lies on the high overpotentials needed upon charge to oxidize the non-conductive discharge product Li_2O_2. This is due to the fact that, at high operating voltages above 4.0 V vs. Li^+/Li^0, many parasitic processes that lead to cell damage and early failure are triggered[2,3]. A major role in these detrimental phenomena is played by the formation of molecular oxygen in its singlet excited state, which is highly reactive and unmanageable[4].

With the aim of mitigating the charge overpotentials, many redox mediators (RMs), soluble catalysts that facilitate Li_2O_2 oxidation, are proposed in literature[5]. Among them, lithium halides LiI and LiBr are considered attractive because of their favourable thermodynamics, simplicity and reduced costs[6,7].

However, their impact on parasitic processes, including the formation of singlet oxygen, needs to be further explored. Our studies aim at revealing the correlation between thermodynamical and kinetical properties of LiX redox mediators, that vary basing on the solvent employed, and their tendency to favour singlet oxygen evolution. The spin trap 4-oxo-TEMP was used as probe of singlet oxygen and detected by EPR spectroscopy. Moreover, in order to obtain a more reliable and quantitative analysis of the singlet oxygen evolved, fluorescence measurements were carried out using 9,10-dimethylanthracene as probe molecule. The results demonstrate a strong correlation between solvation, kinetics and singlet oxygen evolution in LiX-mediated Li-O_2 batteries[8,9].

Over the past decade, lithium-oxygen aprotic batteries (aLOBs) have emerged as a promising advance in energy storage technologies, provided they realize a substantial portion of their theoretical specific energy. However, their path to commercialization faces obstacles due to several technical challenges[1].Current implementations exhibit limited energy efficiency and a departure from reversible electrochemistry. This discrepancy can be attributed to the insulating nature of the discharge product, lithium peroxide, Li_2O_2, and the formation of singlet oxygen resulting in the need for high charge overpotentials[2]. The presence of singlet oxygen initiates parasitic chemistry, leading to the formation of secondary products and contributing to the degradation of battery components. This interrupts the reversibility of the redox process, further complicating the efficiency of the overall system. A promising strategy to address the slow decomposition kinetics of Li_2O_2 involves the use of redox-active and soluble molecules known as redox mediators[3], RMs. These serve as catalysts for the oxidation of Li_2O_2, significantly reducing the charge overpotential that attends as the source of harmful singlet oxygen formation. Unlike solid catalysts, redox mediators have the advantage of enjoying a larger reaction interface as they are dispersed in the electrolyte. The catalytic effectiveness of the RM is strongly influenced by the environment in which it operates. Therefore, the choice of solvent in the electrolyte is a key factor, as it must be able to stabilize the species acting as the mediator. RM can pose a risk of ionic short-circuiting due to a shuttle effect between the anode and cathode. This can lead to corrosion at the lithium metal anode, causing the loss of the active redox mediator and the oxidizing species. One solution to this problem could be the use of self-defending[4] RM, which serve a dual function as catalysts for the oxidation of the discharge product and as protectors of the lithium metal anode. Based on the information just presented, our contribution involves a combined experimental and computational approach to investigate the effective pairing of RM and solvents to address some of the critical issues affecting these systems.

m.gonzalezmonroy@student.unisi.it

Hydrogen plays an essential role as an enabler of the energy transition as it can make a significant contribution to storing and distributing renewable energies and for the decarbonization of hard-to-abate sectors and energy-intensive industries[1].

Although hydrogen can be seen as a clean energy vector, currently its global production is derived from fossil fuels. Low-emission hydrogen, better known as green hydrogen, is referred to as the hydrogen obtained using electrolysis coupled with a renewable electricity source and therefore having no associated emissions, but nowadays it accounts only for 0.7% of the total hydrogen demand (95 Mton by 2022)[2].

With the aim of increasing green hydrogen production to meet the target of the growing sustainable hydrogen demand, in line with the target set by the strategic research and innovation agenda of the Clean Hydrogen Partnership[3], several alternatives to water and steam electrolysis have been developed based on photoelectrocatalytic water-splitting processes and thermochemical processes using renewable or recycled carbonaceous feedstocks.

Nevertheless, challenges regarding raw materials used, equipment set-up, the energy losses during the entire supply chain, and the environmental consequences within the scaling-up process, are still critical points that require methodological scientific investigation to address the potential of green hydrogen to implement a new global economy.

In this work, we present a comparative analysis of the emerging processes for green hydrogen production in alternative to electrolysis-based technologies (currently closer to market) from an environmental life cycle assessment perspective aiming at highlighting the strengths, drawbacks, and hotspots in terms of resource and process efficiency.

On the evolution of stability and quality of bake-on PDMS coatings upon extended thermal treatment

C.
C. Passet,[a] L.Carnelli,[b] G. Ricchiardi,[b]

chiara.passet@unito.it

Siliconization of glass primary packaging containers is increasingly adopted in order to reduce drug-glass interactions in primary packaging. Bake-on siliconization is used when a robust and well-adhered PDMS layer is required[1]. In this process, a PDMS emulsion is sprayed in the containers, which are then heat-treated in order to obtain a thin densified coat. Before use, the containers are washed and depyrogenized before filling. In this study, we explore the stability and the quality of siliconization layers upon these further treatments. Stability and quality of the PDMS layer upon further extended thermal treatments have become recently of particular concern due to the evolution of filling technologies. In fact, we observe a trend in filling machinery manufacturers towards higher capacity and speed of all phases of the process (washing-depyrogenation-filling). Because of the different specific speeds of the different phases, the depyrogenation oven is often used as a buffer for matching the speeds of the upstream and downstream phases. This imply a variable duration of depyrogenation, whose duration is increased when the downstream phases do not accept new vials. In this study, standard siliconized vials were subjected to a heat treatment in a muffle at 300°C in of air at different exposure times ranging from 2 to 96 hours. The vials thus obtained were analyzed by optical, SEM and AFM microscopy, contact angle with water. The same samples were also exposed to a selection of drug simulants including surfactants, complexing agents and proteins, and the quality of the PDMS after exposure was characterized with the same techniques. The data obtained from different analyses show that the bake-on PDMS layer remains stable upon extended heat treatments with minor changes in morphology and hydrophobicity.

In the tire industry, resins are essential ingredients because of their curing, reinforcing, and tackifying properties. They modify the rheological behaviour of rubber compounds, improving processability and enhancing mechanical properties.[1] Resins change the dynamics of the polymer chain, which affects the viscoelastic behavior and the mechanical characteristics at the end. In this research, we focused on comparing the effect of a natural- and a petroleum-origin resins on SBR compounds. The resin content was varied from 15 to 45 parts per hundred parts of rubber. To gain insights into the molecular dynamics and structural properties of the elastomeric blends, we employed different Solid-State Nuclear Magnetic Resonance techniques,[2-3] combined with dynamic-mechanical, rheometric, calorimetric and chemical analyses. These techniques have provided a comprehensive understanding of the mechanical, thermal and vulcanisation properties of the elastomeric compounds, as well as of the polymer chain dynamics, as affected by the resin nature and content.

cambiotti@csgi.unifi.it

Semiconductor quantum dots (QDs) have become highly adaptable materials, possessing distinct physico-chemical properties that can be tuned through a variety of methods including morphological control and surface passivation.[1] The groundbreaking advancements in QDs research were recently recognized with the Nobel Prize in Chemistry in 2023, underscoring their profound impact on technology and society.[2]

Generally, QDs are treated and studied under nitrogen conditions since their optical characteristics could be irreversibly degraded when they are exposed to oxygen for long time.[3] Considerable focus has been directed towards the investigation of QDs in solution; however, there is a discernible lack of established methodologies for their integration into solid-state systems. The aim of this study is to develop oil-core silica-shell microcapsules, thereby establishing a compartmentalized solid-like system dispersible in water and potentially capable of tolerating air exposure.[4] Through this strategy, a dual protection mechanism against oxygen is achieved, where the silica shell constitutes a physical barrier against oxygen diffusion while unsaturated fatty acids can act as oxygen scavengers.[5,6]

We studied CdSe- and PbS-QDs in oleic acid with different capping ligands. The oily dispersions were then encapsulated in silica microcapsules and characterized via steady-state PL, time-resolved PL, SEM, SAXS, and EDX to determine optical and morphological properties of the core-shell systems. After solid-state analyses, dispersions of CdSe/capsules and PbS/capsules were prepared in water to determine the influence of the medium. Through this approach, successful QDs encapsulation was achieved for the two different nanocrystals exhibiting remarkable stability in aqueous environment when working in air-balanced environment.

Metallic nanocrystals (M-NCs) are of great interest due to the possibility of controlling the plasmonic band through three-dimensional self-assembly arising from the interactions between neighboring NCs, which can result in new properties non-present in the original constituents of the superlattice. That is because the Localized Surface Plasmon Resonance is highly affected by the surface-surface distance between the NCs. Capping agent shell plays a key role in this kind of structuring particularly the interactions between the carbon chains of such shell and the organic solvent in which are dispersed the NCs. To better understand if this kind of interaction can influence, we carried out an extensive study on recently obtained Au-NCs capped with oleylamine. We dispersed such NCs into four different solvents, characterized by increasing dielectric constant: cyclohexane, toluene, ethyl ether, and chloroform. This resulted in a different extension of the oleylamine alkyl chain in such solvents. After this first characterization, through a microemulsion method, adding water and using oleic acid as a functionalizing agent, we induced the self-assembly of such NCs into the abovementioned superlattices in water. The characterization of such superlattices was carried out through a multi-technique approach exploiting TEM, SAXS, and UV-Vis approach which allowed us to understand the key role of the interactions between the alkyl chain of the capping agent and the organic solvent in such a structuring process.- The functionalization procedure, carried out on all the samples gave interesting results, with different kinds of superlattices obtained which translated into different optical properties of the resulting systems. Of great interest are the results obtained for the optical properties of such superlattice, which is clear from Figure 1 B, monodisperse Au-NCs show the typical absorption band at around 520 nm, while the structured superlattice of Au-NCs shows a huge blue shift of more than 300 nm since we can identify a clear peak at 205 nm. These results show the power of such ordered 3D organization which gives origin to completely new and engineerable properties that open the route to uncountable new applications and developments.

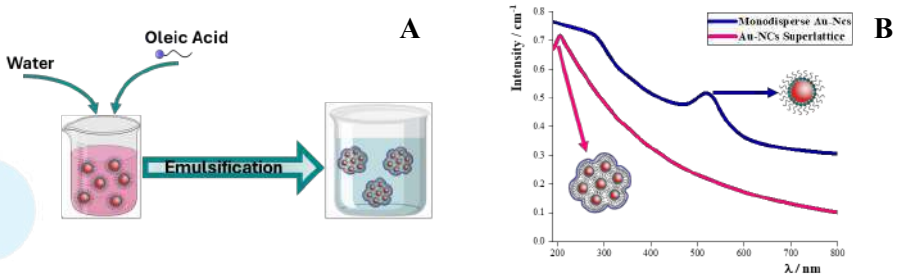

Figure 1. UV-Vis Spectra of unstructured Au-NCs (A), and UV-Vis Spectra of structured Au-NCs

Luminescent materials can emit photons after the absorption of energy. Among these, inorganic emitters, also known as "phosphors", are of great interest due to their excellent stability, if compared to their organic counterparts. Usually, phosphors consist of an inorganic host matrix in which luminescent ions are located as dopants[1]. Silicates, along with aluminates, are widely studied as host to produce high efficiency phosphors, displaying great chemical stability, high water resistance and relatively low calcination temperature[2]. Rare-earth ions are often used as luminescent ions in phosphors due to their capability to emit visible light under UV-Visible excitation, with very high quantum yields[3]. Europium is a very fascinating element and it is widely studied since its luminescent properties can be tuned by engineering the surrounding media[4]. In this work we focused our attention on silicate-based phosphors, choosing europium as luminescent centre. We investigated different synthetic strategies, trying to rationalize how the properties of europium are dependent on the crystal environment, with the purpose of achieving the best performances. The as-synthesized phosphors are then included into different matrices and the mutual effects of the interactions between the two components have been investigated. The final goal is to develop innovative luminescent devices to be used as lighting sources.

Figure 1: Luminescent properties of Europium-doped silicates in powder and into hydrogels.

Photochromic molecules are molecular switches that can be toggled between two or more states by one of the most abundant energy sources found in nature, i.e. light. Their structural design enables to programme their chemical and physical properties [1-3], such as their capability of absorbing visible light, the time-responsiveness to the optical stimuli, the stability of the various states, etc. The optically-modulated changes in their structural, mechanical and electrical properties[4,5] has been exploited for the fabrication of multi-responsive (nano)devices[6,7].

In this work, we report on the self-assembly of a photochromic diarylethene (DAE) molecules equipped with two alkyl sidechains. We demonstrate that the exposure of this molecule to blue or green light makes it possible to switch it between two thermodynamically stable isomers [5]. The efficient photoresponsive nature of this DAE was revealed in studies performed solution and in the solid state. The structural, electronic and optical properties of ultrathin DAE films onto graphene have been investigated, and exploited for the fabrication of light-responsive electronic devices based on this hybrid assemblies.

e-mail: Simone.Micheloni@phd.units.it

The study of the adsorption and self-assembly of organic molecules on metallic surfaces, with the aim of understanding the electronic interaction between the organic active layer and the underlying metallic surface, plays a key role in determining the possible applications of these systems in organic-based opto-electronic devices. Among the various systems studied, very promising results have been obtained with boronic acids derivatives, namely Boroxines, which derive from a self-condensation reaction of three boronic acids molecules leading to a six-membered ring made up of alternating boron and oxygen atoms. Notably, Boroxines are much studied due to their high chemical and thermal stability, the wide range of applications of these compounds in synthetic organic chemistry and the well-established procedures for 3D COFs formation. Concerning their electronic properties, the presence of an ultra-fast charge delocalization channel between the boroxine ring of TriPhenylBoroxine (TPB) molecules and the underlying Au(111) substrate was evidenced[1], thus suggesting good performances of the interface in terms of electronic transport. With this in mind, in present work we explore the properties of TriPyrenBoroxine (TPyB) /Au(111) interface. Pyrene has spectral features in the UV-Vis range, which might be exploited to promote specific electronic transitions in TPyB molecules and to study optical-induced electron dynamics both within the organic film and from the organic film towards the underlying Au(111) substrate. In detail, a TPyB molecules film on a Au(111) substrate has been grown, by thermal treatment of 1-Pyreneboronic Acid (PyBA) in a quartz crucible at a temperature of about 300°C in Ultra-High Vacuum (UHV) conditions. The organic film formation has been monitored by XPS (X-ray Photoelectron Spectroscopy), to verify the actual presence of TPyB molecules on the Au(111) substrate; then, the system has been studied through NEXAFS spectroscopy (Near Edge X-ray Absorption Fine Structure), in order to determine both the molecular orientation and the unoccupied electronic states. Charge dynamics has been explored by RPES (Resonant PhotoEmission Spectroscopy), 2PPE (Two-Photon PhotoEmission) Spectroscopy and pump-probe spectroscopy. The study confirmed the occurrence of ultra-fast charge delocalization at the interface and revealed the presence of dynamics of charge with three different characteristic lifetimes, namely in the s, μs and ps regimes. Finally, for a further molecular valence electronic transitions characterization and to study the equilibrium reaction between PyBA and TPyB molecules, UV-Vis spectroscopy measurements in solution have been performed, whose results have been compared to the theoretical values obtained from TD-DFT calculations (Time-Dependent Density Functional Theory).

claudia.pigliacelli@polimi.it

Self-assembly of metal nanoparticles (NPs) represents a versatile tool for creating materials with new structures and intriguing collective properties. Our work in this field is focused on the design of different self-assembly strategies to form hybrid superstructures, exploiting the templating ability of peptides and proteins.[1] At this aim, we have devised a one-pot procedure to obtain peptide-gold superstructres (AuSP; 200 nm) where a monolayer of 5nm AuNPs surrounds a peptide core.[2] Together with being chiroptically active, AuSPs could act as template to control the formation of a transient 3D-branched Au-nanoshell (BAuNS) stabilized by sodium dodecyl sulphate (SDS). The BAuNS dismantles upon SDS concentration gradient equilibration over time in the sample solution, leading to NP disassembly and regression to PAuSS. Notably, BAuNS assembly and disassembly promotes temporary interparticle plasmonic coupling, leading to reversible and tunable changes of their plasmonic properties.[3]

The Interaction between Fluorescent Molecules and Plasmonic Nanoparticles: From SERS to SEF

A. Mercedi,[a] L.Litti[a]

[a]*Department of Chemical Sciences, University of Padova, Italy*
anna.mercedi@studenti.unipd.it

The electric field intensity can be locally enhanced thanks to metallic nanoparticles (or surfaces) that give rise to localized surface plasmon polaritons (SPPs). This mechanism is the basis for electromagnetic enhancement (EM), which plays a crucial role in amplifying Raman signals within Surface Enhanced Raman Spectroscopy (SERS).

Raman scattering, however, is not the only process affected by the increase in the electric field intensity; fluorescence can increase as well, resulting in Surface Enhanced Fluorescence (SEF).

While SERS peaks at very close distances from the metal surface, fluorescence is often quenched at such proximity, necessitating distances of the order of a few nanometers to tens of nanometers for SEF[1]. The distance from the metallic surface, however, is not the only factor affecting these phenomena; particle material, morphology[2], as well as excitation wavelengths are also involved.

Here, the interaction between a fluorescent molecule and a plasmonic nanoparticle is studied to deeply investigate the balance between these two processes. Plasmonic nanoparticles of different materials (silver and gold spherical nanoparticles) as well as different morphologies (gold nanorods) are employed. Additionally, different distances as well as different excitation wavelengths are explored. All these parameters are evaluated to obtain a deeper understanding of all the complex mechanisms involved in the interaction between a fluorescent molecule and a plasmonic nanoparticle.

Stabilizing carbynes

P. Tarakeshwar,[a] S. G. Sayres,[a,b] P. R. Buseck[a,c] and M. Meneghetti[d]

Carbyne is the name given to a chain of sp carbons. Despite several claims, existence of a solid consisting of such chains has not been substantiated. Solids with sp^3 carbons, namely diamond, and sp^2 carbons, namely graphene, C-nanotubes and fullerenes, are well known and widely accepted. Chains of sp carbons can occur in two forms: cumulenic with equal bonding between all atoms, and polyynic, with alternating short and long bonds deriving from a Peierls instability. In the first case the interpretation is that bonds are all 'double bonds' whereas in the second case bonding arises from alternating 'single and triple bonds'. Although the polyynic form is more stable, chains of sp carbons are too reactive to condense into a solid.

Stabilization has been achieved by attaching large groups at the ends of the chains, which suggests the importance of the chain-ends.

In this work, we show how gold nanoclusters obtained by laser ablation can stabilize solids formed from sp carbon chains, pseudocarbynes.[1,2,3] Model calculations also make it possible to hypothesize that a cumulenic structure can also stabilized.[4]

Nano- and microplastic toxicology has appealing global consideration. As matter of fact, the plastic materials are disposed in to the environment and degrade by releasing micro- and nano plastic, which are very dangerous, due to their potential to bypass the biological membranes. In order to perform toxicological studies on human cells, it is necessary to produce particles with nanometric dimension, which can be difficulty extracted and characterized from environmental matrices [1]. In this work, we have produced of PET Nanoparticles from commercial grade PET resin, by grinding the PET pellets and dissolving the powder in a solution of hexafluoro isopropanol: chloroform (1:1), then extracted in water. By using this feasible method, PET nanoparticles have been characterized by UV spectrophotometer, optical microscope (bright field), scan electron microscope (SEM) and dynamic light scattering (DLS). Furthermore, PET fluorescence properties have also been characterized by spectrofluorometric techniques.
This work approaches a simple and easy way for PET nanoparticles production, which can be very useful for the study of cell toxicology of this kind of plastic. Furthermore, the spectroscopic properties of PET can be used for the evaluation and quantification of PET nano- and microparticles in environmental samples.

Solid State Nuclear Magnetic Resonance (SSNMR) is one of the most powerful techniques for obtaining a deep understanding of the structural and dynamic properties of materials, over very wide spatial (0.1-100 nm) and time (10^{-11}-100 s) scales[1]. The possibility of performing SSNMR experiments on photo-responsive materials while they are interacting with light is very attractive, since it could reveal the structural and dynamic modifications occurring in the material due to its interaction with light. This appears of particular interest in the field of photovoltaics since it can improve the understanding of the material performance and its design. In this contribution we present the preliminary results of the project PRIN 2022 "NUTSHELL", aimed at developing SSNMR apparatuses for performing SSNMR spectroscopic and relaxation experiments on organic and inorganic photoactive materials during their illumination.

Exploring the depth of Deep eutectic solvents: structural insights and molecular dynamics

E. Pietropaoli[a] G. Mannucci,[a] M. Palluzzi,[a] M. Busato,[a] P. D'Angelo[a]

[a]*University of Rome La Sapienza, P.zle Aldo Moro 5, Rome*

eva.pietropaoli@uniroma1.it

A deep eutectic solvent (DES) stands out as an interesting solvent due to its distinct thermic properties, resulting in a significant decrease of the mixture's melting point (MP). The recent introduction of type V DES represents a highly biocompatible alternative to traditional solvents by being both hydrophobic and free from chlorides and metal ions. The formation of these DESs relies heavily on the structural attributes of their precursors, distinguishing between hydrogen bond acceptors (HBAs) and hydrogen bond donors (HBDs).[1]

The main aim of this study is to quantify the depth that makes such a DES. Our interest lies in comparing precursor pairs with and without hydroxyl groups, aiming to guide DES formulation with minimal alterations to the compounds. The addition of a hydroxyl group to one of the components can significantly alter the solid-liquid equilibrium (SLE). Consequently, our investigation seeks to examine the role of all interactions that take place in these systems, focusing specifically on π-π stacking.[2]

This study concerns comparing the eutectic mixture formed by trimethoxybenzene (TMB) and 1,3-diacthylbenzene (13DAB) with the DES formed by 3,5-dimethoxyphenol (DMP) and 13DAB.

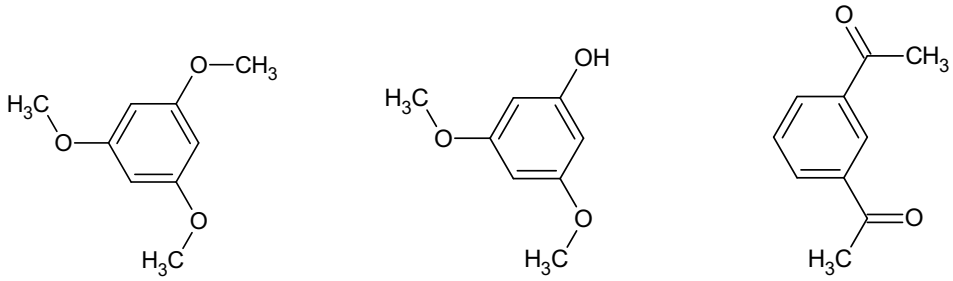

Figure 1: The molecules of TMB, DMP and 13DAB are respectively reported.

We have adopted a combined approach between experimental measurements and theoretical calculations. Most combinations of organic compounds exhibit eutectic behavior that can be easily predicted by conductor-like screening model (COSMO) calculations. Then, thermic characterization is conducted using differential scanning calorimetry (DSC), while molecular level can be investigated with MD's simulations.

Reactivity and stability of the High Entropy Oxide (Mg,Co,Ni,Cu,Zn)O

G. Maranini,[a] M. Fracchia,[a] A. Bianchi,[a] M. Coduri,[a] U. Anselmi Tamburini,[a]

[a]*Department of Chemistry, University of Pavia, V.le Taramelli 12, I27100 Pavia, Italy*
giulia.maranini01@universitadipavia.it

High entropy oxides (HEOs) are single-phase materials composed of five or more cations, some of which stabilized in an unconventional chemical environment, different from that of the simple oxide phase, due to the large configurational-entropy contribution[1]. Despite their potential to yield compounds with unique and promising properties for energy storage, catalysis and thermoelectricity, the role of entropy in the stabilization process is still debated[2], and very little is known about their compositional stability range[3]. An interesting question to address is the role of individual cations in the HEO stability. Currently, one of the most studied HEO, and the subject of our research, is the first one synthesized in 2015 by Rost et al., i.e. (Mg,Co,Ni,Cu,Zn)O. CuO is known to be the most destabilizing component within the solid solution. Through a multicomponent diffusion couple (DC) between CuO and the quaternary oxide containing all cations present in the aforementioned HEO except Cu, we assessed Cu mobility and reactivity. The DC was heated in a tubular furnace at 1000°C for different reaction times. Once the diffusion occurred, the DC cross-section was examined through SEM-EDS for morphological and compositional analysis, and through EBSD (Electron Backscatter Diffraction) to determine the structure in the different sample regions.

Our findings revealed Cu's high diffusivity within the solid solution, and the formation of a product layer, due to the other cations diffusion, with general formula $Cu_2(Mg_xCo_yNi_zZn_n)O_3$, compatible a distorted gugghenite structure (Cu_2MgO_3). Interestingly, EDS analysis also revealed a high solubility limit of Cu within the diffusion region (33%) not reproducible via ex-situ synthesis; indeed, powders obtained via Pechini method showed a Cu solubility limit of 28% with a progressive and long-range structural distortion observed for Cu percentage higher than 25%. Another attempt to assess the single components' role in HEO reactivity was made by progressively reducing the number of components from the quaternary oxide in the DC. First, a DC between the ternary oxide (Mg,Co,Ni)O and CuO was then set-up. We found no product layer is formed demonstrating the Zn has a pivotal role in determining the guggenite stability. By further reducing the number of components in the solid solution a clear trend in the Cu diffusion length was not observed implying that there is no direct correlation between the diffusion kinetics and the number of components, as instead suggested for high entropy alloys. It would be reductive to model high entropy oxide behaviour only based on the configurational entropy of the system. Every composition is unique and has to be analysed considering the nature and the reactivity of every single oxide in the solid solution.

Preparation and physicochemical characterization of a Cobalt-based Deep Eutectic Solvent

A. Volpe[a], C. Pelosi[a], G. Ciancaleoni[a], L. Bernazzani[a]

[a] *Department of Chemistry and Industrial Chemistry, University of Pisa, Via G. Moruzzi 13, 56124 Pisa, Italy*
andrea.volpe@phd.unipi.it

Deep eutectic solvents (DESs) are a novel class of liquid mixtures characterized by significant depressions of the melting point compared to those of their neat constituents, usually compounds classifiable as Hydrogen Bond Donor (HBD) and Hydrogen Bond Acceptor (HBA) species[1]. These materials are promising "designer" solvents[2] exhibiting a host of tunable physicochemical properties as a function of the nature and ratio of their components[3]. Unfortunately, achieving this "tunability" remains elusive due to the many difficulties associated with the development of predictive models for DES physicochemical properties[4]. These difficulties arise from two factors: the inherent complexities in describing DESs through computational simulations[5], as well as the absence of a comprehensive dataset of their physicochemical properties necessary for empirically derived predictive models[6].

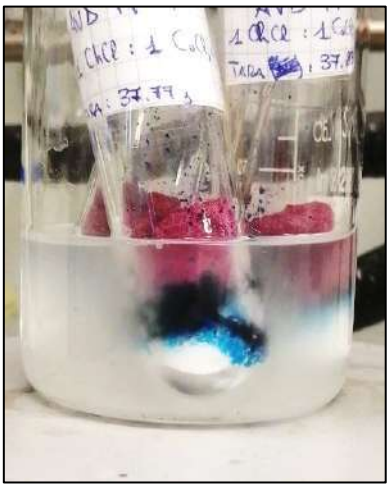

Figure 1: Preparation of DES by mixing Choline Chloride (white) and Cobalt Chloride Hexahydrate (pink) with a molar ratio of 1:1. The formation of a new, deep blue liquid phase can be observed at the interface of the two precursors.

Our research aims to bridge this informational gap by carrying out a systematic evaluation of DES physicochemical properties and how these change as a function of the identity of their constituents. In this work, we report the physicochemical characterization of a DES composed of Choline Chloride as HBA and Cobalt Chloride Hexahydrate as HBD. Cobalt-based DESs were prepared by simply mixing the precursors in different molar ratios and heating them at 70°C for 30 min (Figure 1). Physicochemical properties such as thermal stability, viscosity, electrical conductivity, density and electrochemical window were characterized in a wide range of temperatures and compositions.

Char from pyrolysis of plastics: from secondary product to raw material

M. Signoretto,[a] . N. Vecchini[b]

[a] *CATMAT Lab, Department of Molecular Sciences and Nanosystems, Ca' Foscari University of Venice and INSTM-RU, Via Torino 155, 30172 Venezia, Italy*
[b] *Research Centre, Claudio Buonerba Versalis S.p.A., via G. Taliercio 14, 46100 Mantova, Italy*

[a]*miky@unive.it*

One of the by-products of the pyrolysis of plastics is the Char. The Char is composed by one organic part (manly carbon) and another inorganic (typically Calcium salts, Titanium oxide and aluminum). Currently there are only a few areas of use for this by-product; this aspect, in the future, could become a problem by increase in the available quantity due to the diffusion of pyrolysis plants. It's necessary to find a flexible way to reuse Char like a raw material, even better if this is done within a decarbonization framework. The aim of present work has been to define an industrial process which took in consideration all those aspects. A method was therefore studied to allow char to be included in the chemical production chain in order to obtain new products and in the meantime give a contribute to CO_2 reduction.

Ad-hoc synthesized catalysts and commercial ones: their catalytic applications in the perspective of sustainability

Claudia Antonetti

Department of Chemistry and Industrial Chemistry, University of Pisa, Via G. Moruzzi 13, 56124 Pisa, Italy
claudia.antonetti@unipi.it

Since her education years until today, Prof. Claudia Antonetti's main research interests have focused on **applied catalysis and sustainable chemistry**, investigating with particular attention both the **synthesis, characterization, and application of *ad-hoc* prepared catalysts** and the **optimization of catalytic processes, even in the presence of commercial systems, for the valorization of biomasses**, including waste ones, and/or the platform chemicals derived from them, always working in the perspective of sustainability.
During the seminar, many examples regarding the **synthesis, characterization and applications of nanostructured catalysts** based on different metals, such as **Ru, Pd, Au, Cu, and Ag** will be presented, showing promising performances in several reactions of industrial interest, such as the selective hydrogenation of benzene to cyclohexene, of phenol to cyclohexanone, of *p*-chloronitrobenzene to *p*-chloroaniline and of cinnamic aldehyde to hydrocinnamaldehyde. Among the synthesized catalysts, the role of Prof. Claudia Antonetti as **Principal Investigator of the PRIN 2020 LEVANTE project "LEvulinic acid Valorization through Advanced Novel TEchnologies"** is particularly noteworthy: in this project, the University of Pisa team has studied the synthesis of biomass-derived catalysts, demonstrating a strong effort to promoting sustainability and circular economy.
Regarding **commercial catalysts,** Prof. Claudia Antonetti has investigated their use for the catalytic conversion and valorization of a wide range of biomasses, including waste ones, under sustainable reaction conditions. The studied approaches involved the use of **heterogeneous acid systems, salts, mineral acids and metallic catalysts**, obtaining significant catalytic performances. Several examples of commercial heterogeneous acid catalysts (**niobium phosphate and Amberlyst A70**) and commercial salts (**copper nitrate**) for the production of 5-hydroxymethylfurfural will be shown, together with its conversion to 2,5-bis(hydroxymethyl)furan and to 2,5-bis(hydroxymethyl)tetrahydrofuran in aqueous solution adopting commercial metallic systems (**5 wt% Ru/C, 5 wt% Pd/C, 5 wt% Pt/C**). In addition, successful examples of use of commercial mineral acids, such as **sulfuric acid**, will be discussed, adopted for the *one-pot* alcolysis reaction of many cellulosic residues to *n*-butyl levulinate, an excellent additive for diesel engines.
Finally, Prof. Claudia Antonetti has collaborated and continues to **collaborate with large, medium and small companies** in several projects funded by the companies themselves and/or by the Tuscany Region and/or by the European Community, as evidenced also by her **patent activity**.

Structural Characterization of Olefin-based Multiblock Copolymers by Chain Shuttling Technology

G. Urciuoli[a,b]

[a]*University of Naples Federico II, Via Cintia 21, Napoli*
[b]*DPI, P.O. Box 902, 5600 AX-Eindhoven, the Netherlands*
gaia.urciuoli@unina.it

Aim of this Ph.D. project was to understand the complex and elusive molecular structure of olefin-based multiblock copolymers (OBCs), obtained via chain shuttling technology (CST). The CST is a process in which reversible trans-alkylation reactions take place between two organometallic catalysts through the mediation of a chain shuttling agent (i.e., diethyl-zinc). Since the two organometallic catalysts differ in their comonomer incorporation ability, the repeated exchanges of the growing polymeryl chains between the catalytic metal centers lead to OBC constituted by alternating blocks of different comonomer content. Furthermore, as a result of the stochastic shuttling process that involves homo- and hetero-shuttling events, the resultant OBCs feature a statistical distribution of block lengths and of number of blocks/chain. In particular, ethylene-based multiblock copolymers represent the latest breakthrough in polyolefins and are characterized by alternating hard and soft blocks. The crystallizable hard blocks are constituted by HDPE with very low comonomer content (1-octene, 1-hexene, or another α-olefin), whereas the soft amorphous blocks are constituted by random ethylene/1-alkene copolymers with high comonomer content.

To address the complexity of these systems, research activities were first focused on the systematic characterization of paradigmatic Infuse™ commercial samples, which are the first example of OBCs synthetized in chain shuttling conditions. The commercial grades were selected as benchmarks, since they are available in large quantity, and used to test the different experimental and semi-empirical methods aimed at assessing the non-uniform polydisperse microstructure, the average molecular mass of the blocks, the average number of blocks/chain, and the distribution of methylene sequence length in the hard blocks. Analysis of the inter- and intrachain heterogenous microstructure and of the segmental mobility of the hard and soft blocks have been reported in Chapters 3 and 5.

In a second step, in order to grasp what is the effect of different operating parameters in the chain shuttling copolymerization on the microstructure, phase separation, and on the final properties, OBCs were synthetized ad hoc in a Parallel Pressure Reactor system (PPR), since the high-throughput synthetic approach allows to explore the entire set of variables. A thorough analysis, reported in Chapter 4, of microstructure and morphology was then carried out to understand the role of variables such as weight fraction of hard and soft blocks, different comonomers and differences in comonomer contents between the blocks, different values of segregation strength (χN values), and differences in the distribution of block size.

By closing the disambiguation loop, it has been possible to determine OBCs microstructure and architecture and correlate them univocally to material structure and morphology.

Exploiting Precision Polymers for the Fabrication of Polymeric Nanoparticles

R. Simonutti

Department of Materials Science, University of Milano Bicocca, Via R. Cozzi 55, Milan
roberto.simonutti@unimib.it

The Amphiphilic block copolymers (BCP) can spontaneously segregate (self-assembly) in distinct phases, due to opposed interactions with a selective solvent, generating polymeric nanoparticles (NPs) in solution. The final particle morphology can be predicted to some extent from structural parameters and by thermodynamic considerations, but kinetic effects rising from the macromolecular nature of the amphiphiles further enrich the picture. In fact, it is possible to obtain morphologies ranging from core-corona micelles to vesicles and wormlike micelles. Several methodologies for the synthesis of amphiphilic precision BCP can be exploited, particularly relevant are controlled radical polymerizations, as Reversible Addition-Fragmentation chain-Transfer (RAFT), Photo-induced Electron/energy Transfer (PET)-RAFT[1,2] polymerization, or living ring opening polymerization (ROP). Polymerization-Induced Self-Assembly (PISA) can be also employed together with RAFT and PET-RAFT. These methods allow the synthesis of block copolymers with effective control over ratio between the two blocks, the molecular weight and molecular weight distribution. RAFT is a robust and reliable technique that can be used with a large variety of vinyl monomers (acrylates, acrylamides, functional styrenes, dienes) meanwhile ROP, catalysed by organic bases with low nucleophilicity, is suitable for monomers like lactide, glycolide, ring strained lactones and cyclic carbonates. In both cases preformed polymers, like poly(ethylene oxide), can be used as first block on which polymerize the second one. By means of a careful choice of the common solvent and a controlled process of switching to the selective solvent (water in this case) it is possible to obtain a large variety of morphologies for simple diblock copolymers. More specifically the complex self-assembly behavior of two families of BCP, poly(styrene)-block-poly(dimethylacrylamide) (PS-b-PDMA)[3] and poly(ethyleneoxide)-b-poly(lactic acid) (PEO-b-PLA),[4] will be described by means of Dynamic Light Scattering, Atomic Force Microscopy, Transmission Electron Microscopy and Cryogenic Electron Microscopy. Finally the morphology of NPs directly obtained by PISA-PET-RAFT for the system poly(butylacrylate)-block poly(dimethylacrylamide) will be also described.[6]

Molecular imprinted poly-3,4 ethylenedioxythiophene for supercapacitor application

N. Sangiorgi, [a] A. Sanson, [a]

[a] *Institute of Science, Technology and Sustainability for Ceramics (ISSMC-CNR), Via Granarolo 64, 48018 Faenza (RA), Italy*
nicola.sangiorgi@issmc.cnr.it

Molecular Imprinting Polymers (MIPs) due to their high selectivity versus target molecule have been extensively applied into a lot of different research and application areas (high performance sensors, chromatographic application, solar cells).[1,2] Moreover, they can be easily synthetized by a low cost and environmentally friendly processes. In this work, MIPs are applied to engineering the surface electrode to enhance the specific capacitance of electrode for supercapacitor device. Poly 3,4-ethylenedioxythiophene (PEDOT) was prepared by electrochemical method and tested as electrode materials in supercapacitor. Two different template molecules (oxalic acid and ascorbic acid, PEDOT-MIPs) were used to demonstrate the positive effect of molecular imprinting on capacitance of PEDOT-based electrode. FE-SEM, cyclic voltammetry, electrochemical impedance spectroscopy and galvanostatic charge-discharge analyses were done to completely characterize these materials. The small molecular dimension of oxalic acid influences the film morphology, leading to MIP electrode with the highest performance. Finally, a symmetric supercapacitor based on these electrodes was produced and tested in different conditions (evaluating also its stability under cherge-dischrge cyles). The obtained results shows the possibility of applying the molecular imprinting approach to enhance the electrochemical properties of electrode materials for supercapacitor application.

benedetta.brugnoli@uniroma1.it

Branched polymers have emerged as promising carriers for drug delivery since they have a higher surface area and more available functional groups compared to linear counterparts.[1] These characteristics enable them to encapsulate or conjugate a larger amount of drug molecules. In addition, the branching architecture can be engineered to control the release kinetics of drugs by modifying the degree of branching or the composition and length of branches. Herein, the synthesis of branched poly-L-lactide (PLLA) is reported by using renewable polyols, glycerol (Gly) and diglycerol (DGly) as initiators. In order to evaluate the effect of branching chain length on polymer physico-chemical properties and drug availability, different L-lactide (L-LA)/OH molar ratios (8, 16 and 24) were investigated (Figure 1).

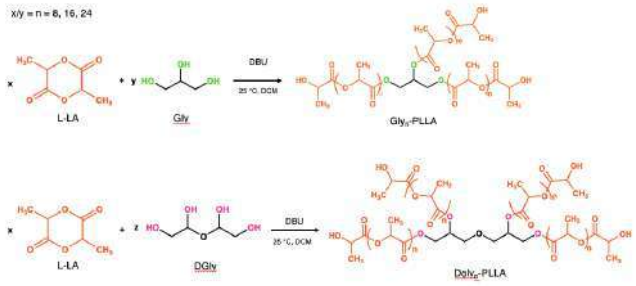

Figure 1: Synthesis of branched PLLA by using glycerol (Gly) and diglycerol (DGly) as initiators.

Polymers with molecular weight (MW) ranging from 4100 to 20000 g mol^{-1} were obtained. An increase in polymer MW and gyration radius was observed with increasing L-LA/OH molar ratio. All branched polymers were amorphous, except for the polymer with the longest branches (DGly24-PLLA), and able to self-assemble in water giving 200 nm-in size polymer nanoaggregates. Usnic acid (UA), a hydrophobic, antimicrobial and anticancer natural compound, was encapsulated in the polymer nanoaggregates. Following encapsulation, a significant increase in UA apparent solubility in water together with a reduced toxicity *in vitro* was observed, highlighting the potentialities of the synthesized systems as carriers for drug delivery.

angelo.nicosia@unict.it

Volatile organic compounds (VOCs) are ubiquitous pollutants in water and air matrices because of their emission sources, which could be both biogenic and anthropogenic. The development of smart polymer-based sensors might provide cheap, reliable, and rapid responses, especially compared to the expensive and time-consuming common analytical methods.

To provide more sustainable devices, the use of naturally derived chromophores as sensing units is a main goal in modern materials science. In this context, Curcuminoids have already been investigated as useful optical sensors for different applications: from pH evaluation to organic and inorganic species detection[1]. Furthermore, the possibility of forming stable complexes of Curcumin with selected metal ions (such as Zn(II) cations) increases the types of chemical species to be detected[2]. However, the application of these systems on an industrial scale must overcome their poor adhesion on the surface of common substrates.

In this communication, to obtain filmable systems suitable for the detection of pollutants in fluids, Curcumin-based polymer derivatives were developed through a covalent approach, aiming to link the curcumin molecule as a side chain group. The starting co-monomers were chosen to guarantee the filmability and adhesion of the final system on different substrates. The presence of suitable functional groups allows to covalently link the Curcumin moiety, which was successively metalated with Zn(II) ions. The so-obtained polymeric sensors (with and without complexed metal) were structurally and functionally characterized.

The functional characterization of the polymeric sensors was performed through sensing experiments using models of VOCs (such as ethanol, toluene, acetone, ethylenediamine, pyridine, and ammonia), exposing thin films of the sensors to the pollutants in the gas phase, and monitoring the related spectroscopic variations.

Experimental data show that the new copolymers, thanks to the synergy between curcumin and the polymer backbone features, allow for an easy and cheap approach to the detection of polar and non-polar VOCs.

This work has been funded by the European Union (NextGeneration EU), through the MUR-PNRR project SAMOTHRACE (ECS00000022).

icontento@unisa.it

Sustainable oxidation of alcohols to carbonyl compounds is a research topic of increasing interest in green chemistry for the synthesis of valuable fine chemicals, pharmaceuticals, agrochemicals, biomolecules, and materials from biomass. Gold nanoparticles (AuNPs) stands out among the heterogenous metal catalysts for their activity and selectivity under mild conditions in the aerobic oxidation route using eco-friendly oxidant such as dioxygen or peroxides. The AuNPs based catalysts are typically stabilized by deposition/inclusion in metal oxides, carbonaceous materials and organic polymer support;[1] more recently, porous organic polymers (POPs) have attracted significant interest because of their easy synthesis and functionalization, low cost, stability and possibility of processing under different morphology (powder, monoliths, films) providing spectacular examples of confined catalysis. Here, we report on the aerobic oxidation of AuNPs embedded in poly(2,6-dimethyl-1,4-phenylene oxide) (PPO) matrix where the nano porosity of the polymer support is able to efficiently sorb small organic molecules from air or water, even in trace levels.[2]

The AuNPs-PPO catalyst (2 %w of Au) was readily prepared by co-precipitation in methanol of the *in situ* prepared AuNPs and PPO, followed by annealing at 170°C; spherical nanoparticles of 7 nm were characterized by WAXD and TEM analysis. The porosity of the polymer support was thus modulated using mixture of organic solvents (toluene, chloroform, tetrachlomethane) and water to produce a variety of gold catalysts showing different morphology. The AuNPs-PPO catalysts were preliminary tested in the benchmark aerobic oxidation of 1-phenylethanol and benzyl alcohols showing high TOF and good thermal stability (30-100°C) in the presence of 1 equiv. of KOH as Brosted base activator. Interestingly this gold catalyst exhibits excellent selectivity in oxidation of benzyl alcohol to produce exclusively benzaldehyde when the catalytic run is carried out a 30°C in water /chloroform mixture (1:1 v/v). Direct oxidative cross esterification of cinnamyl alcohol with aliphatic alcohols was successfully obtained to produce alkyl cinnamates in the presence 1-butanol and 1-hexanol. On the basis of these results, we moved our scientific interests towards more challenging and interesting targets in sustainable catalysis. The synthetic protocol defined in the benchmark oxidation runs was thus extended to the aerobic oxidation of furanic compounds from biomass such as furfural, furfuryl alcohol, furfural and 5-hydroxymethylfurfural. The main results in this field will be discussed in the light of the chemical physical properties of the polymer support that imparts specific selectivity in the reactivity pattern.

Lately, many researchers are focusing on the development of new sustainable coatings to address the familiar challenges linked with the use of polymers derived from fossil sources, commonly employed in paper coatings[1]. Bio-based polymers obtained from biomass are an appealing alternative since they can be usually easily biodegraded[2], thus limiting the environmental impact. Among the available biomasses, one of the most widespread is from by-products of the tomato processing industry, that are very rich in natural biopolymers, such as polyesters. The main component of tomato waste, especially peels, is cutin, that is an amorphous polymeric network of polyhydroxylated C16 and C18 fatty acids monomers cross-linked by ester bonds[3]. The most important role of this biopolyester is to avoid water loss from plant internal tissue, due to its high hydrophobicity, that thus make cutin particularly suitable for applications as coating.

In recent years, a few technologies have been developed to obtain cutin monomers from tomato agro-wastes at an industrial scale, in particular through alkaline hydrolysis[4]. In our work, we exploited these hydrolysed cutin monomers to produce hydrophobic poly(ester-urethane)s, in order to merge the biodegradability of the polyester component and the versatility and adhesivity of the polyurethane component. The synthesis was carried out in two steps: firstly, a copolymerization between cutin monomers and 1,4-butanediol, that allowed us to obtain polyesters with different degrees of conversion (30, 38 and 50%); secondly, reaction of the three prepolymers with isophorone diisocyanate to prepare different poly(ester-urethane) resins. The products were deeply characterized by spectroscopic (FT-IR, ^{1}H and ^{13}C-NMR) and thermal (TGA, DSC) analysis and subsequently applied as coating on two different types of paper. The morphology of the coatings was observed by SEM investigation and the barrier properties to liquid water and grease were also evaluated, showing an excellent impermeability of the samples. Lastly, biodegradability and recyclability tests were carried out on the coated papers, yielding promising preliminary results.

Synthetic fibres are widespread in nowadays society due to their high performances and versatility as well as low price with a global projected to reach 81 Mt in 2025.[1] Nevertheless, only a minor amount get recycled (13%) whereas the majority get either landfilled either recovered, being one of the major global sources of microplastics and of pollution.[1] Elastane, a polyurethanes fibre, is often presents in clothes in a relatively low amount (below 5%). Nevertheless, elastane critically hampers the fibre's mechanically recyclability.[2] It is essential to selectively extract and cleave elastane from fibres to enable the recuperation of those synthetic materials (Figure 1).

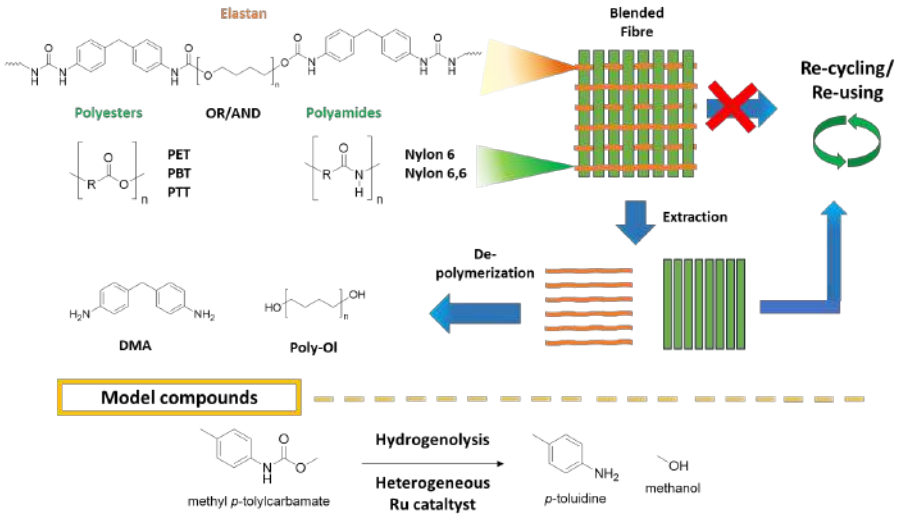

Figure 1: Possible strategy for the elastane-containing textiles (**up**) recycling of elastane blended fibres, (**down**) carbamate hydrogenolysis as model compound.

A possibility is to selectively separate the blended fibres by extraction, followed by selective catalytic de-polymerization of the polyurethane into the major precursor, namely diamine (a.o.4,4'-Methylenedianiline DMA) and a polyols. To date, few studies have been focusing on polyurethanes and elastane depolymerization, by solvolysis using inorganic bases or Ru-based homogeneous catalysts.[2-3] Therefore, the development of heterogeneous catalysts for this purpose is greatly needed.

Due to the intrinsic complexity of polyurethanes, such as elastane, the development of catalytic active, selective catalysts is extremely challenging. Alternatively, monomeric carbamate, such as the methyl p-tolyl carbamate represents a viable model compound to establish catalytic processes.

Herein, we are developing Ru-supported catalyst for the selective hydrogenolysis of carbamate toward amine and alcohol to be in a second stage applied to blended textiles.

Single-Atom Catalyst Shaping Via Photopolymerization 3D-Printing

Jiachengjun Luo[a] and Gianvito Vilé[a]

[a]*Department of Chemistry, Materials, and Chemical Engineering "Giulio Natta", Politecnico di Milano, Piazza Leonardo da Vinci 32, IT-20133 Milano, Italy. Email: gianvito.vile@ polimi.it*

This study introduces a novel solution to the design of structured catalysts through the integration of single-piece 3D printing with single-atom catalysis. Structured catalysts are widely employed in industrial processes, as they provide optimal mass and heat transfer, leading to more efficient use of catalytic materials. These materials are conventionally prepared using structured (ceramic or metallic) bodies, which are washcoated and impregnated with the catalytically active layer. However, this approach may lead to adhesion issues with the active layer. By employing photopolymerization printing, a stable and active single-atom catalyst is directly shaped and incorporated herein into a stand-alone single-piece structured material. The battery of characterization methods confirms the uniform distribution of catalytic species and the structural integrity of the material. Computational fluid dynamics are also applied to demonstrate enhanced momentum transfer and light distribution within the structured bodies. The materials are finally evaluated in the continuous-flow photocatalytic oxidation of benzyl alcohol to benzaldehyde, an important reaction to prepare biomass-derived building blocks. The innovative approach for catalyst manufacturing reported herein circumvents the complexities of traditional methods, offering scalability and efficiency improvements, and highlights the transformative role of 3D printing in catalysis engineering, with new avenues to tackle adhesion issues and revolutionize catalytic design across diverse domains.

Stability of Ba-based Dual Function Materials (DFMs) for cyclic CO_2 capture and hydrogenation probed by operando FT-IR

G. Nava, A. Porta, R. Matarrese, C. G. Visconti, L. Lietti

Dipartimento di Energia, Politecnico Di Milano, via Lambruschini 4, Milano, 20156, Italy
giuseppe.nava@polimi.it

Dual function materials (DFMs) allows the cyclic capture and hydrogenation of CO_2 over the same material, in principle increasing the efficiency of the carbon capture and utilization processes [1]. The most investigated application for DFMs is the capture of CO_2 from combustion flue gases coupled with the hydrogenation of the stored CO_2 to CH_4. To this aim, DFMs requires a basic metal (alkaline and/or alkaline-earth) to selectively capture CO_2 from flue gases, and a transition metal to convert it into CH_4 upon (green) H_2 exposure. The formulation and stability of these materials are still debated [2], and mechanistic insights on deactivation phenomena are needed to allow for the rational design of these materials. In this study, a $Rh/Ba/Al_2O_3$ DFM is cycled and characterized at different operating conditions by *operando* FT-IR, coupling surface and gas phase analysis. Temperature plays a critical role not only for the methanation rate but also for CO_2 adsorption, determining the geometrical arrangement of the adsorbed carbonates. The basicity of the adsorption sites can also influence CO_2 adsorption, as more basic sites are responsible for more stable carbonates [3], which need higher temperatures to desorb/react. When CO_2 and water are present in the adsorption atmosphere, the CO_2 storage capacity is decreased due to the competition for the same adsorption sites. Nevertheless, in these conditions Ba is still able to adsorb significant amounts of CO_2 in the form of bidentate and ionic carbonates. However, the ability of Ba to form strongly bound carbonates (**Fig 1A**) can also backfire, by leading to a progressive accumulation of sturdy carbonates on the DFM (**Fig 1B**), ultimately leading to a decrease in CH_4 production as the cycles proceed (**Fig 1C**).

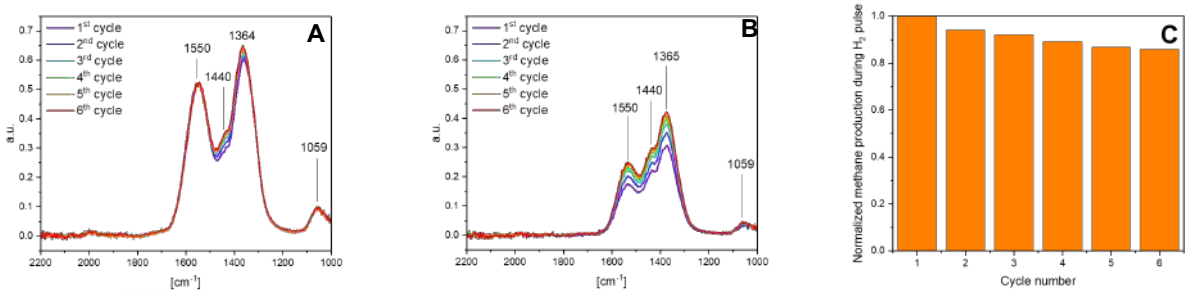

Figure 1: **A**: Carbonates at the end of the adsorption steps; **B**: Residual carbonates at the end of the hydrogenation step; **C:** Progressive loss in CH4 evolved from the DFM during the hydrogenation steps of 6 consecutive cycles. Experimental conditions: 350°C, 200 L(STP)/h/g, P = 0 barg; adsorption: 1% CO_2, 5 min; hydrogenation: 4% H_2, 5 min

Operando-Raman Analysis of Surface Carbon Formation and Its Implications on Methane Dry Reforming Kinetics on Rh-Based Catalysts

R. Colombo[1], G. Moroni[1], C. Negri[1], M. Maestri[1]*

[1]*Politecnico di Milano, Department of Energy, LCCP group, via La Masa 34, 20156 Milan, Italy*
riccardo.colombo@polimi.it

Methane Dry Reforming reaction (MDR) is a promising route for biogas valorization. Nevertheless, MDR industrial scalability is constrained by catalyst deactivation due to carbon deposition, a phenomenon with mechanisms and kinetic implications still under debate.[1,2] In our investigation, we have combined kinetic measurements in an annular reactor, time-resolved and spatially-resolved *operando* Raman spectroscopy to shed light on the carbon formation pathway and its kinetic consequences during MDR over Rh-based catalysts.

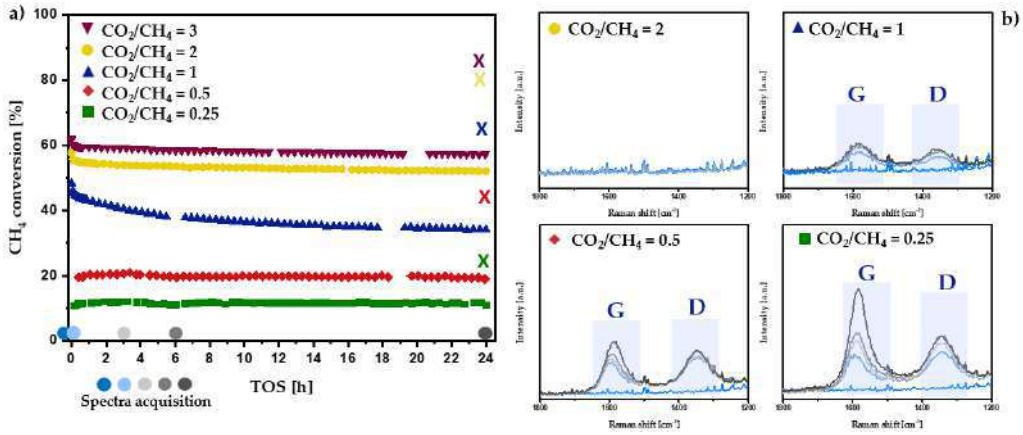

Figure 1: a) Experimental and equilibrium ("X" symbol) CH_4 conversion over 24 h MDR tests on 4% Rh/Al_2O_3 catalyst for inlet CH_4 = 8 vol.% at different CO_2/CH_4 ratios (between 3 and 0.25). T = 600°C, P = 1 atm, GHSV = $1.4*10^6$ $NL/kg_{cat}/h$; b) Time-resolved *operando* Raman spectra acquired before the reaction, at TOS = 5 min, 3 h, 6 h and 24 h.

Our findings (Figure 1.a) indicate that the concentration of CO_2 does not significantly alter MDR kinetics at the start of reaction. However, carbon deposition markedly impacts catalyst stability and activity. The coking process is strongly dependent on the CO_2/CH_4 ratio, and specifically, at a CO_2/CH_4 ratio ≤ 1, carbon formation is evident within 24 hours (Figure 1.b). The resulting carbon aggregates decrease the availability of Rh surface, leading to deactivation and providing an apparent kinetic dependence on CO_2. Additionally, spatially-resolved *operando* Raman spectra has unveiled a descending trend of carbon deposits along the reactor axial coordinate, while tests performed with the addition of a small fraction of O_2 (0.8 vol.%) proved to hamper carbon deposition. In summary, this work highlights the critical role of a multi-technique approach in deepening our understanding of catalytic processes, especially when intrinsic kinetics are obscured by deactivation.

One-pot syncrude production via CO_2 hydrogenation over promoted iron-based catalyst

B. Rolandi[a], M. Piacentini[a], A. Porta[a], C. G. Visconti[a], L. Lietti[a]

[a] *Dipartimento di Energia, Politecnico di Milano, via Lambruschini 4, Milano*
beda.rolandi@polimi.it

The conversion of CO_2 into long-chain hydrocarbons using low-carbon H_2 is particularly appealing for the production of aviation fuels, where a high energy density is required and closing the emission gap is particularly challenging. In most of the R&D papers on this topic, CO_2 is firstly reduced to CO via reverse water-gas shift, and then CO is converted into hydrocarbons via Fischer-Tropsch synthesis (FT). Developing a one-pot process where CO_2 is transformed into long-chain hydrocarbons in a single reactor via a modified Fischer-Tropsch (MFT) process can increase the overall efficiency, helping the final products to become competitive on their fossil-based equivalent[1]. To this aim, a coprecipitated iron catalyst promoted with Zn, Cu and K, which has shown good performances in the FT[2], was studied in the MFT using an experimental setup allowing the speciation and quantification of all products up to C_{30+} (waxes). The catalyst showed high conversion, comparable if not higher than what seen in FT conditions but with higher selectivity towards lighter products (C_{5+} selectivity in FT reached around 60%, while it is little more than 30% in MFT conditions, Fig 1A). Nevertheless, a high productivity towards C_{5+} species was seen (108 mg/h/g_{cat} at 300 °C, 30 barg and 78 mg/h/g_{cat} at 300 °C, 10 barg) and the product distribution hardly changed in the hundreds of hours during which the catalyst was studied, witnessing its stability (Fig 1A). Considering the syncrude fraction, almost 65% of its weight is in the kerosene fuel range i.e., C_8-C_{16} (Fig 1B). Furthermore, in the perspective of economic competitiveness, it is possible to boost the syncrude productivity by olefins oligomerisation, being the products very rich in light olefins, or even by hydrocracking of heavier cuts.

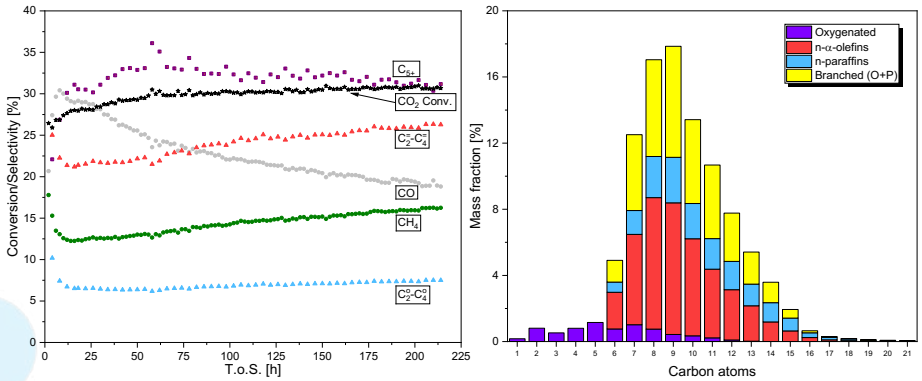

Figure 1. A) Conversion and selectivity at 300 °C, 10 barg versus time on stream (T.o.S.). B) syncrude composition at 300 °C, 10 barg, H_2/CO_2=3:1 mol/mol.

giulia.dapian@unive.it

Hydrogen is selected as one of the main green energy vectors for the future, but its production is still not zero emission. One way to convert this production in a green optic is to exploit CO_2 by Methane Dry Reforming (MDR), that is estimated to have a negative CO_2 balance (-0.44 kg per kg of syngas)[1]. Unfortunately, compared to the classic Steam Reforming, MDR is still not economically advantageous because of the lack of an active, selective, and stable catalytic system. The most studied are Ni supported ones, that suffer of Ni sintering but also coke deposition, because of inevitable side reactions. To minimize these problems, different approaches can be followed. In previous studies is demonstrated that inserting metal promoters in low amount can be effective in preventing coke deposition[2], but also operate on catalyst synthetic method and so on shape and morphology, can be advantageous. In this work, we prepared Ni/Al_2O_3 by incipient wetness impregnation and by co-precipitation, comparing them to a not so common structure for MDR and Ni/Al_2O_3 catalysts: the core shell one ($Ni@Al_2O_3$). This type of catalyst should prevent the coke deposition on the active phase (Ni), that is protected by the shell made of alumina[3]. We tested the catalytic systems at 650°C with a GHSV of 12000 h^{-1}. The $Ni@Al_2O_3$ exhibited an optimal stability, a major selectivity towards H_2 and a lower CO_2 activation energy. We performed some regeneration cycles, being able to repristinate the catalyst's activity. The fresh and exhausted catalysts were characterized by different techniques such as TPR, TPO, TPD, N_2 physisorption, XRD, SEM, EDX and TEM. The core shell catalyst resulted to be a proper structure to minimize the MDR process problems.

Photo-thermo-catalysis (PTC) has recently emerged as an innovative technology able to synergistically combine photocatalysis and thermocatalysis, resulting in a greater solar spectrum utilization and better performances[1]. This proves PTC to be a promising strategy for large scale production of solar fuels[2].

In this work, the PTC H_2 production via methanol steam-reforming ($CH_3OH + H_2O \rightarrow CO_2 + 3\ H_2$) has been investigated under both UV-vis irradiation and dark conditions in the 30-350 °C temperature range, over different oxide materials[3].

Temperature was found to strongly affect the photoactivity of pristine TiO_2, in terms of both hydrogen production rate (r_{H_2}) and selectivity towards the different CH_3OH oxidation products (H_2CO, CO and CO_2). The introduction of heat in the system boosts the r_{H_2} from 2 to 40 mmol h^{-1} g_{cat}^{-1} under UV-vis irradiation at 30 and 350 °C, respectively. Moreover, the surface decoration with Pt nanoparticles led to an impressive increase of r_{H_2} up to ca. 340 mmol h^{-1} g_{cat}^{-1} under irradiation at 350 °C.

However, under these conditions, CO is obtained as main CH_3OH oxidation product, limiting the production of H_2. An increased selectivity to CO_2 (from 5% to 55%) was obtained together with a greater r_{H_2} upon CeO_2 addition in catalyst formulation, promoting the Water Gas Shift reaction ($CO + H_2O \rightarrow CO_2 + H_2$).

Due to the large solar energy absorption capability, $LaFeO_3$ was investigated for the same purpose. This perovskite exhibits a different behaviour compared to TiO_2, where an increase of r_{H_2} from 0.25 to 1.75 mmol h^{-1} g_{cat}^{-1} was observed moving from 30 to 350 °C under irradiation. Its PTC properties were significantly improved by substitutional doping of Fe(III) with Cu(II), where the 20% substitution resulted in a maximum r_{H_2} of 28.5 mmol h^{-1} g_{cat}^{-1}.

The effect of heat and light on the H_2 production and selectivity was studied by *in-situ* DRIFT (Diffuse Reflectance Infrared Fourier Transform) analysis[4]. This allows to study the dynamic of all the reactants, intermediates, and products and thus to understand the reaction mechanism.

Carbon dioxide capture, conversion and storage (CCCS) technologies are becoming crucial in representing a route for the use of carbon dioxide as C1 building block[1]. On the other side, renewable energies face the issue of intermittency, so the surplus energy from renewable resources could be stored in the guise of green hydrogen, which however still lacks a capillary distribution network. It can be used for CO_2 methanation as an interesting solution, due to wide methane grid existing worldwide and the clear regulatory framework.

In our study the methanation of carbon dioxide was approached thanks to the use of two continuous experimental setups. Specific focus is put on the direct methanation of biogas streams to obtain upgraded biomethane. The initial catalysts screening was performed in an Incoloy 800 tubular reactor under atmospheric pressure. Subsequently, high-pressure tests and Gas Hourly Space Velocity (GHSV) screening in the range of 3000 h^{-1} to 400000 h^{-1} were conducted using a PID FR-50, equipped with a SS-316 tubular reactor and a continuous G/L separator. Numerous materials were used to support the Ni active phase, such as Al_2O_3, ZrO_2, TiO_2, ZSM-5, SiO_2, MgO and CeO_2. Catalysts were obtained through the use of various techniques, including wet-impregnation, sol-gel, co-precipitation, radio frequency (RF) thermal plasma and Ultrasound-Assisted synthesis technique. The effect of mixed supports, such as Al_2O_3/CeO_2 and ZrO_2/CeO_2 has been investigated as well. Testing has been done both on pure CO_2 streams, supposed coming from a CO_2 capture process, and on biogas streams, without prior separation.

Several catalysts showed interesting performance and, among them, 36% Ni/Al_2O_3 and 36% Ni/ZSM-5 achieved high CO_2 conversion, approaching the thermodynamic equilibrium. Overall, the use of Ni catalysts, despite the relatively high loading, has proven to be suitable for methanation, presenting an alternative to noble metal-based catalysts.

Ti/Zr/O Mixed Oxides for the Catalytic Transfer Hydrogenation of Furfural to GVL in a Liquid-Phase Continuous-Flow Reactor

Anna S.[a], *Alessandro A.*[a], *Francesca L.*[a], *Giuseppe F.*[a], *Nikolaos D.*[a], *Stefania A.*[a]

anna.saotta2@unibo.it

Thanks to its high reactivity furfural (FUR) can be used as platform chemical to produce a great amount of high-value chemistry compounds. Among these, γ-valerolactone (GVL), a promising five-carbon cyclic ester potentially valuable as 'green' additive for bio-based fuels or as substituent of monomers to produce polymers nowadays derived from oil.[1] The conversion of furfural (FUR) into γ-valerolactone (GVL) includes many reaction steps (*Figure 1*). Reduction steps, which are the most complicated from an environmental point of view, can exploit MPV (Meerwein-Pondorf-Verly) mechanism using isopropanol as H-donor rather than gaseous H_2. The latter choice, together with the use of an appropriate heterogeneous catalytic system characterized by either Lewis or Brønsted acidity, enables the realization of a more sustainable process. ZrO_2 is reported to be highly efficient in hydrogenating furfural (FUR) thanks to its strong Lewis acidity that favors the first and the last steps of the one-pot reaction (*Figure 1*). However, being characterized by weak Brønsted acidity, this oxide is not capable of catalysing the entire cascade reaction. Synthetizing Ti/Zr/O mixed oxides with different molar ratio allows to modulate the acidity characteristics of the overall material. This work aims to study the catalytic performance of Ti/Zr/O mixed oxides in the cascade reaction from furfural (FUR) to γ-valerolactone (GVL) in a continuous liquid-phase plant. The catalysts were synthetised by co-precipitation at controlled pH and characterised by BET, TPD-NH_3, XRD and XRF. Screening tests were made in a PFR alike reactor at defined conditions to assess which one was the most promising catalyst. The latter was then used to evaluate the influence of reaction conditions on the catalyst performance. Promising results have been obtained working with Ti/Zr/O (1:1 molar ratio), reaching selectivities of 45% of furfuryl isopropyl ether (FPE), 20% of GVL and total conversion of FUR. Furthermore, the reaction mechanism was studied, discovering that the conversion of FPE in isopropyl levulinate (IPL) is totally prevented in the conditions used.[2]

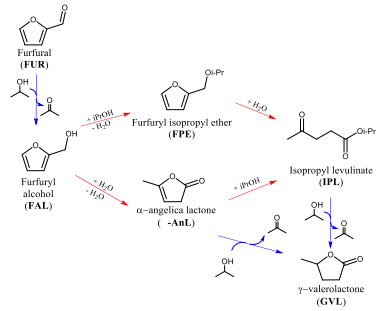

Figure 1: schematic cascade reaction from furfural (FUR) to γ-valerolactone (GVL); blue and red arrows point out Lewis and Brønsted catalysed steps respectively.

Methane decomposition chemical looping (CLD) emerges as a promising and innovative method for hydrogen production, characterized by its ability to efficiently convert different feedstocks into high-purity hydrogen while significantly reducing greenhouse gas emissions. Furthermore, hydrogen obtained through CLD presents an eco-friendly alternative, devoid of direct emissions of air pollutants or greenhouse gases. Additionally, it facilitates the utilization of a wide spectrum of low-carbon energy sources, enhancing its sustainability and adaptability[1]. In this context, supported nickel-based catalysts exhibit promising potential owing to their catalytic activity and stability in reforming processes[2]. The preparation methods of these catalysts are crucial in order to design their structure, thus influencing their performance in CLD applications. The present study focuses on the performance of Ni and Ru-Ni catalysts supported on $LaMnO_3$, synthesized through precipitation assisted by microwave irradiation and sol-gel citrate methods. The redox stability was checked by performing multiple redox cycles during chemical looping experiments carried out isothermally alternating the gas composition every 10 minutes from 15 vol% of CH_4 in N_2 (reduction) to 15 vol% of CO_2 in N_2 (oxidation). The CLD temperature was selected for each sample based on temperature programmed reduction tests with methane, choosing for each sample the temperature of maximum reduction. Through a comprehensive examination encompassing structural, morphological, and catalytic analyses, it was possible to study the impact of synthesis techniques on the performance of these catalysts in hydrogen production via chemical looping decomposition. This research efforts to furnish valuable insights pivotal for the development of efficient and sustainable processes crucial for meeting the escalating demand for clean energy solutions in the contemporary era.

Separation of hydrogen from natural gas in distribution pipelines using electrochemical hydrogen compressor (EHC)

Elisa Zanella, Alberto Vertova, Mariangela Longhi, Carlo Pirola

Università degli Studi di Milano, Dipartimento di Chimica – via Golgi, 19, 20133 Milano (MI), Italy
e-mail of submitter: elisa.zanella@unimi.it

Nowadays energy plays a fundamental role in our society and hydrogen seems to have a key role in a scenario dominated by depletion of fossil fuels, global warming, and rising energy demand[1]. However, its use is limited by storage and transport problems[2]. A possible solution is blending hydrogen into natural gas pipeline network. The separation, purification, and potential storage of this energy vector are therefore important challenges. In this study, low-temperature Electrochemical Hydrogen Compressor (EHC) with Nafion membrane was investigated and tested in hydrogen separation from different methane-hydrogen mixtures. This technology is based on the oxidation of impure hydrogen at the anode and the evolution of pure, high-pressure hydrogen at the cathode[3,4]. The core of this device is the proton exchange membrane (PEM). This component is crucial for EHC system performance, a membrane with high ionic conductivity is required to reduce ohmic losses. In addition, the membrane must have high mechanical, thermal and chemical stability to withstand working conditions. Therefore, it was decided to test three different Nafion membranes, namely N-115, N-117 and N-212. On the best once, the effect of temperature and hydrogen inner flow was evaluated. The purification of hydrogen from a gas mixture was tested and methane/hydrogen molar ratio ranging from 10/90 to 90/10 was investigated (Figure 1b). The efficiency of the system and the purity of the obtained hydrogen obtained were also evaluated, confirming the effective actual purification efficiency of the system. Further studies will focus on the study of the compression step to also evaluate this aspect of EHC technology. Tests carried out to date have highlighted how, in this respect, the criticality factor is linked to the back diffusion of hydrogen from the cathode to the anode.

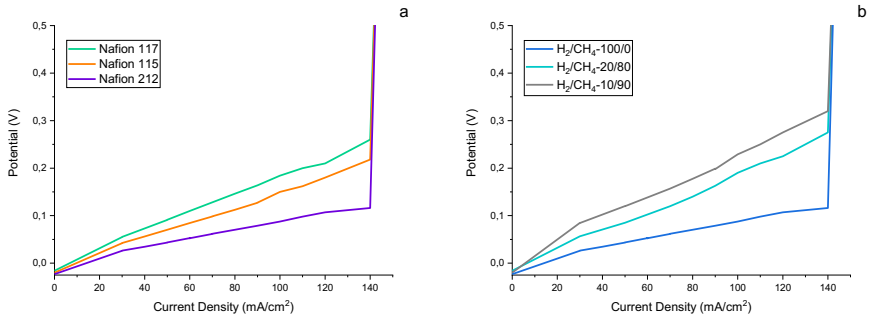

Figure 1. (a) Polarization curves and resistance value obtained for the tested MEAs and (b) polarization curves at different methane/hydrogen molar ratio. Process conditions: ambient pressure for both cathode and anode, 30°C, hydrogen inner flow 20 mL/min, humidity of the gas constant over 90%.

Nowadays, the social and environmental impact associated with the exploitation of fossil resources has resulted in the search for more environmentally friendly alternatives. Lignocellulosic materials, one of the most important natural sources for the production of high added-value materials or biopolymers, are very attractive due to their biodegradability, sustainability and ease of recycling. The increasing of these properties represents an important goal also for eco-design. With this perspective, this work focused on the valorisation of lignocellulosic biomass through different strategies for the development of new materials for various applications within the manufacturing industry. On the one hand, natural fibres or waste fibres can be used through different appropriate protocols of pre-treatments for the production of biomaterials by exploiting the cellulose fraction of the starting biomass. On the other hand, it is possible to design new polymer formulations through the synthesis of new biomonomers and biopolymers obtained from biomass[1]. In particular, biomonomers obtained from saccharides by introducing polar and reactive groups can influence both the properties of the final products and the sustainability and ease of recycling. Starting from these biomonomers, various acrylic and vinyl copolymers can be synthesized. Based on the experimental results, these copolymers show particular interest for the preparation of new adhesives and other polymer formulations with significant application properties for eco-design strategies.

Obtaining chemicals and fuels from biomass is a key step for a sustainable development. From this prospective, cellulose is a potential source for a vast array of bioderived platform molecules, such as ethanol, levulinic acid (LA) and its esters (LE). A promising route consists of the reduction and cyclization of LE to produce γ-valerolactone (GVL), an important platform molecule that find several applications in the chemical industry as green solvent, additive for fuels and intermediate for organic synthesis (figure 1). Usually, this reduction is carried out in the liquid-phase and batch conditions involving the utilization of hydrogen at high-pressure (5-100 bar), in the presence of expensive noble-metal-based catalysts[1]. In this regard, a more suitable approach consisting in the catalytic transfer hydrogenation (CTH) mediated by secondary alcohols as H-donor has recently shown interesting results using zirconia based catalyst[1,2]. More recently, our group has proved the possibility to achieve high LE conversion and a GVL yield close to 70%, using a bio-based primary alcohol, namely ethanol, under continuous flow, gas-phase conditions at relative mild conditions (250°C, 1 bar)[2]. On the other hand, the catalyst is subjected to deactivation due to the deposition of heavy carbonaceous species on its surface. For this reason, the acid/base properties of the catalytic system were optimized by including other metals (and metalloids) in the zirconia structure. Surprisingly, decreasing the basic sites density and introducing the Bronsted acidity, the catalyst lifetime was strongly extended. Moreover, the Bronsted acid sites can catalyze consecutive reactions to produce ethyl pentenoates (EP), which are high value-added compounds, that find several applications in chemical industry due to their dual functionality.

MUR is acknowledged for the financial support provided through the LEVANTE project "LEvulinic acid Valorization through Advanced Novel TEchnologies", PRIN-Bando 2020, Prot. 2020CZCJN7.

luca.mastroianni@abo.fi

3D printing, or Additive Manufacturing (AM), is one of the key technologies of the fourth industrial revolution (Industry 4.0) as it will transform the whole concept of manufacturing. Applied to catalyst shaping, 3D printing paves the way for completely new architectures which have the potential to enhance mass and heat transfer rates in shaped catalysts. Digital Light Processing (DLP) is a highly promising printing technology among the different 3D printing alternatives owing to excellent printing resolution (Fig. 1a) and a high printing speed[1]. When applying DLP printing for ceramic materials, important catalyst requirements (such as the specific surface area) are often sacrificed to obtain mechanically stable parts. Herein, a novel methodology to DLP 3D print γ-Al_2O_3 supports with a good mechanical stability and a high surface area is described. Introduction of active gold nanoparticles on the alumina supports was explored with different deposition methods and the catalytic activity was demonstrated in the oxidative dehydrogenation of ethanol. It was demonstrated that it is possible to tune the location of the active metal within the catalyst structure by changing deposition method, with remarkable differences in the observed catalytic activity (Fig. 1b)[2]. The obtained results demonstrate a high potential of the technology to remove all the constrains in catalyst shaping, paving the way to new features and avant-garde structures in catalyst design.

Diphenolic acid and its esters (DPEs) are regarded as highly promising bio-based monomers for the production of epoxy resins, polycarbonates and polyurethanes[1]. In fact, they can be synthesized from biomass-derived chemicals such as levulinates and phenol in solvent-free conditions and in the presence of Brønsted acid catalysts[2]. In particular, levulinic acid and its alkyl esters are highly available and considered among the top-10 most valuable bio-based chemicals by the U.S. Department of Energy.

Choosing ethyl levulinate (EL) as the substrate, different heterogeneous catalysts have been screened and compared with sulfuric acid as a homogeneous reference catalyst. Amberlyst-15 ion-exchange resin showed the best performance, even after recycling. The general reaction scheme consists of the main reaction i.e., the condensation of EL with phenol producing the ethyl ester of diphenolic acid (DPE), and of a secondary reaction, i.e. trans-esterification of EL with phenol. The kinetic investigation was conducted in a batch reactor producing an extensive experimental matrix. Namely, the reaction temperature, the molar ratio phenol-to-EL, the catalyst load and the mixing rate were varied. The effect of the water concentration, i.e. the co-product of DPE on the reaction rate was investigated as well. The composition of the mixture during the experiment was analyzed both qualitatively and quantitatively with ^{1}H- and ^{13}C-NMR. Finally, a mathematical model was developed considering diffusion limitations inside the catalyst particles. The experimental data were implemented in the kinetic model and the estimation of rate and adsorption parameters was conducted with non-linear regression analysis with gPROMS software.

Process Intensification in Green Extraction of Agri-Food By-Product: Bioactive Potential Applications and Sustainability Assessments

G. Capaldi [a], G. Grillo,[a], C. Aimone,[a] G. Cravotto[a]

[a]Department of Drug Science and Technology, University of Turin, Via P. Giuria 9, 10235 Turin
Giorgio.capaldi@unito.it

According to the Food and Agriculture Organization (FAO), approximately one-third of global food production is lost or wasted in various stages of the food supply chain, with fruits and vegetables often experiencing losses of up to 50% [1]. To tackle this, adopting the Circular Economy approach and striving for a "zero waste" strategy is crucial. Food waste can be transformed into valuable resources, such as antioxidants, phenolic compounds, and dietary fibers, which find applications in functional foods, nutraceuticals, and cosmetics. The underlying principles of green extraction revolve around not only reducing waste but also enhancing efficiency while simultaneously mitigating potential risks to human health and the environment [2]. This approach, referred to as "process intensification" can be attained through the adoption of enabling technologies that seek to optimize heat and mass transfer, thereby promoting elevated yield and conversion rates. In this study, microwave-assisted extraction (MAE) in water is applied to recover metabolites from blueberry pomace (BP), by-product of blueberry juice process, while refining temperature, extraction times, additives and bioactive fractionation strategies. The total phenolic, anthocyanin, and tannin contents of the extracts were determined, as well as their antioxidant activity using both chemical and electrochemical methods, alongside assessment of thermal stability. Furthermore, the potential applications of BP extract as functional ingredient are investigated through *in vitro* enzyme inhibition assays (α-amylase, β-glucosidase, acetylcholinesterase, tyrosinase, and elastase), as well as evaluation of anti-inflammatory and cytotoxic properties on living cells. Finally, the overall sustainability of the process was done screening different Green Metrics as Reaction Mass Efficiency, E-factor and Process Mass Intensity and more elaborated one as ComplexGAPI and AGREEPrep. Among these metrics, GREEN MOTION emerged as the most suitable indicator of sustainability for the examined process.[3] The collected data support the application of an eco-friendly valorization protocol, and associated evaluation methodologies, for transforming an agri-food residue into bioactive products. Furthermore, both its efficacy and sustainability have been demonstrated, paving the way for its potential application to similar plant-based food by-products.

micheleemanuele.fortunato@unina.it

The esterification of oleic acid (OA) with trimethylolpropane (TMP) is the preferred synthetic route to obtain trimethylolpropane trioleate, a commercially significant bio-based lubricant characterized by low-toxicity and biodegradability[1]. Understanding the kinetics of this esterification reaction is crucial for optimizing the synthesis of green lubricants, particularly when utilizing waste materials like used cooking oils (UCO), thereby promoting sustainability within a circular economy framework. Oleic acid, representing UCO due to its prevalence in vegetable oils[2], serves as a suitable substrate for this purpose. Besides, branched polyols, such as TMP (a triol), is widely used to produce polyol esters with enhanced tribological properties as well as thermal and oxidation stability[3]. Despite its importance, the kinetics of this reaction is underexplored, especially when promoted by heterogeneous catalysts.

This research work explores the kinetics of oleic acid esterification with trimethylolpropane in a batch reactor. It compares both the uncatalyzed reaction and that promoted by a heterogeneous catalyst (i.e. tungsten trioxide supported on silica, etc.) particularly focusing on temperature, catalyst bulk density, and reactants' molar ratios effect. The conversion of oleic acid was evaluated through its acidity number using acid-base titration. Additionally, the concentration profiles of the products, including mono-, di-, and tri-esters, were obtained using ^{1}H-NMR technique. An essential aspect of this investigation is understanding the uncatalyzed reaction kinetics due to the significant autocatalytic effect resulting from OA's acidic nature, particularly at temperatures higher than 100°C. Under these conditions, heterogeneous catalyst amounts exceeding 1 wt% relative to the total reactant mass are necessary to observe a notable catalytic effect. Furthermore, optimal triesters concentrations occurred under stoichiometric conditions between TMP functional groups and OA. Finally, a kinetic model was developed to simulate the system's behavior and the experimental data underwent nonlinear regression analysis to derive kinetics and thermodynamic parameters.

chiara.bruschetta@unito.it

Hydrogenations are among the best studied reactions as they are fundamental in petrochemical and coal chemistry, environmental industries, and fine chemicals production.[1] It is estimated that about 25 % of all chemical transformations involve at least one hydrogenation step. Starting from the first hydrogenation reaction of lignin-based chemicals carried out by Harris and Saeman,[2] most of the research aim to transforming monomers derived from lignin depolymerization through hydrogenation reactions. Currently, hydrogenations of lignin-based chemicals can be carried out using hydrogen gas or through the transfer hydrogenation (TH) route, using a H-source solvent (such as formic acid, isopropyl alcohol, or alkanes).[3] Biomass is constituted by lignocellulosic (LB) or non-lignocellulosic (non-LB) materials.[4] Considering lignocellulosic biomass, specifically the three main chemical components (cellulose, hemicellulose and lignin), only lignin has been rewarded less attention as for the bioconversion to biofuels, due to complex structure of the polymer,[5] despite it is characterized by a great amount of functional groups that are important active sites for further chemical modifications.

Among the various transition-metal-based catalysts, ruthenium and rhodium are mainly employed for hydrogenations of aromatics.[6,7] This work aims to investigate the MW-assisted anisole hydrogenation in the presence of Ru or Rh catalysts with molecular H_2 and using an opportunely selected solvent. The conditions were optimised by reducing both the reaction time and temperature and using environmentally friendly and recyclable solvents to increase the sustainability of the process.

Precursor Strategies for the Preparation of High-Molecular Weight Conjugated Polymers with Tailorable Redox Properties

M. Carlotti,[a,b]

[a]*Dipartimento di Chimica e Chimica Industriale, University of Pisa, Via G. Moruzzi 13, 56124, Pisa, Italy*
[b]*Center for Materials Interfaces, Istituto Italiano di Tecnologia, Viale R. Piaggio 34, 56025, Pontedera, Italy*
marco.carlotti@unipi.it

Conjugated polymers, characterized by small bandgaps and accessible states, are exceptionally versatile materials that have found application in disparate fields such as organic electronics, photocatalysis, sensing, healthcare, and energy storage technologies. By combining a plethora of different units and broad variety of preparation methodologies, synthetic chemistry is the most powerful tool a chemist has to control the electronic properties and the arrangements of the polymeric chains, thus allowing the preparation of materials withtailored properties and enhanced performances.

However, the intrinsic electronic properties of the units and the aggregation-prone nature of these materials, often hinder the synthetic process, producing materials with a low degree of polymerization which can present processability issues and different properties compared to their high-MW analogues.

When the use of solubilizing side chains to circumvent these problems is not possible or ineffective – as in those cases where a high specific density of responsive units is beneficial or when immobilization of the activematerial is needed, the use of polymeric precursors and reliable transformation strategies (that can form quantitatively the target materials) can offer an efficient way to access high molecular weights conjugated polymers with a high density of functional units.[1]

In this contribution, I will describe two novel approaches based on the use of different polymeric precursor for the preparation of fully-conjugated materials with a high density of active centres. In particular, these recursors comprise either reversibly-masked quinoid groups, that allow the insertion of expendable solubilizing chains, or aromatic units connected via succinyl linkers, that can undergo pyrrolization in the presence of a primary amine, thus allowing for the insertion of active side groups. Finally, I will show the application of fully-conjugated materials obtained through this strategy as organic cathodes for metal-ion batteries, OFETs with different polarities and miulticolored electrochromic surfaces.

Part of this study was carried out within the POLiBATT project – funded by European Union – Next Generation EU within the PRIN 2022 PNRR program (D.D.1409 del 14/09/2022 Ministero dell'Università e della Ricerca) and the European Union's Horizon 2020 Research and Innovation Program under the Marie Skłodowska-Curie Grant Agreement MP3 – No. 885881.

Nowadays, preserving freshwater is crucial, especially in developing countries, where the risk of disease transmission is elevated.[1] Ibuprofen (IBU) and diclofenac (DCF) are nonsteroidal anti-inflammatory drugs (NSAIDs), whose concentration in surface waters is increasing due to the rapid growth/aging of world population.[1] So, the possible purification/reuse of wastewater represents a challenging task. Among the strategies to abate NSAIDs, photocatalysis exploits solar energy - a free and clean resource. Its potential is to significantly aid the development of regions frequently impoverished and densely populated, demonstrating a practical application of renewable energy in enhancing global water quality. However, the most part of photocatalytic systems hides a practical limitation, *i.e.*, the difficult recovery as powders from the reaction mixture, causing contamination issues and additional costs. In this context, sustainable floating photocatalysts are viable alternatives to be used: their floatability on the air-water interface maximizes both light absorption and surface aeration, enhancing pollutant removal efficiency and reducing post-treatment costs.[1] However, finding a simple, cheap, and universally accessible method for applying photocatalysis in water purification, especially in communities with limited access to clean water, remains an ongoing challenge.

Herein, we propose the development of an innovative sunlight-driven device composed by bismuth oxybromide (BiOBr) grown on a naturally derived material (Lightweight Expanded Clay Aggregate, LECA), to clean surface waters under natural solar irradiation. Photodegradation of IBU and DCF was investigated in laboratory- and real-scale experiments. The BiOBr/LECA photocatalyst fully degrades DCF, whereas restricted abatement of IBU is observed (Figure).[1] The identification of specific transformation products (TPs) during the degradation reveals that this behaviour is related to the different structures of drugs. Reusability tests demonstrate the high stability of the floating composite. These encouraging results pave the path toward a promising novel and sustainable paradigm for water remediation. In this way, the existing limitations can be overcome, advancing the field of water purification.

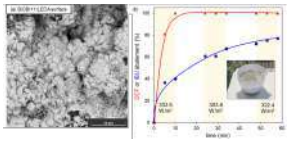

Figure: (a) FESEM images; (b) Real-scale photodegradation of 3:1 w/w drugs mixture (10 mg·L^{-1}, simulated drinking water, 60 g BiOBr11/LECA) under natural solar light (daily medium irradiation from Milan meteorological station).[2]

Photostability is crucial for fluorophores used in Luminescent Solar Concentrators (LSCs), enduring extended sunlight exposure over years.[1] UV radiation can alter the structure of organic emitters, reducing LSC efficiency and causing panel replacement, with economic costs and environmental implications. In this study, we tested two push-pull dyes comprising distorted heptagonal inclusions – namely, Peri2F and Nap2Car[2]– as emitters for bulk LSCs, with concentration ranging from 100 ppm to 250 ppm. The use of chemically regenerated monomer, rather than synthetic monomer, for PMMA slab production has a Global Warming Potential about four times smaller, thereby enhancing the sustainability and circularity of large-scale LSC fabrication. The most effective Peri2F/recycled PMMA system yielded an η_{dev} of 0.7%, lower than that of devices comprising the state-of-the-art emitter LR305.[3] Remarkably, Peri2F showed a far superior resistance to photodegradation. Forecast analysis estimated that the LSC containing 100 ppm of Peri2F can match LR305 performance in PMMA after about 1 year of use, with only 2% decrease in initial emission intensity.

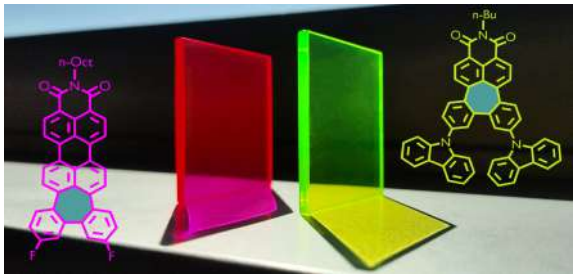

Figure 1: Peri2F (left) and Nap2Car (right) molecular structures and LSC appearances.

Nowadays, the diffusion of new emerging contaminants (ECs) (e.g. surfactants, pesticides, pharmaceutical compound, personal care product, etc.), present in the range concentration of ppt (ng/L) or ppb (µg/L), represent an environmental critical issue. Therefore, it is necessary find new technologies for drugs removal that escape by conventional wastewater treatment processes. Adsorption is the best technique to remove pollutants from water, due to its easy scalability, low cost, versatility, no undesired by-products generation and possibility to reuse the adsorbent into a new cycle of water treatment. Iopamidol (IPM) is a non-ionic X-ray contrast media, injected into the human body at high concentration (1.5 mol/L)[1], and relies into the aquatic environment in no-metabolized form[2]. The new challenge is to design a wastewater treatment plant capable to remove ECs efficiently, allowing the reuse of the aquatic matrix obtained. The best adsorbent for Iopamidol removal is activated carbon, so an adsorption study from batch to continuous flow was performed in this work. Ibuprofen (IBP) is a non-steroidal anti-inflammatory drug used in the treatment muscle pain and inflammation, which concentration in the wastewater is around 18–6297 ng/L[3]. Cellulose is a main component of natural plants, is the most abundant and renewable biomass resource on earth and is if pyrolyzed is a good adsorbent to remove IBP from water. For the intensification of the IPM and IBP adsorption process different kinetics were obtained using different devices, batch comparing a common stirrer with rotating bed reactor (RBR, Spinchem®), ultrasound probe merged into the aqueous solution and, finally, application of the continuous flow with and without ultrasound.

Purge ratio vs Spike & Purge, who wins?

A real case during an API production

R. Rossi,[a] L. Epiglotti,[a] K. Montrasio[a]

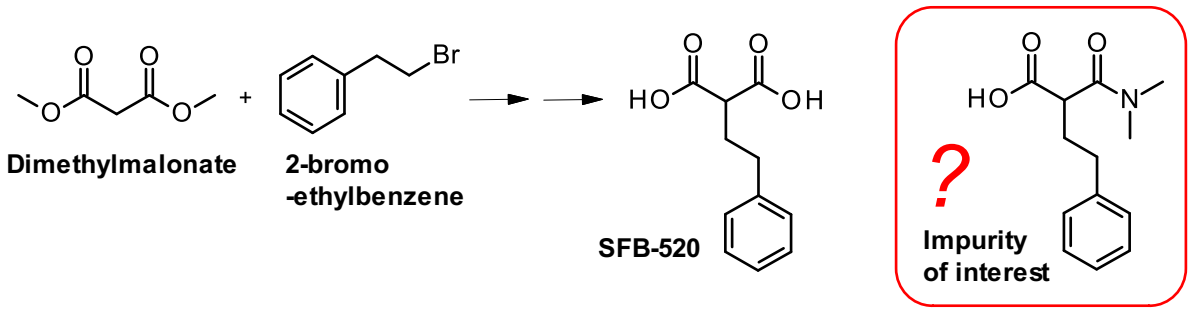
[a]*Dipharma Francis S.r.l., via Bissone 5, 20021 Baranzate (MI)-Italy*
roberto.rossi@dipharma.com

In order to satisfy the requirements of Regulatory Agencies regarding the production and release of an Active Pharmaceutical Ingredient (API), many factors need to be taken into account.

Many resources, both in terms of time and money, may need to be invested to ensure that the specifications set for both the starting materials and intermediates are enough to guarantee the production of an API with an analytical profile complying with ICH regulations.

While a purely theoretical approach can minimize both costs and timelines, can it take the place of experimental studies while yielding comparable assurances of success?

We present here the case of an impurity considered critical and detected in the initial steps (Scheme 1) of the synthetic process of Sodium Phenylbutyrate. In the work carried out the theoretical "Purge Ratio" approach of determining the fate of each impurity was compared with the experimental approach of "Spike & Purge" of the impurity previously identified and synthesized.



Scheme 1

A comparison between the solar photoreforming of natural and synthetic polymeric derivates for the H_2 production

Maria Teresa Armeli Iapichino,[a] Roberto Fiorenza ,[a] Salvatore Scirè,[a]

[a] *Department Chemical Science, Andrea Doria 6, Catania*
maria.armeliiapichino@phd.unict.it

The Hydrogen is considered one of the most promising energy vector candidates for the future. The photocatalytic hydrogen production is present in top ten emerging technologies in chemistry. In particular, the photoreforming (PR) of organic substrates is an attractive way to obtain green H_2 together with the valorization of waste or biomass. This process combines the water reduction with the oxidation of a sacrificial agent using a semiconductor. In this context, in this work, it is presented a comparison, in terms of H_2 production, of two polymeric derivates used for the PR as a natural polymer i.e. the glucose (production of $80*10^9$ t/y) and a synthetic polymer as polyethylene, that can play an important role also in the context of pollution (production of $100*10^9$ t/y) [1]. The focus of this work is also the study of the performance of carbon-based catalysts as g-C_3N_4 and SiC introducing metals or other oxides as co-catalysts to further improve the H_2 formation [2]. The carbon nitride possesses the advantages of low cost, non-toxic, thermodynamic stability, and remarkable optical properties. Whereas the SiC is a widely used semiconductor in the electronic industry and can be used as photocatalyst in the plastics photoreforming due to its high mechanical and chemical resistance. A good production of H_2 was verified from both sacrificial agents (fig.1), however there is an increase of H_2 production in the presence of a metal oxide co-catalyst in the case of glucose PR, and a decrease in the case of polyethylene PR in the presence of the metal co-catalyst.

Thermoelectric (TE) materials enable the direct conversion of heat into electricity through the Seebeck effect. Given that approximately 70% of consumed energy is dissipated as low-temperature heat (<200 °C), the development of TE materials is crucial for reducing our carbon footprint.[1] Most TE materials are inorganic (such as Bi_2Te_3); however, they come with significant drawbacks including high thermal conductivity, high fabrication temperatures, high cost, scarcity, brittleness, and toxicity. Recently, coordination polymers such as poly[Kx(Ni-ett)] have emerged as encouraging TE materials for low-temperature energy harvesting.[2] Different materials can be produced by substituting the metal center or the organic ligand. As a result, nickel has been replaced with the greener and less toxic copper to develop innovative thermoelectric materials. Different polymers have been synthesized, processed as dispersion, and deposited as thin-film. Finally, chemical and electrical characterizations have been performed, showing promising properties for applications in low-temperature heat harvesting.

f.russo@itm.cnr.it

In the framework of sustainability, Membrane Technology can be considered as a green alternative and economically competitive with conventional separation technologies as also confirmed by the European Commission which included it among the Best Available Technologies [1]. Membrane manufacturing is yet to embrace the use of harmful and toxic solvents, such as N-methyl-2-pyrrolidone (NMP), N, N-dimethylacetamide (DMA), and N, N-dimethylformamide (DMF) despite being a sustainable technology with a low environmental footprint [2]. In this work, γ-valerolactone (GVL) was selected as a renewable green solvent for the preparation of poly (vinylidene fluoride) (PVDF) membranes by phase inversion technique that allowed to obtain membranes with controlled morphology, pore-size and physical-chemistry properties for Membrane Distillation (MD) process. A comparison with the performance of PVDF commercial membranes is also included. The results confirmed an asymmetric structure of the membrane and the possibility of obtaining a sponge-like morphology. Generally, the effect of humidity on membrane morphology delays the phase inversion process promoting the formation of porous surfaces and sponge-like structures. The porosity of the membranes was in the range between 84% and 86% with a pore size in the range of 0.2 to 0.8 microns dependent on the composition of the dope solution and the casting conditions. The experimental tests of MD were conducted in Direct Contact Membrane Distillation (DCMD) configuration using deionised water as feed at the following operative conditions: membrane area of 40 cm^2, feed/distillate inlet pressure of 1 atm, feed flow rate (Q_{feed}) of 66 L/h, feed temperature (T_{feed}) around 60°C, distillate flow rate (Q_{dist}) of 42 L/h and distillate temperature (T_{dist}) of 20 °C. The membranes that were tested were very stable in time, with similar flux results to those of commercial membranes.

Pyrolysis of lignocellulosic biomass represents a promising solution to generate liquid biofuels that can help the decarbonization of critical sectors[1]. However, the complex nature of the process has hindered the obtainment of rigorous experimental data. In this study pyrolysis tests are run in a thermogravimetric analyzer (TGA) based setup[2], subjecting biomass samples to a controlled heating ramp (3-100 °C/min) under Helium flow, with the aim of collecting kinetically relevant information. Different analytical techniques and sampling protocols, including commercial sorbing tubes (ORBO 609) for heavy oxygenates collection, an offline GC-MS/FID for heavy and light oxygenates analysis and an online mass spectrometer for gas and H_2O analysis, are employed to obtain a detailed description of volatiles composition and quantification of products. Cellulose and two hemicelluloses – hardwood xylan and softwood glucomannan – have been investigated. Fig.1 shows the peculiar features for both devolatilization trends and product distribution for the three components. More than 45 products are identified and individually quantified, reaching mass balances above 90%, a notable achievement in particular for xylan and glucomannan that are scarcely studied in the literature. In cellulose pyrolysis, the bio-oil yield is maximized, with the prevalence of the C6 anhydrosugar levoglucosan. Xylan products are almost evenly distributed among the solid, liquid and gas streams. Glucomannan, with its hybrid chemical structure, displays a behavior intermediate between cellulose and xylan.

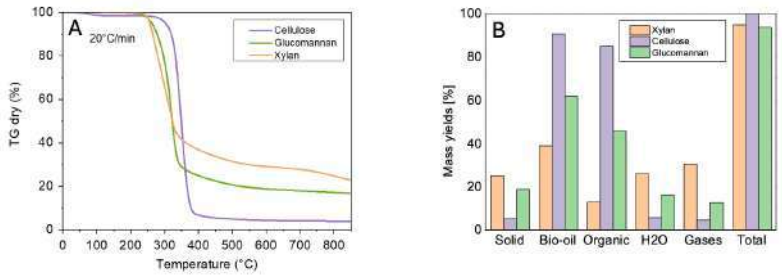

Figure 1: A) TG curves and B) pyrolysis product distribution for cellulose, xylan and glucomannan

[b]*Basic Chemicals and Plastics Research Centre, Versalis S.p.A., via G. Taliercio 14, 46100 Mantova, Italy*
lilia.longo@unive.it

Nowadays, the production of virgin plastic has reached hundreds of tons per year all over the world, and less than 10% is usually recycled[1]; the remaining is ended in the environment or in landfills. Plastic can be recycled over mechanical or chemical method. Only a certain type of plastic can be subjected to mechanical recycling (i.e. PET, PE), and the process is limited by the number of possible cycles and a lower quality of the products[2]. Chemical recycling is a more advantageous method because it allows to decompose plastic in smaller molecules with the same characteristics of the virgin monomers, and therefore allows to have a closed cycle, following the principles of circular economy[3]. Through the chemical recycle it is possible to use plastic as alternative raw material to fossil sources, with a favourable footprint of greenhouse gases.

HOOP® technology, registered trademark by Versalis S.p.A, is a chemical recycling process based on the pyrolysis of mixed plastic (*plasmix*) that cannot be mechanically recycled. Indeed, pyrolysis is a versatile technique that allows to treat different types of plastics without the need of a previous separation steps. During the pyrolysis, in absence of oxygen, the thermochemical decomposition of the material occurs, obtaining three fractions: liquid, gas and solid. The liquid (oil) is the main fraction, made of a mix of liquid hydrocarbons, that can be used as feedstock for steam cracking plants and reintroduced in the plastic production; the gaseous fraction (fuel gas) is mainly made of N_2, H_2 and C_1-C_5 hydrocarbons, and it can be used as fuel for the heat demand of the pyrolytic plant. Finally, the solid fraction (char:≈ 8% of the plasmix fed to pyrolysis plant) is composed by coke (≈50 wt.%) and inorganic compounds present in the plasmix. Considering the production capacity of the pilot plant HOOP®, over 4875 t/a of oil produced, 870 t/a of char would be by-produced, and this material needs to be reused; furthermore, the char is a by-product always present in the pyrolysis plasmix's processes. At the moment, the applications of char range from reducing agent in foundry, to asphalt component, or as fuel in cement plants. However, these applications are translated in a low-value high-volume business. The aim of this work is therefore to investigate alternatives for the valorization of the char, to reuse it in the chemical production chain, and to increase the yield of the total recycling process. In an optic of circular economy, the recovery of this substantial organic fraction would increase the saving of virgin sources, and it would lower the emission associated to the use of fossil sources.

Valorization of Olive Mill Wastewater: From Waste to Biopesticides and Biofertilizers

A. Iebole,[a] A. Comite,[a] L. Banfi,[a]

[a] *Department of Chemistry and Industrial Chemistry, University of Genoa, Genoa (GE), Italy*
andrea.iebole@edu.unige.it

The recovery of waste material is the challenge that has been affecting the last decades worldwide. My doctoral work fits into this context, as part of the PNRR project of Agritech, National Center for Technology in Agricolture. The waste in question is olive mill wastewater (OMW), which along with pomace, represents one of the two by-products obtained from olive oil extraction. To date, there is still no real destination/use mode to dispose of/valorize this waste. Currently in Italy, laws still allow for spreading it on the ground, but this is unsustainable as the water has high COD and organic content and presents phytotoxic and antimicrobial properties due to the presence of polyphenols[1]. However, it is possible to valorize this water because it is rich in molecules of interest such as lipids, proteins, carbohydrates, and polyphenols themselves, molecules that are extremely useful due to their high antioxidant power[2]. Hence, the objective of this research is to exploit various innovative technologies to extract/purify and concentrate polyphenols and produce biopesticides and biofertilizers to be applied in the fields. This document outlines a possible work scheme to be applied from the olive harvesting campaign to the formulation of a final bio product, which will be directly tested in future field studies. The first application is a pretreatment involving acidification with concentrated sulfuric acid of the raw OMW. This process promotes the sedimentation rate of suspended solids in the water, which then settle at the bottom, creating a flocculent solid matrix composed of high molecular weight organic constituents and salts (mostly potassium). The clarified solution obtained is then subjected to a series of membrane processes aimed at removing residual solids, high molecular weight organic compounds, and concentrating polyphenols. After membrane processes, the concentrated and purified water still contains high levels of salts, which is a limitation especially for biopesticide production as high salt content can dry out the leaves. To address this issue, an anion exchange resin capable of adsorbing polyphenols (acids) and carbohydrates while allowing salts to pass in an initial fraction can be utilized. At this point, after desorbing the polyphenols (eluting with H_2O:MeOH + 2.5% of acetic acid), it is advisable to lyophilize the samples, obtaining an oil to be used as a reagent for enzymatic esterification to obtain acylated polyphenols, now lipophilic and hence no longer soluble in water but in organic solvents. The future idea is to formulate a pesticide consisting of the active ingredient constituted by acylated polyphenol (lipophilic) suitably dissolved in an organic solvent, partially soluble also in water such as tetrahydrofuran (THF). Once sprayed on the leaf and after the water has evaporated, leaving the dispersed acylated polyphenol, the active ingredient remains adhered to the leaf, without the risk of being washed away by rain, exerting a barrier effect against insect or fungal attacks.

michele.offidani2@unibo.it

Plastics are often described as the materials "God forgot to create" and thanks to their extraordinary properties, they have brought countless benefits to our society. According to the Global Plastics Outlook published by OECD, 431Mt (million tons) of new virgin plastics were produced in 2019, 353Mt of which became a waste. Unfortunately, most polymeric wastes are currently disposed in landfills (49%) or incinerated (19%) and only a tiny fraction is recycled (9%). Over the last years, pyrolysis is emerging as a promising and versatile technique to chemically recycle mixed plastic wastes. The implementation of a catalytic system is a key factor to lower the required energy demand and achieve better selectivity towards the desired products. Among all the possible catalysts, zeolites are the most studied systems reported in the literature. H-ZSM5, Y-zeolite, β-zeolite, FCC catalysts etc. are known to promote hydrocarbon cracking, reducing the average molecular weight and improving the quality of the oil produced.[1] Deactivation by fouling and reduction of the oil yield are known problems shown by those types of acid catalysts. In order to mitigate those drawbacks, is of vital importance controlling the acidity and morphology of the catalytic system (Figure 1).[2] Indeed, the lower the acid strength, the less cracking is promoted, but on the other hand, if the acidity is too high, coke-forming reactions are overly favoured. As for the acidity, also the right structure as to be selected. Channels dimensions and morphology play a key role in the shape selectivity toward reactants, transition states and products. Moreover, the diffusion of coke precursors and therefore catalyst deactivation are vastly affected by the shape of the pores. We are currently studying those aspects in order to optimise the catalyst design and process efficiency in both the in-situ, in which the catalyst is directly in contact with the molten plastic, and ex-situ configuration.

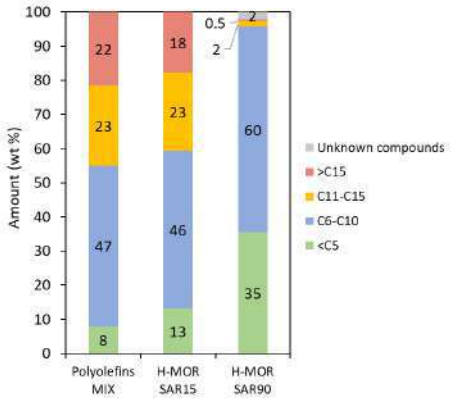

Figure 1: Effect of the SiO_2/Al_2O_3 ratio (SAR) on the oil composition in terms of number of carbon atoms

Alice.Gramegna@guest.unimi.it

Ruminants, mainly dairy cattle, are widely recognized as one of the main contributors to methane emissions in the environment, playing a significant role in the global warming phenomenon. Considering that a cow emits about 500 L/d of methane [1] and in view of the increasing population of cows due to the intensive farming activities, the daily methane emission is considerable. Extensive efforts have been made to reduce methane emissions from ruminants prior to their release into the environment; however, considering that the enteric fermentation process is unavoidable, it is crucial to establish methods for capturing the emitted methane.
Given the common practice of implementing forced ventilation within barns for animal well-being, the discussed process aims to capture methane via adsorption on zeolite through the barn ventilation. The literature review has identified commercial zeolite 13X and Clinoptilolite as suitable materials. The Adsorption isotherms of the gases on the selected adsorbent materials were taken from the literature and are being currently validated through experiments. It is estimated that a cattle (600 kg of body weight) consumes 21 kg DMI /day and due to the enteric fermentation and respiration releases 23 g CH_4 / kg DMI and 647 g CO_2 / kg DMI [2]. Carbon dioxide poses a significant challenge for methane capture on zeolite, because adsorption competition exists between CO_2 and CH_4. Therefore, it is suggested that the adsorption process is dominated by the carbon dioxide adsorption. The design work, performed using Aspen Adsorption® V11 software, revealed the necessity of a two-stage adsorption system, with two beds in series. An initial "guard bed" filled with zeolite 13X is used to adsorb carbon dioxide and other gases from the barn, while efficiently adsorbing methane in the second bed of the same volume filled with Clinoptilolite, a cost-effective natural zeolite with excellent properties for methane adsorption. With the current configuration, the first bed reaches saturation in 210 days whereas the second bed reaches saturation in 40 days; consequently, five replacements need to be executed while keeping the guard bed in operation. The designed plant allows to obtain an exiting flow consisting only of air, therefore mitigating the environmental impact of the agricultural sector.

Removal of chromium (VI) from water exploiting maltodextrin-based cationic adsorbents

C. Cecone,[a] M. Ginepro,[a] F. Trotta,[a]

[a] *Department of Chemistry, University of Turin, Via P. Giuria 7, 10125 Torino, Italy*

claudio.cecone@unito.it

Developing polymers obtained from renewable sources, encouraged by the spreading of "Green Chemistry" concepts, has gained scientific and industrial attention. Maltodextrins are water-soluble D-glucose oligomers produced from starch via enzymatical or thermal treatments, widely employed in the food and pharma industry.[1] Furthermore, because of their good water solubility, numerous studies reported the possibility of cross-linking maltodextrins into insoluble polymer networks by exploiting suitable cross-linkers, aiming for application in aqueous media. However, many of these compounds, namely, epichlorohydrin, diphenyl carbonate, and isocyanates, are toxic and require the use of organic solvents. As lower-toxicity alternatives, water-soluble diglycidyl ethers have been studied and reported. In addition, alongside diglycidyl ethers, the introduction of tertiary amines during the synthetic step has been exploited to obtain hydrophilic cationic maltodextrin-based adsorbents, which displayed promising removal performances towards both organic and inorganic contaminants.[2,3]

Chromium, predominantly as Cr(VI), is among the most prevalent water contaminants generated by the metal finishing, textile, electroplating, and leather industries. Cr(VI) is highly soluble in water and can enter the human body through dermal and oral exposure. Moreover, it is extremely toxic and carcinogenic in long-term exposure and therefore must be removed from the effluents before disposal. However, conventional techniques for chromium sequestration, such as filtration, reduction, precipitation, and ion exchange, have still limited applicability.[4]

In this work, cationic bio-derived polymers obtained via a sustainable approach by crosslinking maltodextrins with suitable diglycidyl ethers were studied as adsorbents for removing Cr(VI) from aqueous media.

gabriele.viada@unito.it

The enormous worldwide employment of single-use plastic materials is leading to ever-increasing waste generation. Therefore, the use of the latter as a feedstock for the production of waste-derived materials has emerged as a hot topic within both the scientific community and the industrial area. However, to accelerate the creation of an effective and reliable market for secondary raw materials, an essential requirement for circular materials is the ease of implementation in current processes and products[1].

In this perspective, we have started to investigate bis(2-hydroxyethyl) terephthalate (BHET), a low molecular weight diol as the main product of the glycolysis of polyethylene terephthalate (PET), as a promising circular component in the formulation of more sustainable ready-to-market polyurethanes[2]. This approach is particularly appealing considering that the end-of-life of a preeminent thermoplastic polymer on a global scale (i.e. PET) would serve as feeding for the most prevalent thermosetting polymer worldwide[3] (i.e. PUs), thereby offering an alternative route for closing the loop on a not negligible portion of PET waste.

In this contribution, we explored an innovative approach to implement BHET as a secondary raw material in the formulation of NCO-terminated prepolymer tailored for thermosetting resins. BHET was seamlessly integrated into the prepolymer formulation, removing the need for modifications to the industrial process, and demonstrating outstanding compatibility with other components within the mixture. The impact of BHET concentrations and its relative ratio with polyether and polyester constituents of the prepolymer on the final resins were systematically evaluated, showcasing the feasibility of fine-tuning the physical, chemical, and mechanical properties of polyurethanes while preserving market-level properties. In conclusion, we proved the successful incorporation of a significant amount of BHET (up to 20% w/w) into novel, eco-friendly prepolymers using a solvent-free methodology, without necessitating additional steps in the industrial workflow.

arian.grainca@unimi.it

This study proposes a risk assessment framework for Fischer-Tropsch synthesis experiments in academic laboratories and pilot plants, focusing on addressing the prevalent issues of accidents and incidents due to variable conditions, human error, and inadequate training. By integrating Hazard and Operability Analysis (HAZOP) and Layers of Protection Analysis (LOPA), the work aims to tackle the unique risks in academic environments, including manual operations and transient processes. It emphasizes analyzing operability issues, identifying high-risk deviations, and assessing the effects of manual interventions and laboratory infrastructure on safety. Key areas like the Fischer-Tropsch reactor and feed section were pinpointed as high-risk, revealing inadequately mitigated risks. An in-depth LOPA analysis led to identifying essential preventive and mitigative strategies, recommending automation, safety interlocks, automatic control loops, and redundancy to improve safety. The study highlights the significant impact of manual operations and laboratory infrastructure, such as ventilation and safety equipment, on risk scenarios.

Offering a comprehensive view on safety management in academic settings, the study suggests moving towards automation and strategic safety implementations to boost experimental setup safety. This approach aims to elevate safety standards in academic labs and pilot plants, significantly reducing accidents and injuries.

nicola.difidio@unipi.it

Defatted wheat bran, an industrial waste of the food chain, represents a strategic renewable material for modern biorefinery schemes. Through a combination of chemical and biological catalysis, a cascade process was developed to produce high-value fine chemicals, such as carotenoids and lipids, from polysaccharide fraction. Due to the low lignin content and suitable particle size of defatted wheat bran, pretreatment steps are unnecessary, allowing the direct enzymatic or chemical hydrolysis of polysaccharide components to give fermentable sugars. Regarding the biocatalytic approach, the optimisation of the main reaction parameters, such as enzyme dosage and biomass loading, was performed to improve the monosaccharide yield. Regarding the chemical route, a microwave-assisted $FeCl_3$-catalysed approach was optimised in terms of catalyst amount and reaction time to maximise the sugar yield, minimizing the formation of furanic derivatives which are strong inhibitors for the subsequent fermentation step. The biological conversion of sugars obtained by both catalytic routes into carotenoids and lipids was performed by the commercial yeast *Rhodosporidium toruloides*. The simultaneous production of carotenoids and lipids was optimised by investigating the effect of the C/N ratio in the fermentation medium. The highest carotenoids cell content achieved in this study (14.8 mg/g) is about 5 times higher than the maximum value reported in the literature to date for this yeast. Moreover, *R. toruloides* achieved the complete conversion of sugars into desired bioproducts for both the biomass hydrolysates demonstrating the effectiveness of the two different catalytic approaches adopted for biomass hydrolysis.

federica.valentini@unipg.it

Nowadays, the design of more sustainable processes, aiming at the waste prevention, is of crucial importance. Additionally, strategies such as recycling and upcycling are promising tools to contrast the waste disposal. In this context, the definition of suitable methods for the valorization of urban waste is pivotal to promote a circular economy.

We report the upgrading of pine needles urban waste in PiNe,[1,2] a porous carbonaceous material used as support for metal nanoparticles (M/PiNe).[3,4] To meet the future generations needs, the immobilization of low-cost Ni as active site afforded a competitive and performant heterogeneous catalyst. Ni/PiNe proved to be efficient, also for consecutive cycles, in cross-coupling reaction under MW irradiation (Figure 1).

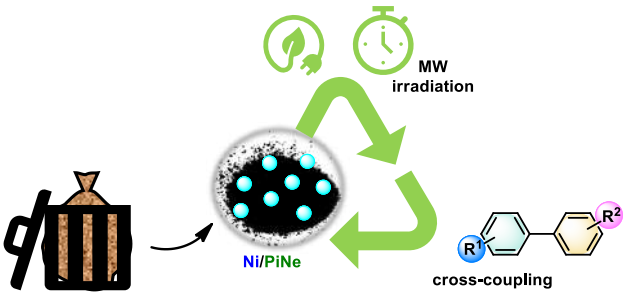

Figure 1: Waste valorization to recyclable Ni/PiNe used in cross-coupling under MW irradiation.

luca.soldati@chimieparistech.psl.eu

Excessive mechanical stress on polymeric materials can result in the rupture of macromolecular chains, causing degradation and macroscopic failures which can compromise the functionality of devices and even pose relevant safety issues. Reliable rapid and accessible strain monitoring would be a potent preventive measure against premature and potentially debilitating damage. One way to achieve this is by employing mechanochromic probes which, once dispersed or covalently bound to the desired material, make it able to change its optical properties in response to mechanical stimuli, thus providing reliable and direct clues to easily address mechanical stress.[1] This approach also allows to target commodity polymers which are largely available, already find several applications, and can be easily reused/recycled.

In this study, we have developed a novel design for a two-layers mechanochromic device capable of producing a large variation of fluorescence upon stretching thanks to synergic response of the different mechanophoric systems present in the different layers. In particular, the bottom layer comprises a pyrene-based aggregachromic system capable of switching its fluorescence response to lower wavelengths upon mechanical deformation, while the top layer contains a red pigment, based on perylene bisimide dyes, that act as a filter to absorb the radiation coming from the bottom layer in the relaxed state.[2,3] Upon stretching, the combination between the shift of the fluorescence in the bottom layer and the thinning of the filter in the top layer result in large and rapid variation of the intensity.

We investigated the optical response of different dye-filter combinations and tested different host materials to better understand the efficacy of the proposed design. By employing elastomeric matrices, it is possible to obtain reversible off-on systems. This approach provides an affordable and effective method to prepare versatile mechanical stress indicators.

Ketonization of bio-based hexanoic acid for the synthesis of 6-undecanone: a possible alternative route to produce sustainable aviation fuels (SAFs)

D. Allkanjari,[a] E. Valzano,[a] J. De Maron [a], L. Bertin,[b] G. A. Martinez,[b] F. Cavani,[a] T. Tabanelli.[a]

[a]*Dipartimento di Chimica Industriale "Toso Montanari" and Center for Chemical Catalysis-C[3], Università di Bologna, Viale del Risorgimento 4, 40136 Bologna, Italy*

[b] *Department of Civil, Chemical, Environmental and Materials Engineering (DICAM), University of Bologna, Via Terracini 28, 40131 Bologna, Italy*

The ketonization of a bio-based hexanoic acid (BIO-HA) was investigated with the aim of selectively synthesizing 6-undecanone (6U), a symmetric ketone that has various industrial applications, such as serving as a solvent, flavour or could be utilized as a precursor for sustainable aviation fuels (SAFs).[1] This synthetic approach (figure 1), in respect to the traditional fossil-based jet fuel production, would benefit from utilizing bio-based feedstocks. Our raw material was obtained through an effective fermentative process able to produce renewable hexanoic acid from waste grape pomace, which is obtained with high purity by exploiting its immiscibility with acidified water, as recently reported.[2] Moreover, the catalytic tests were carried out in the gas-phase using a continuous-flow fixed-bed reactor at 350 °C. Unreacted reactants and products were quantified by means of GC-TCD (online) and GC-FID (offline). Unknown products were identified by means of GC-MS. The yields and selectivities of various products in the presence of different catalysts such as ZrO_2, TiO_2 and a mixed oxide (Zr/Ti/O) were analysed and compared. The effect of the main impurities contained in the BIO-HA, such as butyric acid, valeric acid and water, on the catalytic activity and performances was also investigated in detail. Long term tests have clearly underlined the negative effect of these impurities on catalyst lifetime compared with commercially available, highly pure, hexanoic acid. Interestingly, the results showed that ZrO_2 is the best catalyst for the ketonisation of anhydrous medium chain acids, however water strongly inhibits its activity even in small quantities. On the other hand, TiO_2 is less active than ZrO_2 when tested with anhydrous acids, but its activity is not strongly influenced by the presence of water in the feed. All in all, the results indicate that BIO-HA can be used as raw materials for the synthesis of bio-6U, nonetheless the presence of unknown impurities lead to catalyst deactivation after around 50 hours of reaction.

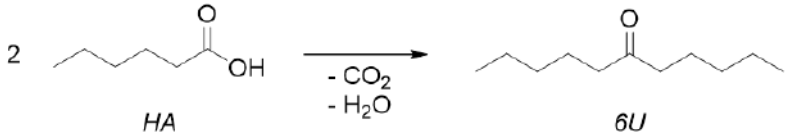

Figure 1: The ketonization reaction of hexanoic acid (HA) to 6-undecanone (6U).

From Waste to Catalyst: Pyrolysis-Based Valorization of Biomass

D. Baldassin.[a] L. Longo,[a] F. Menegazzo,[a] M. Signoretto[a]

[a]*CATMAT Lab, Department of Molecular Sciences and Nanosystems, Ca' Foscari University of Venice and INSTM-RU Ve, Via Torino 155 (30172), Venezia Mestre (Italy)*
davide.baldassin@unive.it

A way to valorise agricultural and other organic waste is thermolytic transformation via pyrolysis, resulting in different products: biogas, bio-oil and biochar, corresponding to the gas, liquid and solid fractions, respectively[1]. The solid phase, biochar, is a promising carbon-rich material that can be applied to various fields, such as wastewater treatment, soil remediation, as a material for electrodes, and catalysis, replacing other carbon materials from less sustainable sources[2]. The properties of biochar are influenced by the nature of the biomass and pyrolysis parameters such as temperature, heating rate and residence time. Moreover, its physicochemical features can be enhanced through activation with different agents, such as steam, CO_2, KOH, or ZnCl2. In this study, different biochars have been activated with steam as a more sustainable activating agent to obtain high surface area carbons suitable as supports for metal nanoparticles[3]. Two different biomasses, one of vegetal origin (rice husk) and one of animal origin (leather tanning scraps), were used to produce steam-activated biochars (AR, AL). A 1:1 wt% mixture of the two (ARL) was also investigated. The three samples were employed as a support for Pd nanoparticles using a deposition-precipitation method. The synthesized catalysts (Pd/AR, Pd/AL, Pd/ARL) were characterised with N_2 physisorption, CHNS elemental analysis, SEM, XPS, Raman spectroscopy, CO chemisorption and MP-AES to investigate the physicochemical properties of the carbonaceous supports and their interaction with the metal phase. They were also tested in benzaldehyde hydrogenation, evaluating reactant conversion and hydrogenation product yield. The results of the reaction show that the catalyst supported on the biochar produced from the mixture yields a more active catalyst than the one produced from leather scraps and a more selective catalyst than the one produced from rice husk, showing a synergic interaction between the biomasses constituents during the pyrolysis process. These results will be discussed with respect to the data from characterizations.

Sample	BET surface area (m^2/g)	V_{tot} (cm^3/g)	I_d/I_g	Effective wt% Pd (nominal: 0.7 wt%)	$D_{(Pd)average}$ (nm)	TOF (h^{-1})	Yield (%)
Pd/AL	380	0.12	1,113	0.44	4.6	149	15
Pd/AR	680	0.18	1,086	0.64	4.2	1297	77
Pd/ARL	450	0.24	1,037	0.67	2.0	1084	93

The HYDREAM project: Tailoring the Hydrophilic-Hydrophobic Reaction Zone for the Electrochemical Nitrogen Reduction Reaction to Ammonia

F. Bella,[a] G. Pagot,[b] C. Ampelli[c]

[a] *Department of Applied Science and Technology, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129 – Torino, Italy*
[b] *Department of Industrial Engineering, Università degli Studi di Padova, Via Marzolo 9, 35131 – Padova, Italy*
[c] *Department of Chemical, Biological, Pharmaceutical and Environmental Sciences, Università degli Studi di Messina, Viale Ferdinando Stagno d'Alcontres 31, 98166 – Messina, Italy*

The preservation of our planet is the most urgent issue in the world and the scientific community is pushing a lot of researchers to work on technologies for the storage/conversion of CO_2 into chemicals. However, it is easier not to produce CO_2 than setting-up plants to treat it. Therefore, new industrial processes have to be conceived with a new perspective.

In this framework, the HYDREAM project focuses on the development of a gas/liquid/solid three-phase interface (TPI) that endows electrodes with enhanced performance for target electrochemical reactions involving gases, due to its ability to mediate local interfacial environments and inhibit side reactions. Such a TPI concept is starting to be considered by the scientific community due to its promising potentialities in several strategic research fields, e.g. electrocatalyzed reduction of CO_2, O_2 and N_2, fuel cells, sensors for liquid and gas substrates, anti-corrosion systems, etc.

The main goal is to tailor the TPI within a double hydrophilic-hydrophobic reaction zone, bearing a controlled grade of hydrophilicity at the microscale. The achievement of the co-existence of hydrophilic-hydrophobic conditions within the electrocatalyst/electrode will permit a compromise between efficient gas transport to the electrocatalyst and good contact of the electrocatalyst with the electrolyte (i.e., to provide the needed protons for the reduction reaction).

HYDREAM activity is exploring these key experimental points:

- Design of heterogeneous electrocatalysts able to show hydrophobic-hydrophilic conditions in the reaction zone.
- Formulation of non-aqueous liquid electrolytes showing optimal electrode wettability, reactant solubility and mass transport.
- Advanced physico-chemical characterization to assess specific materials features and electrochemical reaction aspects at the nanoscale.
- Exploitation of TPI concept in a highly significant case study, i.e. the electrochemical N_2 reduction reaction (E-NRR) to NH_3 under mild conditions.

With the energy transition, the energy world is moving toward more sustainable, renewable sources, which offer several advantages such as a reduced CO_2 emissions, an improvement in the general public health, and promotes energy independence and security. However, they also suffer several drawbacks due to their cyclic, seasonal, and regional characteristics. Efficient energy storage technologies, such as batteries, can mitigate this problem and will cover a prominent role in the energy infrastructure of the future.
Currently, Li-ions batteries (LIBs) are among the best performing batteries commercially available, as they offer good stability toward charging-discharging cycles, large power densities and large conversion efficiency. However, they currently rely on the use of specific metals (Li, Ni, Co) the production of which is not sustainable and localized in geopolitically unstable areas of the world. Redox-active polymeric materials as electrode materials can circumvent these issues, as they are obtained from more available resources, they can have a greener footprint, and easily allow for various modifications via chemical synthesis. In addition, thanks to their light weight, organic materials can reach very high specific capacity values compared to the inorganic counterparts.

Materials proposed so far show limited lifetime, due to solubility in the electrolyte, and slow/incomplete discharging. To overcome these limitations, we propose a novel strategy based on processable precursor polymers which can be employed to prepare high molecular weight (disfavouring the solubilisation process), fully conjugated polymers (characterized by a higher charge mobility), comprising either in chain or pendant redox units. In this study, we report an example of such systems consisting in polymeric precursors comprising aromatic moieties separated by 1,4-dicarbonyl fragments which break the conjugation. These units can then be used as scaffold for pyrrole formation in the Paal-Knorr reaction, allowing the insertion of different redox units and, at the same time, making the structure of the polymer flat and conjugated, reducing the solubility.

This study was carried out within the POLiBATT project – funded by European Union – Next Generation EU within the PRIN 2022 PNRR program (D.D. 1409 del 14/09/2022 Ministero dell'Università e della Ricerca).

Sergio.bocchini@polito.it

The pressing need to reduce atmospheric CO_2 has spurred the search for carbon capture and sequestration technologies. Ionic Liquids (ILs) have shown promise for CO_2 capture due to their properties such as minimal vapor pressures, high thermal stability and the capacity to dissolve CO_2.. Their tunability enables the enhancement of CO_2 absorption allowing their application in gas separation and industrial capture efforts. Nevertheless, challenges such as high production costs, increased viscosity compared to traditional solvents, and uncertain long-term environmental impacts hinder their widespread. Research efforts are now focused on the realization of more economical ILs with reduced viscosity and improved CO_2 selectivity, alongside evaluating their ecological effects.

Amino Acid Ionic Liquids (AAILs), noted for their superior CO_2 absorption, low vapor pressure, and thermal stability, are being extensively studied. This research traces the development from our initial studies on biobased ILs to recent advancements [1,2], highlighting significant progress in AAILs for industrial CO_2 capture.

Starting from the utilization of choline-based amino acids ([Cho][AA]) in solutions with DMSO to mitigate the intrinsic high viscosity of AAILs throughout the development of other solutions were described emphasized the role of solvents for the improvement of absorption rates while presenting an environmentally benign and economically viable alternative to traditional carbon capture methodologies.

Stone materials have been extensively used in the past as primary materials for construction due to their high strength and good durability. Nevertheless, when exposed outdoors they undergo a gradual decay caused by environmental agents, such as pollutants or microbiological species responsible for the colonization of surfaces [1]. In order to preserve these materials and to prevent their decay, it is common practice to apply protective coatings of various nature, that form a physical barrier on the stone surface making it hydrophobic and inhibiting microbial growth [2]. Current stone surface coatings are often harmful to the environment and to operators, thus innovative solutions are needed.

This work aims to develop a sustainable protective coating for stone surfaces based on a mesoporous silica (SiO_2), MCM-41, loaded with titanium dioxide (TiO_2). In this multifunctional system, the structure of MCM-41 can host antimicrobial products, while TiO_2 gives self-cleaning properties to the surface thanks to its photocatalytic activity [3]. In particular, the photocatalyst will degrade atmospheric pollutants such as VOCs and NOx, which interact with the surface of stone causing chemical degradation and altering its aesthetic appearance. Self-cleaning properties could also help in the degradation of vandalic stains.

Specifically, MCM-41 nanocontainers were synthesized and subsequently enriched with three different types of TiO_2 nanoparticles (*i.e.*, P25, Kronos, Mirkat) to test the photocatalytic activity changes of the materials. The obtained composite materials were characterized through several analytical techniques: N_2 physisorption, FT-IR, SEM-EDS and HRTEM.

To investigate the photocatalytic activity of the synthesized nanomaterials methylene blue was employed as a model stain compound. This test was conducted both in liquid, with subsequent monitoring by UV-visible spectrophotometry, and on plaster mock-ups exposed outdoors to visible light.

In summary, the synthesis and characterization of TiO_2-loaded MCM-41 nanoparticles were pursued to develop a coating for stone surfaces, aiming to extend protection duration and enhance self-cleaning action.

A recent approach in mitigating the emissions of CO_2 is the integrated carbon capture and utilisation for the synthesis of CH_4 from waste flue gases by using Dual Function Materials (DFMs).[1] The DFMs are formed by the CO_2 capture component, usually an alkaline oxide, and the catalytic component, usually a transition metal. The two parts must interact in synergy to be able to convert the captured CO_2 efficiently with a spillover mechanism from the adsorbent phase to the catalytic sites.[2]

In this work, we report the preparation and performances of bimetallic RuNi DFMs with CaO and Na_2O as adsorbent phases supported on CeO_2-Al_2O_3. The DFMs have been prepared by a mild-energy solventless mechanochemical process. The materials were tested at 650 °C for the cyclic CO_2 capture, both in lean conditions and with the presence of O_2 in the stream, and the reduction to produce CO by the Reverse Water-Gas Shift reaction (RWGS). Compared to the conventionally impregnated samples,[3] these DFMs show increased CO_2 capture capacity and CO production (Table 1). Yet, undesirable CO production is observed also during the CO_2 capture step due to the strong reducibility of the milled DFMs. The presence of O_2 during the capture step suppressed the formation of CO without negatively affecting the CO production by RWGS and the DFMs stability in cyclic operations, showing good potential in real flue gas applications.

Table 1: CO_2 capture capacity and CO production during the capture and the RWGS steps for selected samples prepared with the mechanochemical method (M) compared to reference impregnated samples (W).[3]

Dry Reforming of Methane (DRM) is the process of simultaneous conversion of CH_4 and CO_2 to obtain syngas (CO and H_2). The process enters in the field of green energy transition, since it uses CO_2 to produce hydrogen in a more sustainable way[1]. However, the DRM process is not yet applied at the industrial level, due to the limitations of the catalytic system, that affects the overall economy of the process. Because of the reaction conditions adopted, the catalyst suffers from coke deposition and sintering of active phase[2].
In this work, to enhance the catalytic resistance, is evaluated the introduction of promoters on a Ni-based catalyst, supported on γ-Al_2O_3. In particular, vanadium and calcium are studied as promoters, to determinate the optimal weight percentage to introduce. Different catalysts are synthetized by incipient wetness impregnation method, and tested for the DRM reaction at 650°C in a fixed bed reactor, with a GHSV of 12000 h^{-1}, using different ratios of the reagent gases (CH_4:CO_2:He), under a total flow of 200 mL/min.
Both fresh and spent catalytic materials are characterized using various techniques, such as: TPR, TPO, XRD, CHNS analysis, SEM-EDX, TEM and nitrogen physisorption. From the activity results obtained, it is demonstrated that these promoters are effective in a low amount (about 1 wt.%), showing a good stability and activity over 25 h of reaction. By characterizing exhausted samples, it is proved that these promoters are suitable to enhance the coke resistance.

We recently reported on a new application for the [Cu(6,6'-dimethyl-2,2'-bipyridine)$_2$][PF_6] (coded CuBPA) system as an active catalyst for allylic oxidation of cyclohexene by tert-Butyl hydroperoxide (TBHP) in dichloromethane[1]. Such a redox cycle was not observed for [Cu(2,2'-bipyridine)$_2$][PF_6] (coded CuBPD) system where the oxidation by TBHP is a fast but irreversible process, and the back-reduction with cyclohexene is not observed. The slow kinetic of the oxidation of CuBPA by TBHP, in contrast with the almost immediate oxidation of CuBPD, prompted us to explore the system [Cu(6-methyl-2,2'-bipyridine)$_2$][PF_6] (coded CuBPAD), aiming at a complex with intermediate redox and catalytic properties: it is known that the backbone substitution is crucial for the properties of these systems[2]. Preliminary computational study showed an encouraging linear correlation between the grade of methyl substitution and the ΔE and ΔG of the two oxidation reactions. Thus, we synthesize the BPAD ligand and prepared the corresponding Cu complex. The good match between computed and experimental Raman spectra confirmed the good quality of the models, corroborating the computational result, cyclic voltammetry confirmed the intermediate redox potential of CuBPAD, while UV-Vis study monitored the oxidation for CuBPAD in the same conditions used for CuBPA, confirming an intermediate behaviour that we expect to be reflected in the catalytic performance[3].

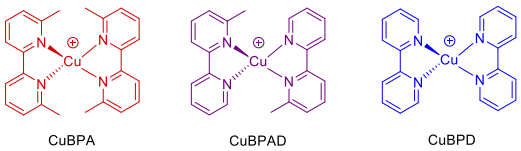

Figure 1: From left to right: CuBPA, CuBPAD, CuBPD.

Polyurethanes are one of the most versatile and requested polymers on the market[1]. In particular, rigid polyurethane foams (PUR) are widely used in thermal insulation, furniture and automotive applications. Because of their commercial success, million tons of polyurethane waste are produced every year. Landfilling and incineration are still the most common ways of processing polyurethanes in Europe[2], while mechanical and chemical recycling remain limited due to the thermoset nature of polyurethanes and the high energy demand requested for the processes. According to the 12th goal of the 2030 Agenda for Sustainable Development, it is necessary to identify efficient methods for the recycling of plastic waste. In this study, a promising valorization of PUR by thermochemical recycling was evaluated via hydrothermal liquefaction (HTL), to obtain a solid product, named hydrochar, with high added value. A rigid and thoroughly characterized[3] PUR for model making, was used as feedstock for the tests. Reactions were carried out using a Parr reactor 4576 and ultrapure water in subcritical conditions, with temperature ranging from 250°C to 345 °C and different reaction times (from 20 min to 120 min). Moreover, for the first time in literature an acidic environment was experimented, using a mixture of water and acetic acid, with a volume ratio of 2,5:1 (pH =2,06). The hydrochars thus obtained were characterized by ultimate analysis, ICP-MS, FTIR, porosimetry and SEM to evaluate the influence of the reaction parameters on the hydrochar properties such as elemental composition, degree of functionalization, morphology, and porosity.
This in-depth characterization of the hydrochars will make it possible to evaluate their applicability in different industrial fields according to a circular economy perspective.

Methane dry reforming (DRM) stands as an innovative catalysed process pivotal in sustainable fuel alternatives development, efficiently transforming CH_4 and CO_2 into syngas ($CO+H_2$), thus reducing greenhouse gases concentration unto the atmosphere.[1] Despite the interest to environmental issues, the reaction faces challenges due to side reactions, such as methane decomposition, Boudouard reaction, and CO reduction, leading to catalyst deactivation due to carbon deposits accumulation.[2] Nickel-based catalysts are commonly used in DRM due to their affordability and robust performance,[3] but they undergo deactivation due to carbon deposition and sintering process at high temperatures. To address these issues, different catalysts compositions and various preparation conditions have been explored, aiming at enhancing structural properties, phase composition, distribution of nickel phases, and overall catalytic activity.

In this study, a comparison of catalytic performances of Ni-La catalysts prepared with microwave-assisted precipitation synthesis (MW) and hydrothermal method (HT) has been performed. The differences in CH_4 and CO_2 conversion over the investigated catalysts have been explained by a comprehensive structural analysis, which suggests differences in Ni-La crystal phases and particle sizes. TGA and HR-TEM have been carried out to evaluate coke formation and the influence of time on the stream on Ni particle size, suggesting for MW catalysts good stability and the possibility to regenerate such samples from carbon deposition with limited Ni sintering.

The steel industry plays a key role in the world's industry and economy and the yearly production exceeded 1950 mega tons in 2020. Unfortunately, it is also emitter of carbon dioxide reduction is made by coal-based reduction; in fact, 73.7% of the production exploit *Blast Furnace* (BF). In the BF, the reduction is conducted with carbon monoxide obtained from coke. The coke and iron oxide are charged from the top part of the BF, descend through the shaft where they are preheated and react. The partial oxidation of coke produces CO which starts to reduce the iron oxide and liquid iron slag and CO_2 are obtained. In fact, the steel production is responsible approximately 8% of industrially based global CO_2 emissions, which corresponds to around 2 Giga tons yearly. The most accredited candidate for decarbonization of ironmaking is a shaft furnace where the reduction is carried out in solid state by a reducing gas, yielding *direct reduced iron* (DRI). In the DRI, the reduction of iron oxide is carried out at the lower temperature using reformed natural gas with a H_2/CO ratio of 3. They represent the first important step towards the decarbonization of the ironmaking process, but fossil feedstock is used, and CO_2 is still emitted. Recently, hydrogen reduction has attracted increasing attention to reduce the greenhouse emissions, which requires further development of the process. The focus of the present work, then, is to study the reduction kinetics of iron oxide using hydrogen as reductant. The overall reaction displays interestingly complex behaviour, which depends on gas phase, surface and solid phase phenomena. This explains also the very versatile and partly contradictory observations and interpretations found in literature. Therefore, monolayer and bed experiments with pure hematite and commercial samples were performed in various experimental conditions in order to investigate kinetics and mass transfer phenomena. To support the interpretation of the data morphological and chemical-physical characterization has been performed. The collected data lays a strong basis for understanding the overall reduction dynamics. Finally, it provides a strong basis for developing a mathematic model to describe the overall kinetics of the reduction.

giusy.dativo@phd.unict.it

The Carbon Capture and Utilization (CCU) processes can be efficient solutions for the CO_2 emission mitigation. Here we applied the photothermo-catalysis for the CO_2 conversion into solar fuels[1]. We investigated the performance of modified phyllosilicates (ps) with the incorporation of Ni and Ce ions in their structure and subsequently coated with CeO_2. The modified phyllosilicates were prepared by hydrothermal method at 160 °C and the CeO_2 coating was made by precipitation with KOH. The catalysts were characterized by FT-IR, Raman, XRD, SEM-EDX, XPS, H_2-TPR, CO_2-TPD, UV-DRS and N_2- physisorption. The catalytic activity was determined in the solar photothermal CO_2 reduction both with pure CO_2 and into an integrated approach where the CO_2 was produced from the thermal catalytic oxidation of toluene. The photothermo-catalytic CO_2 reduction was carried out inside a cylindrical batch reactor maintained at 120°C and irradiated with a solar lamp. The results showed that the Ni/Ce-ps@CeO_2 catalyst achieved a CO_2 conversion of 87% after 5 hours of photothermo-catalytic (Fig.1) test using pure CO_2 with a production rate of 15.8 $\mu mol/g_{cat} \cdot h$ of CO and 5.6 of CH_4. In the integrated approach, the CO_2, produced in the thermo-catalytic oxidation of toluene, was converted at a lower extent (50% over Ni/Ce-ps@CeO_2) into CO and CH_4. The peculiar structure of the phyllosilicates permitted to efficiently expose the surface active sites of the deposited CeO_2 to the solar irradiation. The high versatility of the proposed approach paves the way for the use of modified phyllosilicates (montmorillonite, bentonite) with the incorporation of different ions and with the coating of other semiconductor photocatalysts to improve the performance in the photothermo-catalytic CO_2 conversion.

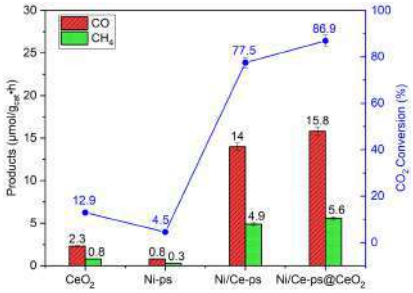

Figure 1:Photothermo-catalytic CO_2 reduction using pure CO_2 at T = 120 °C after 5 h of simulated solar irradiation.

Carbon dioxide emissions into the atmosphere are ever increasing due to the massive use of fossil fuels. To overcome this issue, an attractive strategy is photoreduction of CO_2 which has the potential to transform this pollutant into useful and valuable products by leading to circular economy, avoiding the use of net CO_2-producing energy sources and raw materials.

In this work, an innovative high-pressure batch photoreactor was used for the photoreduction of CO_2 at a constant temperature 80°C. It allowed operating pressure up to 20 bar. The reactor was made of AISI 316 stainless with an internal capacity of 1.7 L, allowing semi-pilot scale demonstration and it is completed by a magnetic stirrer and a double-walled thermostatic system. A 250 W medium-pressure Hg vapour lamp was immersed vertically in the reactor axis as an irradiation source. The optimum reaction time was 1.5 hours. Sodium sulphite was used as a hole scavenger, leading to maximum productivity. Somehow lower performance was obtained testing widely different hole scavengers, possibly from renewable sources, such as alcohols, amines and alkanolamines. The reaction was carried out at pH=14 and this favoured 100% selectivity towards HCOOH as product.

Environmentally friendly graphitic carbon nitride (g-CN) was used as a photocatalyst to avoid toxic or rare materials. Different preparation methods were compared and its exfoliation through either thermal, chemical or ultrasound treatment was compared. The semiconductor was also functionalised with different oxides in a Z-scheme fashion, e.g. with ZnO, SnO_2 and Fe_2O_3 with different loadings. Among the best performing examples, the hybrid 8wt% Fe_2O_3/g-CN photocatalyst returned ca. 8 mol/kg_{cat} h of HCOOH, with respect to ca. 6 mol/kg_{cat} h of the bare g-CN. The synthesized catalysts were characterized by XRD, BET, DRS, TEM and SEM. Some interesting materials were also tested by spectrofluorimetry, demonstrating interestingly that exfoliation is an important strategy to improve the lifetime of the photogenerated charges.

In the realm of mechanochemistry the integration of gases in solid-gas reactions has been recently unveiled as a viable synthetic strategy.[1] However, storing and handling gases can lead to safety and technical concerns limiting the wide application of potentially attractive methodologies. The utilization of solid surrogates offers several benefits, such as the safe and simple handling of reagents instead of dangerous gases.[2] Furthermore, solid compounds are highly suitable for ball milling conditions, which not only helps reduce the need for solvents but also enables faster reaction times.

Carbon dioxide has been successfully employed for the synthesis of fine and bulk chemicals.[3] Herein, we report $NaHCO_3$ as an extremely cheap, safe, and easy to handle solid surrogate of gaseous CO_2 for carboxylation reactions. In particular, cyclic carbamates and carbonates can be conveniently obtained from the corresponding propargylamines and epoxides, and $NaHCO_3$ under mechanochemical conditions.

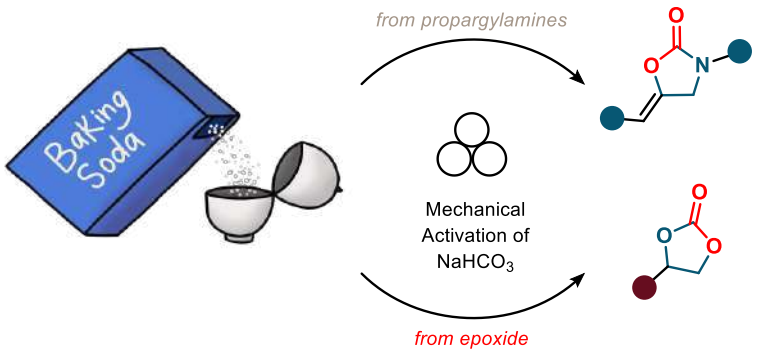

Figure 1: Mechanochemical catalytic synthesis of cyclic carbamates and carbonates from $NaHCO_3$.

Rare Earth Elements (REE) are at the core of critical components for the energy transition, from storage batteries to magnets, lasers and efficient electrical applications. Their status of critical resources renders their recovery and recycling a priority for a sustainable circular economy. Individual properties of "light" and "heavy" REE for specific applications set the requirements for high selectivity in their separation in hydrometallurgical and recycling processes.

Zeolites are well-known and unexpensive cation exchangers but their competitivity vs. other REE recovery techniques has been hampered by their poor stability in acid solutions. In this project, effective conditions have been searched for the extraction of Ce, La, Eu and Y cations from pH 4 solutions and their recovery from saturated exchangers by NH_4 solutions [1]. The nature of the REE affected both affinity and loading, with selectivity of exchange controlled by the coordination of the hydration sphere of each cation, The collected data are at the basis of possible procedures of selective separation by proper cycles of controlled loading and recovery.

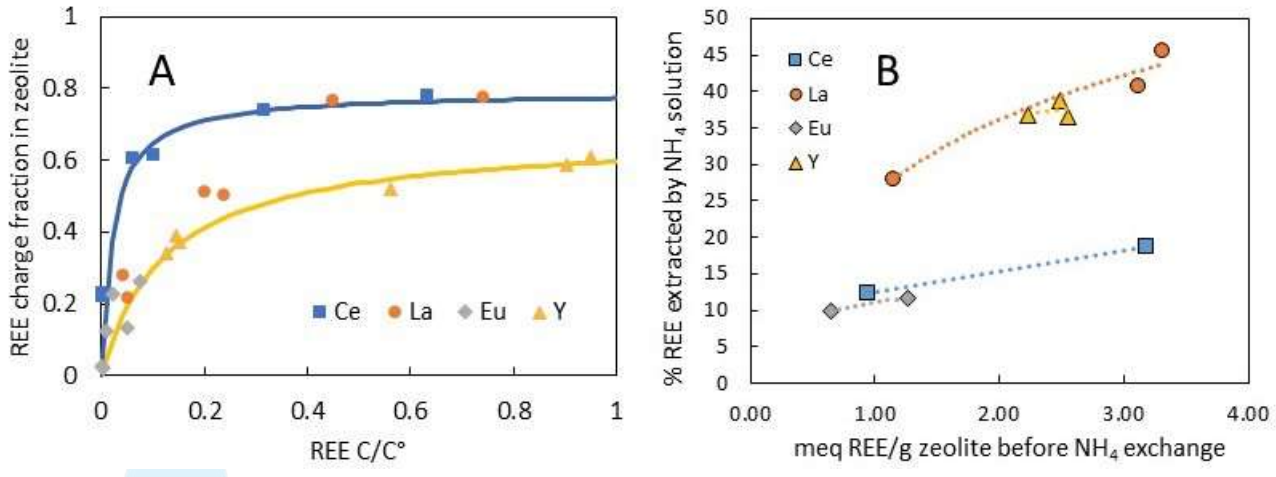

Figure 1: isotherm of NH_4-REE cation exchange on zeolite X (A) and effectiveness of back-exchange of REE by NH_4 solution (B).

diserio@unina.it

The Neapolitan Industrial Chemistry Laboratory (NICL) of the Department of Chemical Sciences of the University of Naples Federico II is a player in the MICS (Made in Italy–Circular and Sustainable) Extended Partnership, on the synthesis of green and sustainable products & materials from non-critical and secondary raw sources, with the aim to synthesize non-isocyanate polyurethane foams (NIPUs).

Polyurethane (PU) foams represent a wide class of polymeric materials, having implications in different sectors from automotive, packaging, cushioning/bedding to construction building. However, their synthesis requires the use of oil-based components, mostly harmful and toxic isocyanate components. On this account, NIPUs foams have been indicated as suitable candidates to replace conventional PUs, where foams can be obtained through "non-isocyanate" routes such as aminolysis between 5 or 6 membered ring-cyclic carbonates (5CCs and 6 CCs) and diamines or transurethanization between carbamates and diamines. A sketch of the possible routes is reported in Figure 1 [1].

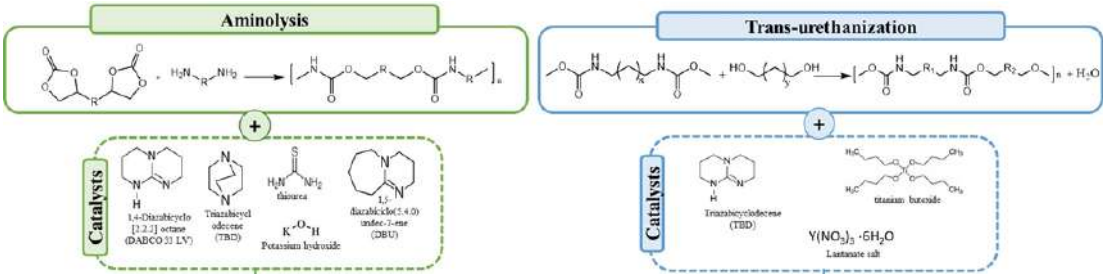

Figure 1: Main polymerization and blowing routes to obtain NIPU foams. Taken from [1].

In the present work, details on the different strategies are provided.

Acidic waters often resulting from industrial processes and other activities typically comprise a range of perilous and harmful substances, including organic solvents, heavy metals, pose a significant environmental challenge with adverse effects on aquatic ecosystems, infrastructure, and public health. Traditional treatment methods have limitations in effectively neutralizing acidity and removing pollutants to mitigate these impacts and restore ecological balance. One promising method for treating acidic waters involves the use of lime (CaO), a versatile and cost-effective solution. However, this method generates large amount of sewage sludge presents its own set of threats in terms of disposal and environmental impact [1].

This research presents a general overview of the treatment of acidic waters through lime utilization and explores the potential valorization of sewage sludge in diverse processes (Fig.1). Through a comprehensive analysis of current research and practical applications, it explores underlying mechanisms and highlights the effectiveness of lime in neutralizing acidic waters by adjusting pH levels, and removing pollutants through precipitation heavy metal hydroxides [2]. Furthermore, this investigation delves into diverse methods, including anaerobic digestion and thermal treatment processes for the repurposing of sewage sludge. It considers its potential applications in waste-to-energy and nutrient recycling beyond conventional disposal practices, aiming to reduce landfill waste volume and environmental pollution while promoting resource recovery. The valorization of sewage sludge entails its transformation into valuable resources such as syngas, fertilizers, biofuel, and biogas [3]. This integration presents synergistic benefits, including improved water quality and promoting circular economy principles.

Explosives compounds, like 2,4,6-trinitrotoluene (TNT), are still widely utilized as a blasting agent not only in controlled explosions for peaceful purposes but also in illicit and terrorist activities, such as in improvised explosive devices (IEDs). The development of novel approaches for rapid, specific and sensitive detection of explosives, based on photoluminescent compounds, represents an important tool for mitigating and preventing risks linked to these materials [1]. In the search for low-cost and user-friendly sensors, fluorimetric techniques have emerged as a promising solution thanks to their high sensitivity and selectivity, short response time, very low limit of detection (LOD) and the ability to work both in solution and in solid phase. In this study, two derivatives of cyclic triimidazole and pyrene, namely the blue emitting 3-(pyren-1-yl)triimidazo[1,2-*a*:1′,2′-*c*:1″,2″-*e*] [1,3,5]triazine, TTPyr, and the yellow-orange emitting 11-(pyren-1-yl)triimidazo[1,2-*a*:1′,2′-*c*:1″,2″-*e*][1,3,5]triazine-3,7-dicarbaldehyde, $(CHO)_2$TTPyr, are exploited through fluorescence-quenching titrations experiments with various nitroaromatic energetic hazardous materials and proposed as sensor species for the quantitative detection of explosives. The performances of the two sensors in the fluorimetric detection of the explosives are reported in Tab. 1. $(CHO)_2$TTPyr shows markedly higher sensitivity for nitroaromatic derivatives compared to aliphatic ones, with picric acid (PA) detection showing the most sensitive response, characterized by a Stern-Volmer quenching constant value of 1.25×10^4 M^{-1} and a calculated detection limit of 0.63 ppm. Such selectivity can be associated with the specific formation of dark complexes through π– π interaction between the analytes and the fluorophore, and a static mechanism is recognized as responsible for the observed quenching [2].

Electrochemical and photocatalytic treatments: an innovative coupled strategy for simultaneous hydrogen production and wastewater remediation

V. Fabbrizio,[a] E. Falletta,[a] M.G. Galloni,[a] E. Marcolini,[a] R. Bernasconi,[b] C. L. Bianchi[a]

vincenzo.fabbrizio@unimi.it

Nowadays, the transition toward carbon-neutral energy production is imperative to mitigate climate change, ensuring a stable energy supply for the future generation[1]. Hydrogen (H_2) is a promising energy storage medium, whose market is expected to increase exponentially due to its use as an energy vector in the transportation sector. Nevertheless, just 4% its production comes from electrochemical water splitting. In this context, the high potential required for the Oxygen Evolution Reaction (OER) constrains H_2 evolution. Additionally, the use of noble metal-based electrodes complicates the practical application due to high costs and limited availability. In this frame, researchers are moving toward the development of noble metal-free electrodes mainly based on earth-abundant compounds.[2] Regarding the anodic reaction, organic pollutants in wastewaters containing high level of chemical energy are excellent electrons donors and suitable candidates for producing H_2 thanks to lower oxidation potential respect the one required for OER. For this reason, the electrochemical treatment of wastewater can represent a viable solution for hydrogen generation and simultaneous wastewater treatment, even if alone it is not sufficient. So, its coupling with other approaches can represent an interesting and efficient solution. Herein, we propose an innovative coupled process involving electrochemical treatment followed by heterogeneous photocatalysis for H_2 generation using noble-metal free cathode and the simultaneous wastewater treatment. In general, electrochemical treatment alone resulted insufficient for wastewater complete mineralization. So, the photocatalytic step using bismuth oxychloride was exploited.[2] This hybrid approach offers a novel and sustainable solution for energy generation and water purification in the face of increasing global industrialization and water scarcity.

The escalating pollution caused by agro-industrial wastewater is an alarming environmental threat. Apart from the obvious water wastage, valuable nutrients within are also lost[1]. Wastewater treatment sector and that of fertilizers' production account for over 3% and 1.2% of world's energy[2]. Moreover, fertilizer costs are continually growing as they are related to the energy cost and population growth. This represents a significant economic damage for companies in the sector. The agro-industrial wastewater treatment market is witnessing a surge in interest towards efficient and sustainable technologies. In fact, technological innovation and the embrace of eco-friendly solutions are driving industry transformation.
In this context, the mission of VisioNing is simple but ambitious: transforming wastewater from a problem to a resource with 100% of circularity and sustainability. VisioNing was conceived after a meticulous examination of the challenges in wastewater treatment. Combining bioelectrochemical and photocatalytic technologies powered by solar energy, our process not only purifies water, but recovers and reuses the nutrients it contains. While numerous wastewater treatment solutions exist, our combined technology offers dual benefits: energy efficiency and recyclability. This empowers us to position ourselves as frontrunners in sustainability and innovation, ensuring a 30% reduction in operational costs compared to traditional systems. Having conducted in-depth research and developed prototypes at the University of Milan, we have now refined an operational and highly-efficient model. A pilot test was conducted with several companies in Lombardy, financed by the "Farming Future" investment fund of CDP Venture Capital SGR and ToSeed & Partners, confirming the preliminary results in terms of nutrients recovery and water purification.

riccardo.ferrero@unito.it

Cyclodextrins (CDs) are cyclic oligosaccharides constituted by α-D-glucopyranose monomeric units connected by α-(1-4) glycosidic bonds, characterized by a truncated hollow cone shape[1]. Thanks to the marked tendency to form inclusion complexes with a large variety of substrates (e.g., pharmacologically active molecules, vitamins, etc.), CDs have been applied as Drug Delivery Systems (DDSs), both alone or in the cross-linked form of nanosponges[2]. These porous materials are obtained through a condensation reaction of a glycosidic monomer and a cross-linking agent and offer several advantages as DDSs with respect to β-cyclodextrin alone. To shed light on the complexation mechanism, computational investigation are increasingly essential, towards a full atomistic representation of nanosponge[3].

The present work relies on previous benchmark Density Functional Theory calculations on monomeric β-CD[4] and inclusion complexes with melatonin (MT) as a guest[5], and then proceeds with classic molecular dynamic simulations both on the inclusion complex with melatonin and on the novel nanosponge model obtained by cross-linking β-CD and citric acid.

These MD simulations carry information on the dynamics of the binding process occurring in both the single host-guest complex and the nanosponge, so as to provide an accurate theoretical model for Drug Delivery applications. Results have shown the presence of D-glucopyranose in two main conformations confirming the high flexibility of β-CD, which disappears both with the complexation and reticulation. Melatonin binding to β-CD is dynamic and not very strong, indeed the guest in some cases escapes from its host but remained enclosed inside the secondary cavities grid.

giulia.ferri@polimi.it

Hydrogen production from biogas is an interesting option for upgrading the biogas plants that today are incentivized for producing electricity. Hydrogen production can be performed in tubular packed-bed reactors by the well-established steam methane reforming (SMR) process, whose heat demand is satisfied by burners. However, at the small scale of biogas plants, the conventional convective heat transfer is severely limited; we thus propose an innovative reactor layout[1], where the heat transfer is enhanced by a conductive copper structure packed with catalytic pellets, and the endothermic reaction enthalpy can be supplied from renewable electricity, which heats a resistive wire placed inside the reactor by the Joule effect. The removal of the combustion heating cuts 40% of the emissions associated with the conventional methane steam reforming. In addition, i) if biogenic CO_2 is captured downstream of the reactor, the process has negative emissions; ii) with the present electrified technology, the energy required for hydrogen production is only 15 kWh/kg_{H2} compared to 40-55 kWh/kg_{H2} for electrolysers. We will report experimental and modelling results obtained in a single-wire lab-scale prototype eSMR which promise high performance in compact reactors, thanks to excellent heat management. Validated mathematical models successfully predict the temperature (see Figure 1) and composition profiles within the reactor and can be used for the design of a scaled-up unit with multiple wires.

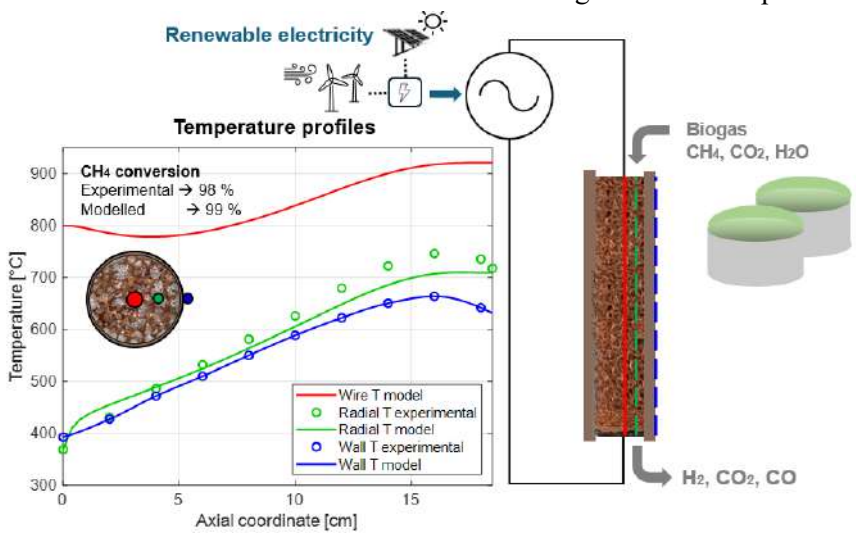

Figure 1: eSMR schematics with experimental and simulated temperature profiles.

giulia.forghieri@unive.it

Carbon dioxide is an abundant greenhouse gas accounting for 79% of global warming. Different strategies aiming at achieving its conversion into high value-added products like fuels and chemicals have been proposed to reduce its concentration[1].

Photocatalysis, intended in this case as CO_2 photoreduction in presence of water vapor, is an alternative catalytic approach, which exploits solar energy as an abundant, unlimited, renewable energy source to enable carbon dioxide conversion into different solar fuels[2], without requiring additional energy input to make the reaction take place. Perovskites such as barium titanate ($BaTiO_3$) and calcium titanate ($CaTiO_3$) are promising photocatalytic materials which show good photostability, corrosion resistance in aqueous solutions and band gap necessary to obtain all the products of carbon dioxide reduction. However, they absorb UV radiation, which constitutes only 4% of the solar spectrum.

The goal of this study aimed at designing efficient photocatalytic materials to enable CO_2 photoreduction under solar light. $BaTiO_3$ and $CaTiO_3$ perovskites were prepared via hydrothermal synthesis and doped with non-metal dopants.

The materials were characterized through FT-IR, DRS, SEM-EDX, TEM, N_2 physisorption, and XRD techniques and then tested in the CO_2 photoreduction in a gas phase batch reactor.

Bare barium and calcium titanates were not active under solar irradiation, however doped perovskites showed good photoactivity under the same conditions. Compared to the bare perovskites, doping the materials with heteroatoms, likely led to a narrowing of the band gap, demonstrating their activity in the visible region of the spectra. N-doped $CaTiO_3$ showed the best photocatalytic activity reaching a TON equal to 1,8 $\mu mol/g_{cat}$ relative to methane production.

The design of polymers from renewable sources or wastes is one of the most intense field of research in the drive towards a fully sustainable and circular bioeconomy. Substances like phenols, terpenes, vegetable oils, are eligible raw materials for the manufacture of a variety of polymeric materials, including elastomers, plastics, hydrogels, and composites.[1] Herein we present the use of bioactive natural phenols, tyrosol (Ty) and eugenol (EU), as building blocks for the obtainment of bioactive polymers. Ty is an abundant phenol in olive oil mill wastewater while EU is a phenolic monoterpenoid obtained mainly from clove oil and lignin. Both compounds were functionalized with acrylic moieities to obtain polymerizable monomers. In the case of EU, the allyl group was submitted to epoxidation and then reacted with 2-hydroxyethyl methacrylate (HEMA) to obtain EUMA monomer (Figure 1).[2]

.

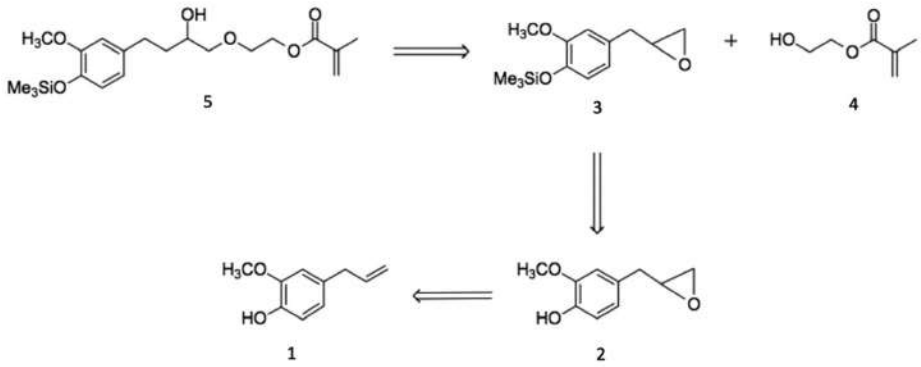

Figure 1: Retrosynthetic pathway for the synthesis of an eugenol-methacrylate monomer

The synthesized copolymers showed significant elastomeric properties and swellability degrees related to the phenol group content. A relationship between polymer composition, structure and biological activity was found. Currently, the synthesised phenol-based acrylic monomers are being tested in additive manufacturing processes to obtain insoluble manufacts with desired geometry and biological features.

riccardo.gallorini@unifi.it

The pressing environmental concerns related to fossil fuel consumption and the growing global demand for energy, chemicals and materials greatly encourage the development of technologies to replace oil with renewable carbon sources[1]. In this context, lignocellulosic biomass (i.e., plant-derived feedstock, particularly from non-edible sources) stands out as a promising alternative carbon source due to its high availability and versatility. The conversion of waste biomass not competing with the food industry, in compliance with the RED II Directive, offers an efficient strategy to produce biofuels for the transport sector while also playing a crucial role in generating secondary raw materials, thereby providing a viable alternative to the fossil-based economy. This work focuses on different thermochemical conversion methods (pyrolysis[2], HTL[3] and HTC) in order to evaluate the most suitable strategy to obtain high value-added products and mainly bio-fuels form residual biomass. The use of different processes and reactors (microwave oven and stainless-steel autoclave), as well as the choice of appropriate reaction conditions in terms of temperature, time, and catalysts, promote the synthesis of the target fraction and affect its chemical-physical composition. Characterization of the products (solid, liquid and gas) was essential to assess the difference effects between the strategies and reaction conditions employed. Emphasis was placed on the chemical characterization of liquid fractions to assess the distribution of different classes of organic compounds, in particular aliphatic and aromatic hydrocarbons. Furthermore, the surface characterization of the solid fractions led to evaluate the most suitable conditions for the production of bio-materials. The study explores the possibility to produce biofuels and high value-added products from waste biomass in a circular economy perspective.

stefano.gazzotti@unimi.it

In the last years, the world of microporous materials has seen a major development, given their outstanding chemical and physical features. Among them, Covalent Organic Frameworks (COFs) are flourishing. COFs can be defined as 2 or 3D networks based on covalent bonds and fully organic structures.[1] They are synthesized starting from monomers with multiple complementary functionalities that combine to form highly ordered and crystalline materials. On paper, almost infinite combinations of monomers can be targeted, leading to an incredible variety of different COF structures. As expected, their properties depend on their structure and, in turn, given the great amount of different available motifs, COFs are characterized by a wide array of different chemical and physical properties.[2] This versatility makes these materials widely applicable in many different fields that go from catalysis to electrochemical applications, through gas and energy storage, just to name a few. Despite the great interest in the field, a possible industrial applicability of COFs has been hindered by some drawbacks, amongst which an inherent lack of processability is one of the most significant. COFs are usually obtained as powders and it is almost impossible to process them in complex shapes with good control.[3] This work aims at solving this shortcoming through a polymer-supporting strategy. Different COFs have been synthesized and then exploited as active components in the synthesis of different polymers. This approach allowed the direct growth of polymeric chains on the COF backbone. These polymeric chains are expected to arrange between the COFs' layers, resulting in an improved processability, possibly close to the one of more classical thermoplastic materials. The covalent bond between the COFs and the polymeric chains has been assessed as well as the thermal and morphological properties of the resulting materials. Processability tests were also carried out, with the successful preparation of films through solvent casting.

The need of a green transition requires new ways to produce and store energy. Among different possibilities, green hydrogen produced from anion exchange membrane water electrolysers (AEM-WE) is one of the most appealing. However, AEMs need substantial improvements to reach longer life cycles and higher efficiencies. Because of this issue, different polymeric backbones and charged groups can be tried to tune properties up to a satisfying level.

In this abstract, we present our research concerning AEMs for water electrolysers based on a functionalised low molecular weight polyketone (PK). We report the functionalisation of PK through a Paal-Knorr reaction using a diamine that can then be quaternised with an alkyl iodide during the casting process to obtain an AEM[1] (Figure 1). Different diiodides, ranging from diiododecane to diiodobutane, have been used together with iodobutane in various ratios to explore thermal and mechanical properties of the resulting membranes.

Membranes have been characterised with common techniques coupled with Solid State NMR (SSNMR) spectroscopy and relaxometry. ^{1}H, ^{13}C and ^{2}H spectra and proton spin lattice relaxation times have been used to get information on possible phase segregation and to monitor the degree of cross-linking achieved in the membranes. Moreover, SSNMR techniques were applied to membranes hydrated with either normal or deuterated water to study water mobility and the formation of ionic channels.

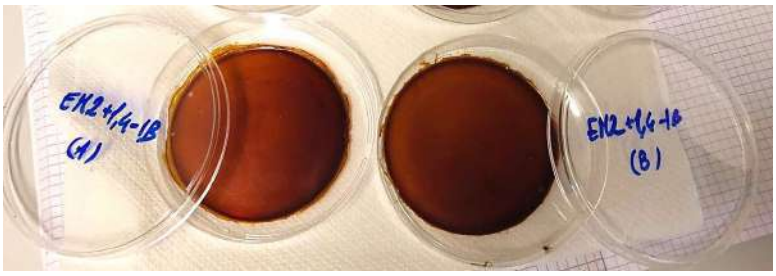

Figure 1: AEMs based on functionalised polyketone obtained through a one-step casting-quaternisation procedure.

Ivan.grigioni@unimi.it

Electrochemical CO_2 and CO reduction reactions (CO_2RR and CORR) with renewable electricity enable the recycling of CO_2 waste into energy-rich chemicals conventionally produced from fossil resources.[1] Liquid hydrocarbons (e.g. formate, ethanol, acetate, and propanol) are widely employed commodity chemicals and can be produced via CO_2RR and CORR. Therefore, we sought to develop electrocatalysts with high selectivity (Faradaic Efficiency, FE) to formate,[2] acetate,[3] and ethanol operating at reaction rates (current densities) of industrial interest.[4]

Upgrade of CO to hydrocarbons favors high selectivity toward long hydrocarbon (C_{2+}) products. Additionally, the low solubility of CO in aqueous electrolytes results in increased energy efficiencies when CO_2RR-to-CO is followed by CORR-to-hydrocarbons.

In one of our recent works, to exploit the advantages of CORR, we developed a carbon reservoir catalyst (CRC architecture, Figure 1) where nitrogen-doped carbon nanoparticles increase CO availability close to Cu catalytic nanoparticles, enabling electrosynthesis of ethanol with high selectivity, energy efficiency, and disfavouring hydrogen evolution from water-based electrolytes. With this CRC catalyst, we achieve ethanol FE and CE of 50% and 93% (CE*Faradaic efficiency [FE] = 47%) at 200 mA cm^{-2}.

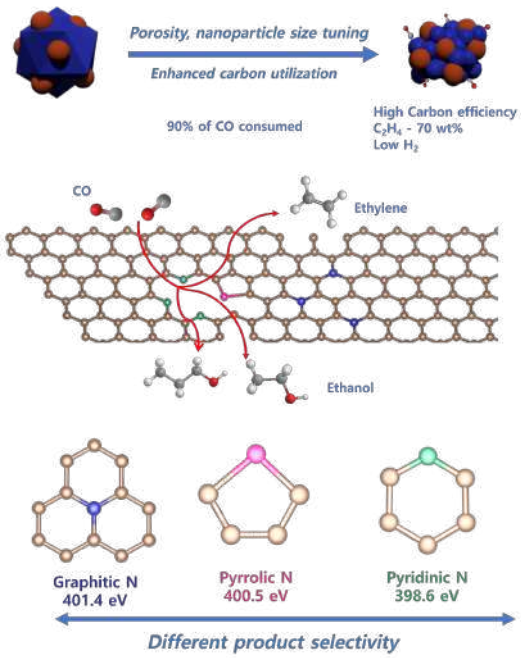

Figure 1: the CRC electrocatalyst architecture from the nano to the atomic scale.

raimondo.insogna@scitec.cnr.it

The recently emerged Inverse Vulcanization (IV) process enables the up-cycling of elemental Sulfur, the main by-product of oil and gas refining, and leads to a new class of amorphous polymers consisting of polysulfide chains cross-linked by organic divinyl moieties.[1] Due to their peculiar nature, inverse vulcanized polymers (IVPs) exhibit unique functional properties, such as dynamic covalent behaviour and self-healing capability. IVPs also boast very high refractive index and excellent transparency in the near infrared region, which make them appealing building blocks for functional photonic structures.[2] All-polymer photonic crystals are indeed technologically interesting for materials affordability, fabrication simplicity and scalability. However, their application in the field of light confinement is still limited by low and similar refractive indices typical of most processable polymers in their transparency range.

Here, novel IVPs with a very high refractive index were synthetized using specifically designed vinyl aromatic derivatives as cross-linking monomers, which were obtained from the corresponding bromide substrates by a single step Suzuky-Miyaura cross-coupling reaction. Comonomers type and amount were varied to enhance both the optical behaviour and filmability. The achieved IVPs were then successfully used to fabricate all-polymer distributed Bragg reflectors (DBRs), see Fig. 1.

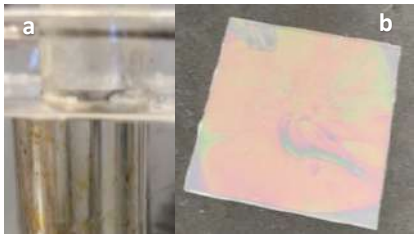

Figure 1: a) Reaction vessel during the IV process; b) a DBR fabricated with a synthesized IVP.

The generation of spent lithium-ion batteries (s-LIBs) worldwide amounts to millions of tons annually. While current recycling methods focus on extracting valuable metals like Ni, Co, and Li, they suffer from poor selectivity, high energy requirements, and expensive by-product management. Consequently, there's growing interest in exploring alternative methods for the direct reuse of s-LIBs [1]. At the same time, lignocellulosic and agro-industrial waste and residues represent a central feedstock for modern biorefineries aimed to the sustainable production of renewable energy and biobased materials and chemicals [2]. Technologies such as hydrothermal carbonization (HTC) have been proposed to upgrade orange peel waste (OPW), yielding hydrochar (OPW-HC) and liquid bio-oil (OPW-OIL), rich in furans derivatives like furfural and 5-HMF, pivotal in modern biorefineries [3]. OPW-OIL can be very rich in furans derivatives (furfural and 5-HMF) that represent one of the most important classes of intermediates in modern biorefineries.

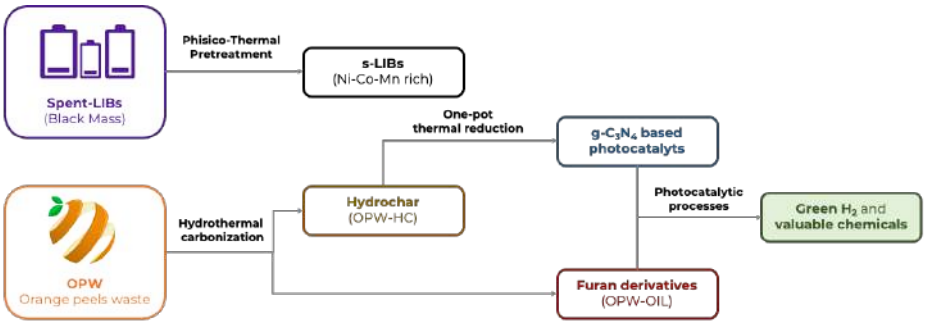

Figure 1: Development of low-cost and robust heterogeneous photocatalyst.

Starting from these two abundant wastes, we propose a simple direct approach to transform s-LIBs into a lithium (Li)-Co-Ni-Mn doped graphitic carbon nitride composites through one-pot in situ thermal process by using hydrochar as co-catalysts to improve the photocatalytic activity in H_2 production and value-added chemicals.

Ammonia poses a threat to biodiversity in aquatic environments, having toxic effects on fish living in freshwater and seawater.[1] In this work, we have designed a photoelectrochemical reactor and tested in a recirculating aquaculture system (RAS, Fig.1a). This technology exploits the UV-electrochlorine advanced oxidation process to improve water quality and fish welfare, performance and sustainability. The photoanode is prepared by anodization of a metal titanium mesh in a ethylene glycol, water and hydrofluoric acid electrolyte solution at 30 V for 6 h in order to obtain a self assembled titania nanotube arrays film (Fig.1b). The illuminated semiconductor film promotes the oxidation of chloride ions naturally present in fresh- (or sea-) water, to chlorine radical which is highly reactive and selective in ammonia oxidation yielding N_2 or nitrate. [2] Preliminary ammonia degradation tests were performed in 5·mM KCl cotaining 100 ppm NH_3 solutions at 4 V potential bias. A stable photocurrent up to 550 mA under UV- irradiation was obtained during the test (Fig.1c).[3] An almost full ammonia conversion was reached after 6 h-long test with a selectivity towards N_2 and NO_3^- of 80% and 20%, respectively. The setup has been shown to be biocompatible in a real rainbow trout farming plant[4] showing a lower nitrate accumulation in water with respect to a traditional bio-filter.

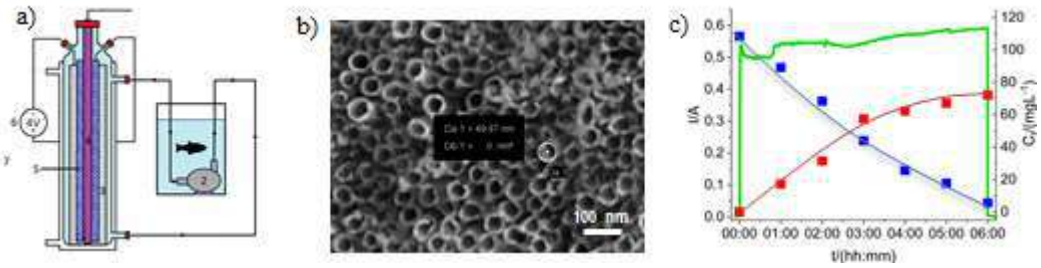

Figure 1: a) Titania Nanotubular film; b) Schematic of the PEC reactor and experimental setup; c) Ammonia degradation and photocurrent performance: Current (green), NH_4^+ concentration (blue), NO_3^- concentration (red)

riccardo.manfredi@cnr.it

Energetically autonomous systems based on lead-free smart materials and energy harvesting devices that reduce consumption of fossil energy resources (no need for battery replacement or recharging) while significantly lowering overall materials and processing costs, operation times and hazardous waste production fully meet the increasingly pressing global environmental challenges. In this framework, polymer-matrix composites embedding ceramic fillers with different functionalities are attracting a great deal of interest for a range of applications, including high-storage-efficiency capacitors, flexible piezoelectric harvesters and portable devices, also exploitable for self-powered electronics, such as wearable or implantable medical devices, safety-monitoring IoT systems, consumable electronics. Polymer-ceramics composites indeed combine typical properties of polymers, as easy processing at low temperature, flexibility and high breakdown strength (BDS), with the dielectric and piezoelectric properties of ceramics, typically ferroelectric perovskites, such as $BaTiO_3$ (BT) and $Ba_{1-y}Ca_yZr_xTi_{1-x}O_3$ (BCTZ). Among polymer matrices, poly(vinylidene difluoride) (PVDF) is largely investigated because it exhibit relatively high dielectric constant, low dielectric losses, ferroelectric character and remarkable BDS, besides being non-toxic and biocompatible.

Here, based on previously achieved results,[1,2] PVDF-BT composite films at 30 vol% of ceramic particles were prepared exploiting and comparing different preparation techniques: namely, solvent casting, melt blending and microwaves heating all followed by a compression moulding step, or directly by hot pressing.

A multi-level characterization of the prepared composites was performed to investigate morphology, mechanical performance and functional properties, thus gaining an insight into the comprehension of process-structure-properties relationships required for the optimization of the envisaged final harvesters based on these flexible piezoelectric composite films.

The use of light in polymer science opens up to multiple opportunities. Among them, exploiting photopolymerization processes, specifically designed materials can be printed allowing for 3D structure preparation at different scales. In this communication, the use of Direct Laser Writing, a technique based on two-photon polymerization, will be presented to realize 3D micrometric objects by shape-changing Liquid Crystalline Networks (LCNs). Such materials are crosslinked polymers prepared by a mixture of reactive mesogens (Figure 1a) able to convert energy from external stimuli (as light) into mechanical motion. Their chemical composition can be tailored to achieve different mechanical properties and to modulate force production during actuation. With this materials, we demonstrated different synthetic micrometric robots entirely powered by light and able to reproduce diverse animal behaviour. Developed microrobots are able to perform humanoid tasks, as walking and swimming, but also to grab and manipulate objects.[1]

In the last year, we have also demonstrated more complex smart microdevices useful for photonic or information encryption systems. In both cases, material shape, birefringence (Figure 1B) and their variation under stimuli have been carefully engineered to demonstrate 3D photonic crystals able to work as tuneable filters for telecommunication wavelenght[2] or an array of responsive pixels able to show or hidden basic information.[3] These examples demonstrate how to introduce enhanced functionalities in smart microsystems spanning from storage devices with physical encryption to complex motion actuators.

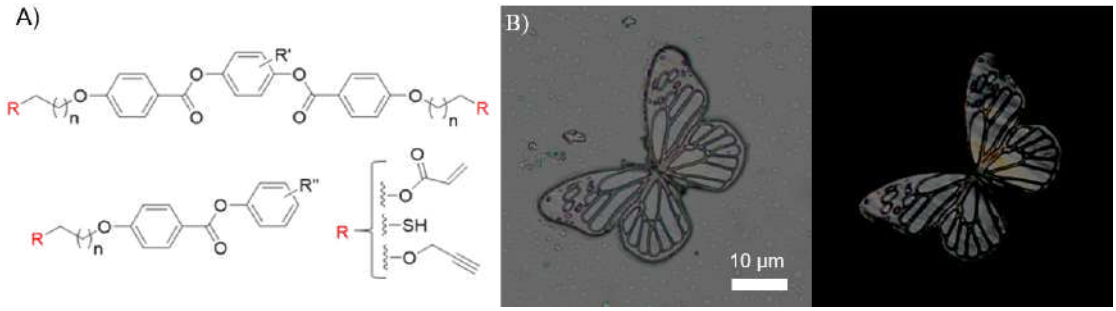

Figure 1: Examples of reactive mesogens (A) and a 3D printed butterfly observed without or with polarized light (B).

The growing demand for sustainable energy, fuels, materials, and chemicals production has led to the exploration of alternative biobased feedstocks that can be processed by modern biorefineries. Among these, levulinic acid and alkyl levulinates obtained from lignocellulosic biomass are particularly interesting, as they can be used to synthesize various value-added chemicals, including γ-valerolactone (GVL). GVL is a fully degradable, non-toxic green solvent, a precursor for valuable chemicals, and a potential fuel additive [1-3].

Currently, most published studies on the hydrogenation of levulinic acid and its esters utilize ZrO2-based catalysts under batch conditions with pressurized molecular hydrogen. However, these catalytic processes often lack selectivity and are challenging to scale up. In contrast, catalytic transfer hydrogenation (CTH) offers a more suitable and sustainable alternative to traditional hydrogenation methods, as it utilizes organic molecules like alcohols that act as hydrogen donors toward the carbonyl group in the presence of a catalyst containing both acid and base Lewis sites. In this study, the catalytic conversion of methyl levulinate (ML) into γ-valerolactone (GVL) through catalytic transfer hydrogenation (CTH) [4] using 2-propanol as the hydrogen donor/solvent is presented under both batch and continuous flow conditions. A series of Al_2O_3-ZrO_2/C catalysts with varying Al/Zr ratios were synthesized using Metal-Organic-Frameworks (MOFs) as sacrificial templates. The reactions conducted under continuous flow conditions were significantly more efficient compared to those carried out under batch conditions, yielding excellent GVL yields. Furthermore, the activity results showed that the addition of Al2O3 improved the catalytic performance in terms of both ML conversion and selectivity towards γ-valerolactone (GVL) by increasing the content of both Lewis acid and base sites.

The achieved results represent significant progress in the selective production of GVL from methyl levulinate, as it combines the preparation of highly active non-noble metal catalysts with the use of a more sustainable catalytic process under continuous flow conditions.

Immobilizing lytic polysaccharide monooxygenases on carbon nanotubes to increase stability and prevent oxidative damage

C. Pontremoli[1], K. Hall[2], F. Careddu[1], M. Bonomo[1], T. Emrich-Mills[2], N. Barbero[1], C. Barolo[1], V.G.H. Eijsink[2], M. Sørlie[2], S. Bordiga[1]

carlotta.pontremoli@unito.it

Thanks to their excellent functional properties, enzymes can catalyse several complex chemical processes under mild conditions and are potentially excellent catalysts for a more sustainable chemical industry. However, low stability and tendency to be inhibited by substrates, products or solvents, limit their application for nonbiological purposes. A promising and successful strategy to improve enzyme stability in industrial settings is the enzyme immobilization onto a suitable carrier, following simple and cost-effective protocols.

Lytic polysaccharide monooxygenases (LPMOs) are mononuclear copper-containing enzymes found in the majority of cellulolytic fungi and actinomycete bacteria that are able to oxidize C–H bonds of the glycoside linkages in polysaccharides[1–3]. However, LPMOs are prone to oxidative damage, particularly in the absence of an adequate substrate[2]. The aim of this contribution is to develop a possible bio-catalyst for C-H activation reactions, based on bioconjugation of LPMOs to Carbon Nanotubes (CNTs), in order to stabilize the biological partner without jeopardizing its catalytic ability. CNTs have been selected since they are conductive, thus allowing the electron transfer processes fundamental to optimize the LPMO activity. Two LPMOs, *Ls*AA9A and *Sc*AA10C, containing lysine residues close to the substrate binding surface, were selected encouraging immobilisation in the desired orientation. Moreover, to increase the chances of successful immobilisation, these enzymes were engineered, introducing two lysine residues on two different loops on the LPMO surface.

Using a two-step carbodiimide activation/immobilization reaction, enzymes were immobilised on multi-walled COOH-CNTs. After the reaction, the oxidase[4] and peroxidase[5] activities of the LPMO bioconjugates was assessed, demonstrating a successful immobilization just for the engineered enzymes. The results on oxidative damage showed that the inactivation of both free LPMOs is already evident after only 10 minutes with less than 20% residual activity, while the bioconjugates retained around 70% residual activity under the same conditions, indicating that the CNT is successful in protecting the LPMO against oxidative damage.

The stability of the enzymes was finally assessed by using circular dichroism, incubating the bioconjugates at different temperatures and in presence of different organic solvents.

Two birds with one stone: green NH_3 production from stationary NO_x emissions

A. Porta, G. Nava, R. Matarrese, L. Lietti

Dipartimento di Energia, Politecnico Di Milano, via Lambruschini 4, Milano, 20156, Italy
alessandro1.porta@polimi.it

Green ammonia is expected to play a crucial role in the energy transition as it serves as a sustainable base chemical and a versatile energy carrier. With its potential to store and transport hydrogen, it will facilitate the integration of renewable energy sources into various sectors, thus accelerating the shift towards a cleaner and more resilient energy infrastructure[1]. Nowadays, NH_3 production is energy intensive, as the energy required to sever the N-N bond is significant. NO_x is a waste toxic compound present in combustion flue gases, which is nowadays abated using NH_3 as a reactant according to the well-established SCR process to comply with environmental regulations. In this scenario, the production of green ammonia using NO_x as N source is very appealing[2], as it could turn emission abatement from a cost to a potential resource, allowing for a decentralized production of green NH_3.

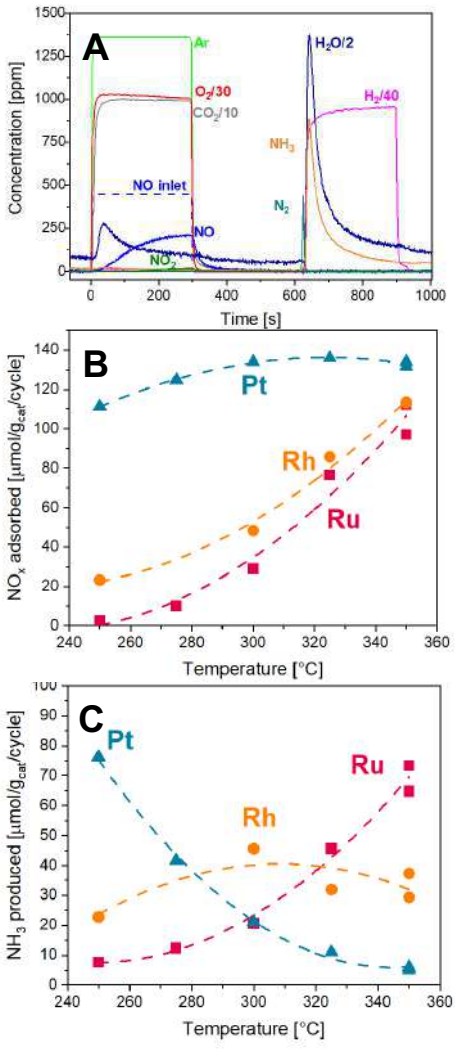

Figure 1: A: cycle at 250 °C with 1% CO_2, 3% O_2 and 500 ppm NO (adsorption) and 4% H_2 during (reduction) on Pt-DFM; **B:** Stored NOx as a function of T; **C:** NH_3 productivity as a function of T

A possible way to abate NO_x while producing NH_3 is to use Lean NO_x Traps (LNTs) materials for NO_x abatement from mobile sources. These catalysts rely on a cyclic process: they can adsorb NO_x when exposed to flue gases; once the trap is saturated the atmosphere is switched to reducing conditions to convert NO_x to N_2 while regenerating the trap. By twisting the formulation and process conditions of LNTs it should be possible to steer the selectivity of the process towards NH_3 rather than N_2.

We have effectively demonstrated this using three home-made catalysts based on 1% Pt, 0.5% Ru or 0.5% Rh, each supported on Al_2O_3 and promoted with Ba. By working at 250°C on a Pt-based catalyst, we managed to obtain a significant NO_x adsorption and a complete regeneration of the adsorbent when exposed to H_2 (Fig. 1A), with a selectivity to NH_3 in excess of 75%, yielding a production of 80 µmol/g/cycle of NH_3. At higher temperatures the amount of adsorbed NO_x increases slightly (Fig 1B), but the NH_3 selectivity drops due to the faster kinetics of N_2 formation causing an overall decrease in NH_3 production (Fig 1C). Ru and Rh show 100% NH_3 selectivity below 300°C, but are unable to store significant amount of NO_x at these temperatures. Operando FT-IR tests are currently ongoing to disclose mechanistic aspects of the reaction.

Blending or bonding? Benzothioxanthene derivatives as emitters in Luminescent Solar Concentrators based on poly(methyl methacrylate) from recycled sources

H. Pryshchepa,[a] A. Picchi,[a] M. Carlotti,[a,b] A. Pucci,[a,c]

hanna.pryshchepa@dcci.unipi.it

Many conjugated planar fluorophore structures utilized for the preparation of poly(methyl methacrylate) (PMMA) Luminescent Solar Concentrators (LSC) face concentration quenching due to the presence of free dye molecules that phase separate from the host polymer matrix, even at relatively low concentrations.[1] One potential strategy to mitigate this effect without diminishing the fluorophore quantity is the covalent integration dye into the polymer chain through co-polymerization with a monomeric unit functionalized with the fluorophore molecule. Benzothioxanthene (BTX) imides have shown promising emitting properties in solution[2] and comparable to commonly used perylene diimides (PDIs). Also, considering the mono-substitution, they are the best candidate since they prevent cross-linking during the polymerization process. Notably, two BTX derivatives were synthesized as fluorophores: i) BTX-EH, which was dispersed within the PMMA matrix; ii) BTX-MA, containing a methacrylic group suitable for co-polymerization with MMA. All devices were based on PMMA manufactured through free-radical polymerization of chemically recycled methyl methacrylate (r-MMA), which exhibits similar properties to virgin methyl methacrylate, but with a lower environmental impact. LSCs with varying fluorophore concentrations (100, 200, 300 ppm) were characterized by determining internal (η_{int}) and external (η_{ext}) photon efficiencies, as well as the fluorophore quantum yield (QY),[3] and the properties compared to define the best (blending or bonding) formulation strategy.

Kinetic investigation of Ammonia Decomposition over Ru-based Catalysts for Hydrogen Production

Yi Qiu, Federico Sascha Franchi, Nicola Usberti, Alessandra Beretta

Dipartimento di Energia, Politecnico di Milano, Via Lambruschini 4, 20156, Milano, Italy
yi.qiu@polimi.it

Hydrogen (H_2) is considered as one of the most prospective energy carriers for the future energy systems[1]. Ammonia (NH_3) as a promising H_2 carrier, has attracted increasing attention, due to its well established production and distribution infrastructure, zero carbon emissions during dehydrogenation and no side reactions[2]. Ru is the most active metal for NH_3 decomposition[3]. In this work, a kinetic investigation of NH_3 decomposition was performed over Ru-based catalysts, with a systematic experimental and modelling work.

Ru/γ-Al_2O_3, Ru/MgO and Ru/$MgAl_2O_4$ catalysts were prepared via an incipient wetness impregnation. Catalysts were characterized by BET, ICP-MS, H_2-chemisorption and NH_3-TPD. NH_3 decomposition was tested in a micro fixed bed reactor with diluted NH3-feeds, in order to guarantee isothermal conditions. Tests were thus simulated by a an isothermal 1D pseudo-homogeneous reactor model. Gas composition was analysed by an on-line MS. In all the test, GHSV=20000 Nl/h/Kg_{cat}.

Catalytic tests showed the activity order: Ru/$MgAl_2O4$ > Ru/MgO > Ru/γ-Al_2O_3 (Figure 1). The kinetic investigation indicated an apparent negative order with respect to NH_3 (Figure 2), but H2 cofeed tests (Figure 3) revealed that the reaction is strongly inhibited by H_2, such that first order dependence on NH_3 is recovered at large H_2 feed content.

A simple power-law expression $r = \mathrm{k(T)} * \frac{P_{NH_3}}{P_{H_2}^{1.5}}$ could well explain the data, suggesting that the rate-determining step is within the NH_3 dehydrogenation pathway. The same dependencies were found over all the catalysts despite the different activity.

Integrated valorization of paper mill wastes for the sustainable production of chemicals and energy

A.M. Raspolli Galletti,[a] L.Bonaldi,[a] R. Lorè,[a] D. Licursi,[a] S. Fulignati,[a] N. Di Fidio,[a] C. Antonetti,[a] S. Frigo[b]

anna.maria.raspolli.galletti@unipi.it

The great world production of paper and paperboard (more than 400 Mt/a) involves the production of significant amounts of waste streams[1]. A cellulose-rich waste (CRW) and the inorganic-rich waste (IRW), supplied by the company Lucart Group, resulted particularly interesting for chemical and energy valorisation as an alternative to costly disposal. CRW, deriving from the converting step, has a content of glucan of 75 wt % but cannot be reused within the paper mill process, while IRW contains 70 wt % of $CaCO_3$ and about 25 wt % of cellulose. Due to its high cellulose content, CRW was employed as substrate for the one pot acid-catalyzed conversion to ethyl levulinate (EL) using ethanol as reagent and reaction medium. The increasing interest towards EL is related to its outstanding characteristics: EL is a promising versatile biofuel which can be employed as bio-blendstock in both diesel and gasoline engines, and also an intermediate for the production of plasticizers, solvents and pharmaceuticals.[2] The optimization of the ethanolysis process, performed in the presence of 1% sulphuric acid, allowed to reach EL yields of 45 mol%, an important achievement given the simplicity of the process involved.

On the other hand, the IRW was employed in a oxy co-gasification process for energy recovery through the production of syngas adopting a downdraft fixed bed reactor with O_2/H_2O as gasifying agents. A blend of IRW and wood pellets in 1/5 wt/wt ratio was adopted as substrate. Notably, the co-gasification in the presence of IRW produced a syngas characterized by high hydrogen content (40 mol %) and CO (21 mol %). Moreover, tar compositional analysis revealed the presence of long-chain (C_{19}-C_{39}) and polyaromatic hydrocarbons. Finally, the ash characterisation evidenced the formation of good quality CaO deriving from $CaCO_3$ decarbonisation, which can be exploited in the paper mill process itself in a circular economy perspective.

A unified approach for the synthesis of heteroaromatics by combining decatungstate photocatalysis and Paal-Knorr reaction in flow

F. Sacchelli,[a] M. Pessina,[a] N. Della Ca',[a] D. Ravelli,[b] L. Capaldo[a]

filippo.sacchelli@unipr.it

Heteroaromatics are coveted scaffolds in pharmaceuticals, agrochemicals and material science: their expedite synthesis is therefore of prime importance. A privileged access point to these precious motifs is the Paal-Knorr approach, especially for the synthesis of five- and six-membered heterocyclic compounds including furans, thiophenes, pyrroles and pyridazines. This approach demands for the wide availability of 1,4-diketones. Consequently, substantial efforts have been directed towards to developing efficient methodologies for preparation of such compounds[1,2]. A very convenient method consists in the decatungstate (DT)-photocatalyzed hydrogen atom transfer (HAT) acylation of electrophilic olefins, which starts from readily available raw materials such as aldehyde and α,β-unsaturated carbonyl compounds[3].

In this study, we present a unified strategy for a streamlined two-step synthesis of heteroaromatics, combining decatungstate photocatalysis and the Paal-Knorr reaction in flow conditions (Figure 1). The first photocatalytic step involves the reaction between an aldehyde and a vinyl ketone to obtain 1,4-diketone via DT-photocatalyzed HAT, which occurs in 5 minutes. Without isolating the intermediate, the diketone enters a second reactor and is reacted with amines, Bronsted acid, Lawesson's reagent, and hydrazine to afford pyrroles, furans, thiophenes and pyridazines, respectively. For example, the modular nature of our method allowed for the tailored, on-demand synthesis of pyrroles in 6 minutes residence time with a Space-Time Yield (STY) of 47 kg h^{-1} m^{-3}, thus offering an operationally simple and scalable route to these commercially relevant scaffolds.

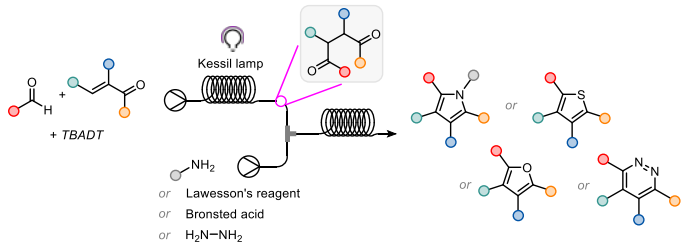

Figure 1: A unified telescoped approach for the synthesis of heteroaromatics.

New materials from lignocellulosic biomasses valorisation

Antonella Salvini,[a,b] Stefano Fabbri,[a] Alice Cappitti,[a] Samuele Visi,[a], Monica Tonelli,[a] Debora Pratesi,[a] Camilla Matassini,[a], Donatella Giomi,[a,b]
[a] Department of Chemistry "Ugo Schiff" University of Florence, Via della Lastruccia 3-13, 50019 Sesto Fiorentino
[b] Laboratorio congiunto VALORE", via della Lastruccia 3-13, 50019 Sesto Fiorentino (FI), Italia)
antonella.salvini@unifi.it

Lignocellulosic biomass is very widespread in nature and its use as a raw material has the advantage of not being in competition with its use in the food and feed supplies[1]. There are also numerous types of waste lignocellulosic biomasses whose valorisation represents an advantage not only for the use of renewable raw material but also for the possibility of reducing the environmental impact of their elimination as waste. Furthermore, in recent years the exploitation of renewable materials from biomass represents a strategic objective for the chemical industry to reduce the depletion of fossil resources while solving waste disposal problems at the same time.

Based on this, the study of new materials with high added value, that can be obtained from the valorisation of waste biomass, is extremely interesting. In particular, cellulose and other polysaccharides can be recovered from biomass waste using specific protocols optimized based on the different composition of the biomass[2]. The mechanical, physical and chemical treatments must be optimized based on the type of biomass studied.

However, to obtain sustainable production processes, even starting from waste materials, it is essential to limit transformation stages with high energy consumption or with the use of high quantities of reagents and solvents, trying to optimize the complete recovery of the biomass.

The objective of this research was therefore a protocol for a low environmental impact biorefinery process for the extraction and/or valorization of cellulose from fibres of a lignocellulosic biomass, aimed at subsequent use in the production of biobased products such as gels, films and panels insulators, intended for processes of interest to various sectors such as the construction one. The main biomass used in this study is *Posidonia Oceanica* Sea Balls (eagropili), a biomass of photosynthetic origin widely present on the coasts of the Mediterranean Sea, often destined for disposal but with the aim of extending the optimized procedures also to other types of waste lignocellulosic material.

Novel approach to produce green aromatics from ethanol and furfural

F. Sandri,[a] N. Kumar,[a] P. Mäki-Arvela,[a] D. Y. Murzin[a]

[a]*Johan Gadolin Process Chemistry Centre, Åbo Akademi University, Henriksgatan 2, 20500, Turku, Finland*
Francesco.Sandri@abo.fi

Aromatic compounds, in particular benzene, toluene and xylenes (BTX) have very broad applications in chemical industry. Production of aromatic hydrocarbons is based only on petrol-based feedstock. Therefore the manufacturing of green BTX from renewable raw materials would widely increase their sustainability.[1] In a very innovative work Gancedo et al.[2] proposed an alternative route for the production of aromatics starting from furfural (FFL) and ethanol (EtOH), both coming from renewable feedstock. The reaction network involves the decarbonylation of FFL to form furan and the dehydration of EtOH to form ethylene and the condensation via Diels-Alder cyclization to form BTX. All these steps are acid catalysed reactions and the catalyst used is a commercial HZSM-5 zeolite. In the present work this novel approach for the production of aromatics is more deeply investigated, focusing on the effect of experimental conditions, such as reaction temperature and composition of the feed, as well as the physico-chemical features of the catalysts such as aluminium content and the metal-doping of the catalyst with acid metals (mainly Zn and Ga).

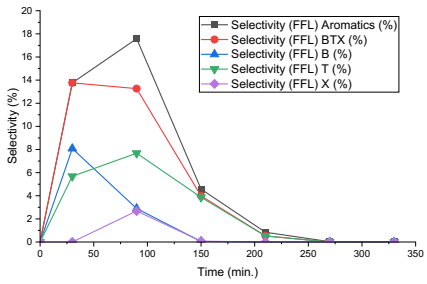

Figure 1: Results of catalytic experiment with H-ZSM-5 40, Selectivity of furfural towards aromatics.

Preliminary studies demonstrated that the H-ZSM-5 zeolite catalyst with Si/Al ratio of 40 is the most active in the production of aromatics (Figure 1), while lower or higher Si/Al ratios are leading to fast catalyst deactivation or absence of production of aromatics, respectively. With all catalysts the production of aromatics stops after 4 hours TOS, whereas the reaction rate of dehydration of EtOH and decarbonylation of FFL are 10% when compared to first 3 hours TOS. This suggests the presence of the catalytic sites of different nature, with only a part of these active in aromatization that suffer from deactivation. With experiments using the single reagents it can be demonstrated that benzene and toluene are mainly produced from EtOH, while xylenes and heavier aromatics are deriving from FFL as well as benzofuran, which is likely the cause of poisoning of the catalytic sites active in the aromatization. Results with metal-doped zeolites will be also presented.

domenico.santandrea@unive.it

Due to the constant increase in society's interest in the realization of ecological transition highlighted by EU Directive 2019/904, the scientific community has increased the focus on the valorization of biomass. Thanks to its abundance in nature and its biodegradability, cellulose is one of the most studied biopolymers, however it also has some disadvantages, which limit its potential: it is insoluble in water, hydrophilic and the defibrillation process are energy intensive. For these reasons, the scientific community has focused attention on the possibility of obtaining more processable nanoscale cellulose derivatives Among others, Isogai et al. in 2011 proposed a method to obtain a stable suspension of C6-oxidated cellulose nanofibers by treatment of cellulose in the presence of the TEMPO/NaBr/NaClO system (TEMPO-oxidized-cellulose nanofibrils TEMPO-ox-CNF)[1]. TEMPO-ox-CNF has carboxyl groups on its surface which can be modified into ester or amide groups to improve its properties[2] or impart new ones[3]. In this contribution, the chemical grafting of TEMPO-ox-CNF by amidation with amines and diamines is proposed using 4-(4,6-Dimethoxy-1,3,5-triazin-2-yl)-4-methylmorpholinium chloride (DMTMM) as a condensing agent. The amidation reaction promoted by DMTMM has various advantages such as the use of water as a solvent and low temperatures. Its effectiveness has already been successfully demonstrated for obtaining high performance films[4]. The material obtained has been characterized by spectroscopic, thermal, and physical-mechanical investigations. Chemical grafting impacts various properties such as hydrophobicity with a significative improvement of contact angle from 40° to 90°.

Rice and soybeans are among the crops that generate the largest amounts of protein-rich waste, *e.g.* the protein content of rice bran and soy meal are 13-19% and 44-49%, respectively. Thus, they have high potential to be used as starting materials to produce value-added products.[1] To this aim, proteins contained in these agri-food waste must be extracted and separated from the other constituents of biomass, and then hydrolyzed. Enzymatic hydrolysis is an easily scalable, green and cost-efficient strategy which involves the use of proteases, eventually in combination with carbohydrases, to produce mixtures of peptides known as protein hydrolysates (PH), for which a number of applications have been reported. Among them, PH can be used as biostimulans in horticulture.[2] Studies show benefits of biostimulants on growth, yield, product quality, resource use efficiency and tolerance to environmental and chemical soil stresses of several horticultural crops[3,4]. In this work an in-depth investigation of different commercially available enzymatic formulations, experimental conditions (T, pH) and time of hydrolysis was performed to obtain soy PHs with biostimulant activity. A scale-up of the enzymatic reaction was also performed, using a 15L reactor. Five different prototypes of soy PHs were prepared, characterized by elemental analysis and subjected to ultrafiltration through increasing molecular weight cut-off membranes to get different peptide size fractions. Moreover, total and free amino acids in soy PHs were determined with RP-HPLC. Moreover, the biostimulant effect of soy PHs was evaluated on growth and quality of *Lactuca sativa* L. var. longifolia, both under nutritive stress and no stress conditions.

Mechanistic insights into r-WGS reaction on Rh and Pt via a combined experimental and structure-dependent microkinetic analysis

G. Spanò[a], L. Nardi[a], G. Contaldo[a], R. Cheula[a], C. Negri[a], and M. Maestri[a]

gabriele.spano@polimi.it

The Reverse Water-Gas Shift (r-WGS) reaction is pivotal among CO_2 utilization approaches since it produces CO, a fundamental block of the chemical industry. However, there are still a lot of debates concerning the precise mechanism of this reaction. We thus combined both theoretical and experimental methodologies to investigate how the reaction mechanism changes according to the oxygen-affinity of the surface, employing two catalyst materials with different oxophilicities, i.e., 4wt.% Rh/α-Al_2O_3 and 4wt.% Pt/α-Al_2O_3.

The reaction rate exhibited a direct proportionality on CO_2 concentrations for both catalysts but showed a significant dependency on H_2 only on Pt. Therefore, we proposed that, on Rh, CO_2 is activated through dissociation into CO^* and O^* (Fig.1a), while, on Pt, CO_2 activation occurs *via* a H-mediated route forming a $COOH^*$ intermediate (Fig.1b), in agreement with previous theoretical investigations from our group[1].

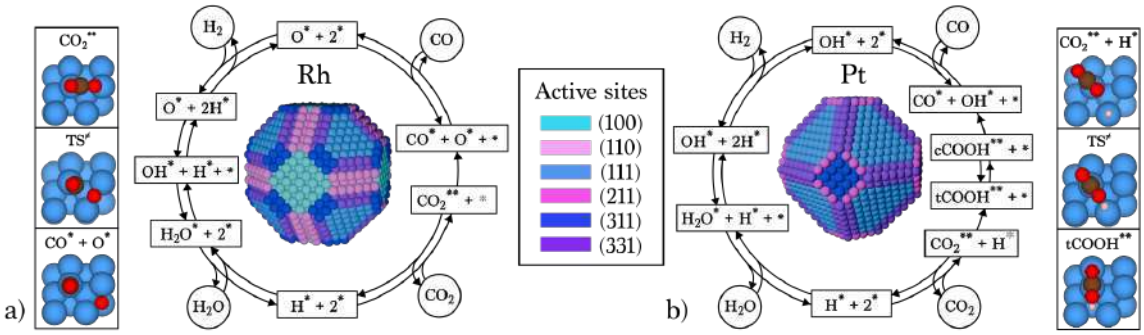

Figure 1: CO_2 activation and reaction mechanisms for r-WGS on Rh (a) and Pt (b).

To elucidate this mechanistic interpretation, we conducted a structure-dependent microkinetic analysis on both materials based on DFT calculations[2]. We found that CO_2 activation is the rate determining step on both catalysts and proceeds *via* dissociation into CO^* and O^* on Rh, while it follows a H-mediated route on Pt, in agreement with experiments. The microkinetic model accounts for both the activity and the abundance of a set of active sites exposed by catalyst nanoparticles. This structure-dependency inclusion was essential to identify the kinetically dominant active sites, i.e., Rh(100) and Pt(111) on Rh and Pt respectively, thus paving the way to derive fundamental rate equations for catalyst design and optimization. Project funded under PNRR-NextGenerationEU "Network 4 Energy Sustainable Transition – NEST".

alberto.soccio@issmc.cnr.it

Perovskite materials (ABX3) due to their optical and electronic properties have been exploited for energy and environmental applications, such as hydrogen production, CO2 reduction reactions and solar cells[1,2]. Recently, perovskites have been also considered to photo-electrochemically store hydrogen into ammonia molecule. Different types of perovskite materials, moving from halide inorganic perovskites to oxidic systems with single or double perovskite structure were considered as suitable and functional materials for this purpose. In this work, inorganic perovskites were produced considering different chemical approaches and structurally, optically and morphologically characterized. Chemical deposition techniques were optimized to create thin film for photo-electrode with suitable properties (characterized by FE-SEM and UV-Vis spectroscopy). The obtained photo-electrodes were tested electrochemically and photoelectrochemically in different conditions (suitable for ammonia production) using cyclic and linear sweep voltammetry and electrochemical impedance spectroscopy. The obtained results show the influence of perovskite composition and morphology on photoelectrochemical properties of the related photoelectrode.

tommaso.tabanelli@unibo.it

Fractionation of 2nd generation lignocellulosic biomasses is an essential step for biorefinery strategies to isolate and fully exploit cellulose, hemicellulose and lignin for the production of materials, fuels and chemicals. One of the most promising strategies aimed to lignin valorisation is based on the extraction, depolymerisation and simultaneous stabilisation of this fraction towards the production of low molecular weight lignin oil through the so called Reductive Catalytic Fractionation (RCF).[1] RCF is a catalyst dependent process capable of producing phenolic compounds and hemicellulose-derived polyols while preserving the carbohydrate cellulose pulp in the presence of a reducing agent, generally hydrogen. Supported noble metal catalysts over carbons or Al_2O_3 were found to be active;[1] however, one major issue, often underestimated, is represented by the inefficient catalyst recovery from the fibrous cellulose pulp which limits catalyst recyclability thus dramatically impacting the economic sustainability of the entire process at larger scale.[2]

For this reason, we developed a novel magnetic catalyst based on supported ruthenium oxide over maghemite (RuO_2/γ-Fe_2O_3), which behave as suitable precursor of the actual, *in situ* obtained, 5%wt Ru/Fe_3O_4 active phase for the RCF. The performances of this system, in terms of delignification of cellulose, lignin oil yield and catalyst recovery, were compared with the one obtained with a commercial 5 wt% Ru/C, considered as a benchmark. A simple, lab-scale, magnetic recovery procedure allows to obtain around 94% of recovery efficiency after the first reaction cycle (while the liquid-liquid extraction reported in literature to recover the Ru/C catalyst only led to 10% of recovery). Ru/Fe_3O_4 allows to obtain excellent delignification efficiency, with the concomitant formation of a highly pure cellulose pulp. On the other hand, both the lower surface area and bigger Ru nanoparticles compared to Ru/C, limit lignin depolymerisation efficiency to phenolic monomers. Preliminary recyclability tests have proven the stability of our catalyst for at least 3 RCF cycles. This innovative approach through the implementation of an active, magnetic, catalyst, never reported in literature in a RCF processes, shows great potential thanks to its good recyclability and its ability to produce very high-quality cellulose pulp together with relatively low MW lignin oil, therefore it was patented.

MUR is acknowledged for the financial support provided through the ENCAPSULATE project, PRIN-Bando2022 (2022KTAH2L).

giulia.tonsi@unimi.it

The quest for sustainable energy sources has led to biodiesel (BD) emerging as an environmentally friendly alternative to traditional fossil fuels. Fatty Acid Methyl Esters (FAME) constitute the primary components of these biofuels and meeting specific standards, such as ASTM D6751 and EN 14214[1], is essential for their direct use in the fuel market. Vapor pressure (VP) is a crucial characteristic related to the volatility of BD, impacting both safety and engine combustion efficiency, but the experimental determination is challenging due to its composition variability, low vapor pressures, and susceptibility to degradation during experiments[2]. Furthermore, the definition and the measurement of vapor pressure for mixtures is strongly dependent on the possible variation of the composition during experiments, due to the different volatility of the single compounds. It is also possible to calculate the vapor pressure of the mixture starting from its composition, but the different thermodynamic scenario (ideal or not ideal mixture as first) must be considered. Moreover, for industrial samples possible effect due to the presence of impurities[3] must be considered.
The study[4] employed two distinct experimental methods to determine the vapor pressure of certain acetate esters and two industrial blends of Fatty Acid Methyl Esters (FAME) from Sabio Fuels srl. The first method used a direct ebullioscopic approach, whereas the second involved an indirect thermogravimetric analysis (TGA). The impact of impurities on accuracy was investigated, and TGA methodology was optimized for ambient pressure operation. An error function was employed to compare the experimental vapor pressure results obtained through both methodologies with theoretical values. Ebullioscopic measurements proved effective only for acetate esters, as FAME mixtures displayed too low vapor pressures for an accurate quantification using this technique. In contrast, the TGA methodology demonstrated greater accuracy for FAME compared to acetates and it allowed a rapid collection of numerous vapor pressure values through a swift analysis. While this method may be less accurate than others, it can be useful for fast screening FAME mixtures, even when contaminated with light impurities, and determining the temperature at which the vapor pressure equals or exceeds a predefined value.

antoniocp.trimboli@unirc.it

Every year, millions of tons of poorly managed plastic waste accumulate in the environment, posing significant challenges to ecosystems. This is particularly evident with polyolefins (POs), where 95% of post-consumer POs become waste, constituting over 60% of municipal solid waste plastic content[1-3]. The limited recycling of POs represents a significant gap in the plastic market loop, contradicting the goals of the "European Strategy for Plastics in a Circular Economy." Despite EU legislation suggesting strategies for upcycling plastic waste, the upcycling of POs remains in its early stages.

This project aims to raise awareness and advance the catalytic upcycling of POs waste into value-added liquid alkanes. The process involves thorough characterization using a multi-technique approach to identify crucial catalyst properties and process variables driving the selective cleavage of C-C bonds inPOs.[4,5]. Two types of catalysts will be developed, utilizing acid sites and ruthenium nanoparticles as active phases, with variations in acidity and support porosity. These catalysts will be compared to a commercial Ru/C catalyst. Various types of polyolefins, ranging from high purity to real waste, will undergo reductive conditions such as hydrocracking or hydrogenolysis, as well as transfer reductive conditions using aliphatic alcohols as green H-donor molecules.

NH_3 catalytic cracking with direct Joule heating in packed POCS

F. S. Franchi[a], M. Ambrosetti[a], A. Beretta[a], G. Groppi[a], E. Tronconi[a]
[a] *Dipartimento di Energia, Politecnico di Milano, via La Masa, 34, Milano (Italy)*
enrico.tronconi@polimi.it

Due to the current need for more environmentally friendly solutions in every aspect of life, the development of a hydrogen economy[1] is gaining interest as a solution to abandon fossil fuels. To overcome the challenge of hydrogen storage and transportation, one possible solution is NH_3, a commodity whose global production is in the range of 150 Mton/year[2] that can be easily liquefied under moderate pressure (10 bar-a @ 25°C). For its use as a hydrogen carrier, however, a substantial development of the ammonia decomposition process is needed. NH_3 decomposition is an endothermic reaction ($NH_3 \rightarrow 3/2\ H_2 + 1/2\ N_2$, $\Delta H°_r = 45.9$ kJ/mol$_{NH3}$) and efficient heat management in the catalytic reactor is of key importance to optimize system performances.

At the industrial scale, high temperature heat of reaction for highly endothermic processes is provided through furnaces, with associated CO_2 emissions. While this solution is a proved and widely used technology, it is only optimal for large scale operations and not suitable for compact, distributed systems; a promising solution to this problem can be the use of cellular SiSiC internals as ohmic heating elements to supply the required reaction heat[3]. In this view, experimental tests were conducted by packing a SiSiC open cell foam (32 mm diameter, 100 mm length, porosity = 0.88) with a commercial Ru-based catalyst (Heraeus, 2% Ru/Al_2O_3) and a variable voltage DC power supply was used to provide the required power. Pure NH_3 was fed to the system at spatial velocities between 1250 Ncc/h/g_{cat} and 10'000 Ncc/h/g_{cat} while recording conversion and energy efficiency for different outlet temperatures. As demonstrated with the experimental tests, conversion in excess of 95% can be reached at GHSV of 3750 Ncc/h/g_{cat} and lower with thermal efficiency in excess of 60%; moreover, as highlighted by a 2D heterogeneous model, significantly higher thermally efficiency can be achieved with the scale-up of the system.

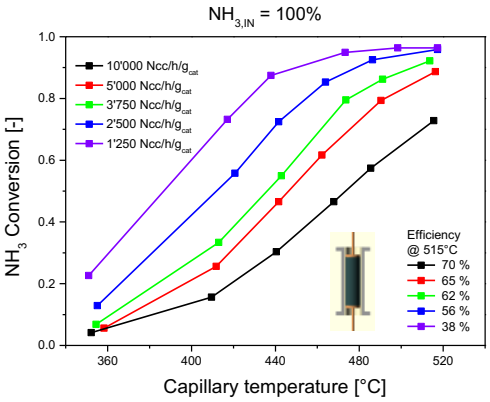

Figure 1: Electrified SiSiC reactor, NH_3 conversion and energy efficiency vs outlet temperature.

The flow of materials during the plastic processing; an uncharted and underestimated field in the carbon footprint analysis of plastic working process

D.Zamboni,[a,b] A.Mazzi,[c] S.Gross,[b]

[a]*Department of Economics and Management "Marco Fanno" University of Padova, Padova*
[b]*Department of Chemical Sciences University of Padova, Padova*
[c]*Department of Industrial Engineering University of Padova, Padova*
diego.zamboni@studenti.unipd.it

Researchers have recently outlined that the impact of plastics on climate and environment is bigger than originally thought. In a study published in 2021 in Nature Sustainability, it has been pointed out as the global carbon footprint of plastics has doubled since 1995, reaching 2.2 billion tons of CO_2 equivalent (CO_2eq) in 2015[1]. In this context, studies on the global environmental impact of plastics have mainly focused primarily on the disposal phase, whereas there are few studies about the manufacture and in particular processing of plastics, which also remarkably affect the carbon emission and air quality. This produces a knowledge gap about the environmental impact of processing of the plastic, where most companies underestimate the environmental impact of their processes.

The calculation of the LCA, specifically of Carbon Footprint (CF) can assess the industrial environmental impact of a supply chain, but to do so, the study of materials and energy flow must be performed (LCI), where all the input and output in the chain must be identified, quantified, and studied their possible impact in the environment to produce greenhouse gases is concerned. The aim of this work within the PNRR Grins project is to carry out a critical survey in the plastic manufacturing steps, in particular about the most common plastic processing (extrusion and injection molding, mainly) of different polymers in different Italian ad European companies. As initial step the flow of material in input and output (the processed material, the waste and the discarded material) must be assessed. For specific case studies, the use of gas chromatography or total carbon analysis could be considered. The last step of the work is to calculate the carbon footprint of the processes and quantifying the emission of every single steps. These results would support the development of strategies to reduce the environmental impact of the plastic manufacturing process.

zppfrc@unife.it

Natural enzymes have revolutionized chemistry through biocatalysis, blending molecular precision with environmental care. This approach has provided sustainable methods for producing fine chemicals and a greener alternative to conventional synthesis, moving from harmful solvents to eco-friendly, regio- and stereospecific biocatalysts[1]. Biocatalysis has enabled the production of complex, water-soluble derivatives by combining pharmaceutical knowledge with biobased molecules, leading to safer prodrugs that mitigate the side effects of traditional active ingredients[2]. Herein, we highlight the synthesis of compounds with significant market presence, like ursodeoxycholic acid, utilized in treating gallstones[3], and a range of cinnamic acid derivatives, such as ferulic and caffeic acids, which are biobased molecules celebrated for their antioxidant and anti-inflammatory properties, as well as ibuprofen, one of the most used anti-inflammatories in the world. Centered on the molecular dynamics of biocatalysts for optimized reuse and stability, these advancements not only showcase the effectiveness of prodrugs over traditional compounds but also reflect a commitment to the principles of sustainability and the circular economy. This journey illustrates a harmonious blend of chemical innovation and environmental responsibility, marking a future where chemistry continues to evolve in alignment with sustainability and health protection.

giorgia.ferraro@unive.it

In the last decades, the rising levels of carbon dioxide (CO_2) in the atmosphere have been increasingly attributed to the global warming effect[1]. Photocatalysis, which exploits the energy of light and abundant semiconductor materials, may represent a promising method to enable more sustainable catalytic reactions[2]. However, the applicability is currently mainly hindered by design of materials able to efficiently harvest solar light to carry out photo-catalytic reactions.

In this context, the conjugation of carbon dots with semiconductor materials was studied as tool to increase the visible-light sensitivity of titanium oxide (TiO_2) and barium titanate ($BaTiO_3$). The hybrid materials were tested for their photo-activity in two distinct reactions and upon the irradiation of either UV or solar light. Two different deposition methods were studied as to provide a scalable strategy to the design of versatile photocatalyst.

As results, only carbon-modified semiconductors were able to convert CO_2 into methane upon solar light excitation. In addition, carbon-dots-$BaTiO_3$ conjugates were proposed for the first time as valid alternative to TiO_2-based photocatalysts, especially in the CO_2 photo-reduction reactions.

If properly designed, carbon dots may represent a way to overcome some of the current limitations to the application of photocatalytic processes for the development solar-powered technologies.

Biological properties of "inorganic" phosphorus dendrimers

A.-M. Caminade[a]

[a] *Laboratoire de Chimie de Coordination (LCC), 205 Route de Narbonne, 31077 Toulouse Cedex 4, France*
anne-marie.caminade@lcc-toulouse.fr

Dendrimers are hyper-branched macromolecules, synthesized step by step from a multifunctional core. Different types of dendrimers are known, depending on their chemical constituents. Among them, dendrimers having a phosphorus atom at each branching point have particular properties, compared to purely organic dendrimers. Indeed, the internal structure of dendrimers cannot be considered as an "innocent" scaffold.[1]

Depending on the type of their terminal functions, phosphorus-containing dendrimers display different properties, in particular as potential drugs in biology/nanomedicine. Dendrimers bearing phosphonate terminal functions (Figure 1, left) display anti-inflammatory properties, against rheumatoid arthritis,[2] multiple sclerosis, or psoriasis. Diverse dendritic architectures functionalized with metal complexes (Figure 1, right) display anti-cancer properties by themselves,[3] whereas others, functionalized with ammonium terminal functions, act as carriers of drugs against cancers.[4] In addition, phosphorus dendrimers largely enhance the detection accuracy of biochips, enabling the accurate and rapid detection of several diseases.[5]

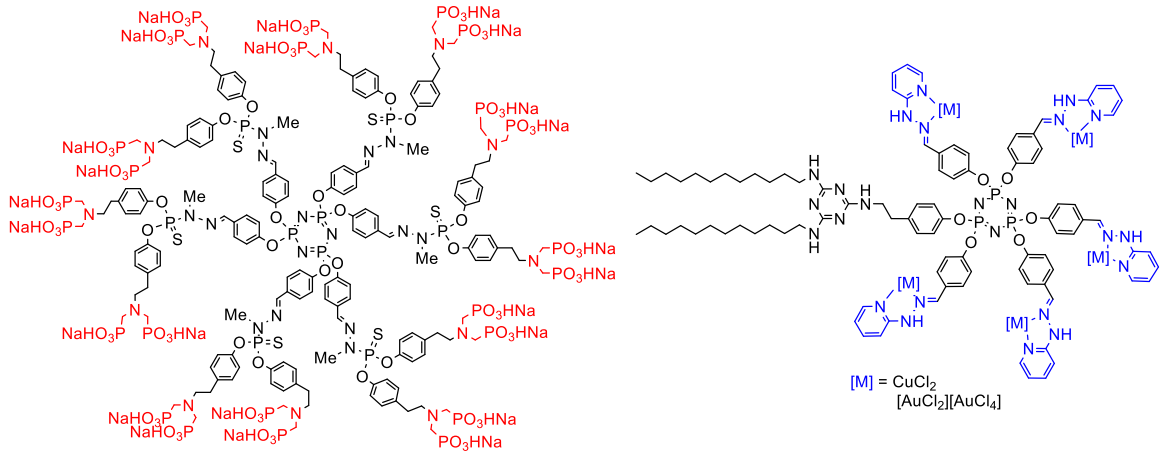

Figure 1: Two examples of phosphorus dendritic structures having biological properties.

Modeling Materials and Processes in Hybrid/Organic Photovoltaics: From Dye-sensitized to Perovskite Solar Cells

Filippo De Angelis [a,b]
[a] *Department of Chemistry, Biology and Biotechnology, University of Perugia, Via Elce di Sotto 8, I-06123, Perugia, Italy.*
[b] *Computational Laboratory for Hybrid/Organic Photovoltaics (CLHYO), CNR-SCITEC, Via Elce di Sotto 8, I-06123, Perugia, Italy.*
filippo.deangelis@unipg.it

Over the last two decades, researchers have invested enormous research effort into hybrid/organic photovoltaics, leading to the recent launch of the first commercial products that use this technology. Dye-sensitized solar cells (DSCs) have shown clear advantages over competing technologies. The top certified efficiency of DSCs exceeds 11% and the lab-cell efficiency is greater than 13%.

In 2012, the first reports of high efficiency solid-state solar cells based on organohalide lead perovskites completely revolutionized the field. These materials are used as light-absorbers in DSCs and as light-harvesting and electron conductor in meso-superstructured and flat heterojunction perovskite solar cells (PSCs) and show certified efficiencies that currently exceed 26%.

To effectively compete with conventional photovoltaics, emerging technologies need to achieve higher efficiency and stability, while maintaining low production costs.

Many of the advances in the DSCs and PSCs field have relied on the computational design and screening of new materials. Suitable modeling strategies further allow researchers to observe the otherwise inaccessible but crucial hetero-interfaces that control the solar cell operation, allowing researchers the opportunity to develop new and more efficient materials and optimize processes.

We illustrate the basic device architectures and operating principles of both DSCs and PSCs highlighting the fundamental modeling strategies and revealing fundamental aspects of the device's operational mechanism. Although the modeling of DSCs is relatively mature, the "perovskite storm" has presented new problems and casted new modeling challenges, such as understanding defect activity, interface functioning and carrier recombination in these materials. Solving these issues may contribute to further optimize materials and processes towards the wide uptake of perovskite solar cells.

Sodium: the journey of a "diffusion catalyst" from the surface to the bulk of $Cu(In,Ga)Se_2$

D. Colombara[a]

[a]*IMAGO Research Unit, Università degli Studi di Genova, via Dodecaneso 31 16146, Genova*
diego.colombara@unige.it

$Cu(In,Ga)Se_2$ (CIGS) is the commercially viable thin film semiconductor that is currently most efficient at converting sunlight to electricity through the photovoltaic (PV) effect.

This outstanding achievement is a seeming paradox because the thin film is polycrystalline, thus it displays extended defects potentially acting as recombination centres for photogenerated carriers. Moreover, CIGS contains a high density of oppositely charged point defects: a condition known as compensation. Compensated semiconductors give rise to a photoluminescence emission that is red shifted with respect to the relevant optical absorption onset. The red shift is due to charge carrier thermalization, a source of performance losses that results from an electronic band structure affected by electrostatic potential fluctuations.

Within this context, the success of CIGS technology would simply be impossible in the absence of sodium. The effect of sodium is so powerful that traces of it are enough to boost CIGS solar cell efficiency from few percent to over 23 %, along with other strategies[1]. But what is the exact role played by sodium in CIGS?

The dramatic improvements of optoelectronic properties associated with sodium are accompanied by a multitude of complex effects impacting the whole of CIGS thin films from the surface and grain boundaries to the core of the grains. Disentangling these effects is far from trivial, as confirmed by 30+ years of R&D.

The research I present here solves crucial fundamental puzzles by revealing the ability of sodium to (i) catalyse the diffusivity of matrix atoms within the bulk of the material[2,3,4], and (ii) catalyse oxygen absorption and desorption at surfaces and grain boundaries[5,6]. Both features contribute to the reduction of electrostatic potential fluctuations and -through an interplay between composition and microstructure- abate parasitic recombination of charge carriers[7]. The findings confirm that sodium in CIGS is not a simple dopant. I define it as a "diffusion catalyst": a new concept worth exploring in other chalcogenide materials.

This "sodium journey" started at the University of Luxembourg, it passed through the International Iberian Nanotechnology Laboratory in Portugal and reached the University of Genova. Along the way, numerous researchers based in Europe and USA enriched it enormously; I am indebted to all of them.

Ziegler-Natta Catalysis: a Journey in the Land of Serendipity

V. Busico, R. Cipullo, G. Antinucci

Department of Chemical Sciences, Federico II University of Naples, Via Cintia, Naples, Italy
busico@unina.it

There are areas of chemistry where the contribution of serendipitous discoveries to the overall progress is overwhelming, because the variables hyperspace is too complex for rational design. One such area is heterogeneous catalysis, and the breakthrough invention of isotactic polypropylene by Giulio Natta in March 1954[1] represents a paradigmatic case. On the other hand, the subsequent progress in Ziegler-Natta polymerization is described in the books[2] as the result of a robust mechanistic underpinning based on crystallochemical models. In fact, the field is currently perceived as fully mature, and academic research has been almost completely discontinued.

Polypropylene industry, on the other hand, is a giant constantly in demand of scientific support, and throughout the last decades in our laboratory we have always been running R&D projects aiming to improve catalysts and products. To our surprise, day after day we accumulated a growing body of experimental and computational data indicating that the popular narration of a smooth, logical evolution from first generation $TiCl_3$ catalysts to $MgCl_2$-supported 'High-Yield' (HY) homologs is –in reality– wishful thinking. This lecture illustrates how serendipity, again and again, contributed to the implementation of HY systems, and popular hypotheses seemingly in line with common sense represented a mind trap rather than a thought accelerator.

Bonding and Reactivity in Heterobimetallic Bridging Hydrides Across the Transition Series

M. Landrini[a]

[a]*University of Perugia, Department of Chemistry, Biology and Biotechnology, Via Elce di Sotto 8, Perugia, Italy*
martina.landrini@studenti.unipg.it

The establishment of donor/acceptor interactions has important implications in organometallic chemistry and its application in homogeneous catalysis.[1] In this context, heterobimetallic bridging hydride complexes are an interesting class of compounds,[2] which have been found as products in several H_2 activation reactions.[3,4] These species are an interesting platform to study, owing to the possibility of activating the hydride moiety and trigger potential bimetallic cooperation.[5]

The present work set to investigate the structure, bonding and reactivity of different classes of heterobimetallic bridging hydride complexes along with potential metal-based FLP cooperativity for the development of novel metal-metal reactivity at the metallic interface (Figure 1).

The new bimetallic compounds obtained were mainly analysed by means of NMR spectroscopy, X-Ray diffraction and DFT analysis. The metal chosen span over the periodic series, to underline the versatility of such approach in organometallic chemistry. The different bimetallic combinations have been exploited to investigate different reactions such as hydride transfer, olefin and alkene insertions, hydrogenation and C-H activation, paving the way for a much better understanding of the potential role of bimetallic complexes in catalytic reactions.

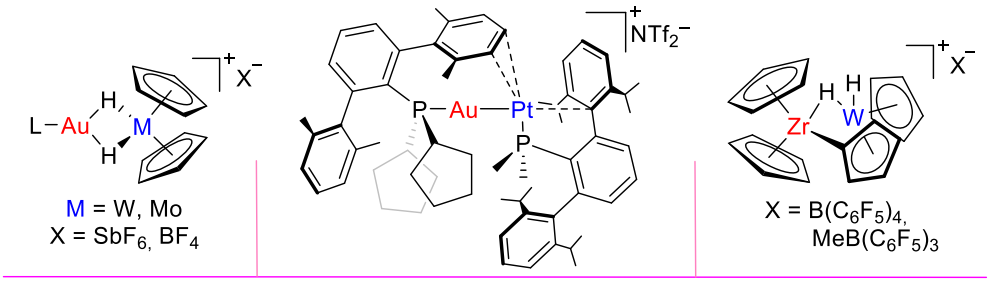

Figure 1: Three main bimetallic cores studied in this work.

letizia.liccardo@unive.it, letizia.liccardo@trieste.ism.cnr.it

In the field of heterogeneous photocatalysis, the present work explores the design and development of novel metal oxide-based nanostructured materials as efficient photocatalysts for organic contaminants photodegradation[1] and H_2 production through photoelectrochemical water splitting (PEC WS)[2] and alcohol photoreforming.[3] Focusing on titanium dioxide (TiO_2),[4] known as the benchmark photocatalyst, several strategies have been investigated to tailor and improve its optical and electronic properties, using smart and cost-effective synthetic routes to boost both the overall photoresponse and catalytic activity. A direct correlation among morphological, structural, optical, and electronic properties and the photoactivity of the synthesized nanomaterials has been established by critically discussing the experimental results obtained by using advanced experimental techniques. Overall, the research findings provided by the nanostructured systems designed and investigated in this work aim to significantly contribute to the development of new and sustainable solar-driven technologies for future large-scale applications in the field of heterogeneous photocatalysis.[3,5,6]

mirco.scaccaglia@marionegri.it

The continuous rise of antimicrobial resistance is a serious threat to human health and already causing hundreds of thousands of deaths each year. Metal complexes have recently shown promising results as antimicrobial agents, but the number of studied compounds is still vanishingly small, making it difficult to identify promising compound classes or elucidate structure-activity relationships. To accelerate the pace of discovery we have applied a combinatorial chemistry approach to the synthesis of metalloantibiotics. Utilizing robust Schiff-base chemistry, we have prepared a library of 420 novel manganese tricarbonyl complexes. All compounds were evaluated for their antibacterial properties and 10 lead compounds were identified, re-synthesised and fully characterised. All 10 compounds showed high and broad activity against Gram-positive bacteria. The best manganese complex displayed low toxicity against human cells with a therapeutic index of >100. In initial mode of action studies, we show that it targets the bacterial membrane without inducing pore formation or depolarisation. Instead, it releases its carbon monoxide ligands around the membrane and inhibits the bacterial respiratory chain. This work demonstrates that large numbers of metal complexes can be accessed through combinatorial synthesis and evaluated for their antibacterial potential, allowing for the rapid identification of promising metalloantibiotic lead compounds.[1]

Hydrogen is potential candidate in supporting the energy transition to a more sustainable economy. Its production from ethanol (obtained by fermentation of second-generation biomasses) through photocatalytic processes allow to exploit two renewable sources. In this context, the development of innovative photocatalysts active under solar and visible irradiation represents an important technological advancement to the large scale diffusion of this technology.

In the present work, the effect of metal doping of $ZnIn_2S_4$ (ZIS) photocatalysts on their photocatalytic activity in the photocatalytic production of H_2 from ethanol was studied. The photocatalysts, obtained by hydrothermal synthesis, were active in producing H_2 under irradiation with simulated sunlight or visible light, with an important dependence of the performance on the nature of the dopant metal (Figure 1). The main by-products detected was acetaldehyde while minor amounts of CH_4, CO_2 and ethylene were detected by on-line GC-FID analysis. The photocatalysts have been deeply characterized by complementary techniques, such as XRD, physisorption, ICP-OES and SEM, confirming effective doping of the ZIS structure. Photoluminescence spectra revealed that metal dopants affect the recombination process of photogenerated electron/hole pairs. Insight into the reaction mechanism have been obtained by in-situ ATR-IR spectroscopy, revealing the formation of formates, acetates and carbonaceous C = C species as intermediates or the reaction.

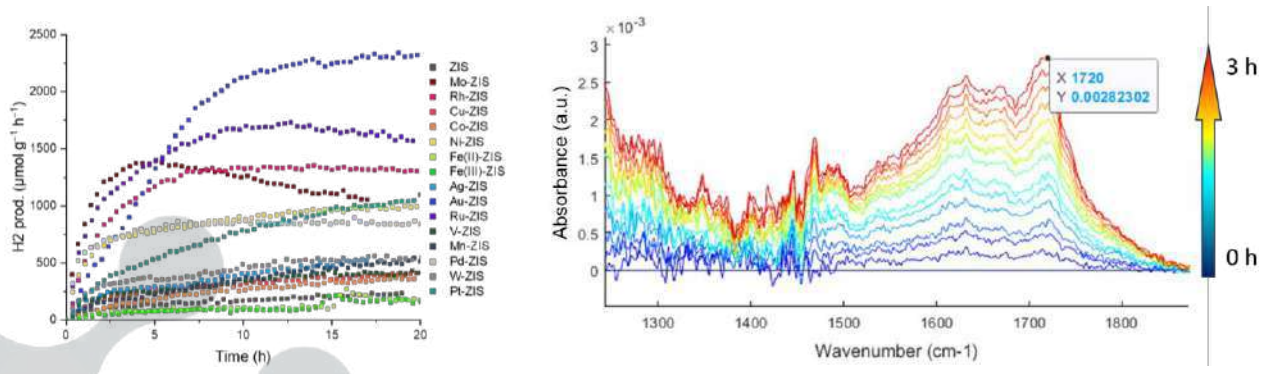

Figure 1: H_2 production rates for metal doped ZIS under simulated sunlight (right) and evolution of ATR-IR spectra in the range 1250 – 1900 cm^{-1} on Au-ZIS under simulated sunlight (left).

Enhancing Antitumor Activity of Platinum-Based Organometallic Compounds: Investigating the Effects of Ligand Substitution and Hydrophobicity. A Study of Novel Water-Soluble Monofunctional Organometallic Pt(II) Complexes $[PtL(\eta^1\text{-}C_2H_4OEt)(phen)]^+$ (L = DMSO, NH_3, 1-hexyl-1H-imidazole, 1-hexyl-1H-benzo[d]imidazole)

M. Benedetti,[a] A. Ali,[a] E. Stefàno,[a] F. De Castro,[a] G. Rovito,[a] A. Muscella,[a] S. Marsigliante,[a] F. P. Fanizzi[a]

michele.benedetti@unisalento.it

Since the discovery of cisplatin's ability to inhibit tumor growth, numerous studies have focused on understanding the relationship between the structure of platinum compounds and their antitumor activity[1]. It has been found that substituting the chlorido and ammonia ligands with other ligands can greatly enhance the effectiveness of these compounds, leading to the development of 2nd (e.g. carboplatin, nedaplatin, etc.) and 3rd (e.g. oxaliplatin, heptaplatin, etc.) generation platinum drugs[1]. However, there is still a need to better understand the factors that determine the antitumor activity of platinum-based organometallic compounds[2]. In this study, we investigated a series of new organometallic compounds containing phenanthroline (phen) and σ-C_2H_4OEt groups bonded to the central Pt(II) ion, along with a variable L ligand (DMSO, NH_3, 1-hexyl-1H-imidazole, or 1-hexyl-1H-benzo[d]imidazole). These complexes were synthesized from the precursor complex of the type $[PtCl(\sigma\text{-}C_2H_4OEt)(phen)]$ (**1**), which was then reacted with an entering ligand to replace the coordinated halide[3]. The resulting complexes, $[Pt(DMSO)(\eta^1\text{-}C_2H_4OEt)(phen)]^+$ (**2**), $[Pt(NH_3)(\eta^1\text{-}C_2H_4OEt)(phen)]^+$ (**3**), $[Pt(1\text{-hexyl-1H-imidazole})(\eta^1\text{-}C_2H_4OEt)(phen)]^+$ (**4**), and $[Pt(1\text{-hexyl-1H-benzo[d]imidazole})(\eta^1\text{-}C_2H_4OEt)(phen)]^+$ (**5**), were then tested for their anticancer activity on various tumor and healthy immortalized cell lines[4,5]. The cytotoxic activity of these complexes was compared to that of cisplatin. Initial results showed that the cytotoxic activity increased in the order **3** < **2** < **4** < **5**, which can be attributed to the increasing hydrophobicity and intercalating ability of the L ligand, leading to different mechanisms of action. Complex **5** exhibited the highest level of cytotoxicity against the HeLa cell line, while complex **4** showed the highest selectivity for malignant cells (Caki-1). Furthermore, the effects of these new compounds on cell migration and invasion processes were evaluated, indicating their potential to prevent the induction of metastasis.

Electrochemistry is a very promising and appealing technology able to accomplish the conversion of renewable sources into fuels for energy applications in a green way, alternative to the traditional fossil fuels, such as the CO_2 reduction reaction (CO_2RR) into valuable C_1-C_{2+} products. However, the possibility of exploiting these catalytic routes to produce fuels at large scale is still strongly affected by the selection of the best catalysts and the optimization of the process parameters.

In this context, different Cu oxides (selected for their strong coordination ability with CO intermediates)[2] and Cu-containing mixed Ni-Co-Zn ferrites were synthesized following different soft-chemistry approaches (i.e., co-precipitation, hydro/solvothermal, sol-gel routes), by varying the Cu oxidation state, the chemical surrounding, and the final morphology (i.e., size/shape, aspect ratio, crystal planes orientation). In particular, in the case of the mixed ferrites, different degrees of Cu-substitution were investigated.[3]

The most promising Cu-containing compounds were deeply characterized, evidencing their morphological and physicochemical properties, and compared with reference substrates. This way, an effective screening of the fundamental properties necessary for maximizing their catalytic performances in electro-CO_2RR was achieved, monitoring how changes at the catalyst and process parameters level might enhance the yield of conversion and selectivity towards final products.

Ternary Lanthanide (III) complexes with Fluoride ion: solution structures and dynamics investigated with ^{19}F-CEST

Francesca Garello,[a] Diana Costanzo,[a] Carla Carrera,[a] Gianluca Destro,[a] Silvio Aime,[b] Enzo Terreno[a]
[a] *Centro di Imaging Molecolare e Preclinico, Dipartimento di Biotecnologie Molecolari e Scienze per la salute, Università degli Studi di Torino, Piazza Nizza 44/bis, 10126 Torino, Italy.*

e-mail: francesca.garello@unito.it

Chemical exchange saturation transfer (CEST) is a powerful NMR technique that enables the investigation of dynamic processes between two (or more) chemicals in which a given nuclear spin displays a different chemical shift in the mutually exchanging species. CEST has found relevant applications in the field of ^{1}H-MRI, where it can reveal the presence of low-concentration solutes via the transfer of their saturated magnetization to a bulk nucleus, from which the MRI signal is detected. Moreover, heteronuclear CEST has an important advantage in terms of detection sensitivity because the response is directly dependent on the molar fraction of the saturated spins over the bulk ones, which is several orders of magnitude higher when the bulk signal is different from water protons. ^{19}F nucleus is well suitable for this purpose due to the high NMR receptivity and null biological background. However, the development of ^{19}F-CEST is still in its infancy with few literature reports.[1-2] In this contribution, ^{19}F-based CEST was assessed to investigate, for the first time, the dynamics of the metal-binding of fluoride ions in a series of tri-positively charged lanthanide(III) complexes formed by tetra-amide derivatives of DOTA ligands (Fig. 1a). In an aqueous solution of the metal complex added with an excess of fluoride ions, the halide distributes between the bulk F- ion and the metal-bound fluoride (LnL-F, Fig. 1b). By analysing the dependence of the bulk F- NMR signal over the saturation frequency (Fig. 1c), it is possible to measure the exchange rate of the metal-bound fluoride and assess how it is affected by the structure of the metal complex. In addition, as the metal complexes themselves possess amidic protons in exchange with water, ^{1}H-CEST experiments were performed to evaluate whether their exchange is affected by the fluoride coordination to the metal center.

Hybrid Ag+/TiO2 nanocomposite coatings via Aerosol assisted atmospheric pressure plasma deposition for environmental remediation

Regina Del Sole[1], Fabio Palumbo[2], Chiara Lo Porto[3], Roberto Comparelli[4], Maria Lucia Curri[1,4], Francesco Fracassi[1,2], Antonella Milella[1,2]

Nanocomposites have been a topic of increasing interest in the last decades because of their superior properties when compared to their single components. Metal oxide nanocomposites are largely studied for environmental remediation applications (such as wastewater treatment, photodegradation of organic pollutants or antimicrobial activity). In particular, NPs of TiO_2, an n-type semiconductor, show valuable photocatalytic properties, although affected by several drawbacks, such as a wide band gap of 3.2 eV that leads to a strong absorption in the UV region, thus requiring a high energy irradiation, and a fast electron-hole recombination rate. Noble metals nanoparticles, e.g. AgNPs, are often used as co-catalyst together with TiO_2 in order to reduce the electron-hole recombination time. On the other hand, there are very few examples in the literature on the applicability of Ag^+/TiO_2 composites in photocatalytic technologies, as they are more renowned for their antibacterial properties. Furthermore, the immobilization of photocatalysts onto a solid support can make them suitable and technologically viable for environmental applications, as they can be more easily retrieved and recycled.

In this work, the deposition of TiO_2-based nanocomposites coatings with the addition of $AgNO_3$ in a hybrid siloxane matrix by Aerosol Assisted Plasma Deposition (AAPD) will be presented. The versatility of AAPD has been well demonstrated by this research group in the past by depositing TiO_2, TiO_2/rGO and TiO_2/C_{60} nanocomposite coatings. Indeed, this technique allows to deposit thermodegradable or scarcely volatile species, hence also NPs, in nanocomposite coatings, keeping the activity and structure of the additive, e.g. enzyme, drugs, and so on.

In the present study the coatings are deposited in a dielectric barrier discharge reactor, feeding the plasma with two aerosol generators: one is fed with TiO_2 NPs dispersed in a HMDSO/isopropyl alcohol mixture, and the other with a $AgNO_3$ solution. The chemical composition and the morphology of the coatings have been characterized by means of FT-IR, EDX, profilometry, XPS, SEM and TEM analyses, evidencing the complex nature of the structure of these materials. The photocatalytic activity towards the degradation of methylene blue has been evaluated under UV light irradiation and rationalized. The recyclability of the photocatalysts was assessed over 3 cycles and even an improvement of the performances was found upon reuse; a post-operational characterization via XPS and ICP was carried out to better understand this result.

Light-Activated Therapeutics: Designing Photoresponsive Bioactive Compounds with Ruthenium(II) Polypyridyl Complexes

G. E. Giacomazzo,[a] L. Conti, [a] V. Ceccherini, [a] B. Valtancoli,[a] C. Giorgi [a]

[a] *University of Florence, Department of Chemistry 'Ugo Schiff' via della Lastruccia 3, Sesto Fiorentino (FI)*
ginaelena.giacomazzo@unifi.it

The quest for more precise and controlled photodynamic therapy (PDT) modalities has directed substantial interest towards the development of innovative photosensitizers (PSs) capable of targeting both tumorous and bacterial afflictions with high specificity. In this scenario, Ru(II)-polypyridyl complexes (RPCs) emerge as a promising class of compounds, attributed to their rich chemical-physical repertoire, which makes them ideal candidates as PSs for PDT. Their versatile chemistry allows for the fine-tuning of some important photophysical properties that can maximise their behaviour as PS.

The work explores the significant impact that strategic ligand design has on the photochemical and photobiological performance of RPCs, highlighting the potential for improved spatiotemporal control of drug activation. Our investigation begins with the employment of bis-heteroleptic RPCs decorated with extensive aromatic polypyridyl ligands, such as the popular benzo[i]dipyrido[3,2-a:2',3'-c]phenazine (dppn) ligand. In this arrangement, π-expansive chelate ligands into Ru(II)-scaffolds can change the lowest-lying excited state from ^{3}MLCT to long-lived intraligand ^{3}IL states, efficiently enhancing the crucial production of harmful cytotoxic oxygen species.[1] Secondly, to further extend the ^{3}MLCT emission and further improve the $^1O_2$ photosensitization, we investigate the incorporation of distinct organic chromophores on Ru(II)-scaffolds to form bichromophoric systems where the ^{3}IL states serve as an excited state energy reservoirs. Finally, extending the scope of our research, we introduce the principle of photoactivated chemotherapy (PACT) to the antibacterial field, introducing the term *photorelease antimicrobial therapy – PAT,* by exploiting the unique photophysical properties of RPCs to trigger the release of Metronidazole-derivatives in a controlled manner, offering a chance to specifically activate the drug and thus reduce the development of antibiotic resistance.[2,3]

Our findings highlight the critical role of ligand architecture in dictating the efficiency and versatility of RPCs as PSs. By advancing our understanding of these mechanisms, we are paving the way for the development of next-generation phototherapeutic agents capable of addressing the complexities of tumour and bacterial disease treatment through enhanced precision and efficacy.

Gold-Catalyzed Cycloisomerization and Hydration/Homocoupling Reactions of Terminal Alkynes

Nicola Sargentoni,[a] Lorenzo Luciani,[a] Rossana Galassi[a]

[a] *School of Science and Technology, Chemistry Division, University of Camerino, Via Madonna delle Carceri, I-62032*
nicola.sargentoni@unicam.it

Over the last few decades, due to their π-affinity, gold(I) and gold(III) complexes have been mostly applied in the activation of terminal alkynes toward inter- and intramolecular nucleophilic attack.[1] Within this domain, cycloisomerization and hydration/homocoupling reactions have emerged as robust methodologies for the production of cyclic and acyclic organic compounds, respectively.[2] Following ongoing investigations into the influence of counterions and oxidation state[3] at the metal centre of N-heterocyclic carbene (NHC) gold catalysts towards the cycloisomerization reaction of N-propargyl amides, this study has been broadened to include the hydration/homocoupling reaction of terminal alkynes.

In this work, starting from the homologues series of NHC-gold(I)X and NHC-gold(III)X_3 (X = Cl, Br or I) complexes applied as catalysts in the cycloisomerization reaction, these catalysts were employed in the hydration/homocoupling of the phenylacetylene, chosen as the benchmark reaction for this work. The reactions were performed by using water under additive-, silver- and acid-free conditions,[4] at 110°C, with a catalysts load of 0.5% molar. Methanol was chosen as the solvent and the reactions were performed under both solvent and solvent-free conditions. Interestingly, under solvent-free condition, an homocoupling reactions occurred and 1,4-diphenylbuta-1,3-diyne was selectively obtained as sole product (on the left, Figure 1). Conversely, acetophenone and small amount of phenylacetaldehyde were obtained when methanol was present in the system (on the right, Figure 1).

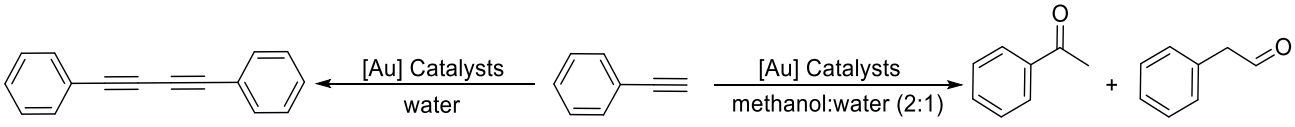

Figure 1: Selective solvent-controlled hydration/homocoupling of phenylacetylene NHC-gold-catalyzed.

TARGETING MCT1: FROM FLUORINE TO COPPER IN NUCLEAR MEDICINE

M. Mari,[a] J. Storchi,[a] E. Frignani, M. Asti,[b] V. Patinec,[c] R. Tripier,[c] A. Zambon,[a] and E. Ferrari[a]

matteo.mari@unimore.it

MCT1 is a membrane protein responsible for the transport of lactate normally expressed in healthy tissues. However, in some cancer lines its expression results dysregulated and allows the establishment of the "Warburg effect". This mechanism explains the aggressive character of specific tumoral types and allows MCT1 to be a potential target for theranostic applications in oncological field[1]. To date, only few molecules acting as inhibitors for MCT1 are known[2], and the interaction of some of them with MCT1's pocket has been elucidated by Xray crystal data[3]. Some of these are Diclofenac and 7ACC2, a Coumarin derivative.

Coumarins are natural phyto-compounds known since the 19th century, their scaffold has attracted the attention of synthetic and medicinal chemists for decades and showed a large variety of biological activities[4]. One of the recently developed MCT1 inhibitor (7ACC2), that reached clinical trials, is a coumarin derivative[2].

Starting with preliminary docking calculations, the structure of 3-carboxy,7-hydroxycoumarin and Diclofenac was modified to retain a high affinity for the protein structure and to insert an additional specific moiety that allows the radiolabelling with 18-Fluorine.

18-Fluorine was the first radionuclide considered because of its wide presence in the everyday reality of nuclear medicine departments and because of the small structural modification that it induces on the radiolabelled molecule. However, it is a pure positron emitting isotope. For this reason, its application is limited to diagnosis. Our intention is to shift to the use of a bifunctional chelator (BFC) approach to envision Copper (II) isotopes radiolabelling. This would indeed permit to reach the so called "theranostic-pair approach" exploiting different copper isotopes (61-Cu, 64-Cu and 67-Cu). To exploit a radio-metal such as copper, a suitable chelating system must be grafted on the targeting vector trying to reduce the impact on the interaction with the target protein as much as possible. For such goal, a known bifunctional polyazamacrocycle, namely no3py[5] was conjugated on the targeting vector using a PEG chain as a spacer.

Disclosing the role of catalyst-substrate interaction and surface dynamics in liquid-phase heterogeneous catalysis

M. Stucchi,[a] J.P. Korb[b], A. Villa[a], L.Prati,[a]

[b]*Sorbonne-université, CNRS, PHENIX, 75005 Paris*
marta.stucchi@unimi.it

NMR relaxometry can be used to guide the understanding of a catalytic reaction considering that the molecule-catalyst interaction is one of the fundamental parameters of a catalytic cycle. By high-field liquid state ^{13}C NMR analyses (400 MHz) the relaxation time (T1) of organic molecules in the presence of a solvent can be measured [1]. Precisely, the T1bulk is measured for the molecule in solution and the T1ads in the presence of the catalyst; a decrease of the T1ads is expected when the molecule interacts with the catalyst surface, so NMR experiments in high-field allow collecting information of local molecular dynamics, where the variation in T1 is essentially a proof of a preferred orientation. However, the absence of a preferred orientation does not always imply the absence of interactions. For this reason, similar adsorption measurements at low field (20 MHz) can be critical to prove the reality of the surface dynamics [2]. As consequence, ^{1}H Low-Field NMR and ^{13}C High-Field NMR could be considered as complementary analyses to collect information on local molecular dynamics and on surface dynamics, returning a complete picture of the interaction between a molecule and a catalyst.

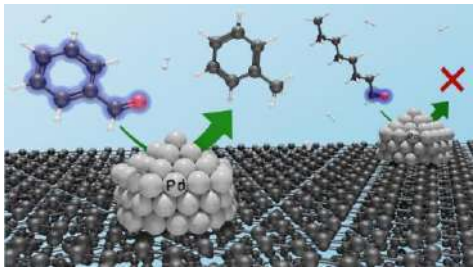

Fig. 1 Aromatic and aliphatic aldehydes hydrogenation on Pd/C catalystss

The hydrogenation of an aliphatic (n-octanal) and aromatic (benzaldehyde) aldehyde in p-xylene has been selected as case-study reaction by Pd/C catalyst (Fig. 1). Pd/C showed a very different activity towards the two substrates, which was correlated with the different T1ads/T1bulk ratio. In particular, by NMR we demonstrated the fundamental role of the solvent and by parallel low-field NMR experiments we were able also to qualify and quantify the affinity of the substrates with the catalytic surface.

Paddlewheel diruthenium complexes: potent inhibitors of amyloid-beta aggregation

S. La Manna,[a] D. Florio,[a] A. Cugudda,[a] A. Merlino,[b] D. Marasco[a]

sara.lamanna@unina.it

Metallodrugs have attracted a great deal of interest in the field of neurological disorders due to their potential to effectively modulate the aggregation of amyloid proteins, a prominent feature of many neurodegenerative diseases. These conditions are characterized by the build-up of misfolded proteins, like amyloid-beta (Aβ) in Alzheimer's disease and the subsequent formation of toxic amyloid fibrils[1]. Due to their unique properties, metal complexes can inhibit the formation of large oligomers through direct and indirect interactions with amyloid peptides. Several studies have shown that ruthenium (Ru)-based complexes are an excellent choice due to their capability to inhibit the aggregation and toxicity of Aβ. Within the group of Ru-compounds, paddlewheel diruthenium complexes (Ru_2^{5+}) have emerged as source of inspiration for drug design, because they offer a novel plethora of valuable molecular scaffolds that are not possible with mononuclear compounds[2-3]. Herein, we report on the ability of two paddlewheel diruthenium compounds to act as aggregation modulators of $A\beta_{1-42}$ and its peculiar fragments $A\beta_{1-16}$ and $A\beta_{21-40}$ (Figure 1)[4]. By means of different spectroscopic (e.g., fluorescence assays, UV-vis absorption, and electrospray ionization mass spectrometry) and microscopic (scanning electron microscopy and confocal microscopy) techniques and cellular assays, their Mechanisms Of Action (MOAs) have been elucidated. The overall data may open new perspectives for the use of Ru_2-based compounds as novel neurodegenerative therapeutics.

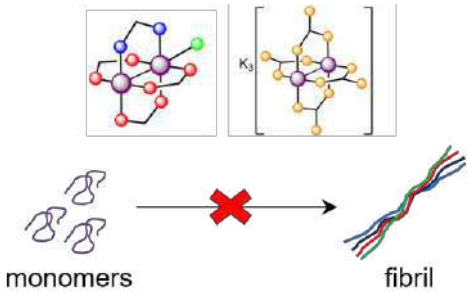

Figure 1: schematic representation of MOAs of diruthenium complexes targeting Aβ peptide.

lorenzo.marchi@unimore.it

H_2salben (Figure 1a, X = H) is a tetradentate Schiff base derived from the condensation of salicylaldehyde (salH) with phenylmethanediamine. This N_2O_2 ligand can coordinate various metal ions, including copper,[1] cobalt,[1] iron and manganese,[2,3] and the presence of only one carbon atom bridging the two iminic groups leads to the selective formation of oligonuclear complexes.[1-3] In particular, the complexation of copper(II) and H_2salben results in the dinuclear [Cu_2(μ-salben)$_2$] (Figure 1b, X = H).[1] The copper(II) ions in this complex exhibits a coordination geometry between tetrahedral and square planar, which confers the possibility to stabilize also copper(I). Therefore, this species is highly suitable for catalytic applications, as it can be easily handled in air while being readily activated *in situ*. In this contribution, a series of different substituted sal(X)ben copper(II) complexes have been synthesized and tested in catalysis. The steric and electronic effects of the substituent X have been explored on a prototype C-N cross coupling reaction (Figure 1c). The best performing catalyst has demonstrated high reactivity and selectivity and afforded the coupling product in high yields at low catalytic loadings and under relatively mild conditions. The reaction's scope has been then explored, highlighting the catalyst activity toward a broad range of substrates.

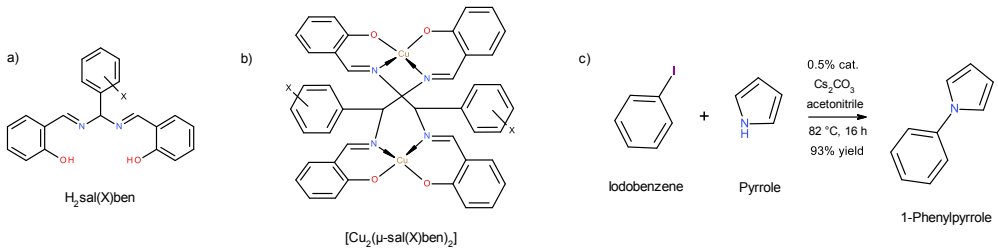

Figure 1: Molecular scheme of a) H_2sal(X)ben and b) [Cu_2(μ-sal(X)ben)$_2$]; c) prototype catalytic reaction.

giulia.saggiotti@studenti.unipd.it

Despite the late appearance of molecular gold nanoclusters (AuNCs) stabilized by N-heterocyclic carbene (NHC) ligands,[1] we have successfully reported a new synthetic methodology to obtain three new classes of mixed PPh_3 and NHC ligated AuNCs through a controllable reaction sequence.[2]

Exploiting the strict stoichiometric control on the ligand sphere, a precise structural regulation at atomic level of these nanometric supramolecules is derived, also reflected in their chemical physical properties.

Relying on a robust synthetic approach, a systematic study in complex biological media is accessible, aimed at assessing their stability, optical properties, and possible interactions with biomacromolecules, up to clarify the impact of NHC ligated AuNCs on cellular recognition and response.

Supported by the promising results of gold-based species as potential anticancer agents and their actual involvement in medicine as anti-inflammatory drugs, we describe here AuNCs as novel engineerable vectors for the target delivery of gold units. More in-depth, their size in the nanometric region joined with their controlled biodegradability to gold complexes under physiological conditions can be a powerful tool for unlocking anticancer agents with an unprecedented selectivity and effectiveness.[3]

antonio.vittoria@unina.it

In this study, a state-of-the-art high-throughput experimentation (HTE) workflow for catalytic olefin polymerization,[1,2] covering an unprecedented wide part of the polymer knowledge and value chains from catalytic synthesis all the way down to "engineering" microrheology, was thoroughly assessed with respect to its ability to prepare new materials and produce large and accurate databases for the investigation of quantitative structure−property relationships (QSPRs).

Olefin block copolymers (OBCs) produced under chain-shuttling polymerization conditions were used as a demonstration case. The strategy was to integrate offline a 48-cell PPR platform with a debottlenecked array of high-end characterizations that were compatible with the low yields (100−300 mg, generally) of PPR cells, namely R-GPC, ^{13}C NMR spectroscopy with high-temperature cryoprobe technology, analytical crystallization elution fractionation (A-CEF), and microcapillary rheometry.[3]

The results of a thorough microstructural, structural, mechanical, morphological, and rheological characterization of OBC replicas prepared with the HTE synthetic platform and a commercial sample, chosen as a benchmark, demonstrate the robustness of the approach.[4] The proposed workflow can become a paradigm for the high-throughput synthesis and investigation of novel materials, thus reducing the time to market of new products. In our opinion, this opens the door to integrated HTE and artificial intelligence approaches to QSPR problem solving in the numerous cases for which a thorough understanding of the theory is not sufficient to deterministically unravel the complexity of practical applications.

Selective oxidation of halogenated phenols catalyzed by a miniaturized heme-enzyme: insight into the mechanism of action

Maria De Fenza,[a] *Daniele D'Alonzo*,[a] *Linda Leone*,[a] *Ornella Maglio*,[a,b] *Vincenzo Pavone*,[a] *Flavia Nastri*,[a] *Angela Lombardi*[a]

maria.defenza@unina.it

Metalloprotein design is currently aimed at reproducing, enhancing or even expanding the properties of natural metalloenzymes by means of artificial biocatalysts.[1] Miniaturization represents one of the strategies employed for this purpose. This approach seeks to identify the minimal peptide scaffold bearing the necessary information to reconstruct the coordination environment of a metal binding site, thus preserving its catalytic function. Our research group has employed this strategy for the development of heme-containing synthetic biocatalysts, known as Mimochromes (MCs).[1] The latest and most promising member of this family, MC6*a, demonstrated to act as an exceptional and versatile catalyst, enabling a wide range of functionalities after metal ion replacement.[2-4] Herein, we have further expanded the catalytic potential of Fe-MC6*a by investigating its ability to catalyze the oxidation reaction of 4-halogenated phenols.[5] Unlike all natural and artificial metalloenzymes tested thus far in the same reaction, Fe-MC6*a induces substrate-dependent chemo-divergent transformations, selectively producing oxidative dehalogenation or oligomerization products, depending on the nature of the halogen atom in the substrates. Mechanistic studies have been performed to elucidate this peculiar reactivity. This investigation not only underlines the unique role of Fe-MC6*a in oxidative catalysis but also suggests the use of this biocatalyst for future applications, such as bioremediation and the synthesis of complex halophenol-derived building blocks.

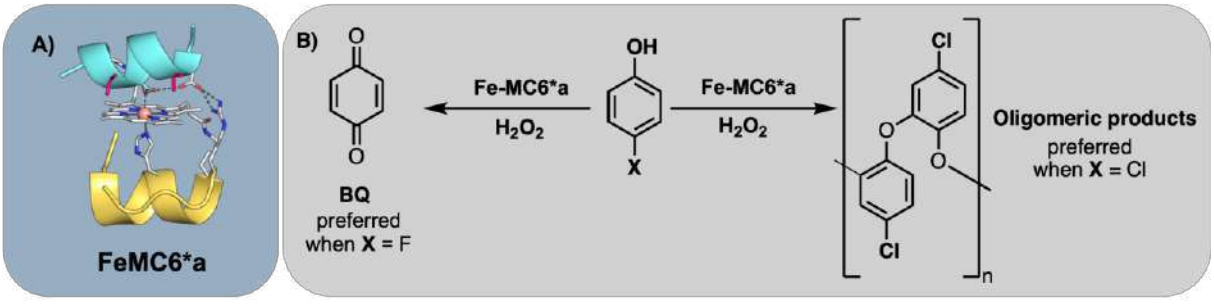

Figure 1: Selective oxidative dehalogenation of 4-XP catalyzed by FeMC6*a.

Schiff bases are a significant category of N,O-chelating ligands known for their notable biological properties, related to the azomethine (-CH=N-) or imine (-C=N-) group, as the imino nitrogen provides a binding site in drug activity, that can be enhanced through complexation with various transition metals.[1] In the context of Zn-based anticancer drugs, Zn(II) complexes with Schiff bases can serve as Zn suppliers in the reactivation of mutant p53, one of the most studied proteins as a cancer target. The p53 suppressor is a transcription factor that contains a single Zn^{+} near its binding interface. Insufficient or excess zinc causes p53 to misfold, inducing the loss of its tumour suppression.[3] Here we present a series of 4-aminoalkylidene-5-pyrazolone molecules, their Zn(II) derivative homoleptic complexes (figure 1), and correlation studies on their structural, photophysical and anticancer properties. Both Zn(II) complexes and their corresponding ligands underwent testing on U373 glioblastoma multiforme cell lines. Preliminary findings concerning the downregulation of p53 by some zinc derivatives are outlined. Additionally, a comprehensive theoretical examination is provided, focusing on the potential dissociation mechanism of the ligands in Zn(II) derivatives, paying specific attention to the impact of various substituents on the aromatic segment of the pyrazolone-based Schiff base ligands.

chiara.saviozzi@phd.unipi.it

Iron is an attractive element for developing drugs alternative to platinum chemotherapeutics, due to its bioavailability, non-toxicity in many forms, and feasible redox chemistry in physiological media. In the last years, we unveiled the anticancer potential of two families of dinuclear iron compounds resembling the structure of the active site of [FeFe] hydrogenase enzymes. Importantly, **I** and **II** feature a combination of appealing requisites for medicinal applications: multigram-scalable synthesis from inexpensive precursors, wide structural variability, adequate water solubility, and outstanding stability in aqueous media.[1] Over 70 compounds of types **I** and **II** have been preliminarily screened for their cytotoxicity in vitro, with some of them investigated in 3D cell models and also in vivo, providing promising results and highlighting structural-activity relationships that encouraged us to design novel structures with optimized activity.

It is extensively documented in the literature that incorporating sulphur functions is beneficial to the biological activity of diverse drug candidates.[2] Inspired by the anticancer properties and preventive effects of naturally occurring organosulfur compounds, the bridging vinyliminium ligand within **II** has been functionalized through the incorporation of sulphide moieties. The synthetic approach explored in this work takes advantage of the cooperative effects provided by the two adjacent iron atoms, that enable reactivity patterns otherwise unavailable on analogous monometallic compounds.

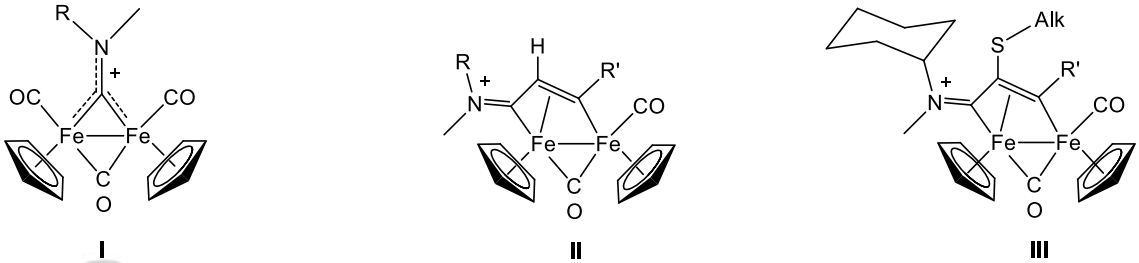

Figure 1: general structures of diiron complexes with anticancer activity (**I**, **II**) and derivatization with sulphide groups (**III**). Triflate or nitrate as counteranion. R, R' = alkyl or aryl groups; Alk = alkyl group.

Does the Oxygen Evolution Reaction follow the classical OH*, O*, OOH* path on single atom catalysts?

Ilaria Barlocco[a], Luis A. Cipriano[b], Giovanni Di Liberto[b] and Gianfranco Pacchioni[b]

[a] *Dipartimento di Chimica, Università degli Studi di Milano, via Golgi 19, 20133 Milano, Italy*

ilaria.barlocco17@gmail.com

The Oxygen Evolution Reaction (OER) is a key part of water splitting. On metal and oxide surfaces it usually occurs via formation of three intermediates, M(OH), M(O), and M(OOH).[1] The last step consists of O_2 release. Generally, it was assumed that the same path occurs on single atom catalysts (SACs). [1] However, the chemistry of SACs may differ substantially from that of extended surfaces and is reminiscent of that of coordination compounds.[2,3] This raises the question of whether on SACs the OER follows the classical mechanism or not. Indeed, a set of 30 SACs were prepared by anchoring a metal atom (Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Pd and Pt) in a carbon matrix (graphene, nitrogen-doped graphene and carbon nitride). Conventional and unconventional pathways, see Figure 1, were then considered,[4] and in all cases at least one unconventional intermediate was found to be more stable than the classical one.

This demonstrates that the assumption done in modelling OER on bulk materials can not be transferred to the SACs as it is. Completely different prediction on the activity of SACs in OER can be made if one follows the assumption that only a sub-set of intermediates can form. Indeed, only once all the possible intermediates are considered, one can speculate about the preferred reaction pathway. The pathway followed to form O_2 from H_2O is metal and support dependent underling the complexity of this "simple" reaction. As an example, on Ti@DV-Gr, only one unconventional intermediate forms, η^2-O_2*. Different is the case of Fe@C_3N_4, where the entire pathway is characterised by the formation of unconventional intermediates. Considering Sc@4N-Gr, two intermediates are "classical" and two are unconventional. Finally, on Pd@C_3N_4 the classical and the unconventional paths lead to completely different predictions about the reactivity of the SAC.

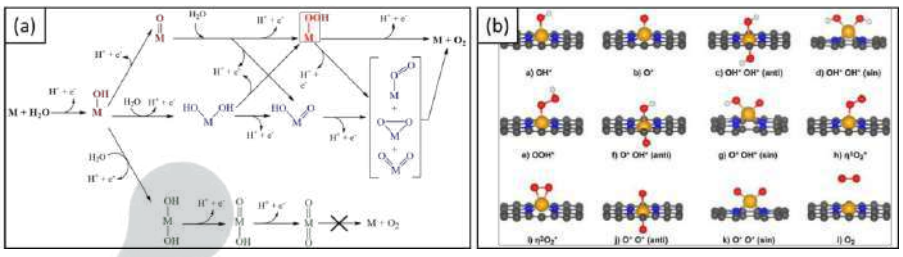

Figure 1: (a) OER scheme were the formation of all possible "classical" (in red) and "unconventional" intermediates (blue and green) are showed and (b) Possible OER intermediates on SACs.

riccardo.dileo@farm.unipi.it

Nowadays, multidrug-resistant *Staphylococcus* strains are involved in nosocomial infections with high morbidity and mortality[1]. Consequently, antimicrobial agents with alternative mechanisms of action or targets are required. Repurposing drug investigations suggested Auranofin (AF, Figure 1), a gold(I) drug currently in clinical trials for treating rheumatoid arthritis, as an anti-*Staphylococcus* agent[2]. Therefore, in a previous study, AF and its *L*-acetylcysteine derivative (AF-AcCys, Figure 1) were tested against resistant strains of *S. aureus* and *S. epidermidis*[3]. Both compounds exhibited similar activity against *S. aureus*, while AF was 20-fold more active than AF-AcCys against *S. epidermidis* (Figure 1)[3]. Computational studies showed that the Au-S bond of AF-AcCys was slightly more stable than the one of AF (Figure 1) affecting the release of the cationic pharmacophore $[AuPEt_3]^+$ and consequently, their activity. Herein, we aimed to develop AF derivatives with a labile bond between the gold(I) pharmacophore and the ligand. Hence, the Naproxen (Npx) drug was selected as a ligand to replace the Au-S bond with the more labile Au-O bond. Additionally, the binding dissociation energy (BDE) evaluation of AF-Npx (Figure 1) confirmed its higher lability. Thus, AF, AF-AcCys, and AF-Npx were tested against *Staphylococcus* strains and biofilm formation. Subsequently, nanoparticles loaded with these drugs will be developed to determine the release and biological activity.

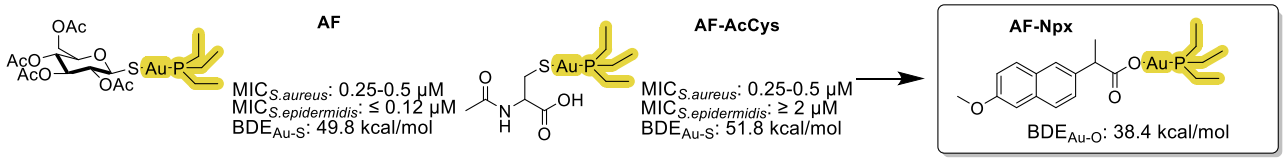

Figure 1: Chemical structures and experimental data of AF, AF-AcCys, and AF-Npx.

Chiral Nickel(II)-based Metal-Hydroxide Organic Frameworks (MHOFs) as Spin-selective Catalysts of Oxygen Evolution Reaction

A. Nicolini,[a] M. Campi,[b] R. Biagi,[b] M. Borsari,[a] A. Cornia,[a] A. Mucci,[a] F. Tassinari[a]

alessio.nicolini@unimore.it

Spin-polarized currents can reduce the overpotential required for the Oxygen Evolution Reaction (OER), which strongly limits the overall efficiency of the Electrochemical Water Splitting process (EWS).[1] Thanks to the Chiral Induced Spin Selectivity (CISS) effect,[2] chiral materials can create spin-polarized currents in the absence of external magnetic fields, promoting the formation of ground state O_2 ($S = 1$) while eliminating by-products with $S = 0$ (*e.g.*, H_2O_2). State-of-the-art catalysts for EWS are based on expensive and polluting noble metals like Pt and Ir. However, Metal Organic Frameworks (MOFs) containing first-row transition metals, including layered Metal-Hydroxide Organic Frameworks (MHOFs, see Fig. 1), are attracting increasing interest[3,4] due to their high surface area and porosity, low cost, "green" character, and tunability by chemical design. Since the use of CISS-active chiral MOFs (or MHOFs) as enhanced electrocatalysts for EWS is still an unexplored field, we synthesized a family of nanostructured chiral (Ni-C) and achiral (Ni-A) MHOFs based on Ni^{2+} and dicarboxylic ligands (Fig. 1), with low (1), intermediate (2) or high (3) crystallinity. The catalytic activity is found to increase with increasing crystallinity and Brunauer–Emmett–Teller (BET) surface area. More importantly, the current densities are systematically higher for the chiral samples than for the achiral ones (Fig. 1), confirming that chirality is a viable strategy to design efficient catalysts for EWS and OER.

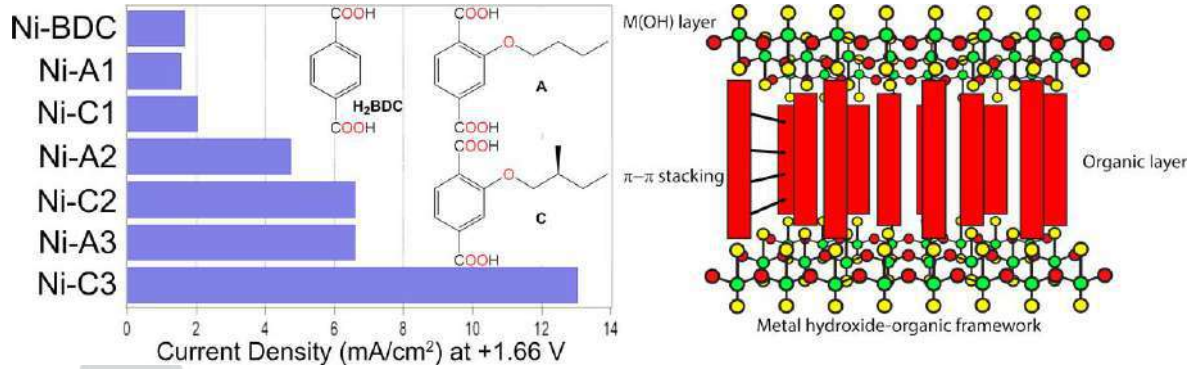

Figure 1: Left: Current densities of the Ni-MHOFs and structure of the ligands. Right: general model of a MHOFs.

Exploring the efficacy of paramagnetic nanogels as MRI probes

M. Ricci,[a] F. Carniato,[a] L. Tei,[a] F. Garello,[b] C. Furlan,[b] E. Terreno,[b] G. Parigi,[c] E. Ravera,[c] C. Luchinat,[c] M. Botta,[a]

In recent years, nanogels (NGs) have gathered increasing interest among the wide array of nanoparticles for biomedical application. These soft and hydrophilic nanoparticles are composed of a 3D crosslinked network capable of retaining a large volume of water, thereby mimicking biological fluids[1]. NGs can be loaded with paramagnetic complexes, which are likely to exhibit a notable increase of relaxivity (r_1)[2]. Despite their appealing properties, little is known about the relaxometric properties and *in vivo* behaviour of these systems. For these reasons, we developed several paramagnetic NGs and fully characterized them. Specifically, we investigated: a) Ionic NGs incorporating Gd^{3+} complexes (type A NGs) with varying coordination geometries and hydration states (q = 2, 1, 0)[3,4]; b) Covalent NGs where Mn^{2+}/Gd^{3+}/Dy^{3+} chelates serve as both paramagnetic probes and cross-linking agents[5] (type B NGs). Ionic NGs demonstrated superior r_1 values compared to clinically available contrast agents, but low chemical stability in biological environment, with a tendency to degrade, leading to a rapid release of the paramagnetic complexes embedded in the matrix. Covalent NGs, instead, show r_1 values remarkably higher than that of clinical contrast agents at 1.5 T, high stability of the suspension in physiological conditions, with the absence of metal leaking or particles aggregation. *In vivo* test revealed good extravasation and accumulation of the NG, with high T_1 contrast (at 1 T) achieved at 24 h post-injection in mice bearing subcutaneous breast cancer model. We consider these findings to offer a valuable insight for the development of biocompatible, stable and efficient MRI probes.

The crucial role of X-ray absorption spectroscopy for catalysts design

P. Dolcet,[a,b] F. Maurer,[b] M. Casapu,[b] J.-D. Grunwaldt[b]

paolo.dolcet@unipd.it

Noble metal-based heterogeneous catalysts play a key role in clean air and environmental applications, since they are highly active for several oxidation reactions. On the other hand, the scarcity and high costs of platinum-group metals (PGMs) demand constant improvements in the design of these catalysts, by reducing the amount of the noble metal while maintaining or, ideally, improving their activity. Common approaches are identifying and stabilizing the active species, exploiting the interaction between the support and the noble metal, and tuning the catalyst structure during the operation (e.g., via pulses).

All these approaches are inevitably connected to the question of the structure of the active species and their fate under working conditions. PGMs are known to be highly mobile on many supports, yielding highly dynamic systems for which establishing structure-activity correlations is no trivial task.

Through the example of platinum-based catalysts for CO oxidation, it is shown how advanced characterization methods, like *operando* X-ray absorption spectroscopy,[1–3] are an essential and powerful complement to common characterization techniques for deriving accurate conclusions on the catalytic performances of the active sites (and in general, of functional materials), and for understanding how to manipulate them to improve the catalytic activity of PGM-based oxidation catalysts.

greta.fogar@phd.units.it

Photosynthesis, a fundamental biological process, involves water oxidation reaction catalysed by three key steps in Photosystem II: initial absorption of visible light by the chromophore, followed by oxidation of the tyrosine donor and reduction of the quinone acceptor coupled with the transfer of a proton, through a *Proton Coupled Electron Transfer* mechanism (PCET).[1] Over the last decades, there has been a growing interest in developing systems that try to mimic natural ones, but most of them are covalent in nature, requiring demanding synthetic protocols.[2] To address this limitation, our focus turned on Sn^{IV}-porphyrins due to their distinctive electronic, optical and redox properties that make them intriguing as photoactive units.[3] Thus, we developed a family of Sn^{IV}-$(aa)_2$ porphyrins conjugates, with aa = *L*-tyrosine or *L*-tryptophan, that were easily assembled by axial ligation of the amino acid carboxylate moiety to the porphyrin metal centre. For two of such conjugates the formation of a radical pair state *via* PCET, by visible light excitation was observed (Figure, left).[4] Encouraged by these promising results, we altered both the relative position of the photoactive units, for instance by conjugating the amino acid residues at the porphyrin macrocycle periphery and the nature of the metal centre (Figure, right). Preparation, full characterization and photophysical studies of these new metallo-porphyrin/amino acid derivatives will be presented, also in comparison with the previously reported systems.

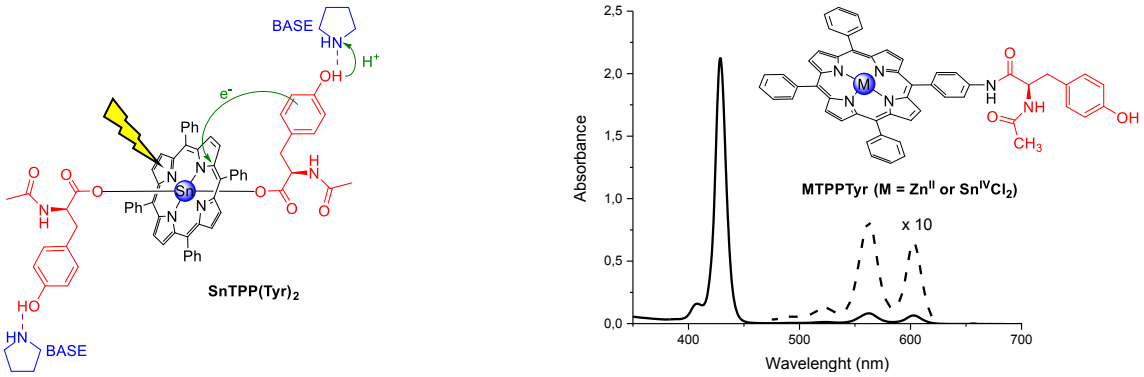

Figure. Left: Schematic representation of $SnTPP(Tyr)_2$ and photoinduced PCET. Right: Schematic representation of MTPPTyr.

asdamato@unisa.it

In recent decades, there has been increased investigation into the potential of late-transition metal owing to their relatively straightforward handling compared to traditional early-transition metal complexes, which are traditionally used in biological and catalytic applications.

In particular, Group 11 metal complexes featuring an *N*-heterocyclic carbene (NHC) ligand give result in readily tuneable species that may frequently be handled in non-inert environments and exhibit a variety of synthetic applications and bioactivities.[1] Our research group main focus is the development of silver(I) and gold(I) NHC complexes, active as catalysts in atom-economic multicomponent reactions, mainly involving carbon-carbon triple bond functionalization. These catalysts (Figure 1), whose imidazolium scaffold can be generated from readily available precursors,[2] are useful for the *A*[3] (aldehyde–amine–alkyne) coupling, hydroamination, and carboxylation of alkynes with a wide range of substrates, often in clean, green environments.

In this contribution, the synthesis and catalytic applications of our complexes will be covered, providing a mechanistic insight into three alkyne functionalizations which yielded us, respectively, propargylamines,[3] imines[4] and propiolic acids with conversions up to 99% in the presence of either our gold(I) or silver(I) based catalysts.

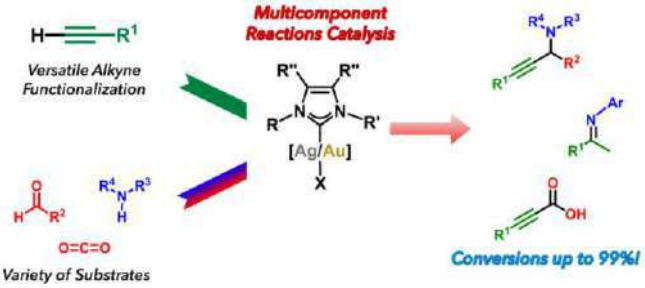

Figure 1: Multicomponent reactions promoted by Group 11 Ag(I)/Au(I) NHC complexes.

s.libri@campus.unimib.it

Lignin is a complex biopolymer, particularly interesting because it is a low-cost material available in large quantities from renewable resources such as waste biomass[1].The chemistry and structural variability of lignin depend on the type of plant/waste from which it is extracted and the type of extraction process that is used. Thanks to the studies carried out on the chemical, physical and structural properties, lignin can be considered as a sustainable material that can be exploited because it can be used in many fields. Self-assembly and supramolecular organization of lignin are properties underlying the realization of drug delivery systems in the form of micro/nanocapsules or particles or a combination of them, capable of carring an active agent for the protection of agricultural and forest product, in the field of crop protection[2].

In this study, a bimodal drug delivery system has been developed using lignins obtained by organosolv processing from different biomasses. The system is characterised by a microscopic core-shell structure, with the shell being of lignin and the core containing a lignin nanoparticle dispersion. The dual character, *i.e.*, a microcapsule containing particles, allows for a timing mechanism that is based on different engineered stabilities of the systems.

Each system has been characterized in qualitative terms by studying morphology and size using microscopy techniques such as scanning (SEM) and transmission electron microscopy (TEM) and dynamic light scattering (DLS), respectively. The stability of the different formulations obtained has been studied through zeta-potential measurement and spectrophotometer release studies of the active agent, varying the salinity and pH conditions of the system. To take into account the variability and performance of the different systems in terms of lignins with different molecular structures, an in-depth structural characterization of the lignins used was carried out by spectroscopic (quantitative ^{31}P NMR, ^{1}H-^{13}C HSQC) and chromatographic (gel permeation chromatography) techniques.

The results of this work hold opportunities as innovative hybrid system for controlled drug delivery in the field of crop protection.

andrea.masetti9@unibo.it

Plants, like any living organisms, require a diverse array of essential nutrients to carry out fundamental physiological processes crucial for growth, development, and defence against environmental stressors. When these vital nutrients are lacking or insufficient in the soil, plants are susceptible to a range of adverse effects that compromise their health. Amongst these, iron chlorosis is a prevalent and widely observed nutrient deficiency, frequently occurring in plants cultivated in calcareous soils, resulting in the manifestation of yellowing leaves, drastic reduction in crop yield and demise of individual limbs or the entire plant. The main remedial approach for iron chlorosis involves the application of iron chelates as fertilizers - however, the synthetic pathways currently in use to produce most commercial products trace their origins back to the 1970s, lacking sustainability and contributing to pollution. Hence, it is crucial to investigate innovative, optimized processes to guarantee both cost-effectiveness and environmentally sustainable production.

To overcome this problem, it was previously proved by Prof. Namba's research group that the soil application of synthetic 2′-deoxymugineic acid (DMA), a natural phytosiderophore from the *Poaceae* family, can recover Fe deficiency in plants grown in calcareous soil. However, the high cost and poor stability of synthetic 2′-deoxymugineic acid preclude its agricultural use[1]. In this work, we develop more stable and less expensive proline-derivative (PDMA) analogues of DMA and demonstrate their practical synthesis, ability to create stable complexes with Fe(III) via DFT calculations, and biological activity.

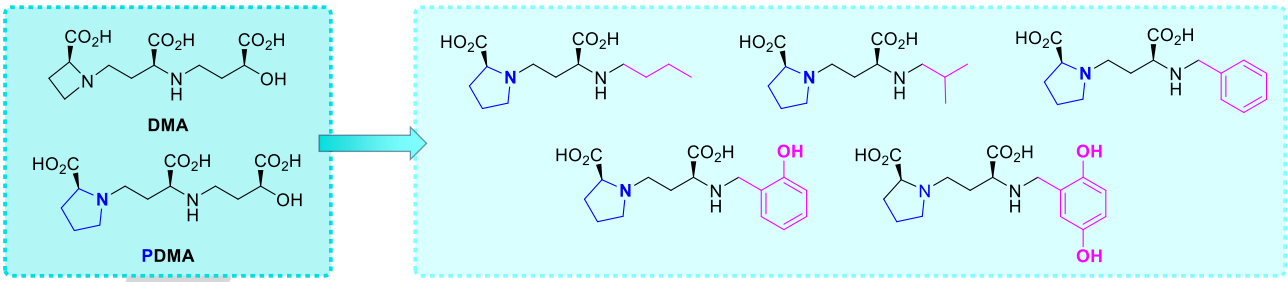

Figure 1: Previous results (left) and new differently substituted synthetic analogues of PDMA (right).

Gold nanoparticles (AuNPs) show peculiar chemophysical properties and have thus attracted in recent years the scientific interest of the academic and industrial communities for the design of tailored applications in personalized medicine. The self-assembly of glutathione-coated AuNPs (G-AuNPs) of ≈2 nm spontaneously produces, in physiological media, aggregates of ≈100-300 nm that are readily internalized in hepatic and neuronal cells [1] whereas the pristine singularly dispersed AuNPs are inactive. Aggregates of G-AuNPs functionalized with the dansyl chromophore are highly thermally responsive after excitation with a pulsed laser emitting in the near-infrared spectral region; considering the efficient penetration of this radiation throughout the tissues without damaging healthy cells this device can represent a powerful tool in photoablation of cancer cells.[1] Additionally, aggregates of G-AuNPs are efficient carriers of metal cations that can modulate the activity of glycogen synthase kinase 3 (GSK-3); the targeted in situ release of these metals at low dosage in specific cell compartments can allow fighting infectious and neurodegenerative diseases or controlling mood disorders regulated by GSK-3.[2] Finally, the incorporation of these systems in liposomes will be reported in this contribution, for the improved delivery of pharmaceuticals.

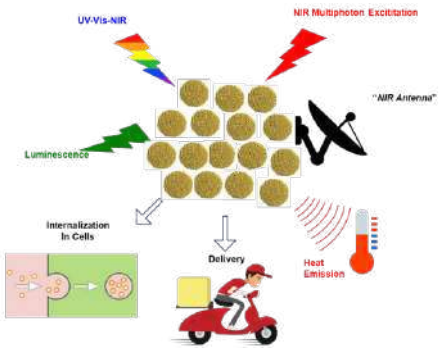

Figure 1. Functionalities of assembled glutathione-coated AuNPs.

This presentation focuses on the characterization of CoAl layered double hydroxide (LDH) as a viable, cost-effective electrocatalyst for efficient oxygen evolution rection (OER) in electrocatalytic water splitting under alkaline conditions. Morphological and compositional analyses were conducted using Transmission and Scanning Electron Microscopy (TEM, SEM), atomic force microscopy (AFM), and synchrotron radiation spectroscopy (at BACH beamline, Elettra), including x-ray photoemission spectroscopy (XPS) and near edge x-ray adsorption fine structure (NEXAFS). Operando NEXAFS and AFM were performed during OER.

Physical-chemical characterizations confirm that CoAl LDH has octahedrally coordinated Co with substitutional Al, and a homogeneous distribution of Co:Al in a 3:1 ratio. In electrochemistry, it exhibits a distinct activation trend with increasing activity in the OER. This enhanced activity is attributed to the leaching of Al and recrystallization, as revealed by operando measurements, which also show a unique redox behaviour different from the parent material, $Co(OH)_2$.[1] Operando measurements proved to be crucial for a comprehensive understanding, as pre- and post-catalysis analyses offer limited insights into real operating conditions.

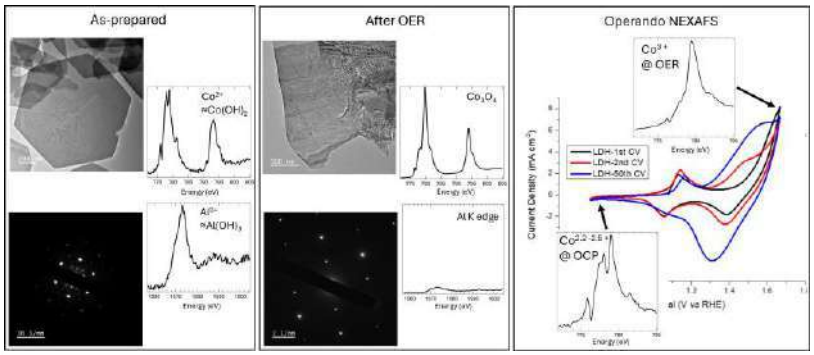

Figure 1: (Left) As-prepared TEM and NEXAFS measurements reveals CoAl LDH with Co^{2+} and Al^{3+} octahedrally coordinated, (centre) post-catalysis investigation shows Co_3O_4 and great loss of Al. (Right) Operando measurements prove a not trivial oxidation state at OCP with $Co^{2.2\text{-}2.5+}$, and Co^{3+} during OER.

* *simone.amatori@uniroma3.it*

Gold nanorods (AuNRs) have become increasingly popular in nanomaterials research due to their unique properties, including a tunable two-component surface plasmon resonance (SPR). This tunability makes AuNRs suitable for a wide range of biotechnological applications, from sensing to drug delivery. However, precise control of AuNR synthesis and functionalization is essential for reliable results[1,2]. We define a reliable route for AuNRs preparation and discuss in detail the surface functionalization of AuNRs using hydrophilic molecules such as L-cysteine, and demonstrate drug loading with *i*. a Cu(I) complex $[Cu(PTA)_4]^+PF_6^-$, known for its antitumour and antiviral activity, and *ii*. the radiopharmaceutical ^{99m}Tc-sestamibi, which is widely used for diagnostic purposes and whose theragnostic potential can be synergistically exploited with AuNRs for localised tumour cell damage[3]. Here, we describe our case studies that illustrate the tunability and versatility of AuNRs in different applications, and we present a multiphysics approach for the reliable structural, electronic and morphological characterization of these AuNRs, both in the bare (pristine) form and functionalized with specific molecules, carried out by combining complementary techniques: UV-Vis-NIR, DLS, XPS, XAFS, FE-SEM and TEM.

marzio.rancan@cnr.it

The step-by-step self-assembly pathway of a series of quadruple-stranded lanthanide cages have been studied and particular attention has been devoted to the energetic landscape of the equilibrium between the triple $[Ln_2L_3]$ and quadruple-stranded $[Ln_2L_4]^{2-}$. As proved by XRD and DFT calculations[1,2,3], the $[Ln_2L_4]^{2-}$ cage is present in solution as an equilibrating racemic mixture of left- and right-handed helicates and eventually the mesocate form. The equilibrium between the two opposite helical configurations can be orchestrated by encapsulation of a chiral guest, *i.e.* through a hierarchical chiral information transfer from a chirality at a primary level (the chiral guest) to the helicate composed of achiral components manifesting supramolecular chirality at a secondary level. Asymmetric induction by the chiral guest was studied by both CD and CPL. Moreover, the guest to host chirality transfer can be photoswitched by controlling the equilibrium between the triple- and quadruple-stranded cages by the addition of a photoacid that trigger the release of the chiral guest due the light-activated cage transformation.

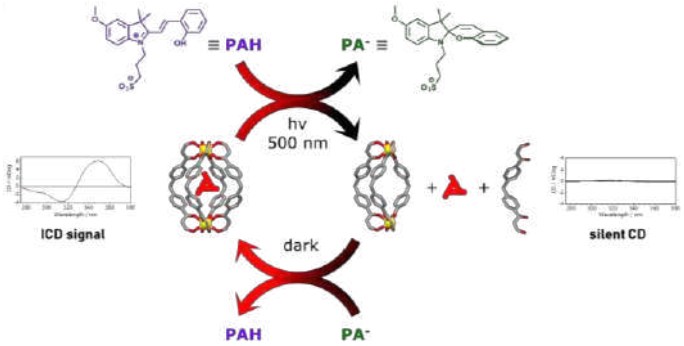

Figure 1: photoswitchable guest to host chirality transfer.

Zeolitic Imidazolate Framework, also known as ZIF-8, is a subclass of MOF that shows excellent biocompatibility, stability under physiological conditions and responsiveness to the weak acidic environment associated with malignant tumors and other diseases, that is why it has attracted attention in the biomedical field.

As illustrated in *Figure 1*, in this work we are presenting the use of ZIF-8 in three different biomedical applications *a)* fabrication of Cellulose/ZIF-8 patches for the management of wound infections[1]; *b)* encapsulation of snail slime[2]; *c)* modification of titanium scaffolds with ZIF-8 for bone substitution and regeneration.

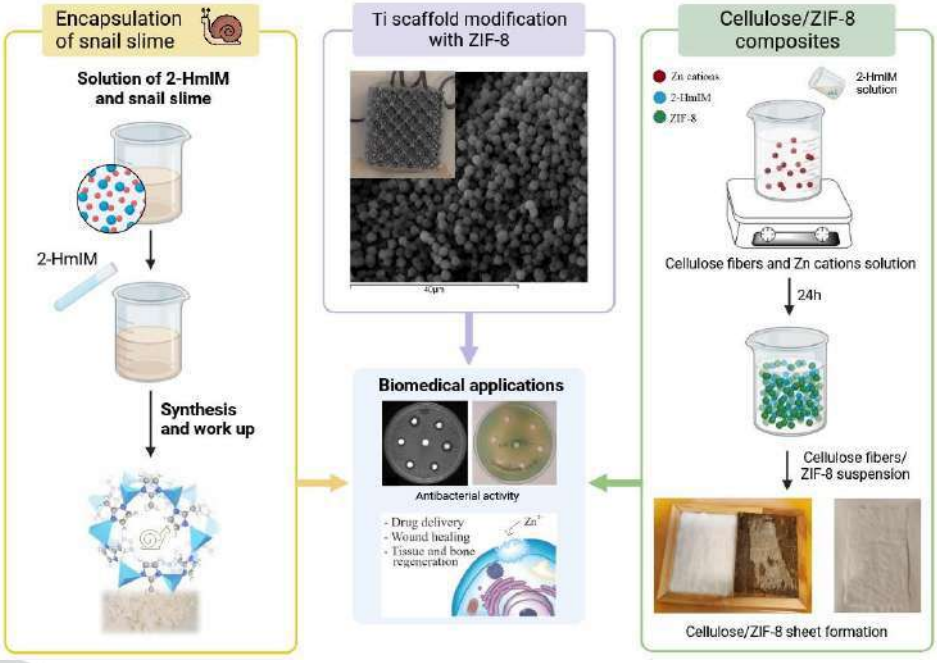

Figure 1: Schematic representation of the different research applications of ZIF-8.

A concise synthetic approach to asymmetric β-functionalized antipodal *push-pull* porphyrins for potential application in photovoltaic, NLO and PDT

M. Demingo[a], A. Lembo[a], L. Gontrani[a], C. Ricci,[a] L. Casoli,[a] M. Carbone[a] and P. Tagliatesta[a]

[a]*STARTNETICS, Dept. Chemical Science and Technology, University of Rome "Tor Vergata", via della Ricerca Scientifica 1, Rome, Italy*
miriam.demingo@uniroma2.it

Owing to their excellent electrochemical and photochemical properties, porphyrins are a class of molecules that have been studied for decades for use in photovoltaics, medicine and optoelectronics. This versatility is due to the possibility of introducing functional groups of different nature (electron acceptors or donors) at the *meso* and β-pyrrolic positions of the macrocycle. This allows fine-tuning of the properties and the generation of a high dipole moment for the *push-pull* effect involved in the aforementioned applications. Nearly all studies have focused on *meso*-substituted asymmetric porphyrins, which are synthesized with great effort. On the other hand, an alternative synthesis could be the post-functionalisation of a symmetrically substituted porphyrin; however, there are less cases in the literature where asymmetric β-substituted porphyrins bearing donor and acceptor groups linked on the macrocycle have been investigated as *push-pull* systems. In all of these β-functionalised architectures, the substituents are attached to the tetrapyrrolic core by the same linker or by the same fused ring, which results in a less effective transition of the dipole moment[1-3]

In our work, we present a new concise synthetic approach that, starting from a free base tetraphenylporphyrin, allows the selective introduction of acceptor and donor group in the final innovative structure, shown in Figure 1, offering the remarkable advantage of a highly asymmetric *push-pull* architecture that can be exploited in photoinduced electron transfer, PDT and NLO materials.

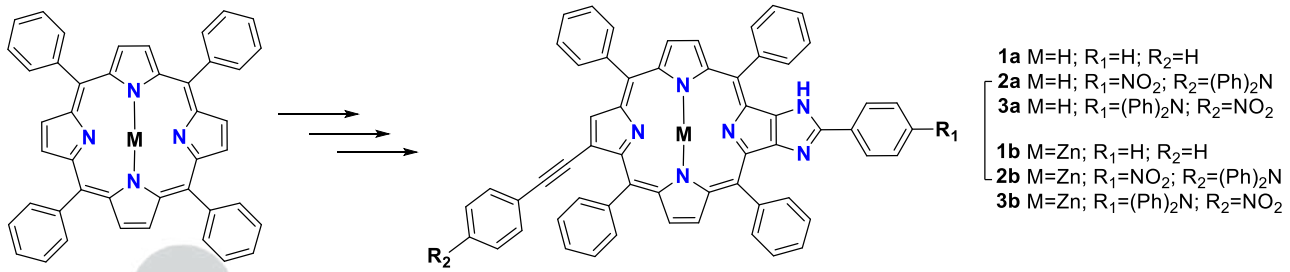

Figure 1: Core structure of asymmetric β-functionalized antipodal *push-pull* porphyrin.

Luigi.talarico@student.unisi.it

The human eye is particularly vulnerable to fungal and parasitic infections, caused e.g. by trauma from penetrating objects, carriage of microorganisms from adjacent structures, use of contact lenses. Negligence in timely treatment often results in vision impairment. Fungal keratitis is a major cause of blindness in corneal diseases and its topical treatment requires several eye-drops applications and may require additional injections or surgery. Natamycin, a tetraene polyene which acts by binding ergosterol, thus blocking fungal growth, is one of the proposed antifungal drug for topical treatments. However, its low retention at the ocular surface and scarce penetration across inner ocular tissues pose significant challenges. In this work, various lipid nanoparticles (LNP) and transethosomal (TE) systems loaded with Natamycin are physiochemically characterized and compared in terms of dimensions and stability studied by Dynamic Light Scattering, morphology investigated by Small Angle X-ray Scattering and Nuclear Magnetic Resonance, and encapsulation efficiency assessed with HPLC-DAD. Permeation in the organ was studied via a 3D-Printed tissue model

Using impacts for the self-assembly of coordination polymers and polynuclear metal complexes

G. Cagossi,[a] P.P. Mazzeo,[a] A. Bacchi,[a] A. Daolio,[a] P. Pelagatti[a]

[a]*Department of Chemical Science, Life Sciences and Environmental Sustainability, University of Parma, Parco Area delle Scienze 17/A, 43124 Parma, Italy*
paolo.pelagatti@unipr.it

Mechanochemistry is based on the use of impacts to trigger chemical reactions.[1] Usually, solid reagents are ground by means of ball-milling apparatuses in the absence of solvent or using a very small volume of it. This makes mechanochemistry highly attracting from an environmental point of view, eliminating the major component that, in a typical reaction conducted in solution, becomes a waste at the end of the reaction. However, one of the major drawbacks of mechanochemistry resides in the difficulty to monitor the progress of the reaction, since the grinding of the reagents occurs inside a closed jar made by hard materials, which is then usually considered a black-box.[2] Furthermore, the high heterogeneity of the reactant system can make mechanochemistry perceived as a way to make reactions by chance rather than an innovative way by which developing selective synthetic processes.

In this communication, the authors will show that mechanochemistry can indeed be used for the selective synthesis of metal complexes and coordination polymers containing carboxylate and pyridine ligands, with considerable advantages in terms of reaction times and yields with respect to the same reactions conducted in solution. Subsequent selective mechanically induced ligand exchange processes will also be shown, to highlight the versatility of the technique.

Finally, the mechanochemical synthesis of new hexanuclear crown-complexes deriving from the combination of Zn-acetate, isonicotinamide and p-halogen-substiuted benzoic acids will also be described, together with their crystalline structure solved by single crystal X-ray diffraction analysis.

alessia.giordana@unito.it

Bioactive glasses (BGs) are bioactive and biodegradable materials capable of releasing biologically active ions being suitable for several applications as regeneration of *soft* and *hard* tissue.[1,2] The loading of BGs with antioxidant substances may result in a more potent regenerative capacity, having the potential of modulate oxidative stress and, subsequently, improving processes time healing.[3,4]

In order to identify materials with optimal antioxidant activity, we carried out an evaluation of a series of mesoporous bioactive glasses (MBGs) (pristine or cerium-doped) loaded with different flavonols (3-hydroxyflavone, quercetin and morin). The modification of the surface properties by Ce-doping and/or impregnation with antioxidant molecules was investigated by FT-IR spectroscopy, electron microscopy (FE-SEM) and nitrogen adsorption–desorption isotherms.

The results of *in vitro* release, performed in PBS (Phosphate Buffered Saline), show a quick bioactivity, i.e. formation of formation of an apatite layer. All the studied materials slowly release the impregnated flavonol. Measurements of the capacity to scavenge DPPH radicals indicate that the antioxidant activity, although always present, depends on the impregnated flavonols.

matteo.alberti@unimi.it

In nature, most enzymatic oxidative processes are carried out by high-valent iron compounds.[1] The search for simple non-heme complexes as simpler synthetic models is crucial to the implementation of similar processes in laboratory and larger scales. Macrocyclic ligands play a leading role in this field, due to their ability to efficiently stabilize high oxidation states of iron-oxo compounds.[2]

Supporting ligands design, moreover, having a significant impact on the spin state of the nonheme iron (iv)-oxo and iron (v) complexes, exerts a huge influence on the outcome of oxygen atom transfer (OAT), hydrogen atom transfer (HAT), and electron transfer (ET) reactions.[3] Hence, a small library of several complexes of the pyclen family was synthetized to elucidate the effect of both macrocycle substituents and anionic ligands. Both iron (ii) and iron (iii) precursors were employed (**Figure 1**), and their structural and magnetic behaviour was fully characterized by means of Mössbauer spectroscopy, magnetometry and Raman spectroscopy. The generation of their active iron (iv) and iron (v) species was attempted with hydrogen peroxide and the characterization of their transition state was carried out with Mössbauer spectroscopy.

As expected, a strong correlation between their measured spin state and their reactivity in both C-H activation and alcohols oxidation reactions was discovered. This study was thus able to reveal the strong correlation between the structural and electronic features of this class of complexes and their observed reactivity.

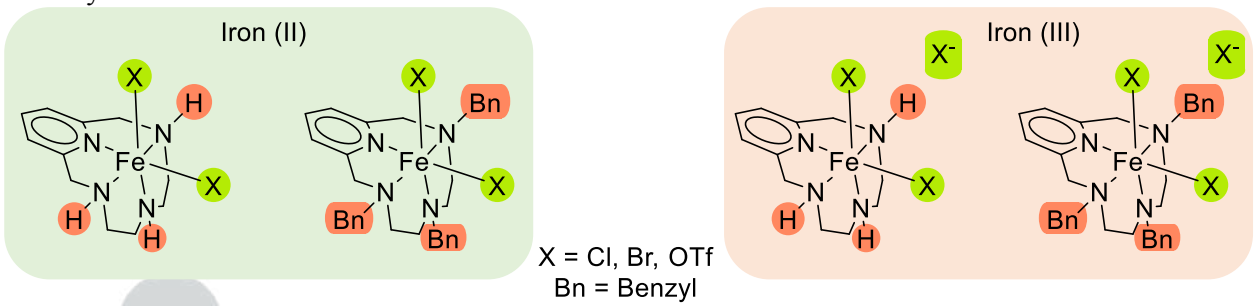

Figure 1: caption.

Novel on/off switch hydrogel functionalized with cyclometallated Ir(III) complexes for in vitro cell imaging in 3D platforms

Ariadna Lázaro,[a] Federica Fiorini,[b] Elena Longhi,[b] Luisa De Cola[a,b,c]

[a] *Institut für Funktionelle Grenzflächen (IFG), Karlsruhe Institute of Technology (KIT), Eggenstein-Leopoldshafen 76344, Germany.*

ariadna.lazaro@kit.edu

Three-dimensional (3D) cell culture has shown to better mimic cells natural environment and to allow cell proliferation in a more realistic manner, compared to two-dimensional substrates in which cells are cultured on traditional flat substrates and adapt to this synthetic 2D environment, often becoming flattened and showing a non-natural behaviour. Therefore, the direct visualization of living cells growing onto 3D platforms in real-time promises to be a powerful tool to reveal information for biomedical investigation. However, cell staining often requires tedious sample preparation and can induce alterations of the natural cell cycle. Thus, the incorporation of a luminescent probe for cells visualization within 3D hydrogels, which combines the advantages of emission detection and hydrogel for 3D *in vitro* cell proliferation, is highly desirable for opening new paths for *in vitro* imaging techniques.[1]

Amongst the most studied emitters, cyclometallated Ir(III) complexes are very appealing as bio-imaging reagents for cellular visualization.[2] Besides their outstanding photophysical properties, they exhibit the possibility to easily tune the excited state energy over the whole visible electromagnetic spectrum, from the ultraviolet to the near infrared region by ligand modification.[3] In addition, the complexes emit from a triplet excited state displaying a very long excited state lifetime, in the microsecond range. These characteristic results in increased sensitivity and possibility of implementation of time-gated techniques with elimination of short-lived fluorescence background (~ns), rendering cyclometallated Iridium(III) complexes optimal candidates as luminescent bio-probes.[4]

Herein, we introduce a novel hydrogel for in vitro cell study, with covalently incorporated cyclometallated Ir(III)-luminescent probes. An Iridium(III) complex was designed with a "off/on" emission response versus different environments. In particular, this turning on and off of the emission relies on the interaction of an Ir(III) complex, covalently anchored to the hydrogel, with the cells plasma membranes or with its position in the water phase. Such a change in the environment, from aqueous solution to lipid layer, causes the turn on of the emission of the iridium complex.

The mechanism for the off/on switching from water to the lipophilic environment of the cell's plasma membranes is studied in detail, demonstrating that this novel luminescent probe-incorporated scaffold is a very interesting 3D platform for in vitro real-time investigation of cells.

A vapochromic chemosensor based on a Zn(II) salen-type complex for the detection of volatile organic compounds

M. Gaeta,[a] I.P. Oliveri,[a] S. Di Bella,[a]

[a]*Università degli Studi di Catania, Viale Andrea Doria, 6, 95125, Catania*
massimiliano.gaeta@unict.it

Volatile Organic Compounds (VOCs) are molecules, in liquid or solid form, which due to their high vapor pressure, can easily evaporate at room temperature. Some VOCs are responsible for air pollution and can be hazardous to human-health.[1] Thus, the development of feasible and low-cost chemosensors is relevant for the direct monitoring of VOCs in specific environments. In this context, the use of chemosensors based on Lewis acidic Zn(II) salen-type complexes can represent a promising strategy. The sensing mechanism implies the formation of stable penta-coordinated adducts between the Zn(II) salen-type complexes and VOCs having Lewis basicity, such as nitrogenous-containing VOCs (N-VOCs), involving significant colour and luminescence changes giving rise to characteristic vapochromism.[2]

In this contribution, we report on the unique thermo- and vapochromic properties of a Zn(II) salen-type derivative from the 2,3-diaminomaleonitrile, Zn(salmal), with 5,5′-tert-butyl- bulky substituents on the salicylidene rings. In particular, both the synthesized and anhydrous complex (i.e., the latter achieved by solvent evaporation under nitrogen conditions) show a marked vapochromism if exposed to saturated vapours of various VOCs.[3] Interestingly, we also demonstrate the possibility to fabricate simple and low-cost paper-based sensors (PBSs) able to discriminate N-VOCs by well-defined spectroscopic and distinct naked-eye colour changes (**Figure 1**).

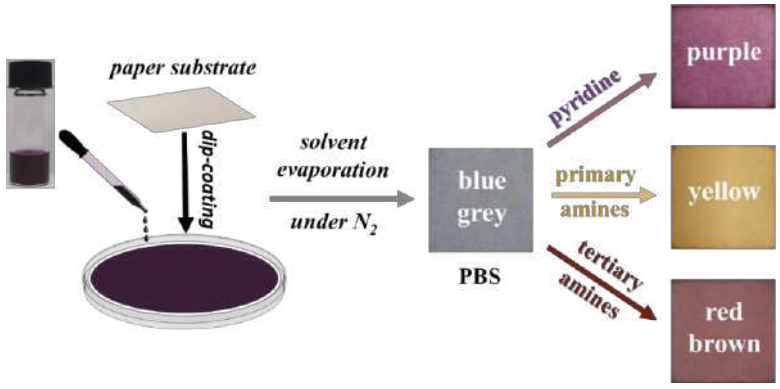

Figure 1: Scheme reporting the fabrication of PBS and its application to discriminate N-VOCs.

This contribution has been partially funded by European Union (NextGeneration EU), through the MUR-PNRR project SAMOTHRACE (ECS00000022)

Monodomain iron oxide nanoparticles with spinel structure (MNPs) are extremely interesting for a wide a range of applications, from technology to biomedicine[1]. Even though there is a well-established methodology to synthesize MNPs, the mechanism of their formation is still under investigation[2]. The co-precipitation of magnetite nanoparticles occurs after the addition of a base to the solution of precursors, typically Fe(II) and Fe(III) chlorides. In this contribution, we explore the formation mechanism of magnetite nanoparticles through different titrations of Fe(II)/Fe(III) solutions with sodium hydroxide in the presence of L-glutamic acid as a capping agent. The titration/co-precipitation experiments are performed by injecting the base at a constant temperature in the reaction batch containing the precursors and the capping agent. Morpho-structural features of MNPs are studied by X-Ray Diffraction (XRD) and Transmission Electron Microscope (TEM). Thermogravimetric analysis coupled with Fourier-transform Infra-red spectroscopy (TGA-FTIR) is used to investigate molecular coating on nanoparticle surface. Colloidal stability and hydrodynamic diameter of the nanoparticle' dispersions are evaluated by Dynamic Light Scattering (DLS). The magnetic properties (i.e. field and temperature dependence of magnetization) and Hyperfine structure of MNPs will be investigated by VSM magnetometry and Mössbauer spectroscopy respectively. Finally, the experiment is repeated by dripping the solution of the Fe(II)/Fe(III) precursors into the reaction batch already containing the sodium hydroxide and the L-glutamic acid.

Polyethylene terephthalate plastic (PET) is one of the most extensively used materials worldwide because it is affordable, lightweight, and extremely durable. A proper end-of-life management is essential, in order to meet growing environmental concerns. In recent years, there has been an increasing focus on the chemical breakdown and recycling of PET materials, whose primary goal is the recovery of the polymer components (monomers) that are used to create PET, namely ethylene glycol and the more expensive terephthalic acid. Such compounds can be used to synthesize again the virgin polymer, resulting in a complete recycling of the original waste.

Zn^{2+} ions have been shown to catalyze PET hydrolysis by attacking the carbonyl group as Lewis acid as described in the reaction in Figure 1. This reaction yields the starting PET monomer but requires high temperature and a long reaction time (180 ° C 24 h)[1], making it economically non-viable for PET waste recycle.

In this work, we present a new approach, based on the use of a deep eutectic solvent (DES) composed of $ZnCl_2$ and urea in 1:3.5 molar ratio. The outcome is an onset of depolymerization of post-commercial PET flakes in a microwave oven, occurring already in less than 5 minutes. To gain insight into the process, the resulting depolymerization products are characterized by FTIR-ATR and XRD measurements.

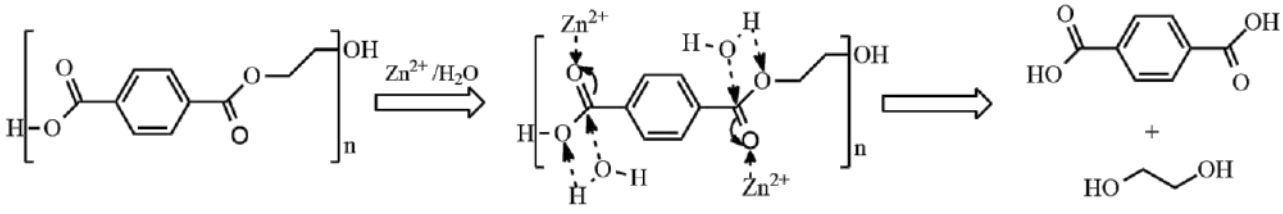

Figure 1: Tentative hydrolysis mechanism of PET using Zn^{2+} as catalyst.

One of the increasingly valuable natural resources is clean water. As an example, intensive farming plays the dual role of an avid consumer and a potential polluter. In this regard, agrochemicals are considered emerging water pollutants that might be harmful to the environment and public health.

Here we propose a new tool for water purification based on sulfobutylether-β-cyclodextrin (Captisol®) and magnetic nanoparticles (MNPs) supramolecular assemblies (MNP@Captisol®). The nano/microstructured morphology and cyclodextrin (CD) functionalization ensure respectively large surface-to-volume ratio and selectivity and sensitivity towards agrochemicals capturing [1]. Once the inclusion complex between CD and the pollutant is formed, it is removed from aqueous solution by simply magnetic settling. The novel assembly based on trade Fe (II/III) oxides nanoparticles covered by Captisol® was prepared under Argon bubbling and vortex mixing, purified by magnetic settling, and characterized by DLS, TGA, XPS, TEM analyses and magnetization measurements. The MNPs@Captisol® assembly showed interesting preliminary results toward Paraquat water remediation. Due to its widespread use in agricultural and non-agricultural settings and its toxicity to humans and wildlife, the herbicide was selected as pollutant model in our studies.

Insights into graphene oxide reactivity through different functionalization strategies

L. Giaccari,[a] F. Amato,[a] A. Motta,[a] A. G. Marrani[a]

Graphene is a bi-dimensional nanomaterial composed of sp^2 hybridized carbon atoms. Since its discovery in 2004, it has catalyzed the interest of the scientific community due to its notable properties and peculiar structure. Its potential applications are countless, nonetheless, it possesses three main drawbacks: it is poorly dispersible in polar solvents, its synthetic pathways are not currently suitable for scalable quantities of products and its functionalization reactions are limited[1]. In the group of graphene-like materials graphene oxide (GO) can be considered an optimal starting point for producing hybrid functional materials. GO is a versatile nanomaterial that overcomes the limitations of pristine graphene while it both retains and can retrieve several of its properties[2]. It is composed of a graphitic sheet decorated with a wide variety of oxygen functional groups (OFGs) e.g. epoxides, hydroxyls, carbonyls, and carboxyls[3]. Such moieties expand the chemistry of GO compared to pristine graphene. Indeed, the properties of GO can be tuned by exploiting these OFGs through a series of functionalization reactions[2].

This study aims to obtain insights into GO reactivity through a series of functionalization strategies. The reaction pathways investigated focused on producing aminated GO (GO-NH_2) and carboxylated GO (GO-COOH) by exploiting epoxide ring opening reactions and O-acylation pathways[2,3]. Through the knowledge obtained the focal point is to produce graphene-based hybrid materials with target properties for applications in specific fields[2]. The reactions proposed are fully characterized by employing XPS, Raman spectroscopy, and UV-Vis spectroscopy.

In recent years, many efforts have been devoted to obtain inorganic nanomaterials with controlled size, shape and crystalline phase, features which all play a relevant role in determining the final functional properties[1]. In particular, it is well known that the conditions under which a material is produced (either thermodynamic or kinetic regime) strongly affect its composition (i.e., distribution and/or intermixing of the present elements), its structure (formation of a particular polymorph, segregation) and therefore the resulting functional properties of materials.

This work is focused on a systematic and comprehensive comparison of the effect of different synthetic routes on the functional optical and chemical-physical properties of luminescent nanomaterials. In this context, we paid special attention to the comparison between two different synthetic routes, i.e., inverse miniemulsion (wet-chemistry)[2] and ball milling (solid state-chemistry). These synthetic approaches are established as powerful methods to control the final size and size distribution of the resulting nanoparticles. Eu^{3+}-doped calcium molybdate $CaMoO_4$ [2,3] was chosen as model system, as it is an interesting promising material for the development of new phosphors for optics and solid-state lighting[4].

The target system was synthesised with different Eu^{3+} amount through the two different synthetic routes, resulting in both cases in crystalline Eu^{3+}-doped calcium molybdate (PXRD). Further XAS analyses at Eu L_3-edge and Mo K-edge were carried out to investigate the dopant-induced variations on the electronic and short-range structure of the Eu^{3+}-doped samples. By performing in situ XAS measurements during annealing processes at 900°C in vacuum and in He flow, we followed the evolution of the Eu^{3+}, resulting in a partial reduction of Eu^{3+} to Eu^{2+}, with different degree and kinetics depending on the different synthetic routes. The presence of Eu^{2+} is hypothesised to be related to the observed quenching of the emission (λ_{exc}=302 nm) both for miniemulsion and ball milling samples, likely due to the presence of an intervalence charge transfer[5].

The crystal site occupancy of different divalent ions and the induction of lattice defects (vacancies, dislocations, stacking faults and antiphase boundaries) represent an additional tool for modifying the intrinsic magnetic properties (e.g. high coercive field and/or exchange bias) of spinel ferrites nanoparticles.[1] An efficient strategy to introduce defects into the ferrite spinel lattice is the controlled oxidation of core@shell AFM@F(i)M $Fe_{1-x}O@Fe_3O_4$ NPs. Interestingly, with this approach also defected cobalt ferrite with very large exchange bias are obtained. However, the final NPs displayed a magnetic behaviour strongly affected by the contribution of the antiferromagnetic component, due to the formation of a large magnetic disorder spinel ferrite sub-domains.[2] A possible strategy to overcome the drawback is to add, to the defected cobalt ferrite, a second divalent cation able to restore the magnetic order while retaining the lattice defects. Here we present an investigation aimed to rationalize the effect of $Co^{(II)}$ and $Ni^{(II)}$ on the lattice defects induced in spinel ferrite NPs by solvent mediated mild oxidation of AFM@FiM precursors, and on how they affect the magnetic properties. 20 nm core@shell nickel, cobalt doped-iron oxide NPs synthetized by thermal decomposition method,[3] were oxidized to the single-phase nanocrystals. As a result, the appearance of crystal defects and antiphase boundaries improves the magnetic properties of the starting compounds and leads to the appearance of exchange bias at room temperature.

alessia.zollo@unito.it

In the past few decades heterogeneous photocatalysis achieved a leading role in the research field of environmental remediation. Among the visible light active materials that find application in this field, titanium dioxide modified with non-metals such as C and N has been, and still is, extensively studied.[1,2,3,4]

This work is carried out in collaboration with Colorobbia Research Centre (Ce.Ri.Col)[5] which develops visible light active materials.[6] Different systems were prepared on a pilot scale with remarkable visible light photocatalytic activity using a commercial TiO_2[7] and ammonium citrate as a simultaneous source of N and C. Furthermore, we were able to shed light on the key role of C modification in driving the photoactivity towards a specific application.

We obtained a family of catalysts of variable composition containing nitrogen mainly in the oxide bulk and a partially graphitized carbonaceous phase at the surface. For the photoactivity assessment two tests were employed: NO_x abatement in gas phase and phenol degradation in aqueous phase. The characterization highlighted that the bulk nitrogen allows the formation of localized states in the band gap of TiO_2 and it is primarily involved in the production of superoxide ($O_2^{\bullet-}$) while carbonaceous species are mainly located at the surface, and linked to the photogeneration of singlet oxygen ($^1O_2$) which has a crucial role in driving the photoactivity both in gas and liquid phase. In gas phase (NO_x abatement) $^1O_2$ is detrimental for the photoefficiency, whereas in liquid phase (phenol degradation) this species has a beneficial role. Therefore, the photocatalyst activity can be modulated according to its actual application tuning the carbon content.

Chiroptical Ln(III) complexes are arousing more and more interest, thanks to their potential application in both optical materials[1,2] and biological[3] fields. In this contribution, the optical, chiroptical and thermodynamic properties of new Ln(III) complexes bearing differently substituted hydroxycoumarins (Figure 1) have been investigated. Different sensitization efficiencies of the Tb(III) and Eu(III) luminescence have been detected, with CoumB exhibiting the highest efficiency for Tb(III) ($\eta_{sens} \geq 62\%$). The energy position of the ligands' excited states has been experimentally determined, whilst the dynamics of the ligand-to-metal energy transfer process has been computationally studied.

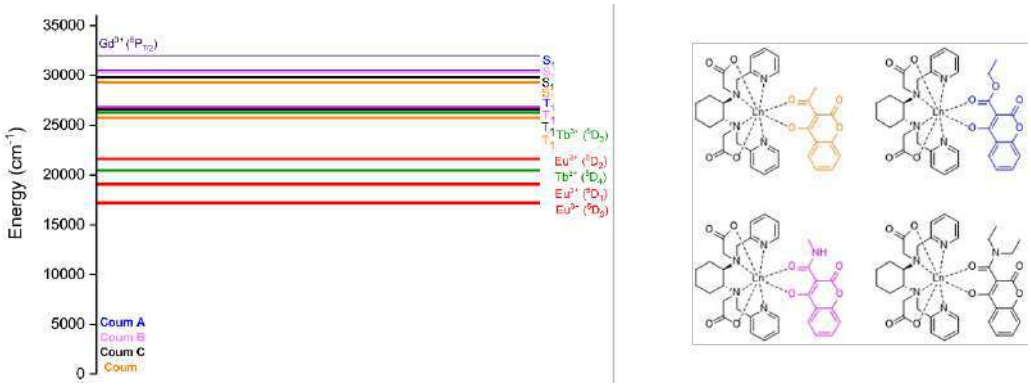

Figure 1: (Left) Energy diagram of S_1 and T_1 levels of the different coumarin ligands and Ln(III) excited states and (right) chemical structure of the Ln(III) complexes (Ln = Eu, Gd, Tb) with differently substituted coumarin ligands.

Quantum dots (QDs) have been extensively studied over the last three decades due to their finely size- and shape-tunable optical and electronic properties. The relevance and disruptive nature of QDs discovery was sealed with the awarding of the 2023 Nobel Prize in Chemistry. Studying and controlling many important structural features like size, size dispersion, crystal structure, defectiveness, surface structure, and faceting was challenging from the early days[1] and still lacks established analytical approaches today. We tackled this problem by combining X-ray total scattering techniques in the wide- (WAXS) and small-angle regions (SAXS), and by using the Debye scattering equation (DSE) based modelling approach.[2] The core advantage of this analytical approach lies in its capability to use specially tailored models, which encompass the studied structural features, to fit high-quality total scattering data. This approach has been successfully applied several classes of QDs including PbS[3,4], zincblende CdSe[5], and perovskites[6,7]. We have now developed a novel approach to characterize wurtzite CdSe QDs in the 2.3 to 5.6 nm size range to obtain an atomic-to-nm characterization encompassing defectiveness and morphology. The simultaneous SAXS/WAXS total scattering data modelling revealed a faceted hexagonal prismatic morphology, characterized by the variable presence of {001}, {100}, and {011} facets. Moreover, the analysis demonstrated a markedly different trend in the concentration of stacking faults within wurtzitic QDs relative to their average size, differing from previous observations in zincblende CdSe QDs.

This work demonstrates the potential of the proposed analytical approach to disentangle complex and intertwined features of structure defectiveness and nanocrystal morphology, which could have a significant impact on the final properties of CdSe QDs and semiconductor nanocrystals in general.

claudio.garino@unito.it

Copper is one of the most available transition metals in the Earth's crust and seawater. It is employed in many natural processes and finds application in different fields, such as dye-sensitized solar cells, solid-state lighting devices, and redox-active catalysts. In particular, the last years marked an increase in the interest for photoactive copper complexes, due to their potential use in solid-state lighting devices. In this context, Light-emitting Electrochemical Cells (LECs) are of high interest for soft-lighting applications and disposable (opto)electronics, and copper complexes offer a sustainable alternative to electroluminescent materials based on poorly available second and third-row transition metals.[1]

Recently, fully Cu(I)-based white LECs have been achieved *via* host:guest approach, reaching on par performances of the Ir(III)-based counterpart.[2,3] Among the variety of possible combinations, tetrahedral heteroleptic $[Cu(P\hat{}P)(N\hat{}N)]^+$ are one of the most studied options. Herein we present a new series of such compounds, with the aim of expanding the colour range of the emission towards the green-blue part of the visible spectrum. The complexes are based on Xanthphos as the P^P ligand and on differently substituted pyridine pyrazoles as the N^N ligand. They have been structurally and electronically characterized and the most promising ones have also been incorporated and tested in prototypal LEC devices.

Figure 1: General structure of the emitting complexes.

serena.schiavi01@universitadipavia.it

Polydopamine (PDA) is a versatile biopolymer with great adhesive properties[1] that spontaneously self-polymerizes from dopamine (DA) in weak alkaline media and in presence of oxygen[2]. Here we describe the coating process of silver nanoparticles (AgNPs) with an ultra-thin layer of PDA to increase SERS signal of Methylene Blue (MB), as hypothesised on the basis of the well-known affinity between PDA and MB[3]. The control of the thickness is crucial since the SERS enhancement is strictly dependent on the distance between the target molecule and the plasmonic substrate. Four different thicknesses were obtained, labelled as @PDA003/006/012/031 stating for the different amounts of DA monomer employed (mg/mL).

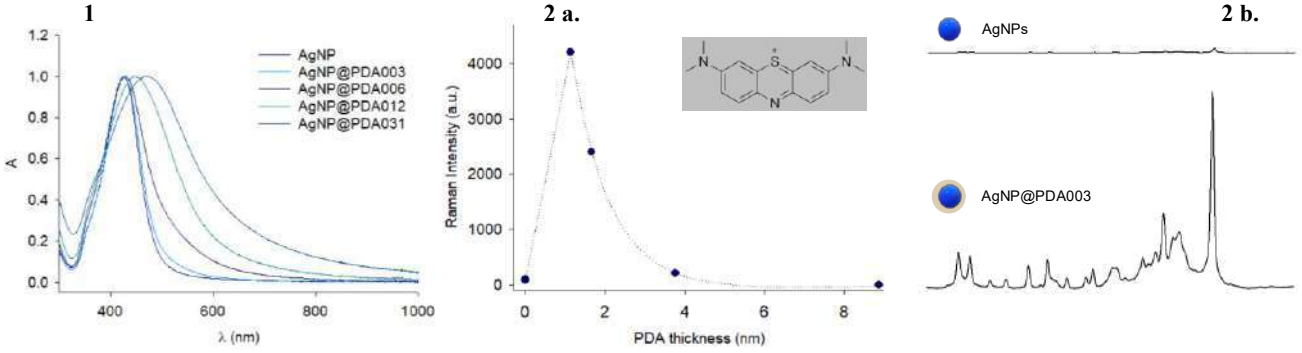

Figure 1: Uv-visible normalised spectra of bare AgNPs and PDA coated AgNPs with different shell thicknesses. **Figure 2 a.:** SERS intensity trend of Methylene Blue 10^{-6} M at 1624 cm^{-1} as PDA thickness increase. **Figure 2 b.:** SERS spectra of Methylene Blue employing respectively AgNPs and AgNP@PDA003 as SERS substrate.

The substrates have been characterized with TEM microscopy, Dynamic Light Scattering (DLS), Uv-Visible and Raman spectroscopy, demonstrating that huge increase in the SERS signal of MB can be obtained with a careful tuning of PDA thickness if compared to bare AgNPs.

eleonora.previati@polito.it

Phosphorescent metallapolymers have recently gained great interest due to the possibility of endowing polymers with the bright and color tunable emission typical of Ir(III) cyclometalates with general formula $[Ir(C^N)^2(N^N)]^{0/+}$ [1]. In this context, we designed a series of "polymerizable ligands" capable of coordinating the metal center and, at the same time, being able to copolymerize with methacrylic monomers. Therefore, we equipped four well-known diimine ligands $(N^N)^{2,3}$ with a polymerizable styril unit. Then, metallapolymers were obtained either by the complexation of a pre-formed MMA-L copolymer with different amounts of appropriate Ir fragments, or by the copolymerization of the mononuclear Ir(III) complexes with MMA. The new hybrid materials displayed intense phosphorescence in the solid state, with high PLQY and Ir(III)-centred emission colors spanning from blue to orange, paving the way for the application of this new class of metallapolymers as LSCs.

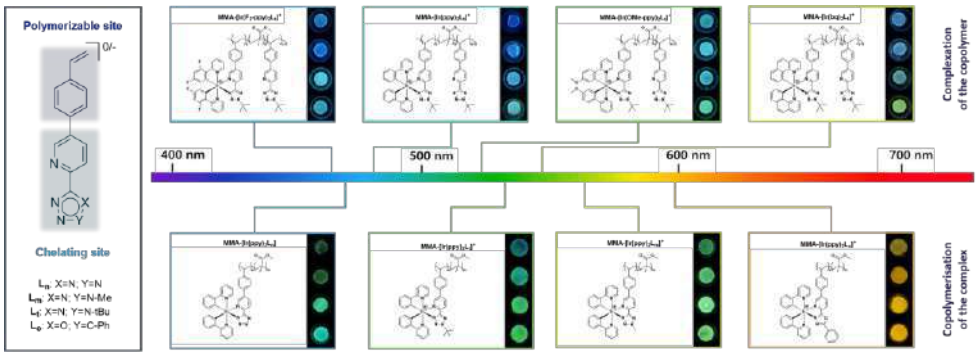

Figure 1: General structure of the polymerizable ligands; materials structures and appearance under UV light.

This publication is part of the project PNRR-NGEU which has received funding from the MUR – DM 351/2022.

Luminescent solar concentrators based on energy transfer in polyurethane matrices

L. Mauri,[a] D. Roberto,[a] F. Fagnani,[a] C. Dragonetti,[a] A. Colombo,[a] G. Griffini,[b] E. Tatsi[b]

[a]*Dipartimento di Chimica, Università degli Studi di Milano and UdR-INSTM di Milano, via Camillo Golgi 19, Milano*

luca.mauri@unimi.it

For a more sustainable energy transition, the use of solar energy has become of paramount importance, and Luminescent Solar Concentrators (LSC) represent an important solution for a smarter and more integrable photovoltaic. LSC are transparent slabs, generally made of glass, coated with a thin polymeric film containing a luminescent dye, that absorbs and re-emits a portion of the solar radiation. The emitted light is concentrated at the edges and converted into electricity by small photovoltaic cells.

Luminescent perylene diimide and benzothiadiazole dyes have been considered because of the possibility to improve the LSC performance through a Förster Energy Transfer (FRET) process, leading to enhanced light-harvesting efficiency and cost effectiveness[1]. Also, their covalent incorporation into a polymeric backbone allows a homogeneous distribution in the matrix, hence allowing an efficient energy transfer, and it also offers a reduced molecular aggregation, thus, a reduced aggregation-caused quenching[2].

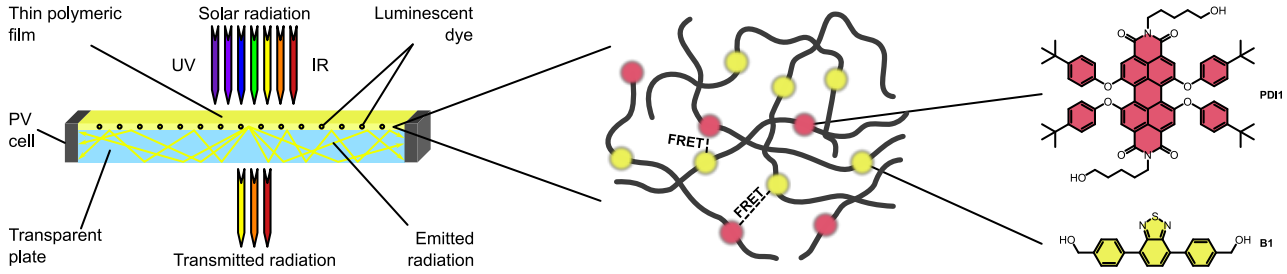

Figure 1: schematic representation of an LSC (left), of the synthesized polyurethanes (centre), and of the dyes **PDI1** and **B1** (right).

Here we present new LSC devices in which the donor, benzothiadiazole **B1**, and the acceptor, perylene diimide **PDI1**, are covalently incorporated into innovative polyurethanes. In particular, an LSC device realized with a polymer incorporating both **B1** and **PDI1** in a 1.00:0.15 ratio exhibited a photovoltaic efficiency of 0.63 % and an impressive external photon efficiency of 3.97 %. Therefore, covalent incorporation of **B1** and **PDI1** in a polyurethane matrix and the FRET process represents a step forward in the development of LSC.

emil.milan@univr.it

Lanthanide-doped alkaline-earth nanoparticles (NPs) are emerging luminescent tools for biomedical diagnostics applications [1-3]. In order to optimize the NPs performances it is of paramount importance to understand how the synthesis conditions influence the chemical-physical as well as the luminescence properties of the NPs.

Microwave (MW) assisted hydrothermal synthesis is a technique that reduces reaction times and at the same time improves the reproducibility of the synthesis due to the possibility of finely tuning the reaction conditions, such as temperature and time. In the present investigation, we focused on the preparation of Er^{3+}, Yb^{3+} and Eu^{3+} ions doped CaF2 or SrF2 NPs using MW assisted procedure by correlating the synthesis parameters, including the concentration of the reagents and capping moieties with the size and morphology of the NPs as well as their luminescence properties.

In particular, luminescence spectra and decay curves in the visible and infrared regions have been investigated. From preliminary data, we observed a relevant influence of the reaction temperature and time on the size of the NPs. Moreover, the colloidal properties as well as structural morphology of the NPs are heavily modified upon the variation of the capping moiety. The concentration of the starting metal and fluoride precursors plays an important role in controlling the NPs size and, in particular conditions, also the crystallinity of the NPs. The growth of a shell of the same host surrounding the NPs can be easily induced with the same synthetic procedure. By proper doping of the shell, it is possible confer different emission properties and also improve the intensity efficiency of the luminescence.

mariagrazia.fortino@unicz.it

Hybrid organic–inorganic perovskites (HOIPs) have emerged as excellent materials for solar cell applications. Indeed, their extreme tunability and facile synthesis have opened the door to many new applications. Chiral HOIPs are attracting great interest as promising frameworks for chiroptoelectronics as well as spintronics applications. The chiroptical properties observed in chiral HOIPs can be explained understanding the chirality transfer from the chiral organic molecules to the achiral inorganic octahedra. A key element of the chirality transfer mechanism involves the distortion of the coordination geometry of the inorganic octahedra induced by the presence of chiral ligands. The specific process through which a chiral bias is generated from a chiral organic ligand to the inorganic scaffold has remained unclear until now. [1,2]

In this study, we propose a tailored simulation workflow based on Density Functional Theory (DFT) and Time-Dependent Density Functional Theory (TD-DFT)[3] to theoretically explore the chirality transfer mechanism inducing chirality generation and coordination geometry distortion. To this aim, we investigate the chiroptical response of lead- and tin-based 2D chiral perovskites, specifically 2D R- and S-(MBA+)2PbI4[4] and R- and S-(MBA+)2SnI4.[5] We explore the most impactful factors influencing their Circular Dichroism (CD) signals through ab-initio molecular dynamics simulations and the analysis of the density of electronic states (DOSs). Our findings reveal that the relevant chiroptical features are linked to a chirality transfer event driven by a metal–ligand overlap of electronic levels. This effect is more evident for tin-based chiral perovskites showing higher excitonic coupling. Recent simulations on thermodynamics and kinetics aspects of the early stage of their chiral formation will be also discussed.

Metal halide perovskite (MHPs) solar cells represent a promising newcomer in the front of emerging photovoltaic technologies to address the dramatic energy crisis and climate change that we are facing. The exceptional properties of MHPs derive from their hybrid organic-inorganic nature, which allows also for low-cost and straightforward processing. Despite the exceptional performances achieved, a major limitation, still preventing the uptake of the technology, is related to the reduced stability of these materials when exposed to the external environment. Herein, an effective defect passivation of MHP surfaces is a key strategy to tackle both the stability and the enhancement of solar cell performances. We propose here an innovative use of plasma, as a solvent-free, scalable, and non-invasive promising strategy to boost MHP solar cells performances[1]. As benchmark material we used Methylammonium Lead Iodide perovskite; thus, we have exposed the surface of polycrystalline thin films made of this material to different plasma conditions implying the variation of power, gas, treatment time and pressure. The impact of *Ar*, N_2, H_2 and O_2 low pressure plasmas (LPPs) on $MAPbI_3$ optochemical properties and morphology was correlated to the performance of the photovoltaic devices and rationalized by density functional theory calculations. An interesting improvement in photoluminescence was observed for the *Ar* and H_2 treated films, while an improvement in PCE was observed only for the *Ar* treated device. This result was ascribed to the efficient removal of the superficial organic component, revealed through X-ray photoelectron spectroscopy (XPS), following suitable surface passivation by the electron transporting layer deposition. Starting from these encouraging results, new plasma surface treatments are now object of evaluation, such as atmospheric pressure plasma processes, the plasma-deposition of thiophene-like films, and the study of LPP treatments applied to tin-based perovskite solar cells.

Electrochemiluminescence (ECL) can be defined as the generation of light by electron transfer between species generated electrochemically.[1] Thanks to the combination between electrochemical and spectroscopic methods, ECL possesses several advantages, such as (i) temporal and spatial control on light emission, (ii) intrinsically very low background and high sensitivity and rapidity, and (iii) broad dynamic range with low volumes (≤1 mL). Thanks to all these advantages, ECL is very appealing for the development of cheap Point of Care (PoC) devices. In this context, we are interested in the design of ECL-based biosensors, with a particular attention, in the framework of the Eclipse Project,[3] for the detection of infectious pathogens. Nowadays, the most accurate *in vitro* diagnostic tests are still mainly based on pathogens' Nucleic Acid (NA) detection by real-time PCR assays. However, PCR-based methods are typically quite complex and slow, requiring NA extraction and purification, and expensive devices. To overcome these limitations, while maintaining the same sensitivity, we are trying to take profit of a synergistic combination of several elements, such as (i) the design of bio- and nano-structures for signal amplification in luminescence-based techniques, (ii) the identification of new biotechnological approaches for the recognition of the desired analytical target endowed with high affinity and selectivity, and (iii) push the electrochemiluminescence detection technologies to unprecedented sensitivities, through a detailed study of all the mechanisms leading to the generation of light. In this context, very promising results have been already obtained for the Hepatitis B Virus[3] and Sars-Cov-2 have been already obtained, with LoD in the aM range, while the extension to other pathogens is in progress.

Acknowledgments: Eclipse project has received funding from the European Union's Horizon Europe EIC Pathfinder Open programme under Grant Agreement N. 101046787.

Transition metal complexes of Schiff base ligands as G-quadruplex DNA binders

G. Barone

Dipartimento di Scienze e Tecnologie Biologiche, Chimiche e Farmaceutiche (STeBiCeF), Università degli Studi di Palermo, viale delle Scienze, Edificio 17, 90128 Palermo
giampaolo.barone@unipa.it

Square planar Schiff base complexes of transition metal ions have been recently designed and synthesized, as potential G-quadruplex (G4) DNA-binders.[1,2] Besides the important role of the metal ion in determining the DNA-binding strength and sequence affinity, the nature of aromatic ring on the N,N' bridge of the Salen scaffold (Fig. 1) and of the positively charged side chains allow to opportunely tune the DNA-binding properties of the resulting metal complexes. Furthermore, these compounds show interesting oxidation activity of guanine DNA bases into 8-oxoguanine. The oxidation mechanism and how this may affect the G4-DNA structure and stability is being investigated by experimental and computational approaches.

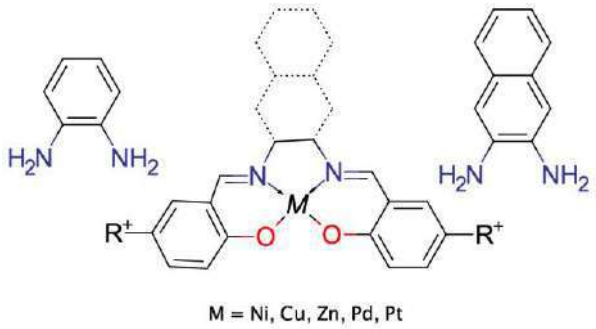

Figure 1: Structure of generic Salen-like metal complexes

Solar to chemical energy conversion with plasmonic photocatalysts

A. Naldoni

Department of Chemistry and NIS Centre, University of Turin, Turin 10125, Italy
alberto.naldoni@unito.it

The storage of solar energy in the form of chemical bonds through the synthesis of fuels and chemicals is a strategic approach to dispatch on-demand and continuous supply of clean energy carriers. Semiconductor photocatalysts naturally transduce solar radiation in redox photo-potentials, thus enabling chemical transformations. In contrast, metal nanostructures present a wide range of non-linear optical effects that enable enhanced light-matter interaction, while keeping unique catalytic properties for the activation of chemical reactions. In this contribution, I will discuss our most recent results showing how interface engineering and nanoscale assembly generate advanced plasmonic photocatalysts with both improved optical and photocatalytic activity for various technologies, including colloidal photocatalysis, fuel cells, photoelectrochemical cells, and solar thermal processes. I will show how plasmonic photocatalysts produce several intense effects such as near fields, hot carriers, and local heating, which can be leveraged to enhance reaction rates or stir product selectivity in ways that are not conventionally observed neither for classic heterogeneous catalysts nor for semiconductor photocatalysts.

Mesoporous bioactive glasses with tailorable antioxidant and therapeutic properties

G. Lusvardi, F. Fraulini, V. Nicolini, C. Cavazzoli, A. Zambon

Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Modena, Italy.

gigliola.lusvardi@unimore.it

Bioactive glasses (BGs) are well-established biomaterials traditionally used for *hard* tissue regeneration[1,2]; to avoid post-surgery inflammation and infections, BGs can be tailored with antioxidant and antibacterial properties by doping with therapeutic inorganic ions (TIIs) or loading with organic molecules. Our research focused on the development of doped and loaded BGs that can act as antioxidant systems and drug delivery systems (DDSs)[3-6]; specifically was developed a series of cerium doped mesoporous BGs (Ce-MBGs)[5] studied by tailored enzymatic and antibacterial assays. Ce-MBGs with high specific surface area (SSA), can dismutate H_2O_2 and simultaneously act as DDSs for biomolecules (e.g. polyphenols), which confers them the additional ability to scavenge $O_2^{\bullet-}$. By loading antibiotics as model drugs, Ce-MBGs present controlled release for up to 10 days in an antibacterial assay on *E.coli*, without affecting bioactivity or antioxidant activity even at high loading. Ce-MBGs are therefore excellent DDSs (**Figure 1**) that also present modulable antioxidant properties[8]. More recently, MBGs are emerging as promising scaffolds for *soft* tissue applications such as muscle regeneration, wound dressing and tendon healing. We explored also the synthesis of injectable composite hydrogels to confer those properties to materials suitable for *soft* tissue applications.

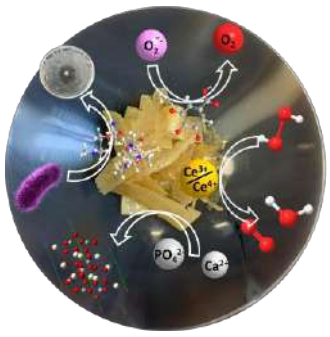

Figure 1: Ce-MBGs applications

Fluorine activation of promising platinum compounds as anticancer drugs against orphan tumors

G. Coffetti,[a] I. Rimoldi,[a] G. Facchetti,[a] F. Paino,[b] V. Coccè,[b] E. Martegani,[b] L. Doneda[b]

[a]*Department of Pharmaceutical Science, University of Milan, Via Mangiagalli 25, 20133 Milan, Italy*
[b]*CRC StaMeTec Department of Biomedical, Surgical and Dental Sciences, University of Milan, 20122 Milan, Italy*
giulia.coffetti@unimi.it

Glioblastoma (GBM) and pancreatic cancer are classified as orphan tumors. For both, the only available treatment includes maximal safe surgical resection, followed by radiotherapy and chemotherapy based on platinum drugs. Unfortunately, neither of these therapies can offer a high survival rate (5-6% maximum).[1,2]

For this reason, nowadays, many studies have been focused on the synthesis of new platinum compounds with the aim to increase the efficacy against these kinds of tumors. Since one of the main issues in cancer treatment is the bioavailability, starting from an already published complex (**Pt-IV**)[3] we decided to synthesized two new molecules (**1** and **2**) in which we modified the diamine core adding a fluorine in different positions in order to change the solubility of the complex and its biological activity.[4]

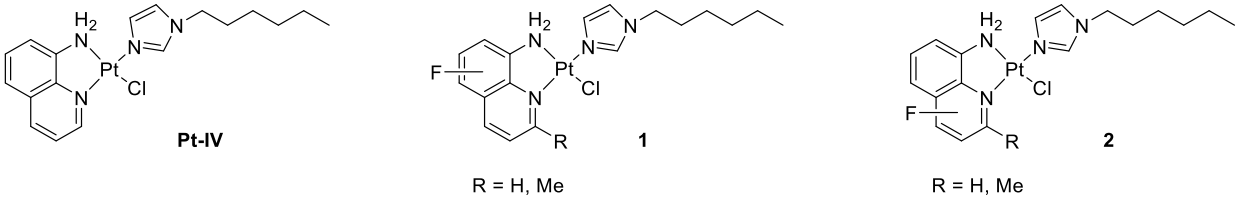

Figure 1: The already published complex (**Pt-IV**) and the new ones (**1** and **2**).

Pt-IV was already tested for its antitumoral activity against glioblastoma cell lines (U87-MG) and the IC_{50}, evaluated in terms of ability to affect cell proliferation, was 5.3 ± 0.55 μM.[5]

The influence of introducing the fluorine atom in the diamine skeleton will be evaluated in terms of cytotoxicity against orphan tumors.

Phosphate-based glasses (PGs) are promising bioresorbable materials for controlled delivery of therapeutic species. In this work different synthesis techniques are used: *sol-gel (SG)* and *coacervation (COA)*.[1] Cerium mesoporous PGs (Ce-MPGs, *SG synthesis*), in the system P_2O_5-CaO-Na_2O-$(CeO_2)x$ (x = 0, 1, 3, 5, 10 mol %), have been developed. Cerium, like superoxide dismutase (SOD) enzyme, is able to destroy highly reactive oxygen or nitrogen species.[2] To increase antioxidant properties, Ce-MPGs were loaded with polyphenols (Quercetin, Morin Hydrate and 3-Hydroxyflavone).[2] The studied loaded glasses show a relevant SOD-mimetic activity, these PGs are able to reduce post implantation inflammation and reduce the recovery time. Manganese and copper powders (Mn-PGPs, Cu-PGPs, *COA synthesis*), in the system P_2O_5-CaO-Na_2O-$(YO)_x$ (Y=Mn or Cu. x = 0, 1, 3, 5, 10 mol %), have been also studied.[3] Bioactivity tests performed on PGPs, Mn1-PGPs and Cu1-PGPs into different medium, show the formation of hydroxyapatite-like precursor, after few days of immersion (Figure 1 red marked). Mn-PGPs and Cu-PGPs have great potential in hard tissue regeneration, not only as a drug delivery system. Copper is also able to mimics the activity of SOD enzyme and Cu-PGPs show a very high antioxidant capability.

Figure 1: SEM image of PGPs (A), Cu1-PGPs (B) and Mn1-PGPs (C) after immersion, respectively, into Tris-HCl Buffer solution, simulated biological fluid and cell medium McCoy's 5A.

nicolo.quadrio@unimi.it

Electrochemiluminescence, or electrogenerated chemiluminescence (ECL), is a process that uses an applied electrical bias to generate reactive species at an electrode surface that undergo subsequent electron-transfer reactions to generate luminescent species[1].The biggest advantages of this technique are the absence of the background noise from the excitation source, used in traditional photoluminescent measurements, high specificity and an excellent sensitivity. Nowadays the ECL technology is largely used in the development of immunoassays[2].

However, sensitivity of ECL strongly depends on the nature of the emitters, therefore the development of new strategies to improve ECL-based assays is still a relevant research topic and the aim of this project. Our strategy to achieve signal increase is to build systems in which a large number of ECL-emitters are anchored on a three-dimensional (3D) platform, which in this case is constituted by silica nanoparticles (NPs), functionalized on the surface with electrochemiluminescent Ir(III) complexes. We selected Ir(III) complexes as emitters of choice since they show outstanding photophysical properties, such as high emission efficiency, easy-tuning of the emission range by changing the C^N ligand and ancillary ligand together, excellent stability[2]. Furthermore, the introduction of negatively charged solubilizing groups (SG, sulfonates) on the Ir complex ligands would allow for both increasing solubility in aqueous media and preventing non-specific binding interactions with unwanted biological targets.

Although some Ir(III) complexes for ECL applications appeared in the literature, only a few examples of Ir complexes soluble in aqueous media or aqueous organic media have been reported[3,4].

In this communication, the synthesis of Ir(III) water soluble complexes, their characterization, as well as their anchoring to nanoparticles (Figure 1) will be illustrated.

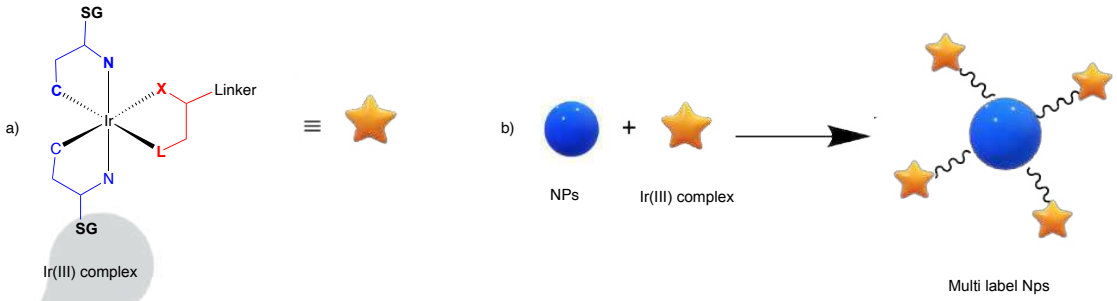

Figure 1. a) Ir(III) complexes structure, b) Anchoring to nanopaticles (NPs)

jennifer.storchi@unimore.it

Nuclear medicine exploits radiopharmaceutical for diagnostic and therapeutic purposes across various diseases. ^{68}Ga ($t_{1/2}$ = 1.13 h, $I_{\beta+}$ = 89%, $E_{\beta+\,avg}$ = 830 keV) stands out as a leading option for Positron Emission Tomography (PET) due to its advantageous characteristics. To effectively bind the metal, chelating agents are essential. Macrocyclic chelators generally show slow kinetics, requiring harsh radiolabeling conditions unsuitable for many biomolecules used as targeting vectors. On the other hand, non-macrocyclic ligands offer faster complexation kinetics under milder conditions, but their complexes typically exhibit lower thermodynamic stability. HBED[1] is a promising acyclic chelator for ^{68}Ga, forming complexes with high thermodynamic stability. To address the drawbacks of acyclic chelators, we have developed a novel class of constrained chelators based on HBED, incorporating a "rigid" *trans*-diamminocyclohexane (DACH) backbone. This structural constrain can enhance the metal-ligand complex stability. In this study, new constrained DACH-containing chelators were synthetized and thoroughly characterized. The complexation with Ga was performed in D_2O and MeOD-d_4 at room temperature, followed via NMR spectroscopy. Preliminary findings suggest promising potential for these chelators in developing novel radiopharmaceuticals for ^{68}Ga. Further studies will focus on completing the investigation of these molecules and performing the radiolabeling of the complexes obtained, as well as evaluate the complexation with other metals of interest.

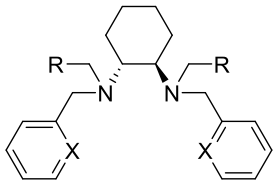

Figure 1: General structure of this new class of chelators.

daab@ufscar.br

Palladium(II) complexes have stimulated the research interest mainly due to their in vitro cytotoxicity against various cancer cell lines, and their low cytotoxicity in healthy cells[1,2]. Thus, in this work, we combined Pd(II)/phosphine systems with the natural product, curcumin, as a ligand, obtaining a series of complexes, which were characterized by elemental analysis, molar conductivity, cyclic voltammetry, mass, NMR (^{1}H, ^{31}C, ^{31}P{^{1}H}), UV-vis, and IR spectroscopies, and four of them (A1, A2, A4, and A5) by X-ray crystallography. The $[Pd(cur)(PPh_3)_2]PF_6$ (A1), $[Pd(cur)(dppe)]PF_6$ (A2), $[Pd(cur)(dppp)]PF_6$ (A3), $[Pd(cur)(dppb)]PF_6$ (A4) and $[Pd(cur)(dppf)]PF_6$ (A5), where dppe = 1,2-*bis*(diphenylphosphino)ethane, dppp = 1,3-*bis*(diphenylphosphino)propane, dppb = 1,4-bis(diphenylphosphino)butane, and dppf = 1,1'-*bis*(diphenylphosphino)ferrocene (P-P). The *in vitro* cell viability of the complexes A1-A5, cisplatin, and the free ligand curcumin were evaluated by the MTT colorimetric assay against the MDA-MB-231 (human triple-negative breast tumor cells), SK-BR-3 (human breast tumor cells), A549 (human lung tumor cells), A2780 (human ovarian carcinoma cells), A2780cis (cisplatin-resistant human ovarian carcinoma cells), and MRC-5 (non-tumor human lung cells). For the tumor cell lines tested, the complexes showed good anticancer activities. The results showed that in general the complexes had lower IC_{50} values than free curcumin and the precursors $[PdCl_2(P\text{-}P)]$. In the MDA-MB-231 cell line, complexes A1 and A5 stood out, with their lowest IC_{50} values, around 5 □mol/L, and the complexes showed to be more active (lower IC_{50} values) against the ovarian cell lines. Complex A1 was 23- and 22-fold more cytotoxic than cisplatin, against the A2780 and A2780cis cells, respectively. The A1 complex was studied on A2780cis cells and it was found that this complex inhibits colony formation and induces cell cycle arrest in the G1 phase in a concentration-dependent manner and leads to cell death by apoptosis. The DCFDA assay revealed a potent ROS induction for complex A1.

The global focus on environmental sustainability has led to a shift towards using renewable resources in various industrial processes. In polymer production, significant progress has been made by using monomers derived from renewable sources to make polyolefins. This departure from traditional petrochemical-based materials signifies a move towards more eco-friendly practices in the polymer industry. Polyolefins like polyethylene and polypropylene are widely used in packaging, construction, and other applications, traditionally made from petroleum-based monomers. However, due to concerns about climate change and limited fossil fuel resources, researchers and industries are exploring alternatives, including using renewable monomers. A significant advancement in synthesizing polyolefins from renewable monomers involves using metal complexes with OSSO-type ligands, which exhibit remarkable catalytic activity and selectivity in polymerizing bio-based monomers, thus facilitating efficient production of high-quality polyolefins[1].

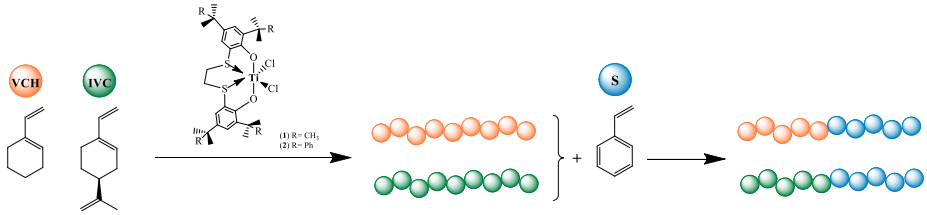

Figure 1: General scheme of the synthesis of polyolefins promoted by [OSSO]-Titanium complexes.

Two titanium complexes with OSSO-type ligands are explored for their catalytic capabilities in promoting stereoselective polymerization of (*S*)-4-isopropenyl-1-vinyl-1-cyclohexene (IVC), a monomer of natural origin that was synthesized starting from perillaldehyde, found most abundantly in the herb perilla[2]. Previously, the same study was conducted on 1-vinylcyclohexene (VCH) using it as a model monomer as it has the same structure as IVC except for the isopropenyl substituent. Both IVC and VCH were copolymerized with styrene (S) to obtain a perfect diblock copolymers.

karim.abdelhady@phd.units.it

During the last two decades Pd(II)-based Brookhart type complexes, of general formula [Pd(Me)(MeCN)(N-N)][PF_6] (N-N = α-diimines, DAB or BIAN), have been extensively studied as homogeneous catalysts for the copolymerization of ethylene with polar vinyl monomers, such as acrylic esters, to obtain functionalized polyolefins (**FPO**), very interesting macromolecules that could represent an environmental-friendly improvement with respect to simple polyolefins.[1]

We have now studied a new series of α-diimine ligands characterized by halogenated aryl substituents on the backbone (Figure 1).[2] In contrast to DAB derivatives, the coordination to palladium of the fluorine substituted ligands **3** - **5** resulted to be rather difficult and new synthetic strategies are under investigation. For instance, we have now found that ligand **5** does not react with [Pd(cod)(Me)Cl], unless [Pd($PhCN)_2Cl_2$] is present in the reaction mixture, leading to [Pd(**5**)(Me)Cl] thanks to the transfer of the diolefin to the latter palladium precursor. In the case of ligand **3**, which is also inert towards [Pd(cod)(Me)Cl], the synthesis of [Pd(**3**)(Me)Cl] was tentatively achieved through the transmethylation reaction performed on [Pd(**3**)Cl_2] that, in turn, was obtained from the reaction of **3** with [Pd($PhCN)_2Cl_2$].

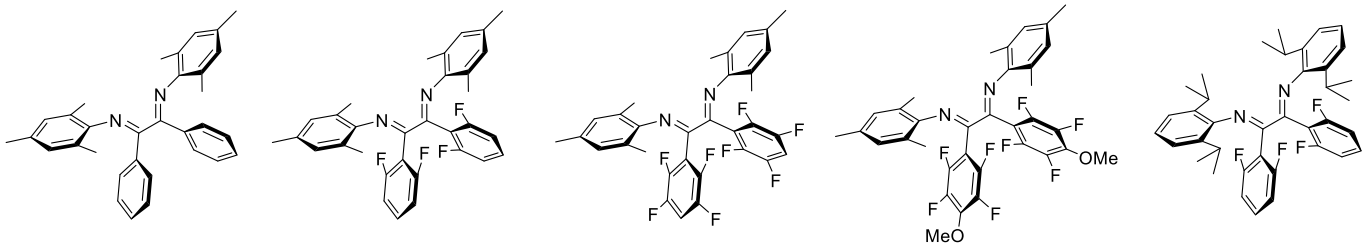

Figure 1: The investigated halogen-substituted α-diimine ligands.

The catalytic behaviour of the corresponding cationic complexes [Pd(**1**)(Me)(MeCN)][PF_6] and [Pd(**2**)(Me)(MeCN)][PF_6] in the ethylene/methyl acrylate copolymerization will be also presented.

The ability of complexes to recognize anions represents a significant challenge for coordination chemistry and it is attracting increasing interest due to its potential applications in technological and biomedical fields. In this work, we investigated the interaction between fluoride ion and two Ln^{III}-based complexes characterized by different coordination geometries and hydration numbers (q = 1, 2) (**Figure 1**).[1] For this purpose, a combination of high- and low-resolution NMR techniques has been employed. Specifically, fast-field cycling relaxometry (^{1}H longitudinal relaxation rates *vs* B_0) and ^{17}O NMR measurements (oxygen transverse relaxation rates *vs* temperature) were performed on the Gd^{III}-complexes. The affinity constant (K_A) of the complexes with F^- was determined *via* relaxometric titration. The thermodynamic and kinetic parameters, associated with the chemical exchange of water molecules with fluoride, were determined by acquiring ^{19}F NMR spectra at different temperatures over the diamagnetic analogue Y^{III}-complexes.[2] The results of this study represent a fundamental step towards the development of new Ln^{III}-receptors with enhanced anion affinity and selectivity.

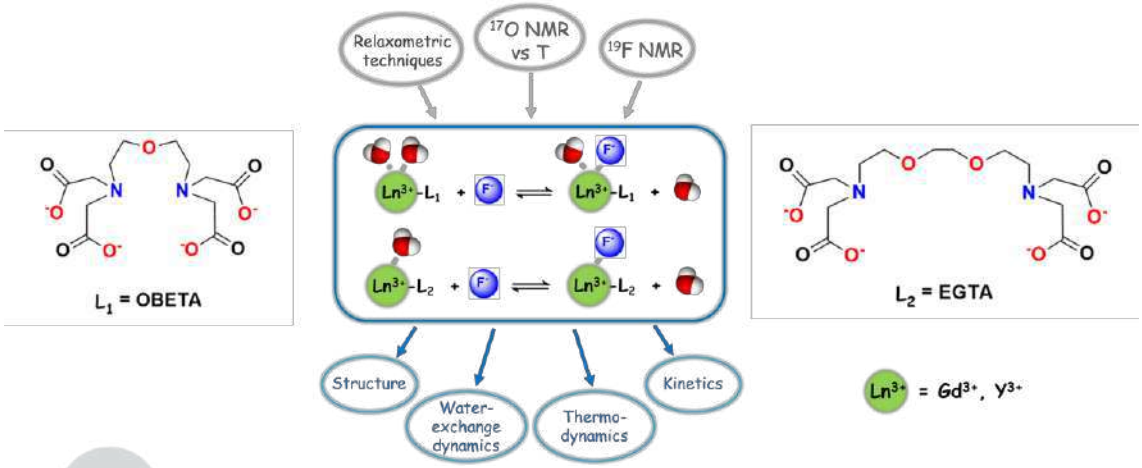

Figure 1: Low- and high-field NMR techniques used to study the interactions between Ln^{III}-complexes and fluoride.

matteo.formenti@unimi.it

Metal ORganic Alloys (MORALs) are a class of materials composed by organic molecules embedded in a metal structure. The chemical reduction of metal salts in the presence of graphene oxide (GO) suspension led us to the obtaining of GO doped metal dusts (GO@metal).

The subsequential reduction of embedded GO using thiophene in order to obtain reduced graphene oxide (RGO) allowed a further modification of the materials to achieve RGO@metal.

These materials have been characterized by different analytic techniques such as TEM microscopy, XRPD, XPS and FT-IR, proving the coexistence of metal nanoparticles together with graphene oxide[1]. Tested in different reactions, their catalytical activity emerged particularly in the nitro-group reduction[2] and Suzuki-type C-C cross coupling.

The incorporation of GO and RGO in the metals has given the materials greater stability as catalysts in subsequential reaction runs and improved conversion when compared to the undoped metals obtained following the same protocol.

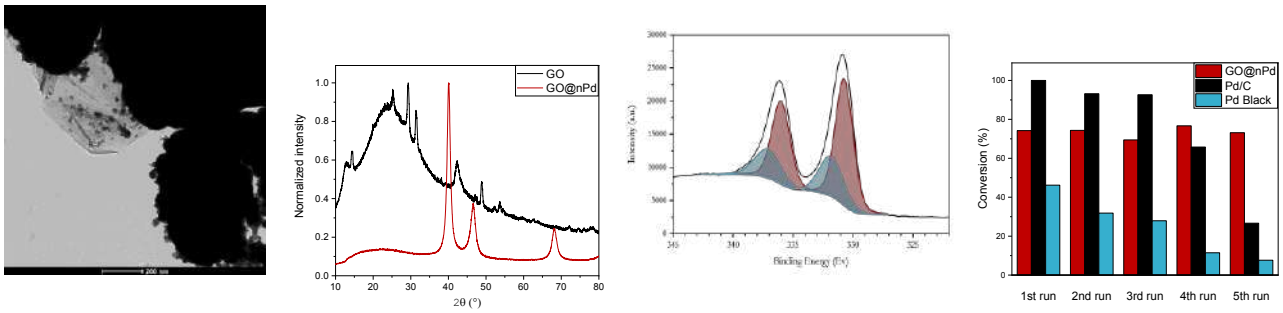

Figure 1: from left to right, TEM image, XRPD spectrum and XRF spectrum detail of the material GO@nPd (graphene oxide in palladium nanoparticles), and conversion of nitrobenzene in aniline compared with other Pd-based catalysts.

alessio.zavaroni@unipr.it

Thiosemicarbazones (TSC), semicarbazones (SC) and acylhydrazones are at the same time molecules with biological activity and versatile ligands towards transition metal ions[1]. Cu(II) complexes are promising compounds as an alternative to platinum based drugs in antitumor therapies, since copper is an endogenous metal and cancer cells have an abnormal copper balance[2]; therefore, the use of this metal could improve the selectivity towards cancer cells. Cancer cell metabolism is also characterized by an enhanced uptake and utilization of glucose[3]: consequently, a useful tool to further increase the selectivity of an anticancer agent is its glyco-conjugation, which also improves water solubility.

In this context, three novel ligands, the TSC $\mathbf{H_2L^1}$, the SC $\mathbf{H_2L^2}$ and the acylhydrazone $\mathbf{H_2L^3}$ and their copper (II) complexes (Fig. 1) have been successfully synthesized and characterized. The coordination properties of the ligands towards Cu^{2+} ions have been studied in aqueous solution by mean of UV-vis spectrophotometric titrations. Evaluation of their cytotoxic activity is currently ongoing.

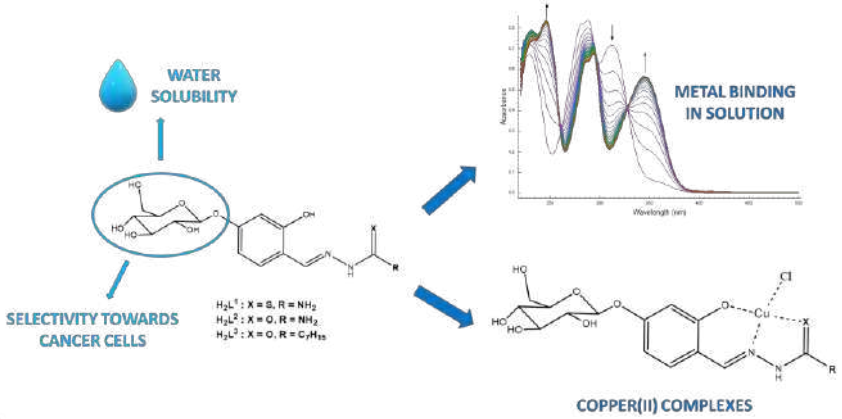

Figure 1: Ligands $\mathbf{H_2L^1}$, $\mathbf{H_2L^2}$ and $\mathbf{H_2L^3}$: molecular structure and coordination properties.

simone.galie@unimi.it

Transition-metal catalyzed reductive cyclization of nitroarenes represents an efficient and versatile strategy to afford N-heterocyclic compounds in one step. In this regard, carbon monoxide emerges as an optimal reductant, allowing clean reactions and a simplified work-up, with gaseous carbon dioxide as the sole stoichiometric byproduct. Recently, the use of CO-surrogates, molecules capable to release CO during the reaction, has allowed to release the constraints for autoclaves, pressurized lines and safety measures, generally required to handle gaseous carbon monoxide.[1] Our group has recently reported that phenyl formate acts as an excellent CO-source in the palladium/phenanthroline catalyzed synthesis of indoles,[2] carbazoles[3] and oxazines.[4] A further improvement has been achieved by employing formic acid, in the presence of an equimolar amount of acetic anhydride and a base[5,6] as a more atom economical and cheaper CO-surrogate. Among the various possible heterocycles obtainable by intramolecular reductive cyclization reactions, those leading to six-membered rings had proven to be more challenging. Here we report the synthesis of phenazines, an important scaffold present in several natural and synthetic products with biological activity. Despite harsher conditions are required to carry out the cyclization with respect to the five-membered ones, it was possible to employ a catalytic ratio of 4000, uncommon for these kind of reactions.

Shape-controlled synthesis of Au nanostructures and their photocatalytic activity

S. Jain,[a] L. Mino,[a] A. Naldoni [a]

[a]*Department of Chemistry and NIS Centre, University of Turin, Turin, 10125, Italy*
swareena.jain@unito.it

We present the synthesis, characterization, and photocatalytic testing of gold nanoparticles of different size and morphologies. Gold nanoparticles exhibit a strong localised surface plasmon resonance (LSPR) when irradiated, which is majorly influenced by the morphology of the nanoparticles and their dielectric environment. This interaction of gold nanoparticles with the light makes them suitable for photocatalytic activity. We optimise the synthetic routes to obtain different sizes and shapes of gold nanoparticles with desired optical response. For size-controlled synthesis of Au nanospheres, we use the citrate-reduction method. This is followed by deposition of the nanoparticles over a metal oxide support, which is crucial to study the interaction of gas molecules with our plasmonic photocatalyst. To preserve the reactivity of the nanoparticles, it is essential to remove the stabiliser ligands. We aim to study the effect of plasmonic excitation in binding and unbinding of the reactants to the catalyst of different morphologies under dark conditions and light illumination (with different intensity and polarisation) using operando IR spectroscopy to unravel the fundamental interaction regulating the plasmonic photoactivity of the prepared materials.

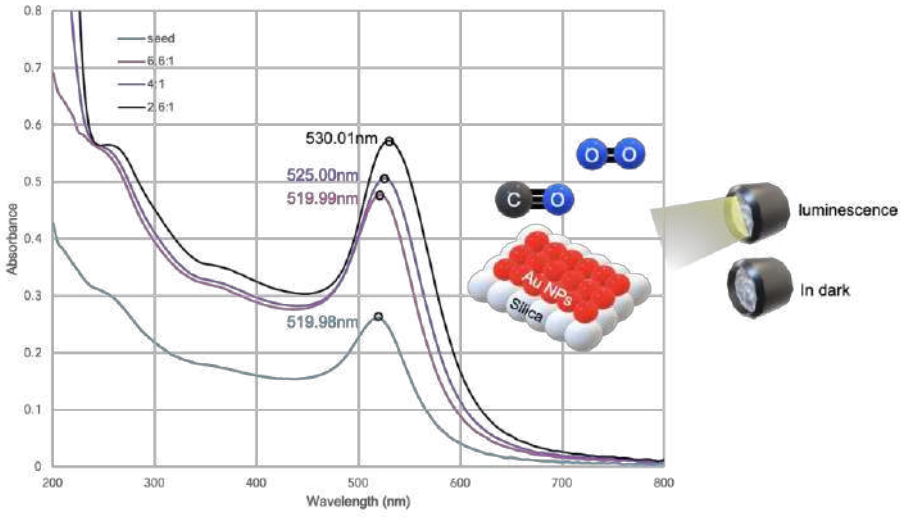

Figure 1: Au nanospheres of different sizes (exhibiting different peaks) supported over silica, used as a catalyst to interaction of gaseous reactants in absence and presence of light.

Nanostructured Catalysts for Enhanced CO_2 reduction: Insight from Electrochemical and Spectroscopic studies

F. Mancuso,[1] F. Franco,[1] P. Fornasiero,[1,2]

[1] Department of Chemical and Pharmaceutical Sciences University of Trieste, via Licio Giorgieri 1, Trieste
[2] Center for Energy, Environment and Transport Giacomo Ciamician and ICCOM-CNR Trieste Research Unit University of Trieste, via Licio Giorgieri 1, Trieste
francesco.mancuso@phd.units.it

The rising levels of atmospheric carbon dioxide (CO_2) and the growing socio-economic impacts of global warming underscore the pressing demand for sustainable approaches to CO_2 utilization and conversion. In this context, the perspective of using renewable sources and low-cost transition metal-based catalysts to promote an electrochemical reduction of CO_2 emerges as a promising avenue to contrast massive utilization of fossil resources for fuel and chemical production.[1,2] However, the efficiency and selectivity of CO_2 electroreduction in aqueous electrolytes is mainly limited by the competitive hydrogen evolution reaction. Recently, the electrodeposition of highly hydrophobic molecular films from water-soluble organic additives was found to significantly improve the electrocatalytic CO_2 reduction performances of polycrystalline nanostructured metal surfaces, thus inhibiting or suppressing hydrogen evolution.[3,4]

According to this strategy, in our group we have designed some heterocyclic organic salts and investigated their adsorption properties on polycrystalline metals as well as their effect as promoters of electrocatalytic CO_2 reduction. In this contribution, we present a molecular tuning strategy involving the functionalization of the surface of some metal electrodes with organic molecules. We firstly synthesized a series of organic salts used as substrates for the functionalization of the metallic surface *via* electrodeposition. Through electrochemical studies, such as cyclic voltammetry, we investigated their electrochemical behaviour in reduction. Furthermore, employing a combination of electrochemical and spectroscopic techniques, we identified and analysed the species adsorbed on the polycrystalline metal foil. We investigated the structural factors and physicochemical properties of the molecular film. Finally, explored their potential catalytic contribution to catalysis by analysing important parameters such as product selectivity, catalytic activity, and the stability.

Overall, this contribution aims to deepen our understanding of CO_2 reduction and advance the development of efficient electrocatalysts for sustainable energy conversion.

a.barbero@unito.it

The increase of carbon dioxide in the atmosphere and the continued use of fossil fuels are two very important problems in nowadays society, the electrochemical reduction of carbon dioxide for the production of high value chemicals can be a partial solution to both of those problems[1]. Catalysts are very important in the development of a system that can be efficient and convenient with this technology, in particular copper catalysts have been studied for a long time because of the multiple shape this metal can assume and also because of the catalysts' versatility and great numbers of possible products obtained[2].

In this work we show how we approached a copper catalyst, Cu_2Se, with a synthesis made via electrodeposition, this type of synthesis was already studied[3], but the resulted catalyst was never tested for carbo dioxide redction. The synthesis of the catalyst and its deposition on conductive support happens at the same time, reducing both the time and the cost necessary for the catalyst's production. We studied different materials as substrates, noticing a different catalytic activity depending on the subrate. The obtained systems have been tested for the catalytic reduction of carbon dioxide in water, the production of formate as a liquid product was identified and quantified.

Synthesis and characterization of electroluminescent copper(I) complexes

C. Reviglio,[a] L. M. Cavinato,[b] C. Barolo,[a] R. D. Costa,[b] C. Garino[a]

[a]*Department of Chemistry, University of Turin, Via Giuria 7, 10125 Turin, Italy*

chiara.reviglio@unito.it

Last years have witnessed an increase in the interest in photoactive copper(I) complexes, because of their potential use in solid-state lighting devices. In particular, ionic copper(I) coordination compounds are currently investigated as electroluminescent materials to be used in the active layer of Light-Emitting Electrochemical Cells (LECs), as a more sustainable alternative to poorly available second and third-row transition metals.[1]

Among the variety of complexes, tetrahedral heteroleptic $[Cu(P\hat{}P)(N\hat{}N)]^+$ are one of the most studied. Focusing on the N^N ligand, 2,2'-bypiridine and 1,10-phenanthroline derivatives have been extensively investigated, but moving to ligands containing 5-membered N-heterocycles can be interesting in term of expansion of the colour range of emission, in particular towards the green-blue part of the visible spectrum.[2,3]

In this context, herein we present the synthesis, the characterization and the application in device of a series of $[Cu(P\hat{}P)(N\hat{}N)]^+$ complexes, based on Xanthphos as the P^P ligand and on differently substituted pyridine-pyrazoles as the N^N ligand (Figure 1). The compounds have been structurally characterized by NMR and XRD techniques. The photophysical properties have been investigated through UV-Vis absorption and emission spectroscopies (Figure 1), while the electrochemical behaviour has been tested by means of cyclic voltammetric measurements. The most promising compounds of the series have also been incorporated and tested in prototypal LEC devices.

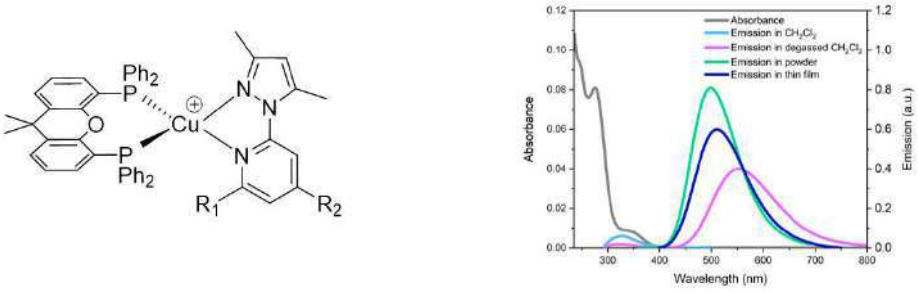

Figure 1: Chemical structure and photophysical properties of synthetized complexes.

silvia.bonabello@uniupo.it

In recent years, research has focused on optimizing light sources for use in the latest technology optical devices, such as linear photonic integrated circuits and telecom optical fibers. Recently, quantum photonics is becoming increasingly popular in view of the potentialities of single-photon emitters and entangled photons in data communication and security. In this framework, luminescent lanthanide ions offer a promising alternative to current quantum light sources based on inorganic bulk materials, in view of the long-lived and highly coherent emission provided by intra-shell f-f transitions. These ions can be combined with suitable organic ligands able to behave as antennas, that is, they absorb light, transfer the absorbed energy to the metal via an intersystem crossing process and induce enhanced sensitized lanthanide emission. In this work, we investigate novel lanthanide-based complexes to be proposed as flexible quantum light sources. Tripodal benzimidazole[1] organic ligands derivatives have been reacted with lanthanide ions (Eu, Tb, Sm, Er, Yb, Nd, Gd), to afford highly crystalline materials showing luminescent properties in the visible and near-infrared spectral ranges. The correlation between the observed emission and the geometry and symmetry of the compounds is investigated. This research is performed in the framework of the EIC Pathfinder Challenges "ARTEMIS " GA 101115149 and PRIN2022 PNRR "QuantaMol" Prot. P2022PKW4T projects.

francesca.loschi@univr.it

The search for novel materials as luminescent probes is a hot topic for the rapid development of optical diagnostic techniques in biomedicine. Among the multitude of phosphors, lanthanide doped inorganic nanomaterials exhibit notable luminescence properties in the optical range (UV, visible and Near Infrared). In particular, the multiple emissions of lanthanide ions can be exploited in non-invasive optical nanothermometers with submicrometric spatial resolution.

In this communication, we will focus on the synthesis and spectroscopic characterization of KTb_3F_{10} nanoparticles (NPs) doped with Eu^{3+} ions. These lanthanide-doped fluoride nanoparticles have been synthesized using hydrothermal conditions and the structural properties have been analysed by X-ray powder diffraction (XRPD) technique. TEM measurements have been exploited to study the size and morphology of the NPs.

The emission properties of the NPs has been measured to investigate the local environment of the Eu3+ dopant ions. Moreover, a preliminary investigation of their thermometric properties has been carried out using a luminescence intensity ratiometric method based on the emissions of the Tb^{3+} and Eu^{3+} ions. In particular, the Stark levels of the $^7F_6$ ground state of the Tb^{3+} ion were selectively excited with laser radiation in resonance with the $^7F_6 \rightarrow {}^5D_4$ Stark transitions. Then the $Tb^{3+} \rightarrow Eu^{3+}$ energy transfer mechanisms [1] have been monitored at different temperatures, in particular in the physiological range (20-50 °C). The emission spectra of energy transfer mechanisms $Tb^{3+} \rightarrow Eu^{3+}$ were compared to the emission of the selective excitation of Eu^{3+} of $^7F_1 \rightarrow {}^5D_0$ transition. Laser excitation was also exploited to study the dynamics of the excited states of the lanthanide ions in order to confirm energy transfers in the NPs.

giorgio.cagossi@unipr.it

IUPAC defines a mechanochemical reaction as "a reaction that is induced by the direct absorption of mechanical energy" and lists mechanochemistry as one of the "Ten Chemical Innovations That Will Change Our World"[1]. The popularity of mechanochemistry is rapidly growing owing to its low environmental impact deriving from the reduced amount of solvent employed and the possibility of reaching new compounds isolable only under mechanochemical conditions [2]. Herein, we present the unexpected self-assembly of hexa-nuclear Zn-complexes synthesized using ball-mill grinding techniques, along with their solid-state structural characterization.

The reaction between zinc acetate, isonicotinamide, and a 4-X-substituted benzoic acid (X = Cl, Br, I) were conducted by means of a vibrating ball mill resulting in the formation of species containing six tetrahedrally coordinated zinc nuclei arranged in a crown fashion, as depicted in Figure 1.

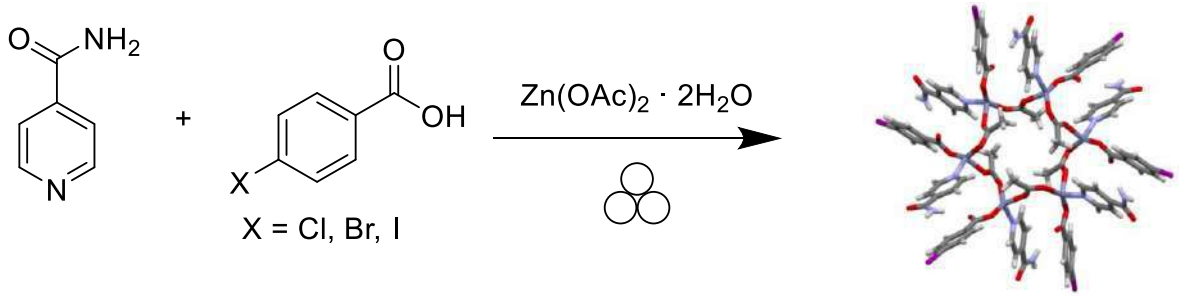

Figure 1: General reaction for the formation of the Zinc complexes.

Isonicotinamide and benzoate ligands act as monodentate ligands, while the acetate bridges two metal atoms. This unprecedented type of assembly is a clear example of how mechanochemistry can give access to unexpected reaction routes and new types of products that are difficult to isolate by solution based synthesis.

Gold nanoparticles (AuNPs) find wide application in nanomedicine, from imaging to therapy[1]. Like all nanomaterials, they have at least a size between 1 and 100 nm, which leads to the phenomenon of plasmonic resonance bands: surface electrons can be collectively excited upon interaction with electromagnetic radiation of the appropriate wavelength, and the resulting absorption is known as Localised Surface Plasmon Resonance (LSPR)[2]. In this framework AuNPs were synthesised using polyethylene glycol (PEG-SH) as hydrophilic capping agent, to enhance the biological response[3]. The AuNPs-PEG have a small size (20 nm x 80 nm), showing LSPR in water at λ_{max} = 530 nm: this increases the surface/volume ratio and the loading of drug used in the treatment of multiple sclerosis. Spectroscopic characterisations by UV–visible (Figure 1), FT-IR, X-ray photoelectron spectroscopies were carried out, verifying the gold surface functionalization. Moreover, Dynamic Lighth Scattering and Z potential studies confirmed the size and stability in water solution. These preliminary studies encourage the use of this system to increase the bioavailability of drugs, reducing their effective dose and therefore side effects.

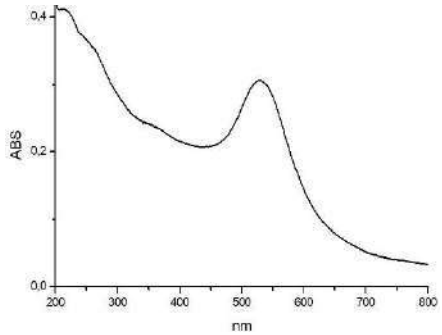

Figure 1**: Uv-vis of AuNPs-PEG in water solution: LSPR at 530 nm**

Inhalation of asbestos fibres is associated with the development of several lung diseases, including incurable malignancies. The production of reactive oxygen species (ROS) is recognized as a significant factor in triggering inflammation, which, if prolonged, can lead to fibrosis and cancer. ROS can originate from cellular processes such as phagocytosis, as well as from redox reactions catalysed by iron sites exposed on the surface of asbestos fibre. While asbestos potency to catalyse free radical generation is well established, few is known on how the interplay between asbestos surface and biological fluids may modify this reactivity.

To clarify whether the interaction of fibres with biological fluids can modify the surface reactivity, crocidolite and tremolite asbestos were incubated in artificial lysosomal fluid at 37°C for 28 days. Biodurability (Si and Mg release) and surface chemical composition were evaluated by ICP-OES and XPS, respectively. ROS generated by pristine and incubated fibres were assessed by measuring •OH radicals through the spin trapping technique coupled with EPR spectroscopy. •OH radical release in oxidizing environment was monitored up to 15 days (indicative of long-term reactivity). To mimic the condition encountered by fibres phagocytized by macrophage and subsequently released into inflamed epithelial tissue due to frustrated phagocytosis, the spin-trapping measures were carried out at pH 4.5 and 7.4, respectively.

Crocidolite and tremolite asbestos showed different durability and underwent changes in surface composition, with alterations in Fe abundance and reactivity depending on the dissolution rate and the amount of Fe in the bulk, which are both higher for crocidolite than tremolite. However, despite the different dissolution, both asbestos were still reactive in •OH radical release following incubation in artificial lysosomal fluid. Additionally, both displayed higher •OH production under neutral than under acidic pH.

The reaction involving 3,5-diamino-4,4′-bis(1H-pyrazole) (3,5-H_2L) with copper (II) and nickel (II) acetates under solvothermal conditions resulted in the formation of four mixed-metal metal−organic frameworks (MIXMOFs). Despite their relatively low specific surface areas, these MIXMOFs exhibited notable CO_2 adsorption capacities at ambient temperature and pressure, with the highest values observed for $Cu_{0.05}Ni_{0.95}$ and $Cu_{0.2}Ni_{0.8}$ (5.6 wt% CO_2), along with reasonably high isosteric heat of adsorption, particularly for $Cu_{0.2}Ni_{0.8}$ (Qst = 26.2 kJ/mol). All MIXMOFs were evaluated as heterogeneous catalysts in carbon dioxide electrochemical reduction (CO_2RR) in acetonitrile solution under varying potential conditions. The most favorable outcomes were achieved at E = −1.5 V vs. Ag/AgCl/KCl sat. In addition to hydrogen evolution (HER) side reactions, the main reduction products observed under these conditions were CO and CH_4. $Cu_{0.05}Ni_{0.95}$ exhibited superior performance, achieving an overall [CO+CH_4] conversion of ~200 ppm and a Faradaic efficiency of ~52%. Notably, the selectivity of CO_2RR products appeared to be correlated with the predominant metal ion within the catalyst: while $Cu_{0.05}Ni_{0.95}$, enriched in nickel, predominantly produced CO, $Cu_{0.5}Ni_{0.5}$, with a higher copper content, mainly generated CH_4. [1]

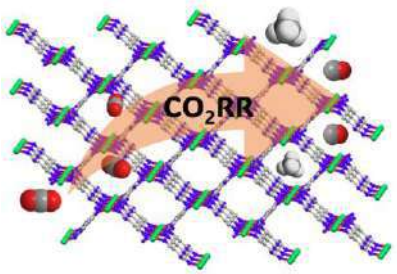

Figure 1: Representation of the crystal structure of [$Ni_{0.5}Cu_{0.5}$ (3,5-L)].

saresposito@unisa.it

Polyesters are amongst the most widely applied oxygenated polymers. Most of commercial polyesters is prepared by polycondensation, they are found in applications spanning packaging, fibres, rigid plastics and engineering materials. Other routes, like ring-opening polymerization (ROP) of lactones and ring-opening copolymerization (ROCOP) of epoxides and cyclic organic anhydrides, have been explored to synthetize polyesters[1] coming from renewable source. With ROCOP the properties of the resulting materials can be easily manipulated by facile substitution of just one of the monomers and it may enable new materials based on aliphatic or semi-aromatic polyesters which are inaccessible using ROP due to thermodynamic reasons and this is interesting to increase thermal and mechanical properties.

In this context, block and multi-block copolymers possessing polyester blocks with different rigidity have been synthesized by ROCOP of phtalic anhydride and epoxides like cyclohexenoxide (CHO) and vinyl-cyclohexenoxide (vCHO) and others from renewable sources like epoxy methyl undecenoate (EMU) and glycidyl geraniol ether (GGE) respectively from fatty acids and terpene alcohols. Polymerizations were conducted resorting to insertion coordination transition metal catalysts like [OSSO]-type-Fe(III) with PPNCl, a catalytic system already demonstrated capable of promoting the synthesis of polycarbonates through ROCOP of epoxides and CO_2[2]. Different synthetic strategies have been explored, monomer conversions were monitored by NMR spectroscopy and, in all cases, block copolymers are obtained due to the different polymerization rate of the epoxides. Furthermore, to modify the thermal properties of the polymers, copolymerization tests were carried out by varying the ratios between the epoxides which influence the formation of blocks with different rigidity. The polymers were characterized by Nuclear Magnetic Resonance techniques (^{1}H-NMR, ^{13}C-NMR, HSQC e DOSY), Gel Permeation Chromatography (GPC), Differential Scanning Calorimetry (DSC) and their ability to separate into microphases was investigated by Atomic Force Microscopy (AFM).
For a possible application these new synthesized polymers can be investigated within the properties of TPEs.

sami.urrehman@unisalento.it

Sustainable food production for the world's growing population is a major challenge. To meet the demand for food, an additional 2.7-4.9 million hectares of land will be needed for agriculture each year[1]. Unfortunately, one-third of arable land is already contaminated with various pollutants, leading to a heightened interest in hydroponic farming for food security. However, hydroponics typically relies on mineral fertilizers, which are derived from finite resources. Furthermore, their continuous use can result in the accumulation of toxic elements in edible plants. As a result, farmers are actively seeking sustainable farming solutions. Vermitea, a liquid extract of vermicompost (organic fertilizer processed by earthworms), has emerged as a potential substitute for inorganic nutrient solutions in hydroponic cultivation[2]. In this study, we evaluated the effectiveness of vermitea in the hydroponic cultivation of *Diplotaxis muralis* plants. Our findings demonstrate that enhanced vermitea solutions (with similar electrical conductivity and pH values to the Hoagland solution) resulted in higher biomass production, SPAD values, and nutrient assimilation. The lower nitrate content in vermitea solutions also improved the quality of rocket leaves. Nuclear Magnetic Resonance (NMR) spectroscopy, a key analytical technique in metabolomics, was used to analyze the metabolic profile of *Diplotaxis muralis* plants grown in three different hydroponic nutrient solutions[3]. Our research suggests that enhanced vermitea can completely replace inorganic nutrient solutions in hydroponic farming.

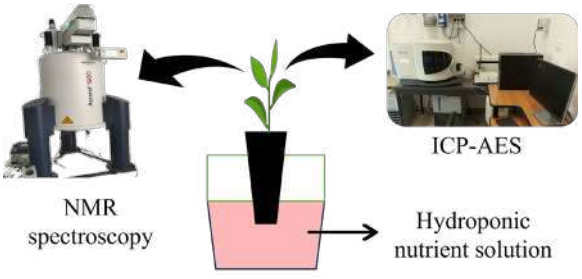

Figure 1: Metabolomic and Elemental Analysis of Rucola (*Diplotaxis muralis*) Plants Cultivated in Various Hydroponic Nutrient Solutions.

Triazoles are versatile ligands for the preparation of copper coordination polymers,[1] magnetic materials,[2] bioactive compounds[3] or copper catalysts.[3] In this work, we synthesized a new triazole ligand, the 1H-3,5-ditrifluoroacetamido-1,2,4-triazole, L, following a literature method.[4] Upon reaction of L with copper(I) oxide in acetonitrile, pale green crystals were isolated from acetonitrile and the single crystal X-ray diffraction evidenced that the copper centres are penta-coordinated affording a roughly square pyramidal geometry. Each Cu ion is respectively coordinated to two oxygens of amide groups and to two nitrogens of two triazoles of the faced ligands, with the triazoles bridging the two metal centres. The two copper ions display planar square geometry extended to a square-based pyramid by coordination of an acetonitrile molecule, resulting in a structure composed of two square-based pyramids oriented in opposite directions, with acetonitrile molecules occupying the apical positions. An additional acetonitrile solvent molecule is present in the asymmetric unit (Figure 1) of the unit cell. The UV-vis spectra display the appearance of a typical broad absorption band centred at around 666 nm. The dinuclear copper complex is persistent in solution as highlighted by ESI-MS with molecular peaks at m/z 702.6 attributed to $[Cu_2L_2\text{-}H]^+$ and at m/z = 704.6 likely due to $[Cu_2L_2]^-$. Preliminary catalytic studies show that $[Cu_2L_2(CH_3CN)_2]$ is active in the Glaser reaction.[5]

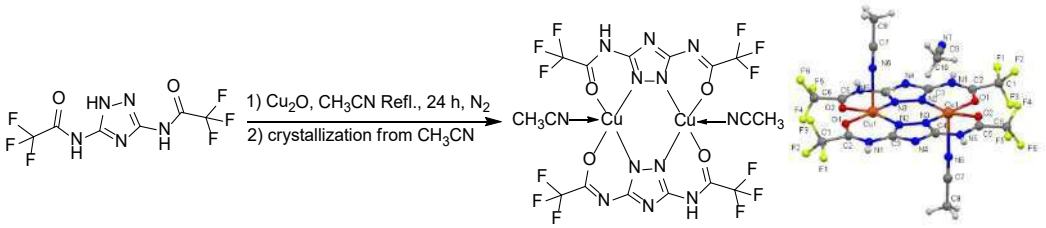

Figure 1: Scheme for the preparation of $[Cu_2L_2(CH_3CN)_2]$ (left); depiction of the molecular structure of $[Cu_2L_2(CH_3CN)_3]$ (right).

erika.stefano@unisalento.it

The investigation of metal-based complexes with potential antitumor activity has been a major focus in recent years, following the success of cisplatin. Despite the effectiveness of approved platinum drugs against various types of cancer, their lack of selectivity towards cancer cells and high toxicity have prompted the search for new platinum-based antitumor agents. Among these, platinum(II)-nucleoside compounds have shown promise as antimetabolites for anticancer therapy[1]. Complexes of the type *cis*-[Pt(NH$_3$)$_2$(Am)Cl]$^+$ (Am = heterocyclic amine derived from pyridine, pyrimidine, purine, piperidine, or saturated amine) have demonstrated high stability and solubility in aqueous media, as well as interesting antitumor potential *in vitro* and *in vivo* against various tumors, including sarcoma and leukemia[2]. Recently, we synthesized six complexes of the type *cis*-[Pt(NH$_3$)$_2$(Am)X]$^+$, where Am = guanosine (Guo, **a**) or 2'-deoxy-guanosine (d-Guo, **b**) and X = Cl (**1**), Br (**2**), I (**3**). These cationic platinum species were characterized by NMR spectrometry and their potential antiproliferative activity was evaluated in different cancer cell lines. Our findings suggest that halogen substitution may be a simple method to alter the cytotoxic and biological activities of these complexes, while maintaining their molecular structure.

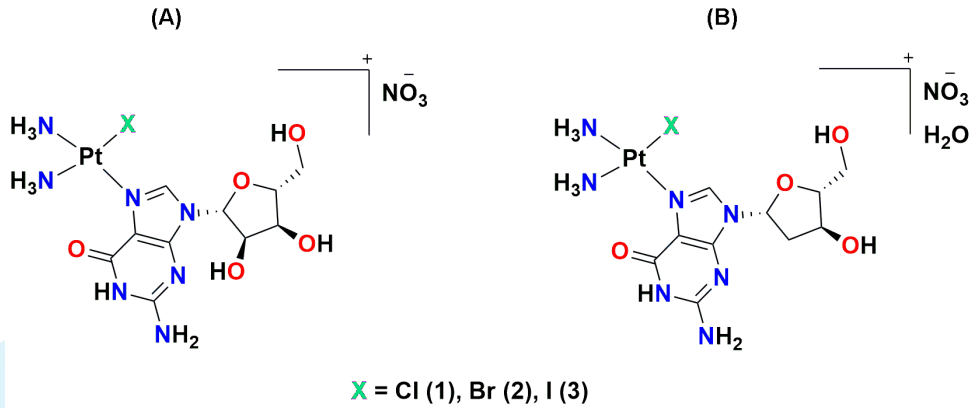

Figure 1: Chemical structures of platinum(II) nucleoside monoadducts, including (**A**) *cis*-[Pt(NH$_3$)$_2$(Guo)X]$^+$ (**1a**, **2a**, **3a**) and (**B**) *cis*-[Pt(NH$_3$)$_2$(dGuo)X]$^+$ (**1b**, **2b**, **3b**) complexes; where X = Cl (**1**), Br (**2**) or I (**3**).

Synthesis, Characterization, and Evaluation of the Cytotoxic Properties of Novel Water-Soluble Monofunctional Platinum(II) Complexes Incorporating Imidazole Derivatives and Phenanthroline

A. Ali,[a] E. Stefàno,[a] F. De Castro,[a] G. Ciccarella,[a] G. Rovito,[a] S. Marsigliante,[a] A. Muscella,[a] M. Benedetti,[a] F. P. Fanizzi[a]

asjad.ali@unisalento.it

Platinum-based drugs such as cisplatin, carboplatin, and oxaliplatin, are commonly used in clinics to treat various cancers. However, due to their limited success, there is a significant need to develop nonclassical platinum complexes. Among these, monofunctional platinum(II) complexes are particularly interesting due to their unique chemical properties, water solubility, and potential biological significance[1]. This study aims to enhance the solubility and anticancer activity of a novel class of compounds that combine imidazole and phenanthroline derivatives. Interestingly, the new complexes [Pt(η^1-C_2H_4OEt)(NH_3)(phen)]Cl (**2**), [Pt(η^1-C_2H_4OEt)(1-hexyl-1*H*-imidazole)(phen)]Cl (**3**), and [Pt(η^1-C_2H_4OEt)(1-hexyl-1*H*-benzo[d]imidazole)(phen)]Cl (**4**) can be synthesized from the precursor [Pt(η^1-C_2H_4OEt)Cl(phen)] (**1**). These complexes are particularly intriguing as they may serve as substrates for cell plasma membrane transporters due to their cationic nature and water solubility, unlike cisplatin[2]. As observed with other monofunctional Pt(II) complexes, these compounds may form sterically hindered adducts with DNA, thereby interacting with DNA-RNA polymerases[3]. Mass spectrometry and Nuclear Magnetic Resonance (NMR) spectroscopy were used to characterize these Pt(II) derivatives. The anticancer activity of the newly synthesized complexes was evaluated using the sulforhodamine B (SRB) assay on both healthy (HK-2) and malignant (HeLa and Caki-1) cell lines. Notably, complex **3** exhibited the highest level of cytotoxicity in both normal and malignant cell lines. However, when compared to healthy cells (HK-2), complex **2** showed the highest selectivity for malignant cells (Caki-1) among the studied complexes.

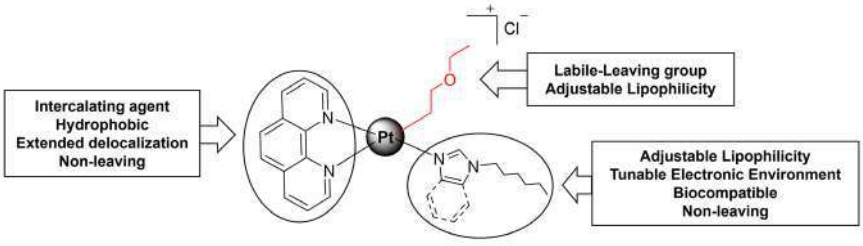

Figure 1: Illustrates the main features of ligands bound to platinum in the investigated complexes [Pt(η^1-C_2H_4OEt)(1-hexyl-1*H*-imidazole)(phen)]Cl (**3**) and [Pt(η^1-C_2H_4OEt)(1-hexyl-1*H*-benzo[d]imidazole)(phen)]Cl (**4**)

Improved mechanochemical synthesis of MIL-100(Fe) and MIL-100(Fe)@Carbon Metal-Organic Framework composite for PFAS polluted waters remediation

M. Forza[a], Giulia Taini[a], Valentina Colombo[a]

michele.forza@unimi.it

MOFs are a class of crystalline solids with permanent porosity. They are coordination polymers made up of metal ions or metal clusters linked together by organic ligands. MOFs are promising materials for application in the chemical industry of the future due to their outstanding properties. Their porosity and the high tunability of internal surface open many possibilities for their use in different fields such as catalysis, gas storage and separation[4]. However, their application is often hindered by the cost of the precursor and by the demanding synthetic conditions. Moreover, the manufacturing of MOFs containing materials is still in early development. One of the most promising MOF is MIL-100 (Fe): it was firstly synthetized by Férey et al. and possesses large cages with diameters of about 25 and 29 Å[1] with reported Langmuir surface area up to 2800 m^2/g. One big advantage of this MOF is that is built by inexpensive and non-toxic constituent such as Iron and trimesic acid. However, its synthetic procedure requires toxic organic solvents, such as DMF and hazardous synthetic additives (i.e. hydrofluoric acid or nitric acid), and high temperature and pressure[1]. Recently there were some attempts to prepare this material in a greener way and a water-based synthesis for MIL-100 (Fe) was developed[2]. However, the use of water as solvent is still problematic since it consumes an important resource and produces a lot of wastewaters rich in inorganic salts and acids. As a result, solvent free synthesis seems to offer an ideal mean to obtain this material. It was recently reported that hand grinding of the precursor powders and subsequent annealing of the mixed powder at high temperature followed by immersion in water can produce MIL-100 (Fe)[3]. Here we propose a new synthetic method which replaces hand grinding with the use of a ball miller to improve reproducibility and scalability of the production of MIL-100 (Fe). This process offers advantages over the previous methods since it is more rapid, preventing waste of time, and it uses lower temperature and less water, thus improving energy efficiency and reducing waste and resource consumption. Moreover, we could extent this procedure to a new method for the creation of a new composite material made of intimately bonded MIL-100 (Fe) on carbon particles. This material opens the possibility of improved manufacturing of MOFs since this powder can be formed in a pellet that better fit existing technology for adsorption of gases or molecules from liquid phase. We assessed the crystallinity of the materials using X-ray powder diffraction and their gas adsorption properties through N_2 adsorption isotherms. We also tested these materials for the removal of perfluoroalkyl substances, PFASs, from water, with promising results.

Ar-BIAN (bis(arylimino)acenaphthene) Schiff bases have found wide application as ligands for both transition and main group metals because their rigid structure imparts the correct geometry for chelation and improves the stability of the compounds against hydrolysis and rupture of the central C-C bond. We have previously reported on the synthesis of the reduced form of the BIAN compounds, Ar-BIANH$_2$.[1,2] We now report that treatment of palladium acetate with these ligands results in the reduction of palladium(II) to palladium(0) and coordination of the so formed Ar-BIAN to the latter. In the absence of other ligands, an unprecedented trinuclear complex was obtained, which is formally the first palladium(0) compound only stabilized by nitrogen ligands. Its X-ray structure shows that each palladium atom is coordinated in a standard κ^2N chelating way to an Ar-BIAN ligand and in a η^2 way to a C=N double bond of another Ar-BIAN ligand. The latter is itself chelating a second palladium atom and the same bonding scheme extend to a third Pd(Ar-BIAN) unit, which closes the loop over the first palladium atom (Figure 1).

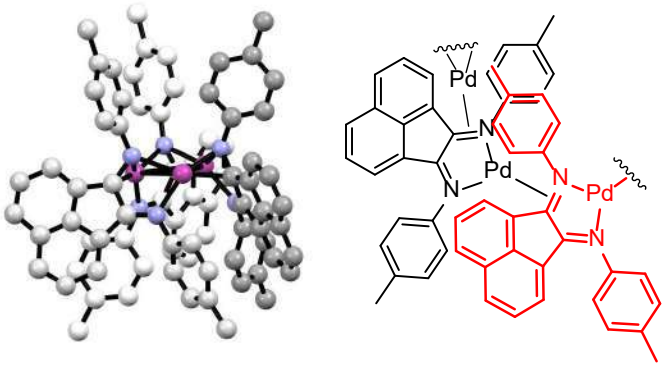

Figure 1: X-Ray structure of trimeric [Pd(4-MeC$_6$H$_4$-BIAN)]$_3$ and its partial bonding scheme.

Overall, the complex has a propeller shape, with the six aryl rings divided in two inequivalent groups. Other complexes have also been obtained showing unusual structures and their synthesis will be described.

Brookhart's and Gibson's independent discoveries that iron complexes with bis(imino)-pyridine ligands (BIP) are excellent catalysts for ethylene homopolymerization had a strong impact on the research in the field of coordination insertion polymerization.[1-3] One of the main unsolved problems in this field deals with the introduction of polar functional groups into the otherwise apolar skeleton of polyolefins. Therefore, there is a remarkable interest in the development of efficient catalysts for the direct, controlled, copolymerization of ethylene with vinyl polar monomers and the use of iron as the metal for such catalysts represents a major, but ambitious, goal. High Throughput Experimentation (Fig. 1) investigation is a powerful tool to unravel suitable candidates for this reaction.

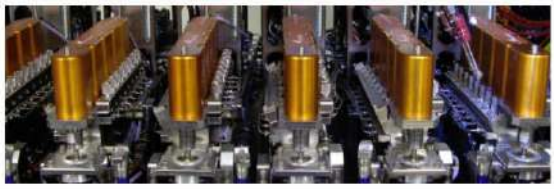

Fig. 1. Parallel Pressure Reactor.

We have now revisited three examples of Brookhart's and Gibson's catalysts (Fig. 2) and applied them to the copolymerization of ethylene with 1-hexene, as a starting alfa-olefin, before addressing our attention to polar vinyl monomers. All precatalysts generated active species leading to ethylene/1-hexene copolymers with an incorporation of the alfa-olefin up to 3.0 mol%. A remarkable effect of BIP ligand and reaction conditions on catalyst performances were observed and will be presented in this contribution. As an example, complex with **L2** generated the most active species with values up to 15.3 kg CP $mmol_{cat}^{-1}h^{-1}$ at 50 °C in the production of the copolymer with an Mn value of 5.9 kDa. This catalyst resulted to be also active at 70 °C. All the copolymers obtained with the three catalysts have polydispersity values in the range 2.3-12.6, thus indicating the formation of multiple active species.

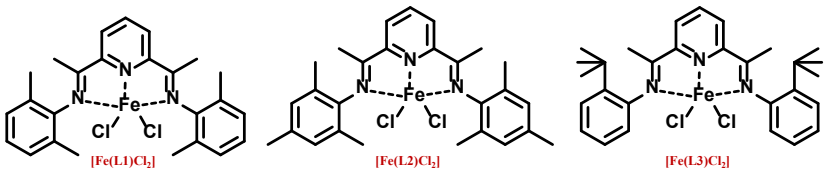

Fig. 2. The studied precatalysts.

agnese.purgatorio@studenti.unipg.it

Batteries are the fastest-growing storage technology and make an important contribution in tackling the effects of climate change. Of all existing types, lithium-ion batteries are extremely effective in powering a wide range of applications, which require high energy densities and safety features.[1] In this scenario, all-solid-state batteries seem to exhibit the right combination of performance and non-flammability.

Sulfide-based materials are promising solid electrolyte candidates achieving ionic conductivities comparable to those of liquid electrolytes. These electrolytic systems are synthesized by the reaction of Li_2S with P_2S_5 in different molar ratios affording several ionic conductors also called LPS systems.[2] Recently, sulfide-based electrolytes can also be prepared in the liquid state using polar and aprotic solvents, offering the prospect of a more scalable approach.[3] However, the ionic conductivity of the so-obtained materials may be lower than those prepared through the other routes, and some attempts to improve their performances are hindered by a lack of understanding of their speciation and formation reaction mechanism in solution. In this contribution, we will show the results of our preliminary spectroscopic studies aimed at assessing the processes of dimensional growth and mixing/integration of inorganic components, by using ^{31}P and $^{6/7}Li$ diffusional NMR techniques.

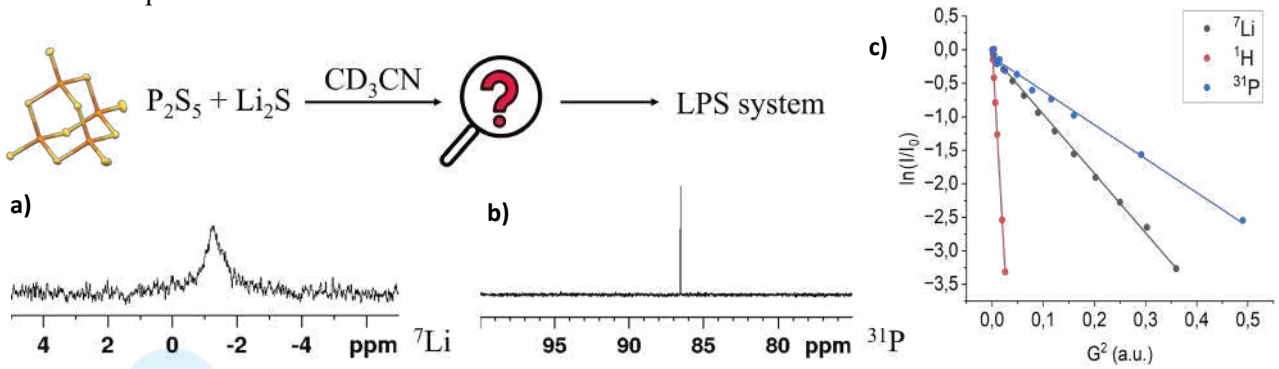

Figure 1: a) ^{7}Li and b) ^{31}P NMR spectra, and c) trends of $\ln(I/I_0)$ vs G^2 (a.u. = arbitrary units) of an LPS sample in CD_3CN. Benzene was used as internal standard in PGSE NMR experiments.

Metals and metal oxides thin films deposition for food packaging application

A. M. Lanza,[a] A. Milella,[a,b] F. Palumbo,[b] A. Perrotta,[b] P. Favia[a,b]

[a] *Dipartimento di Chimica, Università degli Studi di Bari Aldo Moro, via Orabona, 70126 Bari, Italy*
[b] *Istituto di Nanotecnologia, CNR, c/o Università degli Studi di Bari Aldo Moro, via Orabona, 70126 Bari, Italy*

angelica.lanza@uniba.it

In recent years, many innovative food packaging techniques are being developed due to changes in production processes, retail practices and growing consumers demands of healthier, higher-quality and with a longer shelf-life food products.

Cold plasma surface modification of materials, particularly thin film deposition processes, can offer a good strategy to address these requests. Since these processes are carry out at room temperature, they can be used for the treatment of thermolabile materials such as natural and artificial polymers, or to deposit biomolecules or microorganism. These characteristics make these processes less environmental impactful and extremely attractive for industries[1,2].

The purpose of this project is the deposition of inorganic and composite thin film by means of different kind of cold plasmas to improve barrier properties of food packaging or to obtain active coating to control the release of metals and metal oxide.

Enhance barrier properties means to better preserve the food matrix shielding external factors that can impact negatively on food quality like oxygen and moisture responsible of common degradation processes. Active packaging is a recent type of packaging, characterized by the incorporation of bioactive or chemoactive molecules. This technology allows to increase the shelf-life of products and their quality by minimizing or replacing the addition of additives directly to the food[3,4].

Two deposition methods will be investigated and applied both individually or in combination: 1) Plasma enhanced-chemical vapour deposition (PE-CVD)/sputtering processes to obtain barrier coatings and composites made up by a matrix and nanoparticles of metals or the corresponding oxides, which will release ions with an antibacterial function; 2) Atomic layer deposition (ALD) to deposit metal oxides barrier layers or active layers like ZnO and Al_2O_3.

The deposited films will be characterized by means of different techniques. Permeability will be evaluated measuring water vapor transmission rate (WVTR) and oxygen transmission rate (OTR). The effectiveness of the films against bacteria and fungi will also be evaluated through specific tests.

Gold nanoparticles (AuNPs) find wide application in advances technologies, such as optoelectronics, sensing, imaging and therapy [1,2]. This is due to their synthetic versatility, engineering possibilities and particular chemical-physical properties, such as the Localised Surface Plasmon Resonance (LSPR)[3]. Among all challenges regarding the fabrication of AuNPs, the simple production of chiral nanoparticles remains open. Studying the synthesis and functionalization of chiral inorganic surfaces aids in understanding the dynamics at the organic-inorganic interface and will play a crucial role in their translation for biomedical applications. Although a few studies have described the transfer of molecular chirality into micrometre-sized helical ceramic crystals, this technique has yet to be implemented for metal nanoparticles with sizes of tens or hundreds of nanometres [4]. In this framework, chiral AuNPs were synthesised using wet method in tree steps, using Cetyltrimethylammonium bromide (CTAB) and L-cysteine (Lcys) as capping agents. The obtained chiral AuNPs showed typical LSPR at λ_{max} = 580 nm. Spectroscopic characterisations by FT-IR, X-ray photoelectron spectroscopies were carried out, verifying the gold surface functionalization. Moreover, Dynamic Lighth Scattering and Z potential studies confirmed the nanosize and colloidal stability in water solution, preliminary optical investigations the chirality. These preliminary studies encourage the use of this system which shows high potential in the field of optical chiral sensors.

The formation of carbon–carbon bonds is a quest that has required a lot of research throughout the last 125 years of the history of chemistry. These new bonds are the key to producing a wide variety of products with high impact on every aspect of human life, and the Knoevenagel condensation reaction is one of the most important methodologies for this purpose. All the Knoevenagel reactions are performed with nitrogen-based catalysts able to remove an acidic proton from the starting material.[1] Recently, some studies have shown that in many catalytic processes the presence of Schiff bases within metal complexes is an important requirement because the -NH fragment plays an important role in involving atom-transfer intermediates. Herein, we exploited the presence of pyrazolone-based hydrazones as ligands in metal complexes where, in addition, there is a synergistic effect of the metal atom. Several Ru(II), Rh(III), and Ir(III) complexes containing hydrazone ligands were synthesized and characterized, and we explored their catalytic activity toward Knoevenagel condensation applied in tandem reactions. Interestingly, the different metal centre strongly influences the nature of the starting material consistently with their ability to catalyse either de-acetalization or oxidation reactions (Figure 1).

daniele.maver@unimi.it

Triimidazo[1,2-*a*:1′,2′-*c*:1″,2″-*e*][1,3,5]-triazine (**1**) is a nitrogen rich molecule characterized by an intriguing aggregation induced photophysical behavior comprising an ultralong room temperature phosphorescence (RTUP) in the crystalline state.[1] Based on the presence at the vertexes of a regular triangle of three imidazole nitrogen atoms available for coordination, the potentially of **1** as ligand towards different metal ions have been also investigated.[2-4] Interestingly, these studies revealed the ability of **1** to coordinate as mono-, bi- and tri-dentate, affording luminescent metal complexes and coordination polymers (CPs). The functionalization of **1** with a pyridinic fragment as in **2** expanded the possible coordination modes.[4,5] In fact, **2**, due to the presence of one nitrogen atom on the pyridine ring and another on the imidazolic unit at a proper distance is able to act as chelating ligand and to give molecular or extended coordination structures through the additional nitrogen atoms of the triimidazole moiety. The multidentate nature of **2** has also allowed to isolate, by reaction with CuI in slightly different reaction conditions, two strongly luminescent polymorphs of formula $[Cu_2I_2L]_x$ (x = 2, n), namely a yellow emitting one-dimensional coordination network[6] and a green emitting dimeric complex whose structural and photophysical properties will be here presented.

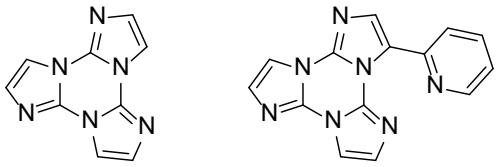

Figure 1: Chemical structures of **1** (left) and its derivative **2** (right).

filippo.bragioto@unipd.it

The European Green Deal is Europe's growth strategy, which aims to ensure by 2050 a climate neutral, clean and circular economy, where the management of resources is optimised and pollution minimised. The Circular Economy Action Plan contains a commitment to review the legislation on end-of-life vehicles (ELVs) with the aim to promote more circular business models by linking design issues to end-of-life treatment, improving the recycling efficiency.[1]

In this context, it becomes imperative to reevaluate waste streams exploring different approaches for their efficient recycling and reuse. Car fluff (light shredder residues of vehicles) is an inevitable by-product of end-of-life vehicles and it is mainly composed of a heterogeneous mixture of plastics, rubber, textile and fiber material, wood, glass and traces of ferrous and non-ferrous metals.[2] It poses challenges for its disposal and recycle; hence on its environmental impact mitigation as required by the European Union's Regulation.

The hydrothermal liquefaction is an efficient and low-energy-demanding approach potentially capable to solve this problem, it is highly flexible in dealing with both pure waste streams and mixed ones.[3]

The present work aims at developing a sustainable wet-chemistry subcritical hydrothermal process for the recovering of some polymeric components of car fluff which have reactive sites suitable for hydrolysis to depolymerize them into small molecules. Initially, the received car fluff is characterised by FT-IR determining its composition. Therefore, the degradation of polymers is tested in subcritical water varying the experimental parameters (time and temperature of the treatment, presence and amount of catalyst), and the depolymerization products are then characterized.

Decoration of polydopamine surfaces with colloidal nanoparticles: a systematic study

Laura Ghidoni[a], Serena Schiavi[a], Angelo Taglietti[a], Giacomo Dacarro[a]

[a] *Department of Chemistry, University of Pavia, Viale Taramelli 12, Pavia, Italy*
laura.ghidoni02@universitadipavia.it

Polydopamine (PDA) is a mussel-inspired polymer enriched in catechol and amine groups, with strong adhesive properties[1]. Lately, it has been widely used as adhesive substrate in different fields, so we decided to study systematically the interactions between PDA and colloidal nanoparticles (NPs). Affinity of NPs for PDA surfaces is expected to depend strongly from surface Z-potential of PDA layers and Z-potential of NPs. As Z-potential is expected to depend from medium pH, we studied the different loading of different NPs as a function of pH of colloidal suspensions of NPs.

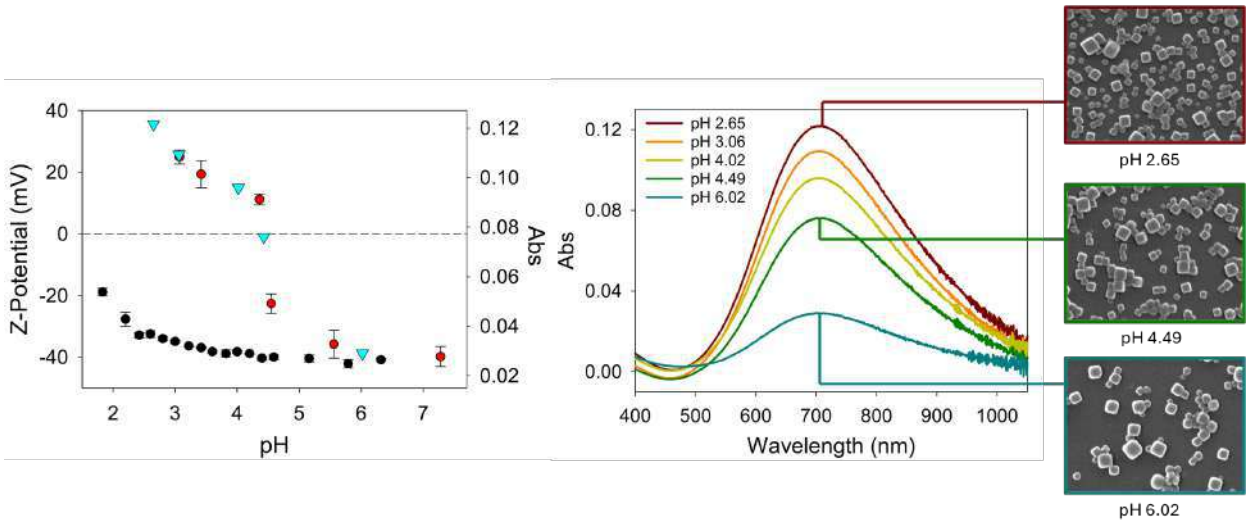

Figure 1: a) Surface Z-Potential of PDA@glass (red dots) and Z-Potential of PBNPs (black dots) at different pH, correlated with the absorbance of PB@PDA@glass obtained at different pH. b) UV-Vis spectra of PB@PDA@glass obtained at different pH and SEM images of the respective sample.

We prepared PDA-coated glass slides (PDA@glass) and grafted on them Prussian Blue NPs (PBNPs), Silver NPs (AgNPs) and Gold NanoStars (GNS), changing the pH of the preparations. We thus demonstrated, using UV-vis spectroscopy, Dynamic Light Scattering and Scanning Electron Microscopy, that the pH controlled difference between z-potentials of PDA and NPs is crucial in determining the amount of grafted NPs.

giuseppe.larotonda@unibas.it

Porphyrazines, structural hybrids of porphyrins and phthalocyanines, represent a fascinating class of tetrapyrrolic compounds characterized by unique molecular structure and diverse array of potential applications. In particular, thioalkyl porphyrazines feature alkyl groups substituted with sulfur atoms, adding a distinct chemical functionality to their structure. Their synthesis and functionalization offer intriguing avenues for exploration in fields ranging from materials science to biochemistry. In recent years we disclosed a novel class of asymmetrically aryl substituted thioalkyl porphyrazines endowed with interesting applications in optoelectronics.[1-3] During the preparation of these compounds by Pd catalyzed cross-coupling reactions, we serendipitously isolated the β-η^1-Pd(II)-thioethyl porphyrazine complex **1**, *i.e.* the oxidative addition intermediate between the parent β-bromo porphyrazine and the [Pd(PPh$_3$)$_4$] catalyst. *Meso* ring-metalated porphyrins have been reported in the past,[4] but **1** represents the first example of isolable *βeta* ring-metalated tetrapyrrole. Therefore, we considered worthwhile to investigate its direct preparation and employment as catalytic precursor in cross-coupling reactions of porphyrazines. The results and the crystallographic structure of complex **1** will be reported.

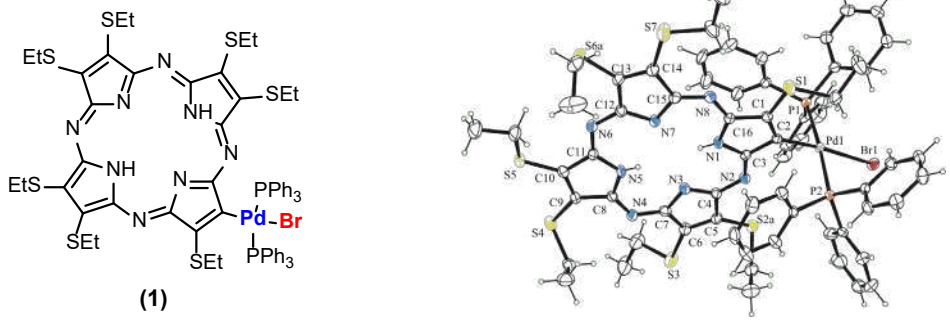

Figure 1: Schematic (*left*) and crystallographic (*right*) structure of compound **1**.

chiara.degiuli@unito.it

Air quality is a main determinant of respiratory health. As for asthmatic people, veterinary species are sensitive to the effect of increased respirable dust[1]. Horses in particular, whose athletic performances concern their owners, are likely exposed to a large burden of inhaled particles originating from the surfaces they work on, with potentially relevant pathologic effects[2]. While little evidence suggests that increased levels of inhaled mineral particles characterize the air of the environments where horses train and perform, no data is currently available on the deposition and distribution pattern of such particles within the equine lungs.

The evaluation of the mineral exposome for understanding the multitude of environmental exposures of inorganic dust continuously over time is crucial[3].

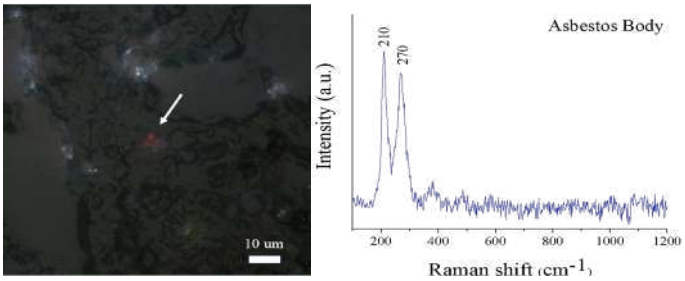

Figure 1. Optical image and Raman spectra of asbestos-body in the lung section[4].

For this reason, understanding the qualitative and quantitative deposition pattern of inorganic dust in the lung is a pivotal step in the comprehension of the respiratory exposure pathway.

This work has been undertaken to describe the qualitative deposition pattern of mineral dust in equine lungs. Post-mortem bilateral lung sections were collected from each lung, following a cranio-caudal and ventro-dorsal gradient.

Observations were conducted with micro-Raman spectroscopy and revealed the presence of different inorganic particles in the range of 2-5 μm in diameter. The main particles found were feldspar (albite), mica (muscovite), titanium dioxide (rutile or mixed phase rutile/anatase), and magnesium calcite (Ca_{1-x}, Mg_x)CO_3. Raman spectrum of an asbestos body, a fiber of asbestos covered with an iron-protein coat, was also recorded (Fig.1). Future studies will be focused on the quantitative determination of the total lung mineral load by digestion of lung tissue of the cranio-caudal sections.

Tetrapyrazinoporphyrazines Carrying Externally *o*-Carboranedithiolate Groups. A Route to Potential Bimodal PDT/BNCT Anticancer Drugs

Andrea Angelucci,[a] Claudio Ercolani,[a] Maria Pia Donzello[a]

[a]*Department of Chemistry, Sapienza University of Rome, P.le Aldo Moro 5, 00185 Rome, Italy*
andrea.angelucci@uniroma1.it

In our previous extensive studies the synthesis, physicochemical properties and photoactivity as anticancer drugs in photodynamic therapy (PDT) were reported of pentanuclear octa(2-pyridil)tetrapyrazinoporphyrazines complexes, carrying externally eight units of *m*- carborane-1-thiolate (CBT) formulated as $[\{Pd(CBT)_2\}_4Py_8TPyzPzM]\cdot xH_2O$, where $Py_8TPyzPz$ = tetrakis-2,3-[5,6-di(2-pyridyl)pyrazino]porphyrazine and M = $Mg^{II}(H_2O)$, Zn^{II}, Pd^{II} (Figure 1A)[1]. The photosensitizer activity for the generation of singlet oxygen, $^1O_2$, the cytotoxic agent in PDT was explored in DMF solution. These species have high quantum yield values (Φ_Δ = 0.6−0.7) which are higher than those obtained for the parent $[(PdCl_2)_4Py_8TPyzPzM]$, and $[Py_8TPyzPzM]$ complexes[2]. Moreover, the presence of high boron content can open perspectives for their use in Boron Neutron Capture Therapy (BNCT), an experimental radiotherapy studied against aggressive and penetrating cancerous pathologies[3].

In an extension of our work on new TPyzPzs it was thought interesting to open additional perspectives of application in a bimodal anticancer therapy PDT/BNCT. For this purpose new homo/eteropentanuclear tetrapyrazinoporphyrazines having externally four units of 1,2-dithiolate-*o*-carborane, formulated as $[\{Pd(CBdT)\}_4Py_8TPyzPzM]\cdot xH_2O$ (CBdT = 1,2-dithiolate-*o*-carborane; M = $Mg^{II}(H_2O)$, Zn^{II}, Pd^{II}) (Figure 1B), have been synthesized and characterized. The photosensitizer activity for the generation of singlet oxygen, $^1O_2$, was explored for the Zn^{II} and Mg^{II} complexes in DMF. The high Φ_Δ value obtained for the Zn^{II} macrocycle (0.58) falls within the range 0.4-0.7 obtained for numerous phthalocyanines and Zn^{II} porphyrazines. These results qualify the Zn^{II} complex $[\{Pd(CBdT)\}_4Py_8TPyzPzZn]$ as an excellent photosensitizer for the generation of singlet oxygen and in addition its high boron content suggests the possibility to be used as bimodal anticancer agent (PDT/BNCT).

Enhancing Electrochemical Performance of Lithium-ion batteries via Coating of Synthesized Single Crystal $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ (NMC-811) Cathode Material.

M. Maryam,[a] S. Khalid,[a] N. Pianta,[a] R. Ruffo [a]

Lithium-ion batteries (LIBs) are a well-known and frequently used renewable energy storage technology, especially in the electric vehicle (EV) and bicycle industries as well as energy storage systems (ESS). The energy density constraint of existing LIBs still affects modern EVs despite their widespread use[1]. Technological improvements in batteries, especially in the positive electrodes, are necessary to address this problem. Lithium cobalt oxide (LCO) was a primary component of commercial lithium-ion batteries (LIBs) due to its superior performance. However, due to its toxicity and poor sustainability, scientists are currently exploring alternative options. The utilization of Nickel Manganese Cobalt oxide (NMC) in different compositions, such as NMC-111, NMC-532, NMC-611, and NMC-811, with a lower cobalt percentage, is one of the most promising substitutes. Despite the large capacity offered by NMC and its variants, its capacity tends to lose over time. This issue can be mitigated by dealing with single crystal phases and applying different coatings to these materials[2]. In our research, we synthesized single crystal $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ (NMC-811) using a Sol-gel method. Various coating techniques are found in literature for NMC materials, including atomic layer deposition (ALD), solid-state, and wet method. We opted for the solid-state coating approach for its simplicity and effectiveness in providing protective layer on NMC. This led to an improvement in the stability, conductivity, and overall performance of the cathode material. To assess the structural, morphological, and electrochemical properties of both coated and uncoated single crystal NMC, we employed characterization methods such as X-ray diffraction (XRD), scanning electron microscopy (SEM), and galvanostatic charge-discharge cycling (GCPL). Our findings demonstrate the formation of well-defined single crystal particles with minimal flaws and the desired crystallographic orientation, suggesting potential enhancements in battery performance and longevity. To assess the structural, morphological, and electrochemical measurements of both coated and uncoated single crystal NMC, different characterization techniques such as X-ray diffraction (XRD), scanning electron microscopy (SEM), and galvanostatic charge-discharge cycling (GCPL) are used. Our findings indicate the formation of well-defined single crystal particles with minimal flaws and the desired crystallographic orientation, suggesting potential enhancements in battery performance and longevity.

Electrochemical NADH Regeneration Mediated by Pyridine Amidate Iridium Complexes Interconverting 1,4- and 1,6-NADH Regioisomers

A. Macchioni,[a] G. Menendez Rodriguez,[a] C. Trotta,[a] C. Zuccaccia[a]

[a] *Department of Chemistry, Biology and Biotechnology and CIRCC, Università degli Studi di Perugia, Via Elce di Sotto 8, 06123-Perugia, Italy*
alceo.macchioni@unipg.it

Although there is a huge interest in redox mediators for the selective electrochemical regeneration of 1,4-NADH,[1] only the class of rhodium compounds with bipyridine ligands, initially introduced by the pioneering work of Wienkamp and Steckhan (*Angew. Chem. Int. Ed. Engl.* **1982**, *21*, 782-783), has been developed over the last decades.[2] Here we report the first two progenitors of a new class of redox mediators for indirect NADH regeneration, namely [Cp*Ir(R'-pica)Cl] {pica = R'-picolinamidate = κ^2-R'-pyridine-2-carboxamide ion (–1), **1** R' = H and **2** R' = Me} (Figure 1),[3,4] which exhibit high TOF values (0.51 s^{-1} and 1.34 s^{-1} for **1** and **2**, respectively), production rate up to 3 mmol h^{-1} cm^{-2}, and Faradaic efficiency up to 99% for both complexes in 0.1 M phosphate buffer (pH 7, 298 K). The reaction exclusively leads to a mixture of 1,4-NADH, the desired product, and 1,6-NADH always in a 91:9 molar ratio, independently of the redox mediator, degree of conversion and applied potential. ^{1}H EXSY NMR unequivocally shows that a rapid equilibrium establishes between 1,6-NADH and 1,4-NADH (K_{eq} = 10.1, ΔG^0 = -1.4 kcal mol^{-1}, 298 K), in the presence of **1** and **2**, suggesting that the latter are capable of rapidly interconverting the two regioisomers of NADH, thus allowing to utilize the totality of regenerated NADH.

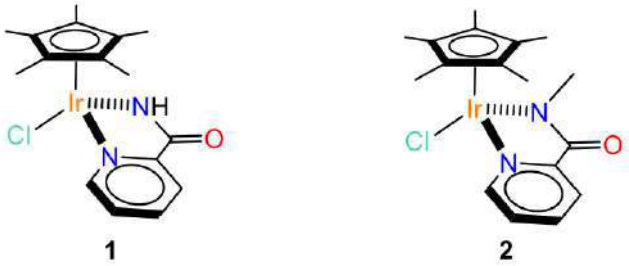

Figure 1: Iridium complexes exploited as redox mediators for electrochemical NADH regeneration.

csangregorio@iccom.cnr.it

Permanent magnets are crucial elements for the green transition as they allow storing, delivering and converting electrical energy into mechanical and vice versa, which means that improving their performance entails transforming energy in a more efficient and sustainable way. The best magnets are based on rare-earths elements, (RE). However, their status as Critical Raw Materials (CRM) has brought forward the consciousness that it is of great strategic and environmental relevance to develop alternative PMs with reduced or no amount of RE.

Sr or Ba M-type hexaferrites are the most popular magnet in the market thanks to the low production costs, thermal stability, and insulating properties.[1] However, their capability to store energy, described by the energy product, is much smaller than that of the high performing RE magnets (20-40 kJm^{-3} compared to up to 400 kJm^{-3}). Since ferrite magnets are constituted by multidomain grains, large improvements in their performances are expected by exploiting nanometric grains. A further increase of the performances can be obtained by realizing hybrid hard-soft nanocomposites magnetically coupled at the interface.[2]

In this contribution we present the synthesis and discuss the magnetic properties of single crystal, monodomain strontium ferrite nanograins prepared by two different techniques, solid state reaction and sol-gel synthesis. The particles have variable average size in the 50 – 100 nm range and larger coercivity compared to commercial powders. The best obtained ferrite was employed for the fabrication of hybrid nanocomposites using, as the soft phase, iron nanowires. The latter were prepared by chemical reduction of metal salts in aqueous phase and consist of small nanoparticles assembled in a chain-like amorphous superstructure, with a mean diameter of 70-80 nm and length of 4-5 μm.

Platinum drugs are the mainstay of the metal-based compounds in the treatment of cancer, even if their use is limited by severe side effects and resistance phenomena. These weaknesses stimulated scientific research to develop new metallodrugs with lower cytotoxicity and acting on different targets. Since copper is a trace element that is essential to all aerobic life forms, and tumour tissues require more copper, Cu complexes may modulate cancer cell survival by generating reactive oxygen species, accumulating excess copper, inhibiting proteasome activity and inhibiting angiogenesis. Cu-based complexes have recently shown interesting antitumor and anti-metastatic properties on several kinds of solid tumours [1].

We designed and synthesized new Cu(I) and Cu(II) complexes and evaluated them as potential agents for the treatment of glioblastoma (GBM) [2]. The bis(pyrazol-1-yl)- and bis(3,5-dimethylpyrazol-1-yl)-acetic acids were selected as bifunctionalizable agents and conjugated to the drug amantadine to obtain the synthesis of the new chelating ligands L^{Ad} and L^{2Ad}. Amantadine was selected because of its recently proven antiproliferative effects in different human tumour cell lines, including hepatocarcinoma, melanoma, and glioblastoma cells. Phosphane co-ligands were employed for the synthesis of the Cu(I) complexes to stabilize copper in the +1 oxidation state and wisely tune solubility properties of the corresponding complexes. The electronic and molecular structures of the new complexes were investigated by X-ray photoelectron spectroscopy, near-edge X-ray absorption and for $[Cu(L^{2Ad})_2]Br_2$ by X-ray diffraction analysis. Interesting results emerged from the biological studies of the new complexes and of the corresponding uncoordinated ligands, investigated for their antitumor potential on different GBM cell lines and for their ability to enhance the chemosensitivity to temozolomide, the standard post-surgical treatment of GBM [2].

Water splitting is considered a sustainable way of obtaining hydrogen but the high overpotential needed in the anodic compartment for oxygen production makes the whole process energetically demanding.[1] To overcome this problem, water oxidation catalysts (WOCs) are required but they are usually based on expensive metals. With the aim of economically viable devices for water splitting and solar fuels production, finding efficient and robust catalysts based on abundant and affordable first-row transition metals is a pivotal point. However, the vast majority of iron WOC catalysts employ sacrificial oxidants and in order to avoid them, electrochemistry offers the alternative. Unfortunately, in the framework of iron electrocatalysts, the few examples reported in literature still show low efficiencies and high overpotential.[2,3]

Recently, our group reported on iron cyclopentadienonic and N-heterocyclic carbene (NHC) complexes that demonstrated to be active, through a stable radical species upon oxidation, in this reaction with competitive activity and low overpotential (TOF of 52 s-1 and η=0,32 V) under basic conditions.[4]

Herein we report on the ligand (NHC) design (Figure 1) towards immobilization on glassy carbon accompanied by characterization (Mossbauer and SQUID) and mechanistic investigation (DFT and EPR studies) on molecular complexes. The peculiar behaviour observed upon immobilization will be also presented and discussed.

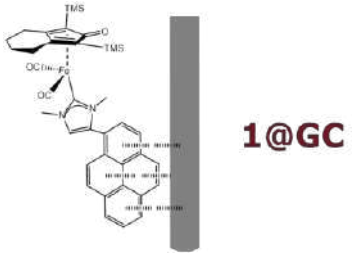

Figure 1. Pyrene functionalized iron electrocatalyst **1@GC** immobilized on Glassy carbon.

Transition metal complexes have attracted much attention because of their rich and peculiar chemical and spectroscopic properties that have found applications in different fields and even as therapeutics.[1] In this field, Pt(II) complexes have been extensively studied. However, even though the emission of platinum complexes has been extensively investigated, the use as luminescent probes, for cellular imaging, has been still poorly investigated. This application requires water solubility of the complexes, and it is limited by the quenching exerted by dioxygen in water and biological fluids because of the long lived luminescent excited state. This severe drawback could however be overcome by exploiting the high tendency of such square planar compounds to self-assembly in supramolecular structures. In this regard, our research group has already demonstrated the aggregation induced emission for Pt(II) complexes[2,3] in different media. In this contribution we describe the synthesis and characterization of luminescent amphiphilic platinum compound, soluble in water, based on a N^N^N pyridil-triazolate functionalized with an ancillary ligand and its behaviour in vivo. An invertebrate freshwater polyp, *Hydra vulgaris*, was treated with the bright orange phosphorescent complexes at only 20 μM concentration

Figure 1: In vivo fluorescence imaging showing a living *Hydra* 24 h post incubation with YAC_2

The compounds self-assembly in vivo and in particular accumulate in the tentacles of the animal. Interestingly, preliminary results suggest not only the use of these compounds for bioimaging and cell tracking but also as enhancer of cell proliferation. Studies are in progress to rationalize such important results.

2,6-*bis*(2-(methyl)-2H-tetrazol-5-yl)pyridine, Me_2btp, related to the most known *bis*-pyrazolylpyridyl R-bpp derivatives (R = variable substituents),[1–3] was employed as neutral tridentate *mer*-coordinating ligand for iron(II). Metalation of Me_2btp with iron(II) perchlorate revealed a non-trivial chemistry with the selective crystallization of $[Fe^{HS/LS}(Me_2btp)_2](ClO_4)_2{\cdot}MeCN{\cdot}2.75H_2O$ ($\mathbf{2}^{HS/LS}{\cdot}MeCN{\cdot}2.75H_2O$) as red rods through accurate solvent polarity control, with half of the iron(II) in the high spin (HS, $S = 2$) state and the second half in the low spin (LS, $S = 0$) state. $\mathbf{2}^{HS/LS}{\cdot}MeCN{\cdot}2.75H_2O$ slowly converts in solution into the co-crystal $[Fe^{LS}(Me_2btp)_2][Fe^{HS}(Me_2btp)(MeCN)_2(H_2O)](ClO_4)_4{\cdot}MeCN$ ($\mathbf{2}^{LS}{\cdot}\mathbf{3}^{HS}{\cdot}MeCN$) through the unprecedented octacoordinated species $[Fe(Me_2btp)_2(MeCN)(H_2O)](ClO_4)_2{\cdot}H_2O$ ($\mathbf{1}{\cdot}H_2O$) as intermediate species trapped in the solid state.[4] The combined use of different spectroscopic techniques, single-crystal X-ray diffraction experiments and magnetic measurements, together with theoretical calculations, will be presented in this contribution.

Enhancing Chronic Wound Healing: Injectable Hydrogels incorporating Cerium-Doped Mesoporous Bioactive Glasses

F.Fraulini,[a] A.Zambon,[a] G.Lusvardi,[a]

[a]*Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Via Campi 103, Modena*
francesca.fraulini@unimore.it

Bioactive glasses (BGs) have traditionally been applied in hard tissue regeneration due to their ability to induce apatitic layer (HA) formation upon exposure to biological fluids. However, research is focusing on expanding their application field to soft tissue regeneration, particularly for chronic wounds.[1] This study investigates the integration of cerium-doped mesoporous bioactive glasses (Ce-MBGs) into alginate/agarose injectable hydrogels to develop delivery systems with enhanced antioxidant properties for chronic wound healing.[2-3]
Ce-MBGs were synthesized via a modified sol-gel EISA method with 0-3.6 mol% CeO_2, then incorporated into an optimized thermoresponsive alginate/agarose hydrogel. The HA formation was monitored via FT-IR and XRDP analyses after soaking in simulated wound fluid (SWF). These results suggested that the hydrogel matrix slowed the HA formation ability of Ce-MBGs, decreasing the possibility of wound calcination. Additionally, ICP-OES analyses demonstrated that the hydrogel matrix did not hinder the ionic release: Ce-MBGs with or without hydrogel exhibited similar Ca, P and Si leakage up to 3 days. It was also verified that the hydrogel did not interfere with Ce antioxidant properties, since all Ce-containing samples maintained their H_2O_2 scavenging ability. If Ce-MBGs were loaded with a mixture of natural polyphenols, the composite hydrogels also exhibited a fast O_2^- dismutation ability.
These findings underline the potential of Ce-MBG-containing injectable hydrogels as promising platforms for chronic wound management. Therefore, future investigations will delve into the drug releasing ability of this composite system and assess the hydrogel cytocompatibility.

Large Pores Mesoporous Bioactive Silica: a New Candidate for Delivery of Big Therapeutics Molecules. A Study of its Behavior in Terms of Drug Loading/Release and Bioactivity

D. Carrozza,[a] G. Malavasi,[a] E. Ferrari[a]

[a]*Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Via G. Campi 103, 41125 Modena, Italy;*
debora.carrozza@unimore.it

Large Pores Mesoporous Silica (LPMS) could be an innovative support suitable to accommodate big pharmaceutical molecules, shield them and maintain their biological activity. Large pores allow the loading of bioactive molecules inside the structure, their stabilization and protection.[1] Indeed, for Classical Mesoporous Silica (MS) only pore blocking occurs. To obtain a synergistic effect between a proper structure and bioactive/pharmaceutical activity, ions with a physiological effect can be added, such as Ca^{2+} (for bioactive activity) and Ga^{3+} (for anticancer action).[2] LPMSs have been synthesized (Figure 1) starting from an acidic water solution of tetraethyl orthosilicate reacting with pore agents (Pluronic® F127 and mesitylene), performing hydrothermal and microwave-assisted reactions. Time and surfactant optimization was performed.

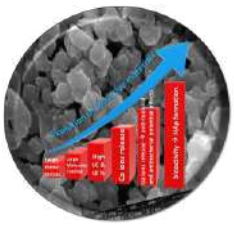

Figure 1: LPMS structure, evolution, and features.

Pore structure characterization has been performed using N_2 adsorption/desorption and Hg-porosimetry, demonstrating that LPMSs have pores in the range of 20–60 and 200–600 nm. Nisin (antibacterial peptide) has been used for load and release tests. Tests performed highlight a doubled loading and releasing for LPMSs if compared to MSs. To confirm the maintenance of the structure of LPMSs, Scanning Electron Microscopy images were acquired before and after release tests. Ca and Ga release in Simulated Body Fluid has been studied through inductively ICP-OES, showing a high release of these ions achieved with LPMSs. The bioactivity of Ca-containing structures has been confirmed using FT-IR, SEM-EDS, and XRDP. In conclusion, LPMSs showed better loading and releasing properties compared with classical MS and better release in terms of active ions. It has also been demonstrated that LPMSs have bioactive behavior.

All the FDA-approved contrast agents (CAs) are Gd(III)-based complexes (GBCAs) and they are used in 40% of the tens of millions of Magnetic Resonance Imaging scans performed each year. Recently, concerns regarding their economic, environmental and clinical impact have spurred interest in exploring alternative CAs, notably those utilizing endogenous ions like Fe(III). Initial studies suggest that Fe(III) chelates, administered at higher doses than GBCAs, exhibit comparable efficacy in typical clinical settings. However, understanding the mechanisms underlying water proton relaxation enhancement by Fe(III) complexes and their structural features is still an open challenge.[1,2] In this study, we investigated Fe(III) complexes with derivatives of EDTA functionalized on the acetic arms with one (EDTA-BOM) or two (EDTA-BOM$_2$) benzyloxymethyl groups. The objective is to explore the effects of ligand modification on the overall efficacy (relaxivity, r_1) of these systems for contrast enhancement. In fact, an increase in the relaxivity of these probes is expected because of the elongation of the molecular tumbling, provided by the increasing molecular mass. Moreover, the lipophilic nature of the BOM substituents allows non-covalent interaction with different substrates (β-cyclodextrin, poly-β-cyclodextrin and human serum albumin), which can further increase their efficacy. For these reasons, we present the ^{1}H and ^{17}O NMR relaxometric characterization of these two novel complexes and their supramolecular adducts, for which we also investigated their thermodynamic stability, kinetic inertness and redox behaviour.

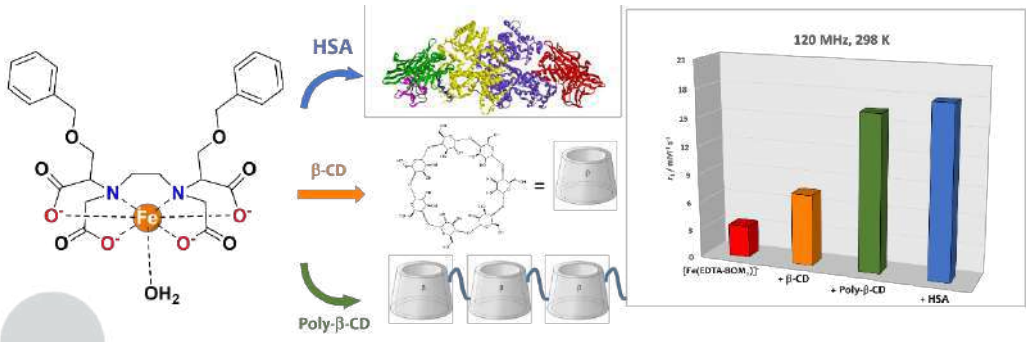

Figure 1: Some of the investigated systems and their r_1 values (120 MHz, 298 K).

Assessing the impact of donor groups on the coordination and magnetic properties of monohydrated Fe(III) complexes for MRI applications

M. L. Macchia,[a] A. Nucera,[a] M. Ricci,[a] F. Carniato,[a] and M. Botta,[a].

[a] *Dipartimento di Scienze e Innovazione Tecnologica, Università del Piemonte Orientale "A. Avogadro", Viale T. Michel 11, 15121 Alessandria, Italy.*

In response to recent safety concerns surrounding Gd-based contrast agents (GBCAs), there has been a surge in research aimed at identifying alternative options for magnetic resonance imaging (MRI)[1]. Trivalent iron (Fe^{3+}) complexes have emerged as promising candidates due to the element's widespread natural occurrence and well-understood metabolic pathways[2], suggesting the potential for the development of safer and more sustainable MRI contrast agents. Previously, our research group investigated the structural and magnetic properties of $[Fe(EDTA)]^-$ and $[Fe(CDTA)]^-$ complexes, serving as model systems for monohydrated Fe(III)-chelates for use as MRI probes[3]. Building upon this groundwork, the current study delves into the impact of complex charge on water exchange kinetics, thermodynamic stability, and kinetic inertness. To explore this, we synthesized four CDTA-amide ligands, each featuring substitutions of one or two carboxylic groups with diethylamine or butylamine functionalities. These alterations resulted in Fe(III) complexes with either neutral or positively charged characteristics. Investigating the water exchange rates (k_{ex}) involved a combination of ^1H relaxometric studies and ^{17}O NMR chemical shifts and relaxation rates. In addition, we evaluated the thermodynamic stability and kinetic inertness of the complexes using potentiometry, UV-Vis spectrophotometry, and capillary zone electrophoresis. As anticipated, altering the charge of the complex leads to a modulation of k_{ex}, aligning with observations made previously for Gd(III) and Mn(II) chelates. Furthermore, the incorporation of amide donor groups has been found to reduce the stability of the complexes, albeit maintaining a relatively high level. These discoveries offer valuable insights for the prospective development of advanced MRI probes.

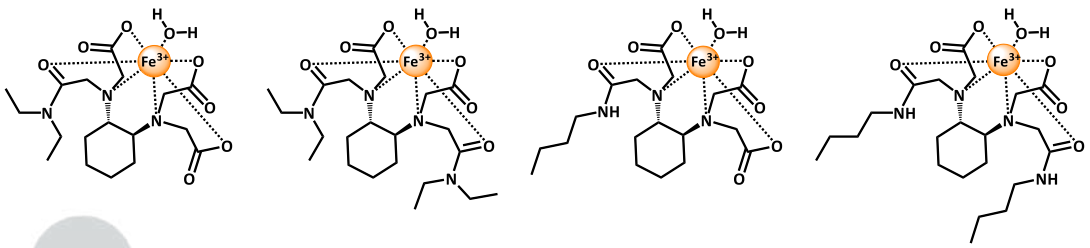

Figure 1: Chemical structures of CDTA-amide derivatives. From left to right: CD3A-DEA, CD2A-DEA_2, CD3A-BUT, CD2A-BUT_2.

Human heavy-chain ferritin (HuHf) is a recombinant protein composed of 24 H-subunits, forming a nanocage with a hollow globular structure. The H-chain is recognized by the transferrin receptor-1 (TfR1), overexpressed in many cancer cell lines. HuHf is a suitable nanocarrier due to its versatility, excellent safety profile and nano-range size[1]. Gold compounds are potential anticancers with antiproliferative and proapoptotic properties[2]. Here, I worked on the development of human heavy chain ferritin conjugates with different gold(I) compounds, i.e. Auranofin[3], Aurothiomalate and a monocarbene, for the production of ferritin-based nanocarriers and their selective delivery toward cancer cells. Five human-H chain ferritins were expressed in *E. coli* cells: the wild type, three different mutants, where I replaced with Alanine one or two cysteines (C130A, C90AC102A and C90A) and a ^{19}F labelled- human ferritin (5-F-Trp93). I exploited the use of recombinant wild type HuHf for the targeted delivery of the gold(I) compounds, the three mutants to determine their binding sites on the protein and the ^{19}F-labelled ferritin as a probe for cellular uptake via ^{19}F NMR studies. For all the HuHf-gold(I) adducts: ESI-MS spectrometry (measuring the disassembled subunits) confirmed the adducts formation and provided information on the chemical nature of the species present in solution. ICP determined the total amount of gold per cage. Also, biological experiments were performed to evaluate the cytotoxicity of the free drugs and their bioconjugates with ferritin against A2780 ovarian cancer cells; moreover, the cytotoxicity of the free compounds was evaluated together with the TfR1 expression in four different cell lines i.e. U87MG glioblastoma cells, MCF-7 breast cancer cells, HCT-116 colorectal cancer cells and MRC-5 fibroblast cells.

The presence of arsenic as contaminant in water for drinking and irrigation is a worldwide issue. This, particularly, where groundwater is the prevalent source. Several technologies have been proposed to address this issue and remove arsenic from water.

The successful development of a porous membrane designed using a bio-inspired and multidisciplinary approach is here presented. This membrane has been tested successfully on model solutions and real groundwater samples. This membrane is able to selectively remove arsenic in both As(V) and, the more toxic and less easy to remove, As(III) oxidation states.

The high selectivity avoids demineralization making the decontaminated water suitable for human use without further processing.

[c]*Skolkovo Institute of Science and Technology Bolshoy Boulevard 30, bldg. 1, Moscow 121205, Russia*

Functionalization is a procedure to anchor a catalyst on a support, to improve its catalytic behaviour, in our case toward the conversion of carbon dioxide into valuable products[1].

Catalysts are usually required to lower the working potential for the reduction of carbon dioxide and also to enhance the selectivity toward one product or to move the possible products into more valuable ones.[2] In our research, we focused on a functionalization with diazonium salt, as shown in Figure 1, on a carbon substrate named Carbon Cloth[3].

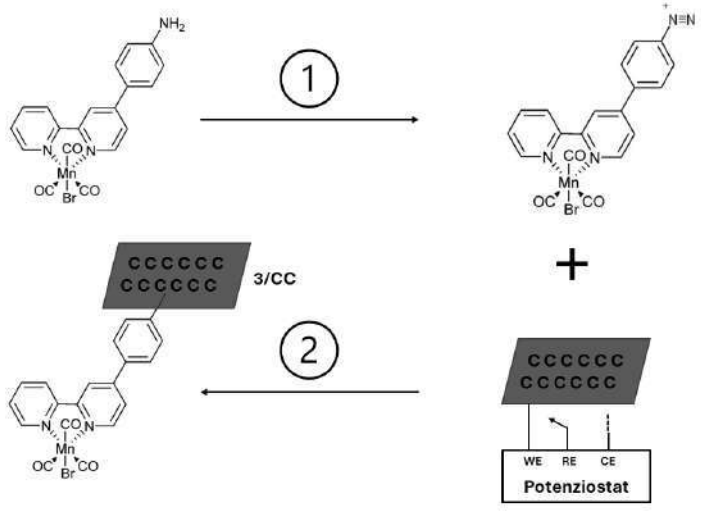

Figure 1: Scheme of the functionalization of the catalyst on Carbon Cloth

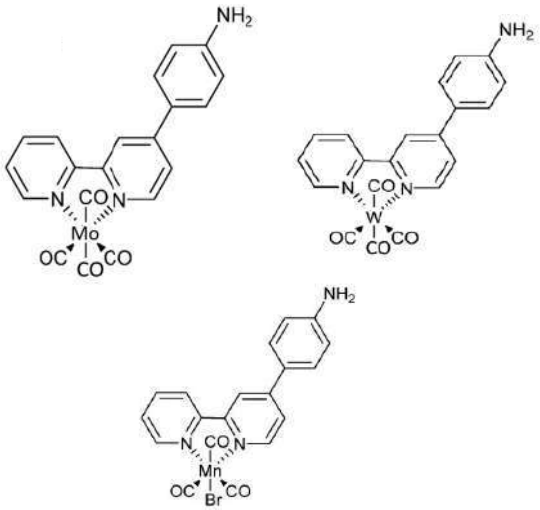

Figure 2: Example of three bipy metal electrocatalysts

Different catalysts were studied with this method, all of them belong to the bipyridine complexes, as shown in Figure 2 with different metals. For Manganese we observed a great improvement in TON and Faradic Efficiency after the functionalization for the production of CO[3]; Tungsten gave production of liquid products such as methanol and formate and Molybdenum produced a very high quantity of methanol in water[4].

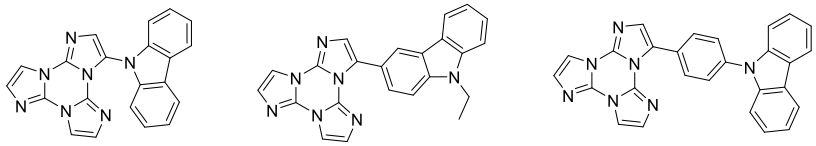
daniele.malpicci@unimi.it

Cyclic triimidazole (**TT**) has recently revealed as an intriguing scaffold for the preparation of new fully organic room temperature phosphorescent (RTP) materials, luminescent coordination complexes, polymers and bio-probes.[1] **TT** displays at room temperature Crystallization Induced Emissive behaviour with a solid state photoluminescent quantum yield equal to 30% due to concomitant fluorescence and ultralong phosphorescence (up to 1 s).[1a]

A new recently reported family of **TT**-Carbazole compounds has been prepared with different connections between the two units, namely a C_{TT}-C_{Cz} bond in **TT-(C)-Cz** or a C_{TT}-N_{Cz} one in **TT-(N)-Cz** and a phenyl spacer in **TT-Ph-Cz**.[2] The three compounds display in diluted solution, films and powders, excitation-dependent emissive behavior with both short and long-lived emissions. Remarkably, **TT-(N)-Cz** and **TT-Ph-Cz** have been isolated in different polymorphs displaying a structural and crystalline grade-dependent photophysics. Moreover, **TT-Ph-Cz** crystallizes as MeOH-solvated (monoclinic) and de-solvated (triclinic and orthorhombic) forms characterized by distinctive emissive features. Notably, triclinic and monoclinic phases are able to interconvert through Single-Crystal to Single-Crystal transition (desolvation) and MeOH uptake (vapochromism) restoring emissive properties. The multifaceted emissive behavior of **TT-Ph-Cz** is enriched by dual fluorescence (clearly visible in viscous solvents) and phosphorescence, RTP from aqueous aggregate and mechanochromism leading to an interesting stimuli-responsive high-performance single-component luminescent material.



TT-(N)-Cz TT-(C)-Cz TT-Ph-Cz

arianna.actis@unito.it

Current research in the field of solar energy conversion is focusing on photocatalysts constituted by earth-abundant inexpensive elements and with good absorption properties in the visible range. These properties are key to foster a greener and sustainable photochemistry. Carbon nitride (CN) is a semiconductor which has raised much interest over the past few years because it possesses all these features and has proved to be active in a variety of chemical processes [1]. Recent studies have shown that it is possible to couple the visible-light-activated photoredox activity of CN with the nickel-based catalysis, which is involved in the synthesis of high-value chemicals [2]. Though this Ni-CN system is frequently described as a single-atom catalyst, a site-specific characterization of the active species is still lacking, as well as a description of the mechanism underlying the supposed energy transfer between the light-excited CN semiconductor and the nickel species.

I will present an investigation of the coordination environment of nickel species on CN and the evolution of their oxidation state upon light excitation of the CN semiconductor or in the presence of chemical reductants (H_2, CO, C_2H_4) [3]. In all cases evidence is provided for the formation of reduced paramagnetic Ni(I) single ion species. Electron paramagnetic resonance spectroscopy (EPR) provides a detailed description of the coordination environment and redox activity allowing to probe the electron transfer from CN to nickel and to pinpoint the excitation wavelengths able to optimize this process under reactive conditions.

Direct oxidation of cyclohexane to adipic acid on Fe-Co based catalysts

E.Fero[a], M.Stucchi,[a] A.Villa[a], L.Prati[a]

[a] Dipartimento di Chimica, Università degli Studi di Milano, Via Golgi 19, 20133, Milano (Italy)
erisa.fero@unimi.it

AA is a widely used chemical with a wide range of commercial uses, as the manufacturing of polyamides, plasticizers, polyurethanes, and other products of relevant importance. Industrially, AA is obtained in a two-step oxidation of cyclohexane. The first step is the oxidation of cyclohexane to cyclohexanone and cyclohexanol (KA-oil), which proceeds through a radical mechanism starting from the activation of C-H bond performed at 150°C and 10-20 bar of air in the presence of an homogeneous cobalt-manganese catalyst. In the second step, KA oil is oxidized to AA by HNO_3. The resultant formation of N_2O and NO_x makes the process not environmentally friendly, leading to serious environmental pollution [1]. Therefore, efforts to develop a greener method capable of directly converting cyclohexane to adipic acid under sustainable conditions is needed. In this view, the replacement of homogeneous catalyst with an heterogynous one would be beneficial facilitating the recovery and the reuse of the catalytic system.

In this study we investigated the direct oxidation of cyclohexane to adipic acid by molecular oxygen and transition metal-based heterogeneous catalysts. In particular, Co and Fe have been selected considering they easily switch between II and III oxidation states, favouring the single electrons exchange required for the C-H bond activation [2]. Fe, Co, and bimetallic Fe-Co supported on different reducible and non-reducible oxides, i.e. Al_2O_3, TiO_2, SiO_2 and CeO_2, have been synthesized by sol-immobilization method [3], a suitable technique for obtaining similar metal dispersion regardless the support. Catalytic tests performed at 120°C and 4 bar of O_2 showed that Fe-Co bimetallic catalysts are able to produce adipic acid directly from cyclohexane differently from the monometallic counterparts, proving the cooperative effect between the two metals. Moreover, we revealed a strong support effect being CeO_2 supported catalyst the most active (AA production 0,074 mmol/h). The effect Fe:Co molar ratio was also investigated, proving a full characterization to disclose the reasons on the basis of the different catalytic behaviour.

Design of novel catalysts for the sustainable synthesis of DME

N.Jabbarli[a], M.Stucchi,[a] A.Villa[a], L.Prati[a]

[a] Dipartimento di Chimica, Università degli studi di Milano, Via Golgi 19, 20133, Milano (Italy)
narmin.jabbarli@unimi.it

Effects of climate change and the depletion of oil reserves require the use of clean alternatives to common chemicals and fuels made from fossil sources. Industrial innovation has recently adopted the responsible practice of reducing waste and energy consumption to match economic and environmental sustainability. In this view, dimethyl ether (DME) recently gains increased interest. Besides, being a well-known propellant and coolant, it is an alternative clean fuel for diesel engines, which simultaneously is capable of achieving high performance and low emission of CO, NO_x and particulates in its combustion [1].

Industrially, DME is presently produced from syngas ($CO+H_2$) in a two-steps process, in which methanol is obtained and then converted to DME in another reactor. The sustainability of the process could be strongly enhanced by producing DME directly from CO_2, which is still a great challenge. Hence, this work investigated the possibility to produce DME from CO_2 [2], developing appropriate bifunctional catalysts for a possible one-step reaction, i.e. catalyst able to convert CO_2 to MeOH and dehydrate MeOH to DME.

As the transformation of CO_2 to MeOH is a well-known and studied transformation operated in the presence of ($CuO/ZnO/Al_2O_3$) mixed oxide, we first investigated the dehydration of alcohol to the corresponding ether for the selection of appropriate support for redox component. Different acidic materials have been tested under standard conditions (180°C and 5 bar N2) as dehydrating agent of alcohol to obtain the corresponding ether. Commercial zeolite like ZSM-5 and mordenite (Degussa), Nb_2O_5, Al_2O_3, Fe_2O_3, ZrO_2, SiO_2 results poorly active. However, by increasing the acidity of oxides with the introduction of sulphonic groups we were able to obtain a neat increasing of the dehydrating activity. Unfortunately, the stability of the sulphonic groups under the actual reaction conditions was poor and we observe a rapid deactivation of modified catalyst. We then turn toward a structural change of oxide instead of a simple functionalization. We then synthesized SiO_2·Al_2O_3 at different internal ratio by Flame Spray Pyrolysis and WO_2-modified ZrO_2 prepared by microemulsion technique. Preliminary results confirmed the activity and the stability of these mixed oxide in the conversion of iPrOH to $(iPr)_2O$ with a productivity of 7,3 mmol/h.

Next steps will be the investigation in a flow reactor.

alessandro.digregorio@uniba.it

Living cells, through their intrinsic nature, can work as natural platforms exhibiting a multitude of functional groups or biomolecules. The application of an engineered chemical surface onto these cells enables bacteria, mammalian and human cells, yeasts, and microalgae to recognize their environment and incorporate both *cell-to-cell* and *cell-to-environment* interactions useful for different applications ranging from industrial to biomedical.[1]

The scientific research here has been focused on the development of a strategy to universally decorate living cells with the use of melanin-like sticky organic polymers. Polydopamine (PDA), a poly-hydroxy-indole specie, has recently been used to achieve self-assembling coating onto living cells, giving them the capability both to continue living/dividing and increase cell resistance under harsh environmental conditions.[2]

This technology is simple, one pot, yielding to allow a highly reactive surface capable to react with other xeno-functional groups to change the chemical reactivity on the living cell surfaces. Our studies are focused on the possibility to co-polymerize dopamine with boronic acid units to obtain engineered cells with new functionalities such as addressing both free and membrane-bound saccharide moieties over cell surface, holding the potential for broad biology and biomedicine.

Other studies are conducted to enhance properties of diatoms in the field of bioremediation. Co-polymerization of dopamine with polyamines trigger the pollutants removal from aqueous environment, and increase the specificity of the chemical type of these (e.g. emerging small molecules, microplastics).[3]

Moreover, redox responsive melanin-like polymers were also synthesized *via* co-polymerization thiol-bearing moieties with dopamine, to add disulfide bridges to the polymer bulk. In this way these bioinspired polymers resulted cleavable under specific redox inputs, ready to be removed after capturing pollutants.

LabXAS: a new table-top instrument for in-lab XANES/EXAFS measurements

R. Sant,[1] M. Corti, [1] P. Florio, [1] G. Ghiringhelli,[1] Moretti Sala,[1]

[1]*Dipartimento di Fisica, Politecnico di Milano, Piazza Leonardo da Vinci 32, I-20133 Milano*
roberto.sant@polimi.it

X-Ray Absorption Near Edge Structure (XANES) and Extended X-Ray Absorption Fine Structure (EXAFS) spectroscopies are powerful techniques used to characterize the oxidation state of the absorbing atom and its coordination to the ligands. However, the need of an intense and tuneable-in-energy x-ray beam has limited the use of these techniques to synchrotron facilities, thus precluding their wide spreading. Giving access to XANES/EXAFS facilities to a broader community of physicists, chemists and material scientists would be extremely beneficial as XANES/EXAFS could provide them with an immediate feedback on the quality of the products of their research.

Recently, the development of novel laboratory x-ray sources with modern technology has favoured the rise of compact, but extremely expensive XANES/EXAFS spectrometers[1,2]. Within the NEXT-GAME and MUSA projects, we have designed a XANES/EXAFS spectrometer, called LabXAS, based on the use of a conventional but micro-focused x-ray source with suitable brilliance. Besides the source, the spectrometer also comprises a Johansson-type Ge(nn0) crystal analyser and a silicon drift detector, installed in vacuum and arranged on a Rowland circle. The instrument will work in transmission, within the energy range spanning from 3 to 15 keV. LabXAS is intended to minimize the costs, the size and the mechanical complexity of existing laboratory XANES/EXAFS spectrometers, while reaching measurement performances comparable to available instruments. Ultimately, it aims to provide a fast access to XANES/EXAFS characterization of novel, freshly synthesized materials, in particular for studies in the field of the next-generation batteries and catalysis. In this talk, we will give a general overview of the LabXAS instrument by presenting the innovative design solutions and the targeted performances, and we will finally discuss the most appealing applications for the community of chemists.

Specific diiron complexes, derived from commercial $[Fe_2Cp_2(CO)_4]$ (Cp = η^5-C_5H_5), have emerged as versatile frameworks for the construction of functionalized organometallic architectures. Taking advantage of the facile substitution of up to three carbonyl ligands and the synergistic interplay between the two iron centres, these complexes enable the assembly of small molecular entities via non-traditional reaction pathways.[1] Cyano-amino-allylidene complexes (**1**) can be synthesized through a sequence of regio- and stereo-selective reactions, being tolerant towards diverse functional groups (esters, pyridyl, thiophenyl, ferrocenyl, etc.).

Within complexes of type **1**, the interaction between the amine nitrogen lone pair and the terminal carbonyl ligand promotes the thermally-induced displacement of this CO. The resulting derivatives with multisite ligands have been evaluated for their catalytic activity in the hydroboration reaction of aldehydes and in the coupling reaction of CO_2 with epoxides under mild conditions.

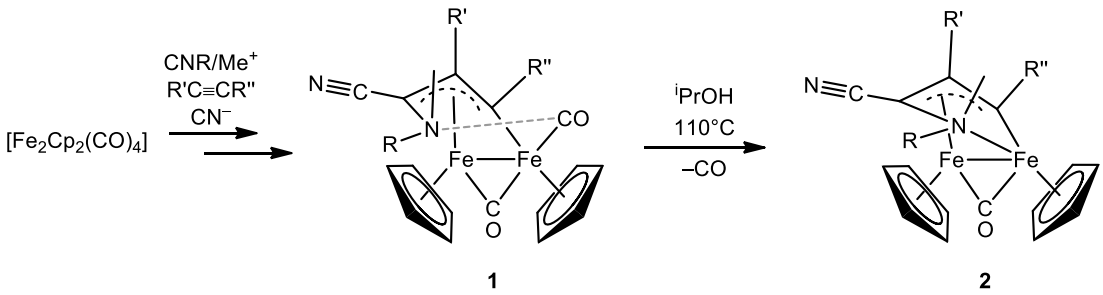

Figure 1: Synthesis of cyano-amino-allylidene complexes (**1**) and their thermal decarbonylation (**2**).

TI_3C_2 MXene heterojunctions for enhanced photocatalytic properties in hydrogen photoproduction

M.C. Paganini,[a] P. Jaconis,[a] V. Lagostina,[a]

[a]*Dipartimento di Chimica, Università di Torino, Via Giuria 7, 10125 Torino, Italy*
mariacristina.paganini@unito.it

The hydrogen production can be performed in different ways: electrolysis, thermo-splitting, and photo-splitting. [1] The methods just mentioned use different types of energy to decompose water into hydrogen and oxygen, even though the efficiencies are really different. Indeed, the efficiencies of these systems are generally 70% when electricity is used, 40% when heat is used, and about 0,5% when light is the source of energy. With the idea of developing efficient green processes to produce hydrogen, among the quoted mechanisms photolysis results be a very interesting and feasible option since harvesting solar energy would directly produce H_2. The efficiency of the technology is still very low, due to several factors that depend on the reaction itself and for the catalyst used.

In the recent past MXene (Ti_3C_2) [2] has been used as a cocatalyst in possible combination with other synthesized semiconductors for an enhanced photocatalytic heterojunction. This material shown a 2D structure and is also interesting the presence of many functional groups that can be tuned by changing the synthesis. It exhibits absorption in the visible spectrum, boasts conductivity comparable to metals, and maintains an ideal Fermi level for hydrogen production when interacting with water.

In this study, the synthesis of this compound was always executed starting using Ti_3AlC_2 as precursor, trying different etching processes. Different semiconductors were also synthesized paying particular attention to different factors such as energy gap, the position of valence and conduction band, and sustainability aspects. All the synthetize materials were then characterized with XRD, SEM and UV-Vis analyses.

In the end, the photocatalytic performances of the materials were tested for the production H_2 by using different LED source (characterize by different wavelengths) to evaluate the performances.

Spinel oxides based on earth-abundant transition metals, such as Cr, Mn, Fe, Ni, Cu, and Zn, have emerged as promising alternatives to 'platinum group metals'-based catalysts in fuel cells and electrolysers, particularly for their application in the oxygen evolution reaction (OER).[1]

A novel and promising approach for developing high performance OER-catalysts involves high-entropy spinel oxides (HESO). These materials, characterised by a single phase spinel crystal structure with multiple metal cations, generally exhibit superior catalytic performance and increased stability compared to conventional binary spinel oxides.[2]

This project aims at optimising a low temperature, sustainable, water-based synthetic route for spinel oxides through the subcritical hydrothermal treatment of an oxalate suspension of the metal cations present in the final structure.[3] In particular, low entropy spinel oxides with the formula $NiFe_{2-X}M_XO_4$, (X = 0.25, 0.50, 1.00 and M = Mn or Cr) were synthesised to investigate the influence of Fe substitution on the structural and catalytic properties of the materials. Furthermore, four HESOs were synthesised: $(Cr_{0.2}Mn_{0.2}Fe_{0.2}Co_{0.2}Ni_{0.2})_3O_4$, $(Cr_{0.2}Mn_{0.2}Fe_{0.2}Ni_{0.2}Cu_{0.2})_3O_4$, $(Cr_{0.2}Mn_{0.2}Fe_{0.2}Ni_{0.2}Zn_{0.2})_3O_4$, $(Mn_{0.2}Fe_{0.2}Ni_{0.2}Cu_{0.2}Zn_{0.2})_3O_4$. Although some samples exhibited a pure crystalline spinel structure immediately after the hydrothermal treatment (150-200°C, 24 h), as confirmed by PXRD analyses, others required a subsequent annealing step (300-500°C) to achieve crystalline purity. Stoichiometries were determined through ICP-AES analyses, demonstrating good agreement with expected values and confirming the successful incorporation of the cations within the crystal lattice.

Currently, electrochemical tests (linear sweep voltammetry measurements) are ongoing on the synthesised materials to assess their electrochemical behaviour. These results will be pivotal in identifying the most promising stoichiometries for future evaluations, where the materials will be tested as electrocatalysts for OER in water electrolysers.

email: alessandra.esposito3@unina.it

A fascinating class of nanostructures known as amyloid fibrils has garnered significant attention in the field of nanotechnology. Recent discoveries are now changing our vision of self-assembling peptide structures from disease related entities to functional tools for diverse biotechnological and material science applications.[1,2] Particularly interesting are catalytic amyloids, which allow to combine the benefits of enzymatic and heterogeneous catalysts within peptide-based nanostructures. In this context, our research focuses on developing functional nanomaterials combining amyloid-like nanofibrils and artificial metalloenzymes, showcasing their potential in flow biocatalysis.

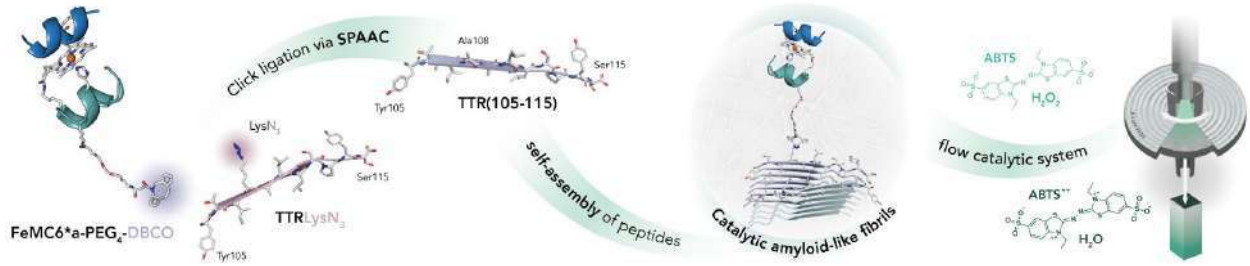

Figure 1: Schematic representation of the conjugation strategy and its application.

For this purpose, we have selected the TTR(105-115) peptide, derived from human transthyretin, which is able to form non-toxic fibrils with unique structural properties.[3] Exploiting click chemistry (SPAAC, illustrated in Figure 1), the synthetic miniaturized peroxidase FeMC6*a[4] has been covalently bonded to TTR(105-115)-based fibrils. Subsequently, FeMC6*a@fibrils were implemented in a flow catalytic system by simple immobilization onto a PVDF filter membrane. This amyloid-functionalized filtering device demonstrated remarkable performance, enabling up to 40 reaction cycles of substrate (ABTS) oxidation. This approach not only enables enzyme recycling, but also facilitates the separation of reaction products. Overall, this research provides a starting point for exploring the catalytic capabilities of amyloid fibrils in various applications.

Copper indium sulfide quantum dots enabling quantitative visible light photoisomerisation of (E)-azobenzene dyes

Marco Villa[a] , Caterina Bellatreccia[a], Zakaria Ziani[a], Filippo Piero Battaglia[a], Paola Ceroni[a]

[a] *Department of Chemistry "Giacomo Ciamician", University of Bologna, Via Selmi, 2, 40126 Bologna, Italy* [b] *marco.villa11@unibo.it*

Azobenzene derivatives are one of the most studied photochromic systems, garnering significant attention in different fields such as photopharmacology and photoresponsive materials[1,2]. However, azobenzenes rely on UV light to generate the metastable (Z) isomer, limiting their use in the previously mentioned fields. The rare cases showing large ratios of the (Z) isomer under visible light irradiation need either the use of a photosensitizer or structural modifications of the azobenzene compound[3]. Our work has focused on investigating various hybrid architectures involving azobenzene and quantum dots. We design an azobenzene with a dihydrolipoic acid chain that is grafted onto the surface of $CuInS_2$ quantum dots (CIS-QDs) (Figure 1). Interestingly, all these hybrid systems show quantitative photoisomerization to the (Z) isomer under visible light irradiation (e.g., 533 nm), with no observable back photoisomerization. We demonstrated that this peculiar effect was also noticed for physical mixtures of CIS-QDs and azobenzene dyes, revealing that this phenomenon can be ascribed to a direct interaction of the (Z) isomer N=N function with CIS-QDs. We showed that this interaction drastically decreases the intensity of the absorption bands of the (Z) isomer in the visible spectrum, shifting the photostationary state to the (Z) isomer, preventing its back photoisomerisation.

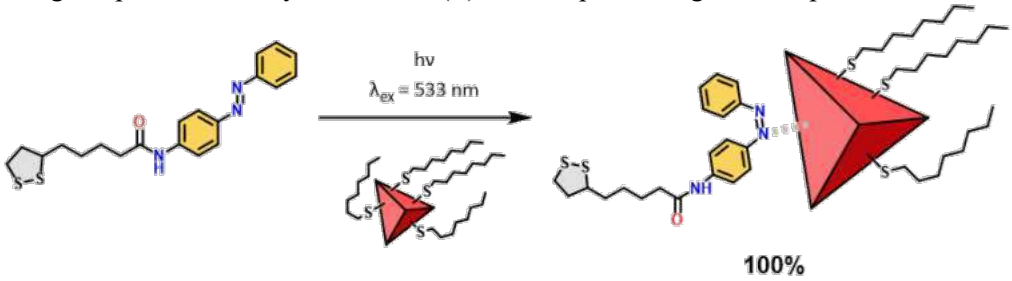

Figure 1: Isomerization process of an azobenzene derivative in the presence of CIS-QDs under visible light irradiation.

The inclusion of catalytically or electrochemically active metal-based systems in ionic liquids (ILs) is attracting a growing interest due to the versatility of this approach and the potential applications in a variety of fields.[1] Molybdate and tungstate-based ILs have been reported in literature as effective catalysts for the cycloaddition of CO_2 to epoxides,[2,3] and other authors have also reported encouraging results concerning the use of tungstate-based ILs for the catalysis of CO_2 reaction with a variety of substrates. Among ILs, dicationic ionic liquids (DILs), which display a positive ion consisting of two cationic moieties covalently connected to each other, represent quite interesting systems from a structural point of view. The type and length of the spacer chain is in fact capable of influencing both the conformation and the reactivity of the DIL, representing a further element of tunability with respect to monocationic structures.[4] Nevertheless, at the best of our knowledge, no literature papers have yet considered tungstate based-DILs.

A panel of DILs with different rigid xylyl spacers (ortho, meta, para) and different anions (bromide and tungstate) has been synthesised and characterized through different experimental and computational techniques. Analogies and differences between the systems have been analysed using information derived from their DFT structures, semiempirical molecular dynamics, thermal behaviour, and catalytic properties versus the CO_2 cycloaddition to epichlorohydrin. The results have shown an interesting correlation between structure, flexibility, properties and catalytic activity.

Ruthenium Complexes as Versatile Scaffolds for Anticancer Drugs Development

Giacomo Drius*[a], Natalia Calonghi,[b] Elisa Moro,[c] and Silvia Bordoni[a]

[a] *Department of Industrial Chemistry "Toso Montanari", Alma Mater Studiorum, University of Bologna, Via Piero Gobetti, 85, 40129 Bologna BO*

Metal complexes are widely used in anticancer therapies, since they offer a wide range of tuning variables, including choice of metal, kind of ligands, coordination geometry, and a variety of oxidation states. This versatility permits to be notable drug design platforms.[1,2]

Clinically approved metallodrugs such as cisplatin, carboplatin and oxaliplatin are currently used to treat severe neoplastic diseases. Due to their versatile biochemical properties, Ruthenium compounds have emerged as promising anticancer alternatives to Platinum. Several types of Ru-based anticancer agents have been developed so far and some of them have undergone clinical trials. They can act by interacting with DNA or proteins, by producing reactive oxygen species to induce oxidative stress, ultimately affording cancer cells death.

A novel class of Ruthenium complexes has been designed by incorporating ligands such as CO, triphenylphosphine, hydride, and a variety of N- and O-donor chelate ligands, including non-steroidal anti-inflammatory drugs, hydroxy-stearic acids, pyrrole- or indole- derivatives. The selection of ligands was based on the purpose of enhancing therapeutic effectiveness of Ruthenium species against cancer cells, while retaining the option of further modification, by substituting the remaining hydride unit with N-donating ligands. Two distinct mechanisms, involving unprecedented chelate ligand exchange from k^2-(O,O) to k^2-(N,O) dihapto fashion mode, have been proposed and supported by DFT calculations.

NMR binding evaluations have been performed to test metal interactions to calf thymus DNA or human serum albumin biological targets. The results exhibit the organometallic species to bind by weak interactions with PPh_3 apical ligands. Preliminary biological evaluations *in vitro* MTT assays on different human cancer cell lines have shown promising anticancer activity by inhibition of cell viability and proliferation.

Mini-protein design: tailoring metalloprotein function for electron transfer and catalysis

L. Leone,[a] M. Chino,[a] L. F. Di Costanzo,[b] S. La Gatta,[a] V. Pavone,[a] and A. Lombardi[a]

linda.leone@unina.it

Metalloproteins display countless kinds of activities, despite employing a limited number or metal ions. From an inorganic chemist's perspective, they can be considered as a special kind of coordination compounds, featuring a complex macromolecular ligand that dictates the properties of metal ions through specific arrangements of aminoacids.[1] Deciphering the intricate mechanisms of metalloprotein function has been a central topic of research. Advances in de novo protein design have significantly contributed to the process, while facilitating the tailoring of enzymes for specific applications.[2] In this field, we have designed small, yet functional, peptide-based models housing different metal sites.[3-5] Our efforts have been recently directed to reproduce the structural and redox properties of the rubredoxin $Fe(Cys)_4$ center within a miniaturized protein scaffold, named METPsc1.[6] Notably, FeMETPsc1 exhibits one the highest reduction potentials among the rubredoxin family, thanks to precise introduction of hydrogen bonds in the second coordination sphere. FeMETPsc1 was able to perform at least 12 reversible redox cycles, prompting us to build a synthetic electron transfer chain by matching FeMETPsc1 with another mini enzyme, ZnMC6*a, as a photosensitizer.
Further, we have obtained the crystal structure of METPsc1 in its zinc and cobalt complexes, showing perfect agreement with the designed model. Our current research is focused on evaluating the effect of metal ion substitution in the METPsc1 scaffold, with the aim of achieving a thorough spectroscopic characterization and expanding the versatility of this mini-protein towards energy-related catalysis. Altogether, these studies open new avenues for exploiting artificial metalloproteins into complex electron transfer and catalytic processes, suggesting a promising direction for nanoscale multi-component mini-protein devices.

adolfo.speghini@univr.it

Fluoride based nanoparticles (NPs) activated with trivalent lanthanide ions (Ln^{3+}) have been extensively investigated in the last years for their interesting luminescence properties in the UV, Visible and Near Infrared (NIR) optical regions. These NPs are particularly interesting for applications in nanomedicine, in particular as optical probes or sensors in the biological windows (700-950 and 1000-1350 nm ranges).

In this contribution, we focus on KY_3F_{10} NPs activated with luminescent Ln^{3+} ions (as Pr^{3+}, Nd^{3+}, Tm^{3+}, Er^{3+}, Yb^{3+}), also considering core@shell architectures[1] (Figure 1).

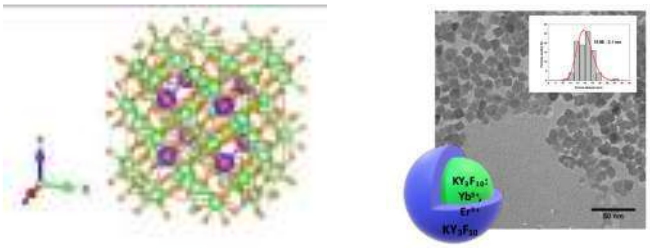

Figure 1: Crystal structure (K, violet; Y, green; F, yellow); architecture, TEM image and size analysis for representative core@shell nanoparticles.

KY_3F_{10} NPs have been prepared as water colloids with a "green chemistry", microwave (MW) assisted hydrothermal technique, using hydrophilic citrate groups as capping agents, which confer excellent colloidal stability in physiological buffers dispersion. Stokes and Anti-Stokes emissions in the UV-Visible-NIR regions have been measured by excitation with laser radiations. Energy transfer processes among Ln^{3+} ion couples (e.g. Yb^{3+}-Nd^{3+} or Yb^{3+}-Er^{3+}) have been exploited to investigate the performances of the Ln^{3+} doped KY_3F_{10} NPs as optical thermometers. In particular, the intensity of emission bands originating from the Ln^{3+} ions have been employed to study the thermometric properties, for evaluating the absolute and relative thermal sensitivities as well as temperature uncertainties of the NPs, using ratiometric methods. The obtained values clearly suggest a promising use of the KY_3F_{10} NPs as nanothermometers in biomedical applications.

carbone@uniroma2.it

In the present work, we implement environmentally friendly water-based Quasi-Solid Electrolytes (QSE) for Dye Sensitized Solar Cells (DSSCs), displaying an unprecedent open circuit voltage (VOC) as high as 750 mV. The production of the hydrogel for QSE-DSSCs is achieved by exploiting the concept of fully green design and fabrication, through the selection of components such as the natural polysaccharide galactomannan (GM), the biocompatible zinc salts, and the employment of eco-friendly synthetic procedures to afford the hybrid gelating agents. In the process, moderate temperature (< 40 °C) and only aqueous solutions are employed. Depending on the type of the initial salt, either zinc hydroxysulfate lamellae or zinc oxide nanoparticles are created within the gel matrix, with a more extended nanoporous structure in the latter case (See Figure 1). Upon addition of the redox mediator I^-/I_3^- and ensuing assembling of the device, aqueous QSE-DSSCs are achieved with state-of-the-art PhotoConversion Efficiency. The latter couples a 2% efficiency (limited by charge diffusion as proved by Electrochemical Impedance Spectroscopy) with a good Average Visible Transmittance (AVT) (See Figure 1), and Light Utilization Efficiency (LUE), a couple of coveted features in wave-selective or semi-transparent devices [1].

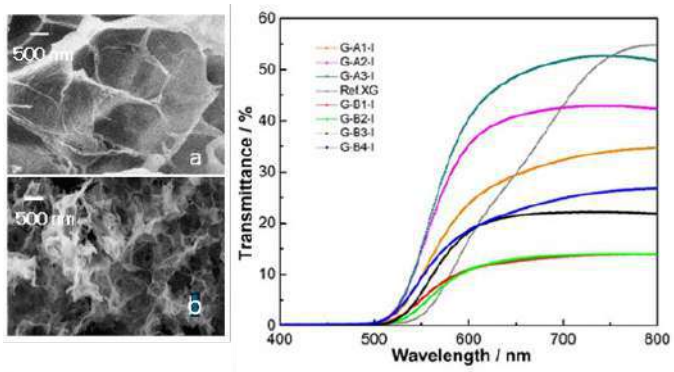

Figure 1: SEM images of the QSE (left). AVT of the devices (right).

In modern agriculture, the application of chlorinated pesticides plays a critical role in managing pests affecting crops, herbs, and spices. However, the extensive use of these organochlorines rises concerns regarding potential residues in food products and their impact on human health[1]. In response, regulatory bodies have established maximum residue levels to ensure adherence to safety standards. Conventional detection methods, like high-performance liquid chromatography, though effective, involve labour-intensive and costly processes. Considering this, is worth exploring alternative techniques for faster, on-field detection. A potentially successful approach is fluorescence-based detection, involving intrinsic fluorophores. Zinc oxide is suitable for these methods, as it is safe and biocompatible. A surface functionalization of the ZnO nanoparticles (NPs) ensures the interaction between the former and the pesticides, resulting in a quenching or enhancing of the fluorescence signal intensity, thus providing the detection[3,4]. In a previous related paper (3-aminopropyl) trimethoxysilane (APTMS) was used as the coating agent and its interaction with the organochlorine penconazol was studied[2]. In this current study, the potential of various amino-silanes is explored. Also, a double functionalization is performed, using tetraorthosilicate (TEOS) to increase the dispersibility of the NPs in aqueous solutions; and then the amino-silane as the outermost layer providing the -NH_2 tail that serves as a hook for the -Cl of organochlorines.

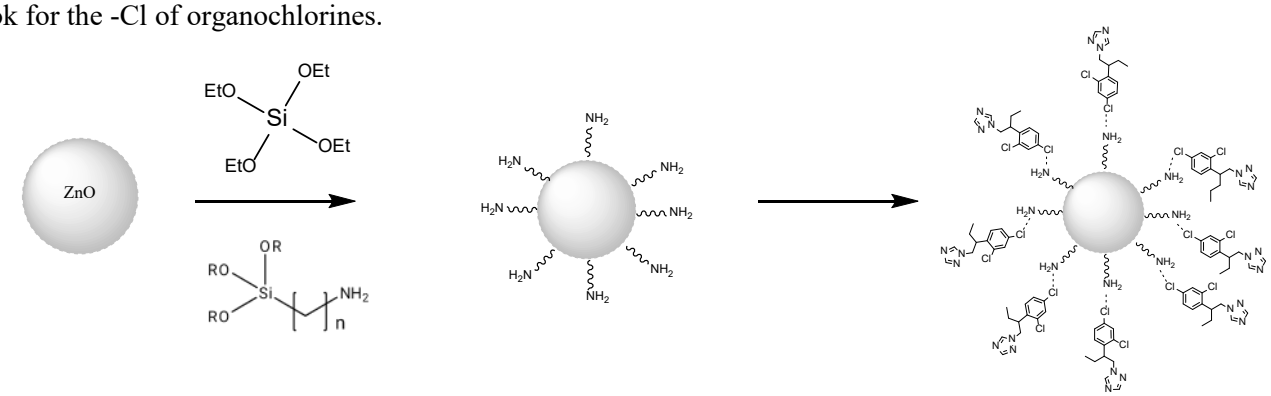

Figure 1: Scheme of the functionalization of ZnO NPs and their interaction with the chlorinated pesticed penconazol.

lorenzo.gontrani@uniroma2.it

In this contribution, we describe the fluorescence properties of high purity nanometrical ZnO synthesized by precipitation in type-IV zinc nitrate-urea Deep Eutectic Solvent, a system inherently endowed with nano-homogeneities in its internal structure[1], that can be easily prepared by mixing the solid components with only little heating and limited workout procedures. The observed photo luminescence (PL) is remarkably brilliant and detailed investigations pointed out that the emitted radiation has quantum yield values that decrease when temperature is increased across a broad range, being very high at low temperature (77 K) but still appreciable up to 373 K. Such behaviour is perfectly reversible upon cooling and can be profited to assess external temperature with quite good confidence[2]. In order to gain further insight on such response property, a series of Raman studies was performed, whose vibrational patterns were assigned according to the crystal structure revealed by XRD experiments. Additionally, the dependence on the system morphology was investigated with FE-SEM microscopy, that depicts different nanoscopical structural arrangements, unveiling the presence of nano lamellar moieties embedded into larger mesoporous domains.

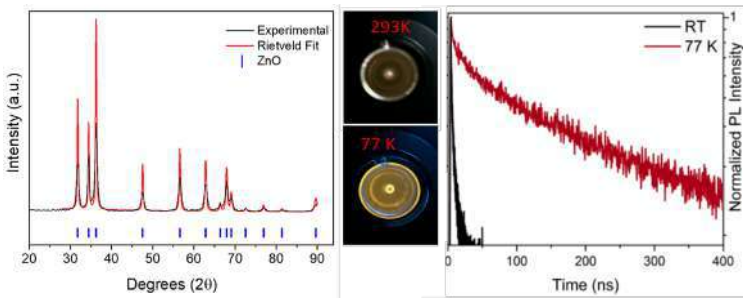

Figure 1: ZnO NPs: XRD pattern (left); PL at RT and 77 K: visual trace (center), lifetime (right).

elisabetta.scalone@studenti.unime.it

Nowadays environmental pollution deriving from anthropological activities is a serious threat to the well-being of ecosystem and its inhabitants, representing the main cause of mortality in the world. The presence of emerging and common pollutants in air, water and soil is a cause of worry and discussion. Effective monitoring methods are indispensable for assessing environmental quality and identifying pollution sources. One of the most powerful analytical tools for determining environmental contaminants is chromatography, which allows for qualitative and quantitative analysis. However, these approaches require qualified staff, expensive instrumentation, and time-consuming sample preparation. In this regard, nanotechnologies represent potential for the development of sensor for environmental applications, thanks to their unique features such as high surface area (surface/volume ratio), catalytic capacity, reactivity and easy functionalization to chemically modulate their properties.[1] In particular, devices based on functional nanomaterials may represent a valid alternative to traditional techniques, compared to which they generate fast responses, addressing at the same time the actual need to use systems with a low environmental impact.[2] Recently, the scientific community is focusing on the development of optical sensor systems for the detection of environmental parameters and contaminants such as heavy metals. In particular, colorimetric sensors exhibit promising potential for the detection of metallic ions, anions, organic dyes, drugs, pesticides, and other toxic pollutants thanks to their easy fabrication, quick detection, high sensitivity, and naked-eye sensing.

In this work, a user-friendly adsorbing system that may either respond colorimetrically to the presence of various environmentally parameters (such as pH) is developed using different chromophores. In particular, a hybrid material based on functionalized clay is produced and used to immobilize seven distinct organic dyes and applied on cotton fabrics. All starting materials and final products have been characterized by means of different chemical-physical and morphological techniques. Finally, their successful employment for the pH variation detection will be shown, together with preliminary tests for pH variations and heavy metal revealing.

e-CCM TECHNOLOGY: TRASFORMING CO_2 INTO BUILDING MATERIALS

P. Cambise[a] R. Millini,[a] M. Bellettato,[a] R. Grana[a]

[a]*Eni S.p.A., Research & Technological Innovation Dept. – San Donato M.se (Italy)*

paolo.cambise@eni.com

Carbon Capture and Utilization (CCU) technologies, i.e. those that use CO_2 as a feedstock and convert it into value-added products (e.g. fuels, chemicals, building materials), are receiving increasing attention. The CCU is also seen to decrease the costs associated with the reduction of GHG emissions by valorizing the products and this is often considered an advantage over the geological storage of CO_2 (CCS).

Among the CCU approaches, mineral carbonation (MC) has the highest environmental benefits as it involves the permanent fixation of CO_2 in form of inorganic carbonates, stable, inert and non-toxic phases. MC processes can be applied on natural (mineral) or synthetic (industrial wastes, by-products) substrates if they have a sufficiently high content of reacting elements (calcium, magnesium and/or iron) to justify the otherwise onerous process. Minerals such as Olivine [$Mg_{2-x}Fe_xSiO_4$], Serpentine [$Mg_3(Si_2O_5)(OH)_4$], Wollastonite [$CaSiO_3$] are well studied for these processes since they have a high CO_2 uptake, nominally ranging from 0.38 $kg_{CO2}/kg_{Wollastonite}$ to 0.63 $kg_{CO2}/kg_{Olivine}$).

In this context, Eni has developed the e-CCM technology which consists of the *ex-situ* mineral carbonation of Olivine, a mineral widely available in outcrops often exploited industrially to produce materials for the steel, metallurgical and building industries. The rate of carbonation is strongly influenced by P_{CO2}, temperature, average particle size of the mineral, and, in lower extent, by the composition of the aqueous phase. Other phenomena may negatively influence the overall rate of the reaction, the most important being the formation of passivating layers of amorphous silica and/or carbonates that, covering the surface of the particles, constitute barriers to the diffusion of reagents and products, thus slowing down the entire carbonation process. Working with rocks mined from different outcrops located in Northern Italy and Norway, with an average Olivine content of 85 wt% and nominal CO_2 uptake of to 0.50 kg_{CO2}/kg_{rock}, we have selected a reactor suitable to manage a reaction that is only apparently simple, involving different gas-liquid-solid equilibria, and optimized the reaction conditions to obtain an almost complete carbonation (> 95%) within 3 - 4 hours, under moderate P_{CO2} (70 - 90 bar). In addition to this result, which ranks among the best reported in the literature, a further important turning point is represented by having discovered that, after simple treatments, the product (consisting mainly of $Mg(Fe)CO_3$ and amorphous SiO_2), develops pozzolanic properties never reported before for similar materials. This paves the way for applications of the mineralized product as a pozzolanic addition in the formulation of cements, limiting the production of clinker, which has a very high hard-to-abate carbon footprint.

angelo.lembo@uniroma2.it

The marriage of porphyrins with ferrocene affords new materials with improved photo- and electrochemical properties for photovoltaics, NLO, fluorescent switches and electrochemical-based devices[1-2], but, if on one hand the introduction of ferrocene in the *meso*-porphyrin positions was well and extensively studied, the difficulty to introduce the ferrocenyl moiety in the *β*-porphyrins positions has limited their application.

In line with our previous work[3], here we report on a comparative study to investigate the regioselectivity of the Heck reaction between free base 2-Br-Porphyrin and vinylferrocene derivatives. In the mild reaction condition adopted, using $Pd(dba)_2/AsPh_3$ as catalytic system, the vinylferrocene showed a peculiar selectivity towards the formation of the *alpha*-isomer rather than the *trans*-isomer. This aspect allowed us to investigate by an electro- and photochemical point of view the properties of the new 2-vinylferrocenyl-substituted porphyrin *alpha*-isomers compared to the respective *trans*-isomers, outlining the importance of the type of *β*-C-C bond in the electron-transfer processes.

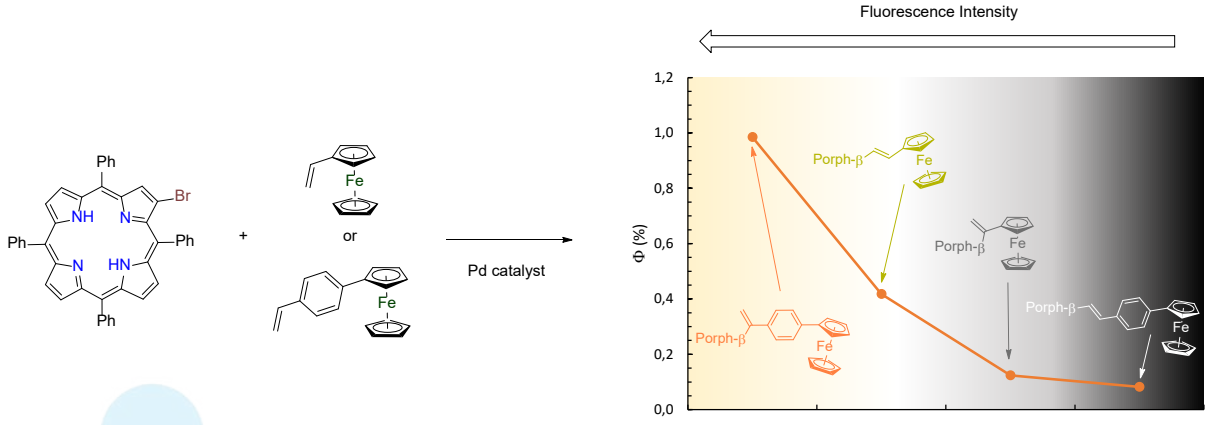

Figure 1: Heck reaction (left) and residual porphyrin fluorescence in the different isomers (right)

marianna.roggio@uniba.it

Cereals can be colonized, throughout the whole crop cycle, by fungal pathogens, including mycotoxigenic species and among these one of the most important is *F. graminearum*, causal agent of different cereal diseases such as Fusarium Head Blight. *Fusarium graminearum* represents both a phytopathological problem and a toxicological risk for human and animals. To date, fungicides represent the most effective strategy to protect cereals against Fusarium species. However, in the last years, as requested by the European Green Deal, more eco-friendly strategies should replace the use of chemicals in agriculture. In this scenario, selection of biocontrol agents and Low Temperature Plasma (LTP) processes recently developed for applications in Agriculture and Food technologies are very promising.[1, 2]

Experiments were conducted on the deposition of barrier films containing fungicides or bacterial spores in a DBD (Dielectric Barrier Discharge) reactor by means of Aerosol Assisted Atmospheric Pressure Plasma Deposition (AA-APPD). With this approach, high fungicide effect with a small quantity of chemicals and less pollution of soil and water is expected. The chemical composition and the morphology of barrier film have been characterized by means of WCA measurements, FTIR, SEM and profilometer. Coating chemistry and morphology and activity against *F. graminearum* have been tested on glass discs, and the viability of the Bacillus spores as well.

Good activity against fungi has been observed both for coatings embedding the fungicide or including the Bacillus spores. Very interestingly the latter retained the viability upon the deposition process. In the case of coatings containing prothioconazole an anti-fungine activity higher than the pure pesticide has been found. Preliminary results showed that Aerosol Assisted Atmospheric Pressure Plasma can represent a good ecofriendly tool for seed coating. Activities aimed to optimize the deposition on maize and wheat seeds of nanocomposite film containing fungicides or bacteria spores, are ongoing.

Cooperative photo-redox catalysis is a cost-effective and sustainable approach allowing the tackling of two major societal challenges: water stress and energy shortage. In the cooperative photoredox approach, (non-)selective oxidation of organic pollutants is exploited for solar fuels production integrated in a light-driven photoredox system, valorising the contaminants in a circular economy approach.

To this aim, we engineered low-cost and bio-derived sorbents, i.e., chitosan-based sponges, integrating photoactive materials to couple the photocatalysis with the excellent sorption properties for water remediation. Specifically, chitosan-based polymers were adopted as porous sponges and non-porous thin films and atomic layer deposition (ALD) was chosen to integrate the photo-active materials.

ALD is a powerful method for the deposition of thin films on 3D porous materials, due to its processing capabilities such as the angstrom-level thickness control and conformal deposition. Zinc oxide (ZnO) was chosen as a starting photoactive material for its well-known photocatalytic and antibacterial properties, representing a good candidate for the above-mentioned applications.

The growth of the ZnO on both chitosan thin films and sponges was studied by means of spectroscopic ellipsometry, XPS, UV-vis Spectroscopy and FTIR. The measured band gap and the chemical composition confirmed the growth of ZnO. Moreover, the photocatalyst was found to grow within the matrix of the sponges up to at least tens of micrometres. Due to the chemisorptive nature of ALD, the growth model suggested a strong integration of the oxide into the bio-polymer matrix, with properties resembling a ZnO/chitosan nanocomposite. Moreover, it was observed that only 10 ALD cycles, resulting in a nominal ZnO of 2 nm, greatly increased the stability of chitosan sponges in water media, enabling pollutants removal.

The adsorption of Direct Blue 78 was studied as a function of the ALD ZnO cycles. Higher direct anionic dye removal from solution was measured for the ALD ZnO/chitosan nanocomposite compared to the pristine chitosan sponges.

ALD was the key-enabling technology for the production of ZnO-based photo-active organic-inorganic hybrid bio-based sponges, setting the first step towards a cooperative photo-redox system.

This research was funded by the European Union-Next Generation EU within the project PRIN-BECOMEH2 (grant n. P2022XHMRY)

Respirable crystalline silica (RCS) remains the leading cause of occupational respiratory disease worldwide and continues to prompt extensive research into its mechanisms of toxicity. Surface characteristics of silica, notably the occurrence of specific silanol groups, the "nearly-free silanols" (NFS), have emerged as pivotal factors in triggering the molecular initiating event of silica toxic pathways[1]. NFS are formed during fracturing of crystalline silica and exhibit a unique arrangement that facilitates the interaction with zwitterionic phospholipids in cell membranes, resulting in their disruption. The amount of NFS can be modified through physico-chemical processes that lead to different surface reconstruction pathways, that in turn modulate the degree of toxicity observed with different silica specimens[2].

To clarify the impact of the silica surface reconstruction on cell membrane damage, quartz was milled in different molecular environments that combined the absence and presence of molecular water vapor and oxygen. Water- and oxygen-free environment ($-H_2O/-O_2$) mainly generated silyl surface radicals (E' centers). Oxygen-rich environment ($-H_2O/+O_2$) favored the peroxyl and surface-bound superoxide radicals, with respect to E' centers. Water-rich environments ($+H_2O/\pm O_2$), on the contrary, reduced the number of electronic defects, and converted them in diamagnetic species, likely surface silanols. Only quartz milled in water-free environments ($-H_2O/\pm O_2$) exhibited highly reactive surface that immediately interacted with water vapor and acquired a membranolytic activity. On the contrary, quartz milled in water-rich environments ($+H_2O/\pm O_2$) showed a negligible membranolytic activity. Mechanistically, E' centers, that largely dominate the surface of quartz milled in water-free environment, seems to be responsible for the generation of the membranolytic silanol species, after reaction with water vapor[3].

The identification of specific silanol configurations that can interact with phospholipid and induce membrane damage may pave the way for a comprehensive toxicity model extended to particles of several metal oxides and minerals with hydroxylated surfaces.

CeO_2 nanoparticles (NPs) are interesting materials for possible applications in biomedicine as wound and bone healing, cancer therapy, and other diseases involving oxidative stress.[1] An intriguing aspect of these NPs is the presence of both Ce^{3+} and Ce^{4+} ions[2] which confers the peculiar ability to both scavenge and produce OH· radicals through redox processes. CeO_2 NPs have been synthetized using several methods,[3] but the preparation of stable colloidal suspensions in water or biological buffers, needed to be used as therapeutic agents, is not trivial. In this contribution, we investigate the synthesis of water-dispersed CeO_2 NPs employing different preparation conditions, from room temperature to higher ones, by microwave-assisted technique, and with different reaction times. The effect of precursors and capping agents (e.g. the citrate group) concentrations on both the colloidal and the redox properties of the CeO_2 NPs have been evaluated. A possible doping with Tb^{3+} ions has been also investigated to exploit the Ce^{3+} to Tb^{3+} energy transfer, serving as a quick tool to probe the presence of Ce^{3+} under different conditions.[4]

The synthesized materials have been characterized by means of X-Ray powder diffraction, Raman spectroscopy and Dynamic Light Scattering. Investigations on the catalytic properties of CeO_2 NPs have been carried out by indirectly following Reactive Oxygen Species (ROS) generation through UV-Vis and fluorescence spectroscopy, exploiting the Fenton reaction to degrade a sample dye or directly tune the Ce^{3+}/Ce^{4+} ratio.

Achieving seamless installation of photovoltaic (PV) devices into buildings requires versatile technologies that can maximise the energy output while preserving the functionality and aesthetics of the existing architectural element. Luminescent solar concentrators (LSCs) are now emerging as powerful tools to turn glazing systems into energy-producing building components. An LSC is conventionally comprised of a glassy or polymeric slate embedded or coated with luminescent species, which light emission can be stimulated by sunlight and collected at the edges of the panel by thin PV cells, to be then converted into electrical power.

Our study reports *i)* the synthesis of strongly emitting $[Eu_2L_4]^{2-}$ cages, where the ligands L are bis-β-diketones capable of sensitizing the Eu^{3+} ion through the benzolytrifluoroacetone (btfa) moiety, *ii)* the preparation of planar LSCs in form of tiles or films having 5 x 5 cm^2 active area by embedding the cages into PMMA, and *iii)* the study of the LSC-PV devices obtained by edge-coupling the LSCs with monocrystalline Si PV cells. The photophysical properties of the luminophores have been fully characterized before and after embedding into the host medium. Measured average visible transmission (AVT), colour rendering index (CRI) and CIELAB coordinates are all well within the industrial standards for glass destined to neutral colour applications, denoting excellent transparency ad aesthetic quality. LSC-PVs have been characterized under simulated AM1.5G illumination. Thanks to increased light absorption, LSCs containing higher luminophore loadings yield better power conversion efficiency (PCE), while maintaining unaltered transparency and colour neutrality. Finally, we compared the fabricated LSC-PVs to other Eu^{3+}-based concentrators present in literature, finding similar performances in terms of PCE, while using a 10 to 100 times lower content of europium in our devices.

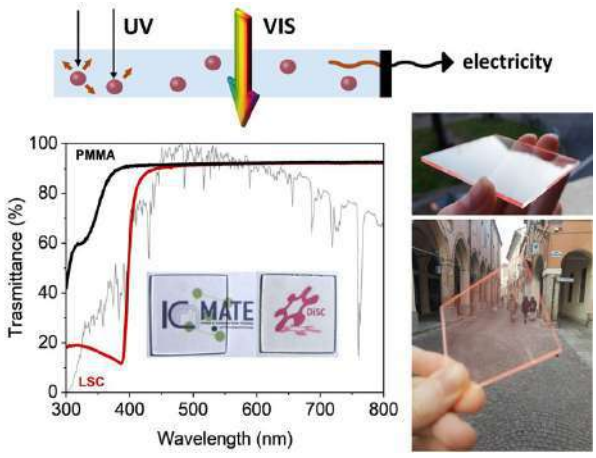

Figure 1: Working principle of a planar LSC embedded with UV-absorbing luminophores (top), transmittance spectrum of one of the proposed Eu^{3+}-based LSCs and of plain PMMA superimposed to AM1.5G spectrum (bottom left), digital photographs of the concentrators under natural daylight (bottom right).

sara.pagliaricci@unicam.it

Curcumin and bisdemethoxycurcumin, bioactive ingredients extracted from the rhizome of the plant *Curcuma longa*, have shown interesting medicinal properties such as anti-cancer activity. However, their clinical application is restricted by low bioavailability due to the low absorption and low water solubility, rapid metabolism, and clearance. In this respect, highly promising approaches dealing with the bioavailability issue involve the coordination of a metal center and structural modifications. Recently, some Ru(II) and Os(II) complexes incorporating palmitic bioconjugates of curcuminoids showed enhanced cytotoxic effects on both cis-platin sensitive and resistant ovarian carcinoma cell lines (AC2780 and AC2780cisR).[1] Herein is reported the synthesis and characterization of new ester-conjugates of curcumin and bisdemethoxycurcumin to investigate if their Ru(II) related compounds could lead to improved efficacy. Ru(II) half-sandwich complexes, synthesized using appropriately modified bidentate curcuminoid ligands (Figure 1), have been studied as antitumor agents.

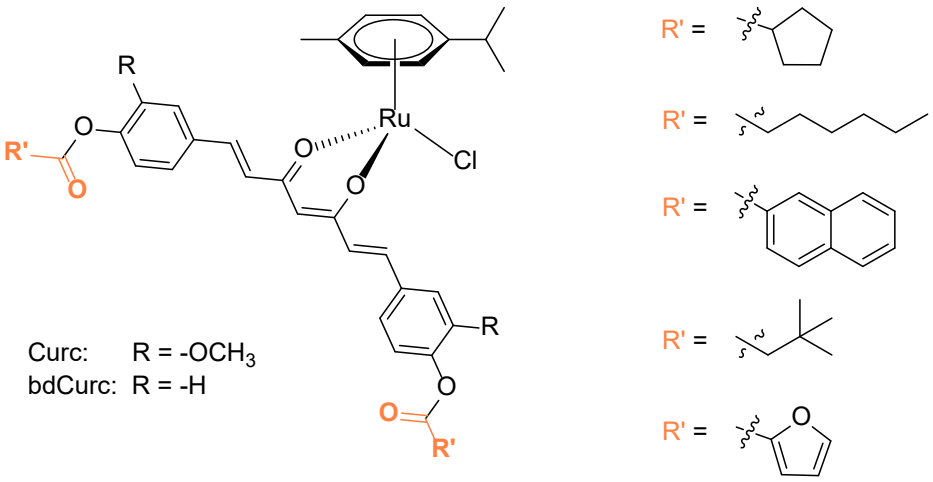

Figure 1: Organometallic Ru(II)-p-cymene complexes with curcuminoid conjugates

Improving the pyrolysis yields of biochar from agrifood wastes for hydrogen storage: the action of fungi

Waste recycling has become a priority in recent years' policies, representing a cornerstone of the Circular Economy model aimed at making the economic system sustainable. Circular principles find ample application in the agri-food supply chain, encompassing agricultural production, processing, and consumption. Recent estimates indicate that waste production from the agri-food sector in Europe amounts to approximately 87 million tonnes, equivalent to 171 kg per capita, with around 20% attributable to the agricultural sector. All these waste materials contain cellulose, hemicellulose, and lignin-carbon bioresources, all substances considered promising for energy storage[1]: in particular, they are seen as suitable candidates if obtained in the appropriate chemical and morphological form through pyrolysis steps. Pyrolysis is a thermal decomposition process that converts organic materials into carbon-rich solids (biochar), condensable liquids (bio-oil), and non-condensable volatile substances (gas) by applying heat in an oxygen-free environment[2].

In our research group, cereals and vegetables waste from Lombardy region (Italy) are considered as good source of C for hydrogen storage. The time and temperature of pyrolysis are undergoing optimization to enhance the chemical and morphological characteristics of the obtained materials. Since the yield for biochar production is still low (maximum 25%), the implementation of a pre-treatment process for biomass/vegetable waste, aimed at making cellulose and hemicellulose components easily accessible, could lead to a higher final yield. One green option is the use of white rot fungi, capable of degrading lignin, cellulose and hemicellulose in lignocellulosic materials. In particular, lignin is a component that proves to be challenging to degrade during pyrolysis. Fungi can assist in breaking down lignin into water (H_2O) and carbon dioxide (CO_2)[2,3] due to their extracellular oxidase. In this study, the capability of six lignicolous fungal strains to colonize different vegetal wastes was tested. The effectiveness of fungal pre-treatment on waste to increase the efficiency of the pyrolysis process was evaluated. Preliminary results pointed out an increase in the solid C production yield during pyrolysis (from 27% up to 40%) for rice bran, the most promising waste from cereals matrices in terms of hydrogen storage gravimetric capacity and kinetics.

Electrochemiluminescence (ECL) – the production of molecular excited states without light excitation but through the recombination of charges – is a well-known process. This method presents diverse advantages due to the absence of excitation light, thus resulting in a sensitive enhancement of the signal-to-noise ratio.[1] Thus, ECL can be exploited for the design of diagnostic tools and it is used extensively in immunoassays. As ECL emitters the most well known compounds are ruthenium and iridium compounds. However more recently also organic molecules have been reported. The emission of heavy metals compounds is strongly influenced by the quenching due to the presence of dioxygen in solution and many attempts have been made to protect the complexes by such detrimental process, such as denritic compounds and encapsulation in silica particles.

The use of the confinement of the emitters in scaffold and nanoparticles can also improve their solubility and stability in aqueous environments, such as biological ones.[2]

Here we report a set of organic and organometallic compounds which have been chemically and spectroscopically characterized. Their ECL and emission properties have been performed in solution and compared with their behavior once they are encapsulated in silica nanostructures that possessing different porosity can affect the photophysical properties and ELC signal.

The chemistry of homo-[1] and hetero-metallic[2,3] rhodium carbonyl clusters has been widely investigated in the last decades. In order to further widen the chemistry of heterometallic rhodium compounds, we investigated the reactivity of the $[Rh_7(CO)_{16}]^{3-}$ cluster precursor with $InCl_3$, obtaining the new Rh-In carbonyl species $[Rh_6(CO)_{15}InCl_3]^{2-}$ and its dimeric version $[\{Rh_6(CO)_{15}InCl_2\}_2]^{2-}$. Furthermore, we synthesised the In-centred icosahedral $[Rh_{12}In(CO)_{28}]^{3-}$ cluster, which parallels the species belonging to the $[Rh_{12}E(CO)_{27}]^{n-}$ family (E = Sn, Ge, Sb, Bi), with which it shares the electron counting (170 cluster valence electrons) and the metal structure.[4]

These new Rh carbonyl clusters have been characterised by IR spectroscopy and ESI-MS spectrometry and their molecular structures fully established by single-crystal X-ray diffraction studies.

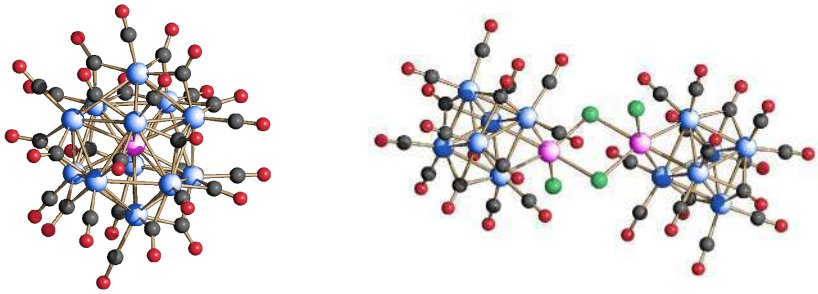

Figure 1: Molecular structures of $[Rh_{12}In(CO)_{28}]^{3-}$ and $[\{Rh_6(CO)_{15}InCl_2\}_2]^{2-}$. Rh is depicted in blue, In in magenta, Cl in green, C in grey, and O in red.

It is known that laccases, both bacterial and fungal, catalyze the activation of Csp2-H bonds through monoelectronic oxidation[1], the mechanism of which is not fully known in detail. This process is generally assisted by a mediator, which is a small molecule with a higher redox potential than laccase and a strong affinity with it. Recent experimental results highlight that some laccases would also be able to oxidize Csp3-H bonds and moreover in the absence of a mediator. What could be the molecular-level mechanism of this process? A possible approach is to study the oxidation process at the classical and quantum molecular modeling level using a model aliphatic and aromatic hydrocarbon substrate linked to the laccase binding pockets.

heiko.lange@unimib.it

Carbon nanofibres (CNFs) are seen as one of the most promising materials when it comes to high performance applications. Yet, CNFs are *de facto* only produced fossil-based resources, mainly in the form of polyacrylnitrile precursors.[1] Renewable resources such as the natural polyphenolic lignin are yet struggling to convincingly perform in this field, despite interesting findings in the recent years.[2]

Being interested to shed light into this intriguing problem, we set out to use our very detailed structural knowledge regarding natural polyphenols to mechanistically study the importance of structural features for winning intermolecular interactions such as to rationalise fibre formation.

To this end, two technical lignins, namely softwood kraft lignin (S-KL) and wheat straw organosolv lignin (WS-OSL) were fractionated by a single-step solvent extraction. The starting lignins and the resulting fractions were thoroughly characterized by means of quantitative ^{31}P nuclear magnetic resonance and quantitative ^{1}H-^{13}C heteronuclear spin quantum coherence spectroscopy, gel permeation chromatography, as well as thermal analysis. Pure low molecular weight fractions of the two technical lignins were converted into fibrous matrices using optimized spinning solutions and electrospinning process parameters. Uniform and bead-free fibres in both random and aligned mode were confirmed by scanning electron microscope analyses. Fibres could be processed to obtain well-defined thermostablised and carbonized fibres on the basis of the pure low MW fractions.

The accumulated insights could be converted into a set of rationales, on the basis of which it became generally possible to determine natural polyphenols most suitable for CF formation. These rationales were ultimately tested generating for the first time electrospun nanofibers from tannic acid (TA) and mono- and dimeric proanthocyanidin, which could equally well be thermostabilised and carbonised to CNFs.[3]

The emergence of hydrogen economy with the current scenario of the need to switch to cleaner and greener forms of energy sources is seen to be inevitable. However, the production cost of green hydrogen is seen to be higher than blue or grey hydrogen in the energy market, especially in Europe[1]. One of the important factors that need to be considered for accessing proper large-scale production of hydrogen apart from the reactor geometry and configuration set-up includes mainly the catalyst. Herein, a catalyst synthesized with the idea of building blocks was tested for the H_2 evolution reaction. The synergistic effect of heterojunction formation between CeO_2 and g-C_3N_4 was taken into account with modification in the ceria lattice by introducing some rare-earth (RE) metals (Nd, Pr, Gd, Y). The catalyst was synthesized by a co-precipitation method with calcination at 400˚C. Further, heterojunction formation was confirmed with characterization techniques such as HR-TEM, Raman, XRD where cubic-fluorite nanoparticles of ceria were formed ~ 5nm with a composite formation with g-C_3N_4. Photocurrent measurements showed impressive e^-/h^+ separation in case of CeO_2/g-C_3N_4. Further, Raman analysis with F_{2g} peak broadening in the case of the RE doped ceria was seen along with UV-DRS showing extended absorption of $Pr_{0.2}Ce_{0.8}O_{2-\delta}$/g-$C_3N_4$ and $Nd_{0.2}Ce_{0.8}O_{2-\delta}$/g-$C_3N_4$ as compared to the undoped composite proving the inclusion of the RE ions.

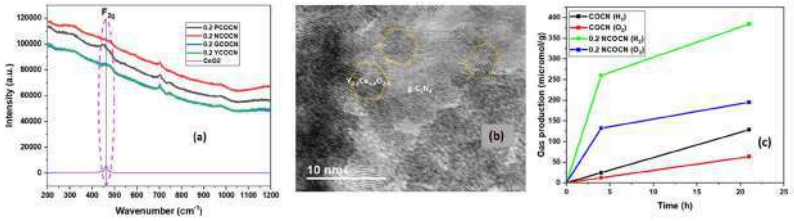

Figure 1: (a) F_{2g} broadening in Raman analysis. (b)HR-TEM image. (c) Overall water splitting.

Testing these materials for H_2 production clearly showed 10 times higher production of hydrogen in case of $Nd_{0.2}Ce_{0.8}O_{2-\delta}$/g-$C_3N_4$ as compared to CeO_2/g-C_3N_4 through overall water splitting with both the catalysts producing stoichiometric amounts of H_2 and O_2. Also, using TEOA as a sacrificial agent, higher production of H_2 for $Nd_{0.2}Ce_{0.8}O_{2-\delta}$/g-$C_3N_4$ (406 $\mu molg^{-1}h^{-1}$) as compared CeO_2/g-C_3N_4 (329 $\mu molg^{-1}h^{-1}$) was observed.

mail of submitter

The paradigms of circular economy include for sure the production of sustainable energy but also the valorization of materials that are currently solely seen as waste. Nowadays, sewage sludge (SS) is one of the most abundant waste produced by municipalities and industries, but it can also be a source of valuable chemicals, including some interesting energy vectors[1].

The significant concentration of ammonia in SS[2] is appealing for this purpose: its oxidation does not produce any carbon containing species and it has much lower energy demand compared to water oxidation[3], thus it represents an innovative and circular way to produce hydrogen.

In this work, we investigated a composite system based on metal nanostructures grown on nickel foam (NF) and others supports for the (photo)electrochemical ammonia oxidation reaction (AOR). Both platinum and more earth-abundant metals such as Ni and Cu were deposited by different synthetic approaches in solution (*e.g.*, static and pulsed electrodeposition and hydrothermal method) to have high dispersed nanostructures. They were characterized from morphological, crystallographic and (photo)electrochemical point of view.

Moreover, (photo)electrolytic experiments were performed to investigate and compare the stability and selectivity for AOR. Our results showed that Pt has some evident tendency to poisoning while materials based on less noble metals could show longer stability.

The Oxygen Paradox, a lifelong challenging dance

V. Conte

Department of Chemical Science and Technologies, University of Rome Tor Vergata
Via della Ricerca Scientifica, 000133 Roma
valeria.conte@uniroma2.it

The use of sustainable oxidants, i.e. O_2 or H_2O_2 easily available and safe reagents, has been the guideline in more than four decades of research.[1] In most cases the best results were achieved using vanadium catalysis but recently our interest has also turned to photo(electro)catalysis.

Efficient metal- (V and Mo) catalyzed oxybromination of alkenes inspired by the activity of haloperoxidases enzymes is one of the finest achievements of the group. A two-phase system, where a brominating intermediate is formed in water from the metal catalyst, H_2O_2 and Br^-, has been developed. The peroxometal complex then oxidizes the substrate dissolved in the organic phase. Observed yields and selectivities, together with replacement of Br_2 with Br-, provide a procedure of sustainable synthetic interest. Indeed, excellent results were obtained with aromatics, alkenes and alkynes. To render our system even more interesting from the sustainability point of view, we modified it substituting molecular chlorinated solvents with ILs. Again, excellent results in terms of reaction rates and selectivities have been obtained with alkenes and alkynes. Our procedure was equally efficient in the bromination of toluene and similar substrates; the reaction proceeds under mild conditions, and solventless functionalization can be also carried out.

Over the years, we elucidated mechanistic details of vanadium based catalytic systems performing, inter alia, NMR, electrochemical and spectroscopic experimental studies as well as theoretical calculations. These studies allowed to establish correlation between the nature of the ligands bound to vanadium centre and catalytic activity in benchmark oxidations.

More recently we synthesized a fully conjugated pentacyclic quinoid class of compounds named KuQuinones (KuQs), molecules close to naturally occurring polycyclic quinones. KuQs show interesting features both as photosensitive material on semiconductive oxides, as well as in biomedical applications, as they showed a significant antiproliferative activity against tumor cell lines.

The use of organic photocatalysts is an appealing and sustainable strategy to promote chemical processes, to this aim use of 1-hexylKuQuinone (KuQ) as metal-free photocatalyst for selective thioethers oxidation to sulfoxides was pursued.[2] The broad and intense absorption spectrum in the visible range and the low reduction potential constitute suitable features for photocatalytic and photoelectrocatalytic applications of KuQs.

Handcrafting Function-Rich Molecules: an Amazing Opportunity to Serve Life Sciences

F. Zanardi,[a]

[a]*University of Parma, Parco Area delle Scienze 27A, 43124 Parma*

franca.zanardi@unipr.it

Over the past century, synthetic organic chemistry has made crucial contributions to the discovery and development of important life-saving drugs, improving the health and wellbeing of people worldwide. Most of these achievements have been possible by drawing heavily from the ever-growing arsenal of ingenious methods and technologies involving diverse sectors of fundamental chemistry, chemical bond construction, and three-dimensional control. Intertwining biomedicine-addressed synthesis ventures with methodology-centred synthetic approaches has been the leitmotiv of our research over the past years, with abounding opportunities to serve life sciences arising from the confluence of basic and applied research.

The lecture will present research results from our laboratories along this double path (see Figure). On one hand, we shall focus on handcrafting novel bioactive peptidomimetics, their incorporation into covalent (or nanosized) conjugates, and their use as proof-of-concept tools in the field of targeted antiviral, antiangiogenic, antitumor, and antifibrotic therapy.[1] On the other hand, the merger between the vinylogy concept with organo- (and photo)catalysis will be illustrated, as applied to the asymmetric synthesis of diverse collections of richly functionalized hetero(carbo)cyclic small molecules.[2]

New Catalytic Approaches Towards the Synthesis of Organic Compounds

G. Filippini[a]

[a]*Università degli Studi di Trieste, Via L. Giorgieri 1 - 34127, Trieste*
gfilippini@units.it

Catalysis has a fundamental role to solve arduous tasks in synthetic chemistry and is thus involved in the global economy in many industrial fields. In fact, in the last 50 years, catalysis has seen enormous progress in the development of optimized large-scale productions within the area of pharmaceutical, agrochemical and petrochemical industry. Moreover, a catalytic approach presents multiple benefits for business and sustainability compared to stoichiometric processes. These include cost reduction, time and energy saving, waste reduction, carbon-footprint minimization, among others. In this context, our research activity aims at designing and developing novel catalytic organic transformations which address unsolved problems in synthetic chemistry. The final goal is therefore the production of effective, inexpensive and safe catalytic systems that will find widespread use in modern organic synthesis. To this end, we effectively employed aromatic molecules as photocatalytic systems to drive the synthesis of relevant organic compounds. As a matter of fact, the great structural variety of these molecules combined with the easy fine-tuning of their electronic properties has unlocked new possibilities for the generation of reactive intermediates under mild operative conditions.[1-4] In addition, we worked on the development of novel nano-catalytic organic transformations. In particular, we design new carbon-based nano-organocatalytic systems, namely carbon nitrides and carbon dots.[5-10] These materials have been efficiently used to drive relevant organic reactions, including enantioselective transformations, under mild operative conditions.

via Piero Gobetti 101, 40129, Bologna Italy
manuela.melucci@cnr.it

In this presentation, I will discuss selected case studies showcasing chemically modified graphene materials and their applications in water purification, electrochemical sensors, and carbocatalysis. I will detail our recent findings on design strategies and covalent functionalization techniques aimed at creating new materials for: i) enhanced adsorption of emerging contaminants such as PFAS and antibiotics from drinking water [1], ii) electrochemical transduction for early detection of pesticides in water [2], and iii) CO_2 capture and utilization in chemical transformations [3]. Additionally, I will describe the development of polymer-graphene membranes [4] and composites produced also through the upcycling of industrial plastic waste [5], and their application in new water filtration systems. These advancements, along with ongoing technology transfer and validation processes from laboratory scale to industrial production and commercialization, will also be covered [6].

One-Pot Asymmetric Organocatalysis: Multipurpose Tool to Access Carboxylic Acid Derivatives

A. Lattanzi[a]

[a]*Dipartimento di Chimica e Biologia "A. Zambelli", Università degli Studi di Salerno, Via Giovanni Paolo II, 84084 Fisciano, Italy*
lattanzi@unisa.it

The development of new methodologies for the catalytic asymmetric synthesis of carboxylic acid derivatives is a central topic in organic chemistry, given their recurrent presence as key motives in bioactive compounds.[1] In this lecture, our results on the application of one-pot strategies to prepare privileged classes of heterocyclic compounds and acyclic products will be illustrated. The sequential organocatalysed reactions, involve ester surrogates as the reagents or electron-poor epoxides as the intermediates, providing the products in an efficient way (Figure 1).[2]

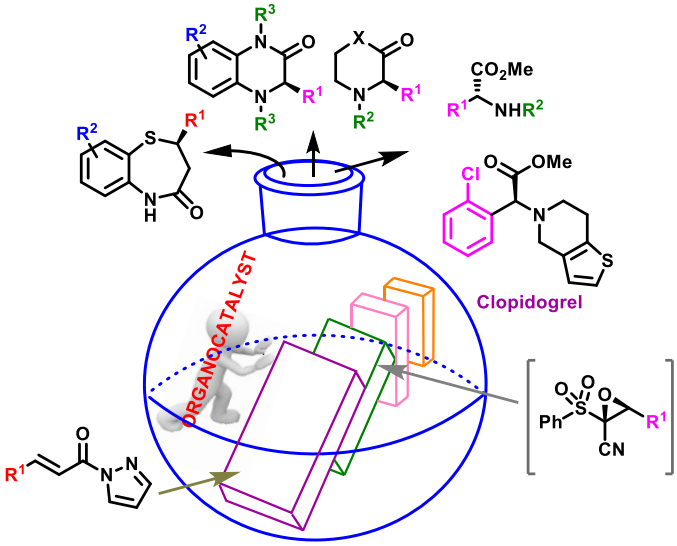

Figure 1: One-pot asymmetric routes to carboxylic acid derivatives.

As a demonstration of the synthetic utility of the protocols, antidepressant drug Thiazesim, a key intermediate to potent antiemetic drug Aprepitant and antiplatelet drug Clopidogrel, have been prepared.

Unveiling the potential of synthetic nucleic acid analogs as versatile tools for enhancing human health

G. Oliviero

Dipartimento di Medicina Molecolare e Biotecnologie Mediche, Universtità degli Studi di Napoli Federico II, Via Sergio Pansini 5, 80131 Napoli

golivier@unina.it

In recent years, besides being the building blocks of life, nucleic acids revealed their enormous potential in diagnostics[1,2] and therapy.[3,4] Not only do they often represent the target for personalized medicine intervention, but they also hold immense potential as targeted drugs.[5] This power lies within their unique properties resulting from nucleobase sequence and structural polymorphism. Researchers have unlocked new possibilities by synthesizing short nucleic acid fragments, called oligonucleotides, incorporating chemical modifications on the sugar, the nucleobase, or both to confer them with specific properties useful for applications in medicine, diagnostics, and even for the creation of new biomaterials.[6,7] In this contribution, I will review the foundation and our recent findings on the design, synthesis, and structural characterization of modified nucleosides, nucleotides, and oligonucleotides. This knowledge paves the way for developing powerful and innovative new tools for fighting diseases, diagnosing health conditions, and potentially even building new materials for biological applications.

Expect the Unexpected: How Understanding Reaction Mechanisms Can Lead to More Efficient Production Processes in the Fine Chemical Industry.

Carla Marchioro

Verona, Italy
carla.marchioro.cm@gmail.com

My presentation will discuss how detailed investigations on reaction mechanisms, kinetic and thermodynamic could positively impact on new larger scale production processes.

Examples will be from my multiyear experience in the small molecules field in the pharmaceutical as well as in the fine chemical industry.

In particular, the presented case studies will span from pure speculative investigations to evolve in the full understanding of the reaction kinetics and thermodynamics and finally transferred into production plant. Environmental and circular economy considerations will also be part of the discussion.

In addition, the multidisciplinary approach to problem solving and the cross-sectors interactions will be also included in the presented work.

Artificial Water Channels in Quantasome Photosynthetic Systems

F. Rigodanza,[a] I. Crea,[a] T. Gobbato,[a] M. Prato,[b] M. Bonchio[a]

a University of Padova, Department of Chemical Sciences, via F. Marzolo 1, 35131, Padova, Italy
b CIC biomaGUNE, San Sebastian, Spain

francesco.rigodanza@.unipd.it

In the design of bioinspired artificial photosystems, the implementation of water channels, to reproduce the protein environment around the PSII, plays an essential role for efficient catalysis.[1] This study presents a synthetic strategy for the introduction of this feature in the artificial quantasomes (**QS**), a water-splitting photosystem made of bis-cationic perylenebisimides (**PBI**) and deca-anionic tetraruthenate polyoxometalates (**Ru_4POM**).[2,3,4] A click-chemistry approach was employed to install hydrophilic bis-azido polyethylene glycol bridges (**PEG_n**) between the PBI units, obtaining **QS_{PEG}-n** with cross-linked units and hydrophilic water channels. **QS_{PEG}-n** are characterized by a more porous structure featuring distinct water channels, as evidenced by SAXS analysis and LF-NMR experiments. Among the series, **QS_{PEG}-6**, emerges as the best performing photosystem, bearing PEG chains that provide an optimal combination of porosity, water interaction, and photocatalytic properties, with a 4-fold increase in photocurrent output compared to the unmodified quantasome (**QS-0**). These results highlight the essential role of water channels in the construction of PSII biomimetic systems and propose the **QS_{PEG}-6** as a promising candidate in bioinspired photocatalysis.

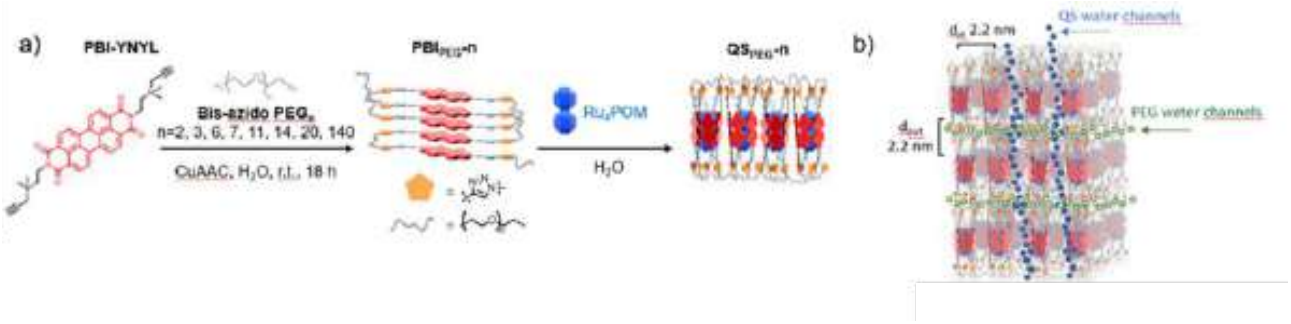

Figure 1. a) Synthesis of **PBI_{PEG}-n** and self-assembly of **QS_{PEG-n}** in water. b) Water channels in the quantasome structure.

Rapid and scalable photocatalytic C(sp^2)–C(sp^3) Suzuki−Miyaura cross-coupling of aryl bromides with alkyl boranes

L. Capaldo,[a,b] T. Wan,[a] J. Djossou,[a] A. Staffa,[c] F. de Zwart,[a] B. de Bruin,[a] T. Noël[a]

luca.capaldo@unipr.it

Transition metal-catalyzed cross-coupling reactions have demonstrated remarkable fidelity, but their success has introduced a bias for "flat" molecules design.[1]

In recent years, there has been notable progress in the application of light-mediated methods to introduce sp^3-hybridized carbons into biologically relevant scaffolds, enhancing compatibility with 3D-shaped protein targets. In essence, photoredox catalysis is working as a guiding light to escape from flatland.

Herein, we present a powerful approach for the photocatalyzed B-alkyl Suzuki−Miyaura cross-coupling between alkyl boranes and aryl bromides (Figure 1).[2] Alkyl boranes are prepared from feedstock alkenes via regioselective hydroboration, allowing for the transfer of a wide array of primary alkyl fragments onto the arene ring thanks to a photocatalyst/nickel dual catalytic system.

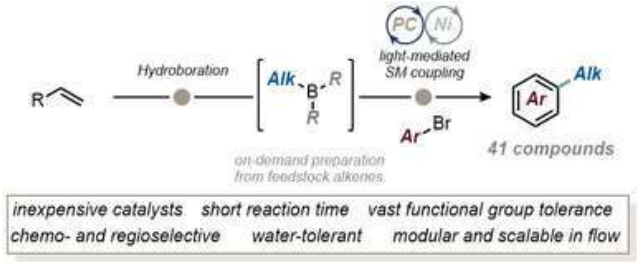

Figure 1: Rapid and scalable photocatalytic C(sp^2)–C(sp^3) Suzuki−Miyaura cross-coupling of aryl bromides with alkyl boranes.

Our approach marks the inaugural instance wherein alkyl boranes are used as substrates in photoredox catalysis. It eliminates the need for expensive catalytic systems and sensitive organometallic compounds, operating efficiently at room temperature within just 30 minutes. Moreover, we demonstrate the advantageous translation of the present protocol to continuous-flow conditions, enhancing scalability, safety, and overall efficiency of the method. This versatile approach offers significant potential for accelerating drug discovery efforts by enabling the introduction of complex aliphatic fragments in a straightforward and reliable manner.

Exploring the Boundless Utility of Chelation Agents: From Therapeutics to Catalysis

G. Floresta

Department of Drug and Health Sciences, University of Catania, Viale Andrea Doria 6, 95125 Catania, Italy
giuseppe.floresta@unict.it

Hydroxypyranones and hydroxypyridinones are important oxygen- or nitrogen-containing heterocyclic nuclei for creating metal chelation agents.[1] Their rapid and efficient binding of hard metals in aqueous media has enabled a plethora of applications in biological, pharmacological, and chemical contexts. Some of these derivatives have recently drawn much attention, such as the hexadentate tris(3-hydroxypyridin-4-one) (THP) based ligand. Because of its strong affinities for oxophilic trivalent metal ions, THP complexes the Fe^{3+} cations at very low concentrations, opening up new uses as bifunctional chelators for the radiometal gallium-68 (^{68}Ga). At room temperature, neutral pH, and micromolar ligand concentrations, THP-bioconjugates bind ^{68}Ga quickly and quantitatively, making them suitable for kit-based radiosynthesis of ^{68}Ga positron emission tomography (PET) radiopharmaceuticals.[2–4] Following their functionalization with other molecules or materials, like cyclodextrins and halloysite, they have also been explored recently for use in catalysis and antibacterial medication development.[5] Different of the newly reported applications will be examined in this communication.

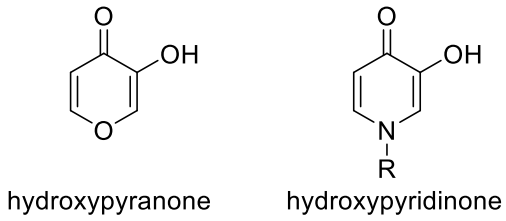

Figure 1: Chemical structures of hydroxypyranone and hydroxypyridinone.

Azides Manipulation: Danger is not our Middle Name

M. Zuffo,[a] G. Razzetti,[a] L. Simons,[b] C. Stewart,[b] B. Loertscher[b]

[a]Dipharma s.r.l., Via Bissone 5, Baranzate, Italy
[a]Dipharma Inc, 4502 Campus Dr, Kalamazoo, US
michela.zuffo@dipharma.com

Azides play a pivotal role in organic synthesis, as they allow to introduce a variety of key functional groups in synthetic scaffolds of interest. These include amines, triazoles, tetrazoles, isocyanates, etc.[1,2] Regardless of azides role in the synthesis -whether only azide-based reagents are used or the azide moiety is also present in the resulting product- this type of chemistry generally involves significant safety risks.[3] Main concerns are linked to azides general toxicity and explosivity. In addition to this, each azide bears the potential to form hydrazoic acid (HN_3) upon decomposition, which is even more dangerous than its precursors.[4]

Despite these caveats, azides are often manipulated, especially at small and medium scale, with insufficient precautions and knowledge about the involved risks.[5,6] At Dipharma, we have extensive experience in the safety evaluation for scale-up of chemical processes involving azides, with multi-ton productions per year of various intermediates and APIs exploiting this type of chemistry. In this presentation, we will provide a general overview about the dos and don'ts in azides manipulation based on this expertise. These will cover the main incompatibilities, some rule-of-thumbs to evaluate the dangers that may be encountered and some strategies to tame the highlighted dangers. These will be supported by tailored examples from our product portfolio, giving a taste of the chemical space that can be accessed at scale when making good use of azides chemistry.

beatrice.bartolomei@phd.units.it

Carbon Nanodots (CNDs) are defined as carbon nanoparticles with size below 10 nm which possess intriguing properties like tunable light-emission and rich-surface chemistry. In recent years, our group has focused on the bottom-up synthesis of CNDs, particularly, starting from *ad hoc* molecular precursors we demonstrated the possibility to tailor the photoluminescent, chiral, and redox properties of these materials, unlocking their use in different fields.[1] In particular, one of the latest research efforts was devoted to the optimization of chiral and catalytically active CNDs able to promote several kinds of organic reactions, promoting the role of these materials as a new generation of catalysts.[2] We have also contributed to the development of reliable synthetic and purification strategies for the preparation of these nanoparticles, exploiting combined characterization techniques to study their purity and composition.[3] Having in hand a reproducible and versatile synthetic method for CNDs allowed to recently use these materials as starting units to develop new kinds of superstructures.[4] Specifically, a covalent interconnection of CNDs was proposed by the use of click chemistry. To this aim, the superficial groups of the particles were exploited as anchoring points to install 'clickable' moieties. Then, a click reaction between the prepared building blocks was tested affording the formation of covalent superstructures. As a step further, the use of rigid aromatic linkers for the CND connection has been explored, moving towards the production of novel porous 3D networks.

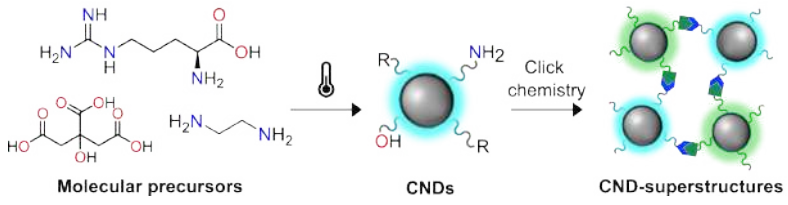

Figure 1: Synthesis of CNDs and following assembly.

Ring-opening reactions of unstrained cyclic aminals with Grignard reagents

L. M. Comparini[a], G. Gallorini[a], F. Sardelli[a], L. Favero[a], M. Pineschi*[a]

[a]*Department of Pharmacy, University of Pisa, Via Bonanno Pisano 6/33, Pisa*
e-mail: lucrezia.comparini@phd.unipi.it

Cyclic aminals such as imidazolidines and hexahydropyrimidines are common scaffolds in natural products, medicinal chemistry, and agrochemicals[1a-c]. A special case of cyclic aminals of particular importance is given by 1,3,5-triaryl-1,3,5-triazinanes which behave as a stable formaldehyde-derived imine offering a large variety of reactions for the preparation of nitrogen containing compounds.[2] Considering the limited literature regarding the use of organometallic reagents in combination with cyclic aminals[3a,b] and the long-lasting interest of our laboratory in ring-opening reactions of heterocyclic compounds with organometallic reagents,[4a,b] we developed a nucleophilic ring opening of unstrained cyclic aminals by the use of Grignard and cuprates reagents to give diversely substituted 1,2- or 1,3-diamines which are important building blocks in organic synthesis due to their presence in natural products, medicines, and ligands in transition-metal catalysis and organocatalysis.[5,6]

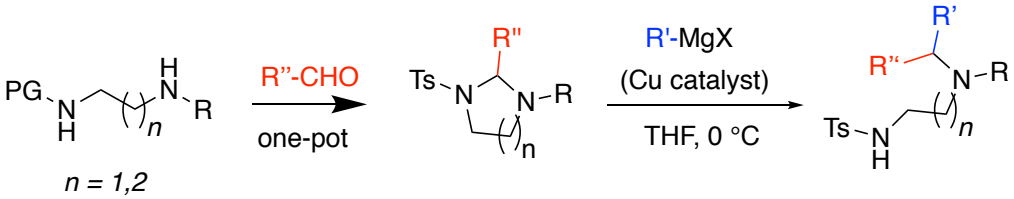

Figure 1. Ring-opening reaction of protected cyclic aminals with Grignard reagents.

Computational DFT data point to the formation of a transient iminium ion intermediate that is energetically accessible only with PG = Ts in which the Lewis acidity of the cationic component of the organometallic reagent triggers the ring-opening process by coordination.

Chalcogens: a Powerful Tool for Helicenes Construction, Organocatalysis and Materials

M. Lupi, S. Menichetti, C. Viglianisi

Department of Chemistry "Ugo Schiff" (DICUS) & INSTM Research Unit, University of Florence, Via della Lastruccia 3-13, Sesto Fiorentino 50019, Italy.
michela.lupi@unifi.it

Over the years, chalcogen chemistry proved a powerful tool in tackling challenges in many fields, ranging from medicinal chemistry to catalysis and materials. Herein we present a peculiar example of thia [4]helicenes in which sulfur has a crucial role in their exceptional configurational stability,[1] allowing an efficient optical resolution approach,[2] and in the modulation of their red-ox potential.[3,4] The exploitation of chalcogen-mediated organocatalytic routes led both to the isolation of thiahelicenes in enantioenriched form,[5] and to the enantioselective construction of other pharmaceutically relevant heterocycles.[6] Furthermore, we report the application of these thiahelicenes in the development of novel spintronic devices,[7,8] in which sulfur seems to play a key role in the spin-filtering process, highlighting the utility of chalcogen chemistry in material science.

Azolium-based organocatalysts immobilized on bamboo as recyclable and sustainable mediators for C-O bond formation reactions

G. Albonetti,[a] G. Di Carmine,[a] A. Massi[a]

[a]*Department of Chemical, Pharmaceutical and Agricultural, University of Ferrara, Via L. Borsari 46, 44121, Ferrara, Italy*
giorgia.albonetti@unife.it

The present work proposes novel heterogeneous catalysts based on triazolium and imidazolium derivatives for C-O bond formation reactions. Homogeneous organocatalysts were anchored onto pre-treated bamboo as natural porous materials by varying the linkers (Figure 1).

The growing demand of green approaches in chemical synthesis led the research to explore new possibilities in terms of inert matrixes for heterogenization of molecular catalysts. The use of natural porous materials enhances the sustainability of the process in this regard.[1]

In detail, the immobilization of 1-Methylimidazole and 1-methyl-1,2,4-triazole onto bamboo has been investigated by exploiting the reactivity of silanes and isocyanates for anchoring the organocatalysts with linkers of different length and polarity.

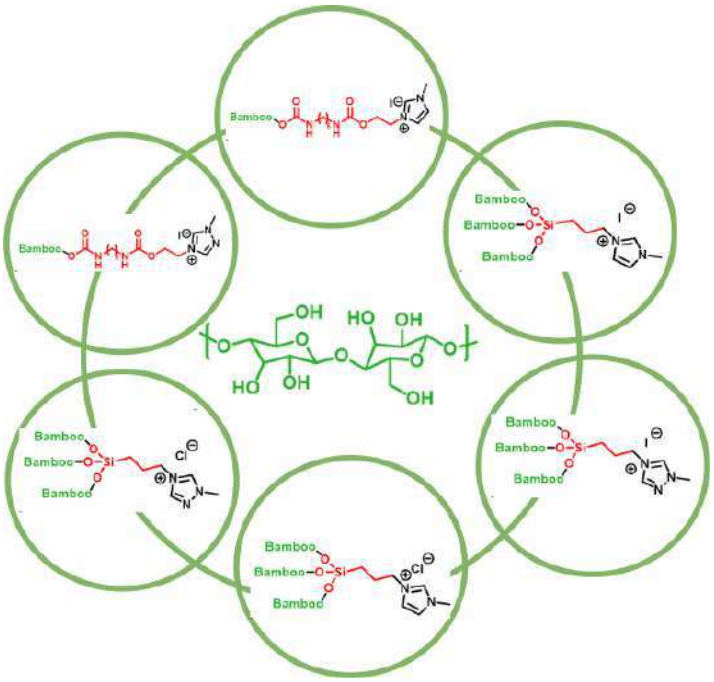

Figure 1: Heterogeneous organocatalysts immobilized onto bamboo with different linkers.

A preliminary study on cyclic carbonates synthesis from epoxides and CO_2 has been performed with the novel bamboo-based organocatalysts, while further studies in batch and flow conditions are currently underway.

simona.aprile@unife.it

Molecular hybridization has been recognized as an emerging strategy to pursue, for multi-target drugs therapy, especially when traditional combination treatments fails.[1] Ursodeoxycholic acid (UDCA) and acetoacetate are natural compounds present in the human intestine and blood, respectively. Nowadays, it is widely known that both compounds possess the ability to influence a variety of cellular processes involved in the etiology of various diseases, playing a relevant role either as bioactive moieties or drug delivery scaffolds.[2] Herein, we describe a synthetic strategy to selectively derivatize the hydroxyl groups of the bile acid with acetoacetyl moieties. These new compounds were obtained via a simple chemo-enzymatic approach, which exploits the selectivity of the lipase B from Candida antarctica. 3α-acetoacetoxy UDCA was obtained (60% isolated yield) via the regioselective transesterification of methyl acetoacetate with UDCA. 3α,7β- bis-acetoacetoxy UDCA was obtained instead by thermal condensation of methyl acetoacetate and UDCA (80% isolated yield). This bis-adduct was finally converted to the 7β-acetoacetoxy UDCA (82% isolated yield) via CAL-B catalyzed regioselective alcoholysis of the ester group on the 3α position. In order to demonstrate the value of the above new hybrids as UDCA-based scaffolds, 3α-acetoacetoxy UDCA was converted into the corresponding 4-phenyl-3,4-dihydropyrimidin-2-(1H)-one derivative in 65% isolated yield exploiting the multicomponent Biginelli reaction.

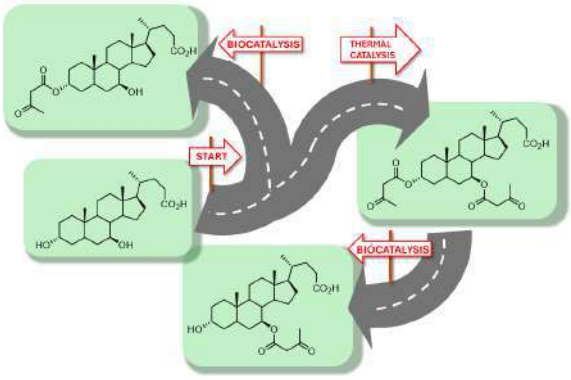

Figure 1: Schematic representation of the UDCA's esters

Divergent Total Synthesis of Tricyclic Clavine Alkaloids via Metal-Free Reductive Coupling

F. Bartoccini,[a] F. Diotallevi,[a] G. Piersanti[a]

[a]*Department of Biomolecular Sciences, University of Urbino Carlo Bo*
Via Ca' le Suore 2, Urbino, PU, Italy
e-mail: francesca.bartoccini@uniurb.it

The actual trend toward "increasing sustainability" calls for a modular, convergent, and versatile platform to form C−C bonds that do not require a metal catalyst. In 2009, Barluenga and Valdés reported the first metal-free C(sp^3)–C bond-forming coupling between tosylhydrazones (highly versatile and safe precursors for *in situ* carbene and diazo compounds formation in the presence of only a base) and aryl boronic acids.[1] Since then, this transformation has shown considerable usefulness in medicinal chemistry and diversity-oriented synthesis,[2] whereas its applications for the total synthesis of natural products, their analogues, and beyond, is undeveloped.[3] In this context, we present here the metal-free reductive coupling of aryl, alkenyl, and alkyl boronic acid with *N*-arylsulfonylhydrazone derivative of *N*-Boc protected 4-amino Uhle's ketone[4] for the asymmetric synthesis of natural, e.g. (-)-6,7-secoagroclavine,[5] and non-natural analogue of tricyclic clavines alkaloids (Figure 1).

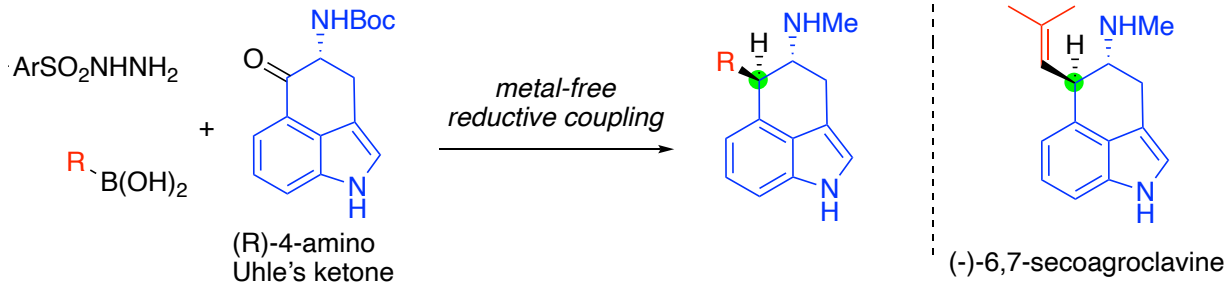

Figure 1: metal-free reductive coupling approach to the divergent syntheses of tricyclic clavine alkaloids.

This work was supported by the Italian Ministry for University and Research (MUR, PRIN 2020, 2020AEX4TA project).

Low Environmental Impact Synthesis of γ-Lactones through Photoinduced Baeyer-Villiger Oxidation of Cyclic Ketones

M. C. Cabua,[a] D. Moi,[a] F. Secci[a]

[a]*Dipartimento di Scienze Chimiche e Geologiche, Università degli Studi di Cagliari, 09042, Monserrato (CA)*
m.cabua@studenti.uniss.it

Five-membered cyclic esters, better known as γ-lactones, are recurring motifs contained in a wide range of biomolecules.[1] Despite the abundance of synthetic approaches concerning their preparation, the oxidation of cyclic ketones through the Baeyer-Villiger (BV) reaction still represents an efficient and widely applied process.[2]

In this project, a new chemo- and regioselective protocol for the atom-efficient photo-oxidation of functionalized cyclobutanones[3] has been developed, to access γ-lactones in good to excellent yields, using anthraquinone and molecular oxygen at atmospheric pressure, as a source of reactive oxygen species, under visible light conditions, in the presence of TFA. The scope of the reaction was studied using both 2- and 3-substituted cyclobutanones, as well as enantiopure ketones obtain full preservation of its stereochemical identity after the oxidation. The process furnishes in most cases the desired compounds with high purity after simple filtration of the catalyst, reducing the production of solvents waste.

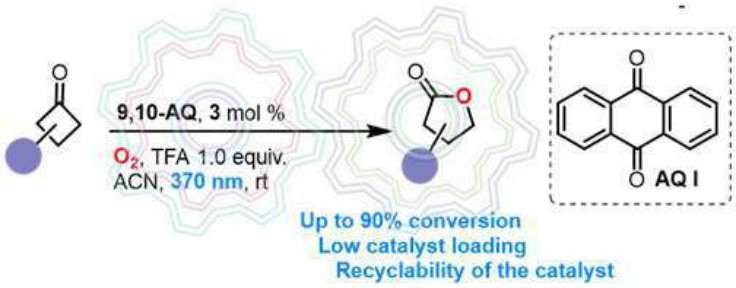

Figure 1. Photoinduced oxidation of cyclobutanones to γ-lactones.

Multi-enzymatic nanoreactors for the synthesis of privileged scaffolds

E. Capecchi,[a] E. Tomaino,[a] V. Ubertini,[a] R. Saladino[a]

[a]*Department of Ecological and Biological Sciences, University of Tuscia, Via San Camillo de Lellis, s.n.c., Viterbo*
e.capecchi@unitus.it

Inspired by nature, considerable efforts have been made in developing enzymatic cascade nanoreactors. We recently demonstrated the efficacy of lignin nanoplatforms in enhancing the performance and stability of multi-enzymatic cascade reactions. [1-2]The immobilization of enzymes was obtained by using concanavalin A (Con A) as a spacer to bind the carbohydrate region of glyco-enzymes, thus favouring the correct orientation of the active sites. First example of application of Con A mediated lipase/tyrosinase cascade reaction systems included the one-pot synthesis of lipophilic esters of hydroxytyrosol from agro-industrial wastes. [3] We describe here the application of the lipase/tyrosinase cascade reaction system for the synthesis of biologically active benzoxazines. The reaction pathway included the generation in-situ of electrophilic quinones from appropriate phenol esters, followed by internal nucleophilic 1,6-Michael addition and subsequent domino intramolecular lactonization and aromatization processes (Figure 1, Panel A). [4] Likewise, the preparation of bioactive flavanones was obtained from aromatic carbonyl derivatives by promiscuous aldolase activity of a tandem lipases by unprecedented intramolecular oxa-Michael addition (Figure 1, Panel B). The cascade reactions showed excellent atom economy and chemo-selectivity, and they were energetically favoured by substrate channelling effects.

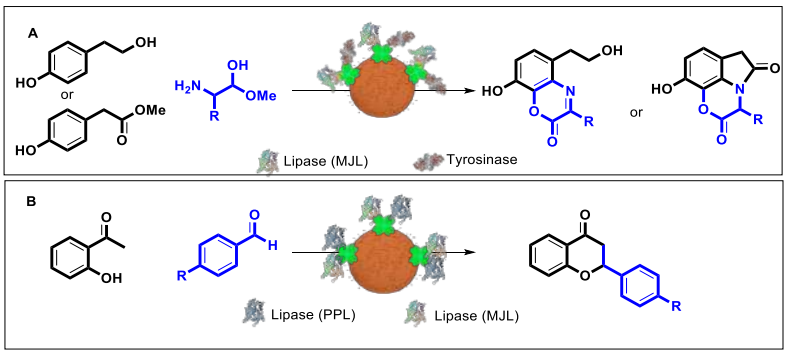

Figure 1: One-pot synthesis of benzoxazines (A) and flavanones (B).

Stereoselective Approach to Heavily Hydroxylated Azepane and Azocane Iminosugars via Osmium-Catalyzed Tethered Aminohydroxylation

F. Cardona,[a] M. Martínez-Bailén,[a,b] C. Matassini,[a] F. Clemente,[a] C. Faggi,[a] A. Goti[a]

[a] *Dipartimento di Chimica "Ugo Schiff" (DICUS), Università di Firenze, 50019 Sesto Fiorentino, FI, Italy*
[b] *Departamento de Química Orgánica, Facultad de Química, Universidad de Sevilla, c/ Prof. García González 1, E-41012 Sevilla, Spain*
francesca.cardona@unifi.it

Iminosugars, namely carbohydrates with a nitrogen atom replacing the endocyclic oxygen of sugars, are among the most challenging glycomimetics known to date. Compared to five- and six-membered iminosugars (e.g. polyhydroxylated pyrrolidines and piperidines), seven- and eight-membered ones (e.g. polyhydroxylated azepanes and azocanes) received little attention. Therefore, the development of efficient and selective strategies for their synthesis is of great interest. We present a straightforward approach to azepane iminosugars **1**[1] and our efforts in the synthesis of azocane iminosugars **2**. Of the five stereocenters in the final compounds, three of them derive from D-mannose, the carbohydrate used as starting material of our chiral pool approach. The key step of our methodology relies on a osmium-catalyzed "tethered aminohydroxylation" (TA) reaction, introduced by Donohoe in 2001,[2] which was previously exploited by some of us for the stereoselective synthesis of 2-and 3-aminosugars from glycals.[3] This reaction was combined with a former addition of vinyl or allyl metal to a D-mannose derived aldehyde which led to the key intermediates **4**, and allowed the stereoselective introduction of the two new C-N and C-O bonds. We report herein the results or our investigation.

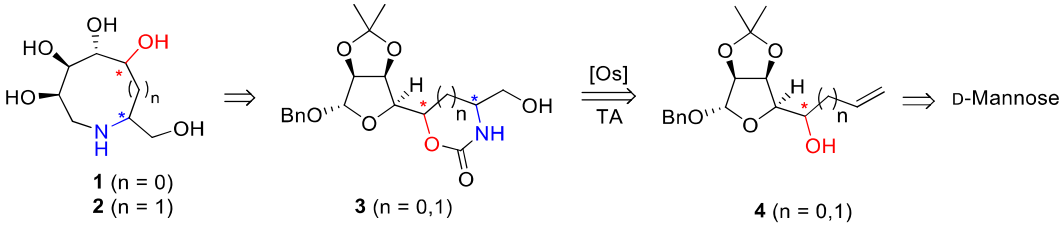

Figure 1: Our retrosynthetic approach for the preparation of azepane and azocane iminosugars.

New Hydrogen Bonding Motifs for Anion Binding Catalysis

A. Carioscia,[a] D. Iapadre,[a] J. Di Pietro,[a] E. Incerto,[a] F. Pesciaioli,*[a] A. Carlone *[a]

[a] *Dipartimento di Scienze Fisiche e Chimiche, Università degli Studi dell'Aquila, Via Vetoio, 67100 L'Aquila, Italy*
alessio.carioscia@graduate.univaq.it

Supramolecular Catalysis refers to the use of supramolecular interactions to accelerate chemical reactions.[1] This field, inspired by nature, has received increasing attention over the years. Within this realm, Anion Binding Catalysis is being explored more and more.[2] This type of catalysis can be accomplished using H-bonding [3], as well as halogen bonding [4] and chalcogen bonding.[5] In each case, the binding of an anion is pivotal to promoting a chemical reaction. In our work, we study the catalytic properties of receptors based on a 1,8-diaminocarbazole scaffold, which is well known for its anion-binding properties,[6] by designing our receptors featuring multiple hydrogen bonding recognition sites. A family of structurally related diaminocarbazole receptors has been prepared using a convergent and high-yielding synthesis, and their anion-binding properties have been evaluated via NMR titrations.

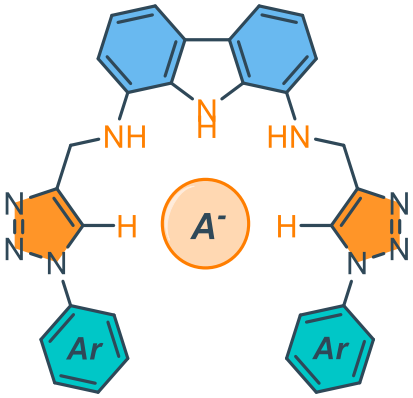

Figure 1: The core structure of the family of receptors based on a 1,8-diaminocarbazole scaffold.

Reductive Dehalogenation Through a New Photo-Generated Super-Reducing Excited State Di-Anion

A. Cerveri,[a] and G. Maestri*[a]

[a]*Università di Parma, Department of Chemistry, Life Sciences and Environmental Sustainability, Parco Area delle Scienze 17/A, 43124 Parma, Italy*
alessandro.cerveri@unipr.it

The reductive activation of aryl chlorides and fluorides is a recurring challenge in synthetic organic chemistry, and over the years various methods based on TM and photoredox catalysis were developed to tackle the issue. Recently was found that some coloured organic anions can be excited by visible light irradiation, making them super-reductants (E_{red} < -3.0 V vs SCE).

Herein we present a new excited state di-anion obtained by the simple and commercially available diphenylacetic acid, which shows extremely efficient reduction of highly unactivated substrates, with high selectivity and FG-tolerance, without need of additives or H-sources.

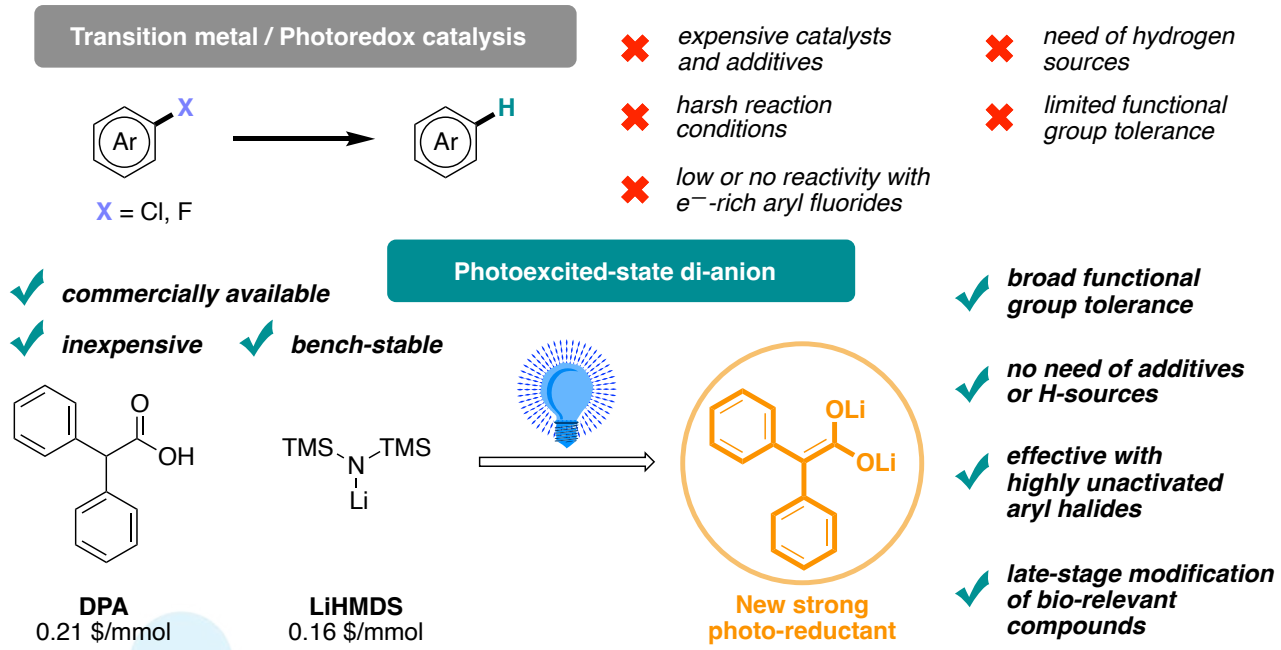

Figure 1: caption.

Nanosized drug delivery systems of anticancer active ingredients: an NMR perspective

A. Cesari, E. Guazzelli, M. Lessi, E. Martinelli, F. Bellina

Department of Chemistry and Industrial Chemistry, University of Pisa, via G. Moruzzi 13, Pisa (Italy)
andrea.cesari@unipi.it

Chemotherapy relies heavily on potent active ingredients, but their efficacy can be limited by poor solubility, degradation, and low selectivity. Drug Delivery Systems (DDS) offers a promising solution by encapsulating anticancer drugs, modulating their cytotoxicity, and ultimately enhancing their therapeutic potential. In this context, Nuclear magnetic resonance (NMR) spectroscopy offers a comprehensive analytical tool for the investigation of novel nanosystems,[1] especially fitting for the necessary molecular characterization required in DDS development. In this communication, the analysis on self-folding and thermoresponsive pegylated-fluorinated amphiphilic random copolymers (PEGMA-*co*-FA), employed as DDS for the potent highly hydrophobic anticancer drug Combretastatin-4 (C-4) will be described.[2] Experimental conformational and temperature-responsive properties have been observed by using ^{1}H-^{1}H, ^{1}H-^{19}F and ^{19}F-^{19}F 2D NOESY maps, above and below cloud point temperature. Size determination of DDS through DOSY and solubility enhancement of Combretastatin A-4 (C-4), has been evaluated. The small size and the stimuli responsive behaviour of these platform could represent a more effective way at delivering drugs to cells than conventional non-responsive nanocarriers.

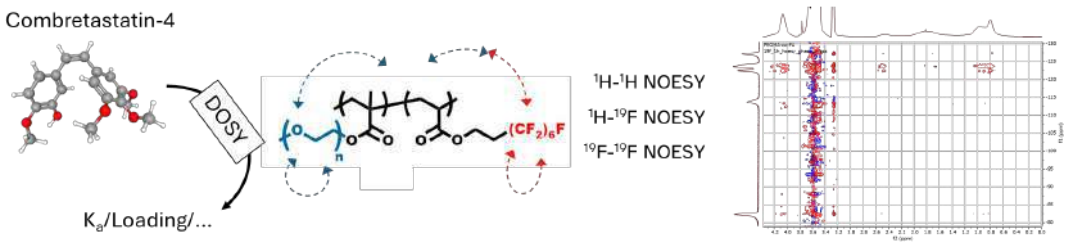

Figure 1: NMR strategies for fluorinated-pegylated DDS: determination of C-4/DDS association constant and loading with DOSY (left); ^{1}H and ^{19}F homo- and hetero-NOEs are useful for a complete conformational description of the DDS during thermoresponsive transitions.

The heterocyclic structure is a common feature in natural and synthetic compounds, often exhibiting important biological properties. Nitrogen-containing heterocycles are frequently found in vitamins, hormones, antibiotics, and alkaloids.[1]

One of the most attractive scaffolds among general nitrogen-containing heterocycles is the 5-hydroxy indole moiety. Discovered almost a century ago, the Nenitzescu reaction remains one of the most useful methods for obtaining 5-hydroxyindoles from simple starting materials. [2] Resonance Acoustic Mixing (RAM) represents a new era of mechanochemistry 2.0, aiming to overcome the limitations of traditional synthetic methods with the use of the latest developments in mechanochemistry.[3] RAM method induces molecule collision, promoting reactivity and overcoming problems of classical mechanochemistry: contamination, scalability, and equipment.

The objective of this research is to synthesize a 5-hydroxyindole scaffold using the Nenitzescu reaction, while avoiding traditional methods that involve long reaction times, the use of acids, and result in low yields. With the ideal conditions at our disposal, we were able to obtain various scaffolds by simply precipitating the product from the reaction mixture and recovering it with ethyl acetate.

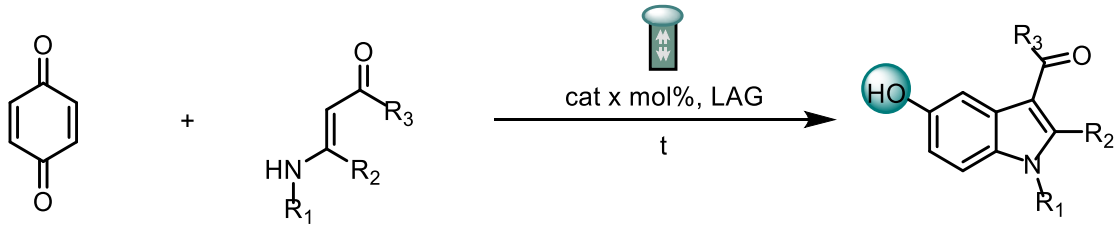

Figure 1: Synthesis of 5-hydroxy moiety by using a Lab RAM II device.

e-mail: vcunsolo@unict.it

Chickpea (*Cicer arietinum L.*) seed proteins show a lot of functional properties leading this legume an interesting component for the development of protein-enriched foods.[1,2] However, both in-depth proteomic investigation and structural characterization of chickpea proteins seed are still lacking. Here we show a characterization of chickpea seed protein fraction by means of SDS-PAGE, in-gel protein digestion, high-resolution mass spectrometry, and database searching. By this approach about 360 different proteins were identified and characterized, a result that up to date represents the most detailed description of seed's proteome of this legume. The most abundant components were vicilins and legumins. Legumins, as expected, were revealed at 45-65 kDa, as whole subunits with the α- and β-chains linked together by a disulphide bond, but also at lower mass ranges (α- and β-chains migrating alone).[3] Similarly, but not expected, also the vicilins were spread along the mass region between 65 and 23 kDa, with some of them identified in several bands. MS structural characterization allowed to determine that, although chickpea vicilins were always described as proteins lacking of cysteine residues, they contain this amino acid residue. Moreover, similarly to legumins, these storage proteins are firstly synthesized as pre-propolypeptides (Mr 50-80 kDa), that probably may undergo to proteolytic steps that cut not only the signal peptides but also produce different subunits having lower molecular masses.

The Truce-Smiles rearrangement is a key-reaction for the preparation of highly functionalized amides via an *ipso*-substitution reaction. While the initial version of the reaction was based on a polar two-electron pathway, a radical variant of this reaction for organic transformations is possible.[1] Arylazo sulfones (**1**, Figure 1), are bench stable and coloured compounds able to release different radical species (e.g. aryl radicals, sulfonyl radicals) when irradiated with blue light.[2-3] Such behaviour has been exploited in the present work to convert a wide range of *N*-sulfonyl-*N*-substituted acrylamides (**2**) into the corresponding *N*-substituted-2-aryl-3-sulfonyl amides (**3**) via a Truce-Smile radical rearrangement. The optimized protocol requires a simple set-up and it is easy scalable under both flow and batch conditions. With the proposed protocol bicalutamide (**4**) analogues (primarily used to treat prostate cancer) may be easily synthesized.

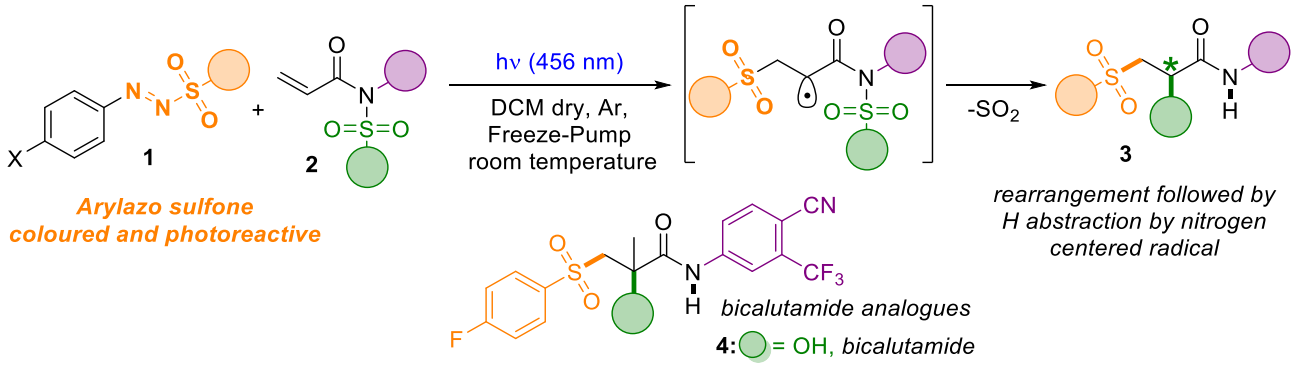

Figure 1: Truce-Smile rearrangement promoted by photogenerated sulfonyl radicals.

Use of ionic liquids in amidation reactions for PROTACs' synthesis

M. Eleuteri,[a] J. Desantis,[a] G. Cruciani,[a] R. Germani, [a] L. Goracci [a]

[a] *Department of Chemistry, Biology, and Biotechnology, University of Perugia, Via dell'Elce di Sotto 8, Perugia, Italy*

Proteolysis Targeting Chimeras (PROTACs) represents an emerging class of small molecule compounds that in the last two decades has gained even more attention as a novel and innovative therapeutic modality.[1] Structurally, PROTACs are heterobifunctional molecules consisting of two ligands joined by a linker: one ligand recruits and binds a protein of interest (POI) while the other recruits and binds an E3 ubiquitin ligase. Simultaneous binding of the POI and the E3 ligase by the PROTAC molecule induces ubiquitination of the POI and its subsequent degradation by the ubiquitin-proteasome system.[1] Despite the advances made so far, the structural chemical complexity of PROTACs poses challenges in their synthetic approaches. PROTACs are typically prepared through a convergent approach, entailing the parallel synthesis of the two fragments (POI and E3 ligase ligands) and then their successive coupling to produce the fully assembled PROTAC.[2-3]

In this context, PROTACs components are often combined via late-stage amide couplings, thus resulting in the amide bond as the most exploited linkage in PROTACs design and synthesis. Unfortunately, the overall isolated yields of such synthetic procedures are usually low due to also one or more purification steps needed to obtain the final PROTAC with acceptable purity. Furthermore, only a few conditions for the amide coupling in the synthesis of PROTACs have been reported so far in the literature.[2,4]

In the present study, we conducted an in-depth study aimed at exploring and optimizing the final amidation step for the synthesis of PROTAC derivatives. In particular, we focused our attention on the optimization of the final amidation step for the synthesis of an anti-SARS-CoV-2 PROTAC, previously reported by us,[5] by investigating different amidation coupling reagents and a range of alternative solvents, including ionic liquids (ILs). Among the ILs screened, [OMIM][ClO_4] emerged as a successful replacement of the commonly used DMF within the HATU-mediated amidation reaction, thus allowing the synthesis of the target PROTAC under mild conditions and in very high isolated yields. With the optimised conditions in hands, we explored the scalability of the synthetic approach as well as the substrate scope of the reaction by employing different E3 ligase ligands-based intermediates containing linkers of different lengths and compositions or by using different POI ligands.

The development of more sustainable chemistry synthesis is mandatory for reaching the target of a carbon neutral European Union in 2050, as stated by the European Green Deal. One of the most impacting parameters in synthetic chemistry is the use of large quantities of solvent. Classical solvents are mainly petroleum-derived, volatile, and show significant hazard for safety and health. To overcome the inherent problems of classical solvents, many new solvents are currently studied as a safer and greener alternative. The pharmaceutical field is an industrial sector that is very demanding in the use of solvents. In this context it is necessary to find safer and more sustainable solvents for the synthesis of active pharmaceutical ingredients (APIs), as well as to find new synthetic pathways capable of reducing energy consumption and waste production and endowed with sustainable work-up. An interesting class of APIs is represented by N,N-Dialkyl-2-arylindol-3-ylglyoxylamides (fig 1). These compounds selectively target the translocator protein (TSPO); interestingly, overexpression of this protein is linked to different diseases. The classical synthesis reported[1] for this class of compounds requires both the use of different hazardous solvents like diethyl ether and chromatographic purification. In this research, after identifying the most impactful parameters in the reported synthesis, we focused our attention on the replacement of classical solvents with less hazardous and more sustainable alternatives. Another key point of this work was the optimization of the synthesis for the reduction of waste and improved work up.

Terpenes represent a large class of natural products with applications in both pharma and fragrance industry. They are characterized by enourmous structural diversity and stereochemical complexity, which ensure a broad range of biological properties.[1] Therefore, stereochemical control is paramount in their synthesis and derivatization.[2] In this context, biocatalytic reduction and oxidation reactions offer an opportunity for both selectivity and sustainability.[3] Herein, we present redox approaches in the synthesis and functionalization of terpenes by chemoenzymatic catalysis. In particular, we will present (*a*) the enzymatic C=C and C=O bond reduction for the stereoselective preparation of sandalwood fragrances;[4] (*b*) a stereoselective chemoenzymatic approach to the fragrance Ambrocenide®;[5] (*c*) a chemoenzymatic approach to bioactive derivatives of Cannabidiol, itself recovered from agricultural biomass waste.[6]

Organocatalytic Asymmetric Reduction of δ-Nitro Dienes: a Viable Entry to Functionalized Amines and Highly Substituted Enantioenriched Cyclopentanes

Chiara Faverio, [a] Francesca Franco,*[a] Giulia Taini,[a] Laura Raimondi, [a] and Maurizio Benaglia[a]
[a] *Dipartimento di Chimica, Università degli Studi di Milano*
francesca.franco@unimi.it

The reduction of conjugated nitroolefins is considered a powerful tool to access nitroalkanes;[1] in the last few years, the organocatalytic stereoselective reduction of nitroolefins received great interest by organic chemists. In this context, the organocatalytic stereoselective reduction of β,β-disubstituted nitroolefins with Hantzsch ester was firstly disclosed by List[2] and further explored by other groups.[3] Nevertheless, no example about the enantio-, chemo- and regioselective reduction of dienes trisubstituted at the double bond bearing the nitro group was found in the literature.

Based on these considerations, a new strategy for the synthesis of δ-nitroalkenes from nitro dienes was disclosed, with complete chemo and regioselectivity and enantioselectivity up to 97%. The enantioenriched products were successfully elaborated and employed in the stereoselective cyclization reaction that affords an almost enantiomerically pure highly functionalised cyclopentane featuring 5 contiguous stereocenters.[4]

email: giulio.gallorini@unibo.it

Homogenous gold catalysis has attained an exceptional degree of maturity, robustness, and predictability concerning both chemical and stereochemical outcomes in site-selective manipulations of unsaturated hydrocarbons. Recently, we have introduced new fluorinated JohnPhos-type ligands (namely PedroPhos) as acceleration tools in benchmark reactions catalyzed by Au(I)[1]. In this context, aiming to employ these catalysts in novel synthetic procedures, we hereby present a gold-catalyzed Friedel-Crafts-like allylation of tropolone derivatives in the presence of diversely functionalized allenes. Tropolones and related derivatives constitute a fascinating class of compounds due to their peculiar geometry and remarkable biological activities, as evidenced by their presence in several natural and synthetic compounds[2]. In this scenario, the selective and mild formation of C-C bonds on precise positions of this scaffold remains largely unexplored[3]. The incorporation of an electron-donor group, elaborated onto the tropolone hydroxyl group, serves as an "umpolung tool" for the cycloheptatrienone moiety, in combination with the elegance and efficiency of homogeneous gold catalysis, allows the formation of allylated tropolone derivatives in high yields and under mild conditions.

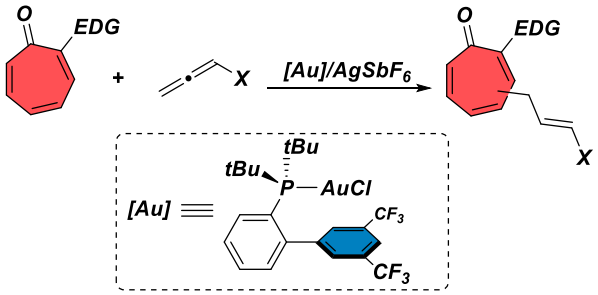

Figure 1: Alkylation reaction of tropolone derivatives exploiting gold catalysis.

Small organic molecules have maintained a central position in drug discovery and development in the 20th century.[1] In 2018, 38 small-molecule pharmaceuticals were approved by the U.S. FDA, of which 17 were fluoro-pharmaceuticals.[2] Among other things, a wise replacement with fluorine atoms in the molecule increases their bioavailability and potency, generally also improving their half-life and metabolism stability.

Based on these considerations, and given the experience of our group in the synthesis of analogues of climacostol,[3] a resorcinolic lipid that shows antitumor activities both *in vitro* and *in vivo* through an effective and potent cytotoxic, pro-apoptotic, and anti-autophagic action on multiple tumour cell lines, we decided to develop the synthesis of a new fluorinated analogue to test its activity as an anticancer agent. After several attempts with the most recent fluorination methodologies,[4] our target fluorinated molecule was obtained using DAST, a powerful reagent utilized for the conversion of alcohols into corresponding fluorides.

The development of new sustainable protocols which enable the use of aerobic/protic conditions in alkali-metal-mediated transformations has profoundly reshaped the conceptual chemistry of these highly polar organometallic reagents.[1] Our recent findings in this field disclosed that highly reactive alkyllithiums can efficiently promote chemoselective nucleophilic acyl substitution (S_NAc)[2] and regioselective metalation[3,4] reactions using deep eutectic solvents (DESs) or cyclopentyl methyl ether (CPME) as sustainable reaction media, working at room temperature, in the presence of moisture and air. Furthermore, we recently illustrated the beneficial active role of protic deep eutectic mixtures in the regioselective metalation/Fries rearrangement of *O*-aryl carbamates, as the commonly detrimental competitive protonolysis of the organolithium occurring in these reaction media prevents the formation of byproducts arising from multiple metalation steps.[5]
Motivated by our ongoing interest in extending the feasibility of organolithium reagents in unconventional sustainable solvents, we herein investigate the usefulness of bench-type conditions to promote the aerobic oxidation of benzylic anions generated from *O*-tolyl carbamate derivatives upon a metalation-Fries rearrangement sequence. Kinetic studies and mechanistic insights into the formation of dianionic species will be also discussed.

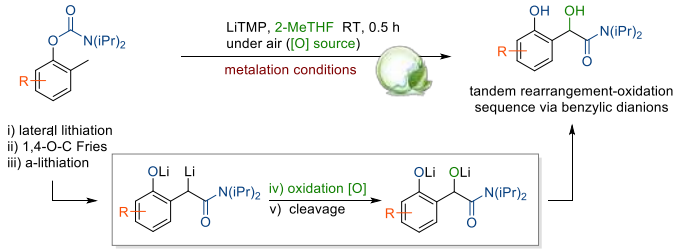

Figure 1: one-pot oxidative anionic homo-Fries rearrangement.

(L)-Mono-methyl Tyrosine (Mmt): new synthetic strategy via bulky 'forced-traceless' regioselective Pd-catalyzed C(sp^2)–H activation

D. Illuminati[a], C. Trapella[b], V. Zanirato[b], R. Guerrini[b], V. Albanese[c], C. Sturaro[d], S. Stragapede[d], D. Malfacini[e], A. Fantinati[c]

llmdvd@unife.it

The enormous influence in terms of bioactivity, affinity, and selectivity represented by the replacement of (L)-2,6-dimethyl tyrosine (Dmt) instead of phenylalanine (Phe) into Nociceptin/orphanin (N/OFQ) neuropeptide analogues, has been well documented in literature.[1] Here we report a new synthetic strategy to obtain mono-methyl tyrosine (Mmt), based on the well-known Pd-catalyzed ortho-C(sp^2)–H activation approach.
The uncontrolled double *ortho*-methylation on tyrosine has been previously reported[2], the aim of this work however, was the obtainment of the mono-alkylated product. The introduction of a dibenzyl-amine moiety in meta position allowed the Pd-catalyzed C(sp^2)–H activation, its bulkiness led to the formation of 2-methyl-tyrosine, acting like an inducer of regioselectivity, indeed, the alkylation occurred exclusively in position 2. (Fig. 1).

In this regard we are pleased to report that the introduction of the dibenzyl-amine moiety on Tyr aromatic nucleus is a convenient and traceless method to achieve such a goal, as a matter of fact, once reduced and converted in diazonium salt, it was easily removable through proto-deamination.[3]

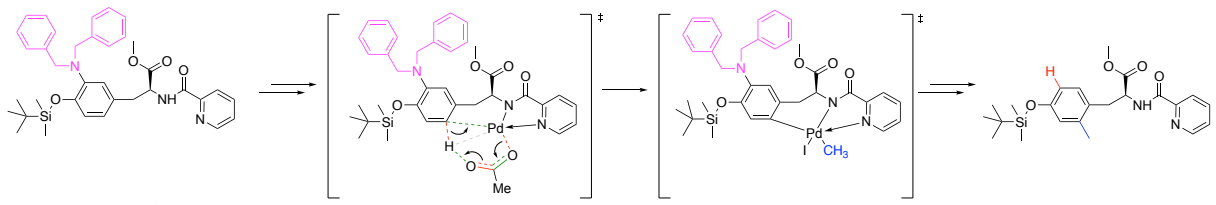

Figure 1: 2-methyl-tyrosine derivative obtained through Pd-catalyzed C(sp^2)–H activation reaction.

elison.lepore@unicam.it

Deep Eutectic Solvents (DESs) are an innovative class of organic solvents that are increasing their importance in the research activity thanks to their environmental-friendly features as well as to their structural characteristics and catalytic properties. Formed by no-solvent mixing of two substances, namely a hydrogen bond donor and a hydrogen bond acceptor, DESs are finding fruitful applications in many different topics as alternatives to common organic compounds.[1,2] One of the most interesting and studied properties of DESs is their peculiar water dilutions structures, because the DESs retain their structural features until high water contents (until about 50% w/w), showing clusters of DESs solvated by water in equilibrium with free-solvated species. The disruption of the DESs' structures occurs over 60% w/w of water added.[3,4]

In this presentation the properties of water dilutions of *aquo*DESs (binary DESs formed with water mixed with counterparts over their maximum solubility)[5] will be shown. Clusters of water-based systems in water were observed and characterized with techniques such as ionic conductivity; rheological measures; high resolution ultrasound spectroscopy; PGSE NMR. Finally, the cytotoxicity of these water dilutions of water-based DESs was tested in an in vitro model of intestinal cell culture (Caco-2) by MTT assay.

f.marra@unito.it

The development of enantioselective strategies is of utmost importance owing to the fundamental role of enantiopure molecules in biological processes. Among these methods, the kinetic resolution (KR) of racemic mixtures is one of the most utilized in organic synthesis.[1] *N*-Acyl 2-phenylpiperidines are optimal substrates for this process giving chiral amines, important scaffolds for the synthesis of bioactive compounds.[2] In particular, we herein investigate the kinetic resolution of the racemic *O*-phenyl 2-phenylpiperidine carbamate **1** (Figure 1) in the presence of (+)-sparteine as chirality inducer; electrophilic quench affords a mixture of enantioenriched starting material **1*** and the α-functionalized product **2** with an adequate enantiomeric ratio. Optimization of the reaction conditions (base, ligand, solvent, temperature) is presented. Furthermore, carbamate **1** represents a versatile reactive scaffold which can be also employed as substrate in an anionic Fries rearrangement process.[3] Several metalation conditions are investigated to promote the anionic migration either of the amide group or the ester moiety on the aromatic rings. Optimization of the reaction, with particular interest on sustainable bench-type conditions, and studies on the regioselectivity of the migration (1,3-*O*-*C* vs 1,4-*N*-*C*) are presented.

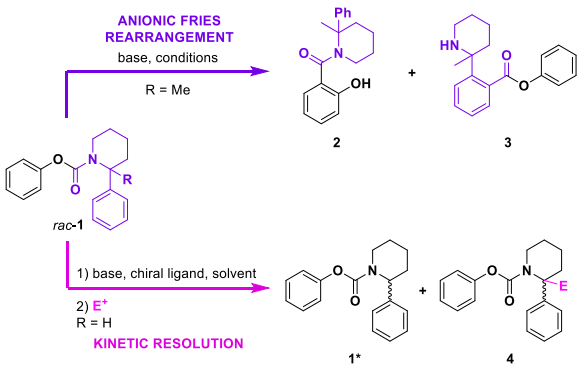

Figure 1: Kinetic Resolution and anionic carbo-Fries rearrangement of racemic carbamate **1**.

daniele.mazzarella@unipd.it

In the realm of asymmetric organic synthesis, aminocatalysis stands out as a well-established tool that enables the production of enantioenriched compounds under mild conditions.[1] Beyond its classic utilization, aminocatalysis serves as an exceedingly versatile tool of molecular activation, as testified by its seamless integration with various synthetic approaches.[2] While the combination of aminocatalysis with metal catalysis,[3] and photochemistry[4] has been extensively explored, its synergy with electrochemical activation remains largely unexplored. Herein, we present the successful merger of electrochemistry and aminocatalysis to perform SOMO-type transformations, expanding the toolkit for asymmetric electrochemical synthesis.[5] The methodology harnesses electricity to drive the oxidation of catalytically generated enamines, which ultimately partake in enantioselective radical processes, leading to α-alkylated aldehydes. Crucially, mechanistic studies highlight how this electrochemical strategy is enabled by the use of a redox shuttle, 4,4'-dimethoxybiphenyl, to prevent catalyst degradation and furnishing the coveted compounds in good yield and high enantioselectivity.

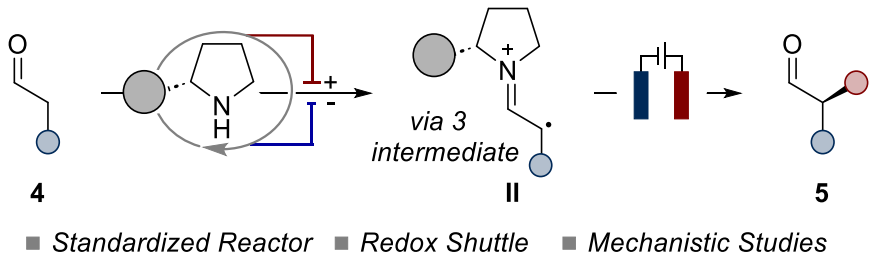

Figure 1: Electrochemical organocatalytic asymmetric radical functionalization of aldehydes.

Electrochemical Stereoselective Pinacol coupling: an Easy Access to Chiral Diamines

F. Medici,[a] B. M. Gazzotti,[a] S. Resta, [a] M. Benaglia[a]

[a]*Università degli Studi di Milano, via camillo golgi 19, 20133, Milano*
fabrizio.medici@unimi.it

Chiral molecules have already become the key target for synthetic chemists.1,2 Thus, it is necessary to create new synthetic routes continuously. Chiral diamines represent an intriguing class of molecules. Indeed, they are useful scaffolds that can be finely functionalised and then used as organocatalysts3 and ligands for transition metals.4 Our work is focused on the use of organic electrochemistry to realise an efficient pinacol coupling, avoiding the use of stoichiometric amounts of metal (Mn, Zn, Sm, among others). Starting from an enantiopure 1,2-diamine scaffold, the stereoselective electrochemical pinacol reaction of several bis-imines was successfully realised.

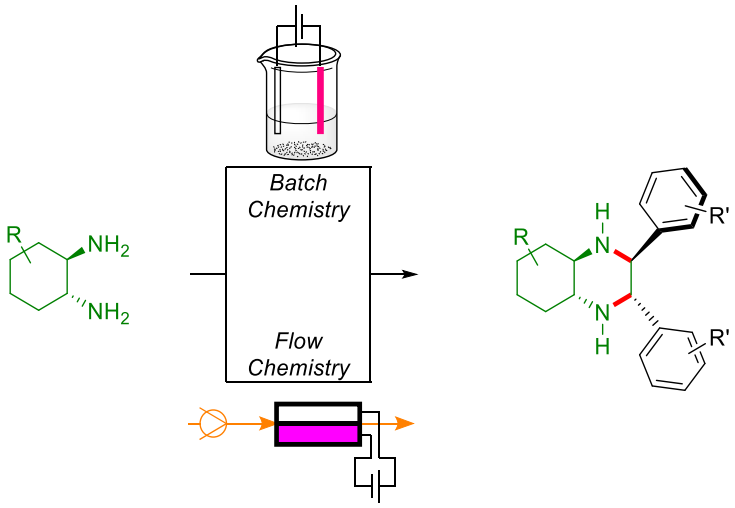

Figure 1 Scope of the work

Here, we will present the batch and flow electrosynthesis of a library of chiral diamines, which were isolated as enantiomerically pure compounds.

Since their introduction in 1981 Weinreb amides,[1] a class of standard acylating agents, were used as acylating platforms almost restricted to carbon-centered and hydride nucleophiles to access carbonyl and alkene motifs.[2] Except for the hydrolysis, acylation operations with heteroatom-based nucleophilic elements remain largely unexplored.

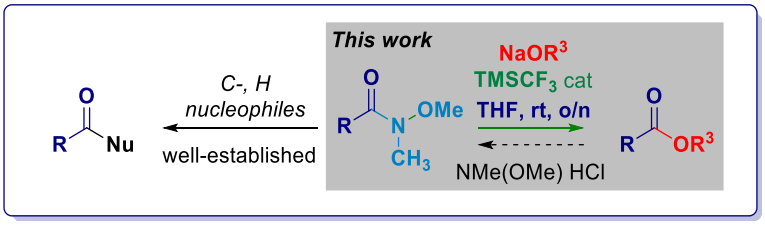

Figure 1: Esterification of amides.

We reasoned that the reaction of an alkoxide with Weinreb amides would represent an attractive synthetic tool for preparing esters through a conceptually intuitive protocol *via* the employment of the Ruppert-Prakash reagent[3] acting as a versatile catalyst enhancing their nucleophilicity.
Wide substrate scope, flexibility, genuine chemocontrol and the complete transfer of the stereochemical information demonstrate the protocol to be an attractive transformation also due to the reach portfolio of operations attainable with this class of products.[4]

OXETANES AS NUCLEOPHILES FOR THE SYNTHESIS OF PHARMACEUTICALLY RELEVANT KEY BUILDING BLOCKS

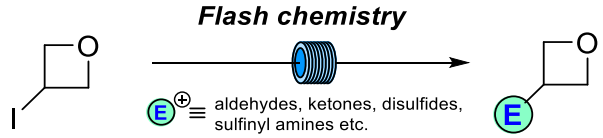
Philipp Natho,[a] Renzo Luisi,[a]

FLAME-Lab, Flow Chemistry and Microreactor Technology Laboratory, Department of Pharmacy – Drug Sciences, University of Bari "A. Moro", 70125 Bari, Italy

Philipp.natho@uniba.it

Over the last 50 years, small-molecule drug candidates have significantly increased in molecular complexity. One reason is the increased three-dimensionality introduced by a higher ratio of sp3-hybridised carbons to manage pharmacokinetic profiles. One motif to introduce three-dimensionality into drug candidates is the oxetane ring, which has found application in several approved drugs and drug candidates currently undergoing clinical trials.[1] Oxetanes exclusively substituted at the 3-position are of particular interest as the introduction of an additional stereogenic center is thus avoided.[2]

The generation of 3-substituted oxetanes has however been most frequently achieved by transition-metal-catalysed cross-couplings or nucleophilic substitutions of 3-halooxetanes, which raises not only concerns of environmental friendliness and cost, but severely limits the accessible chemical space.[3] A method for the 3-functionalisation of oxetanes with pharmaceutically relevant electrophiles are lacking and the development of such methodology is thus imperative to broaden the options space for medicinal chemists. Leveraging our expertise in flash-chemistry,[4,5] we have developed an operationally simple, sustainable and functional-group-tolerant methodology for the introduction of the oxetane moiety to a wide range of electrophiles using flow technology (Figure 1).



☐ Sustainable ☐ Reaction within seconds ☐ Broad substrate scope

Figure 1. Flash chemistry for the 3-functionalisation of oxetanes

A Lewis Acid-Catalyzed Unconventional Behavior of Oxazolines with Aldehydes

M. Papis, G. Broggini

Dipartimento di Scienza e Alta Tecnologia, Università degli Studi dell'Insubria, via Valleggio 9, 22100, Como
mpapis@uninsubria.it

2-Oxazolines are privileged scaffolds due to their widespread presence in numerous biologically significant molecules, but their relevance lies additionally in their versatility as intermediates in organic synthesis or ligands in coordination chemistry. The oxazoline moiety is typically subjected to nucleophilic attack at the C5 position with subsequent ring opening to give β-substituted carboxamide.[1] Although the chemistry of oxazolines has been extensively investigated, the reactivity of bisoxazolines is relatively unexplored. Recently, we have observed that the treatment of various bisoxazolines in the presence of nickel(II) chloride and an aryl or heteroaryl aldehyde could arise in the formation of β-iminoesters. Moreover, the same behavior by starting from oxazolines can be accomplished by using trimethylsilyl triflate since nickel proved to be ineffective. To the best of our knowledge, just one example reports the ring opening of oxazolines in the presence of aldehydes to access a tetrahydroisoquinoline scaffold.[2]

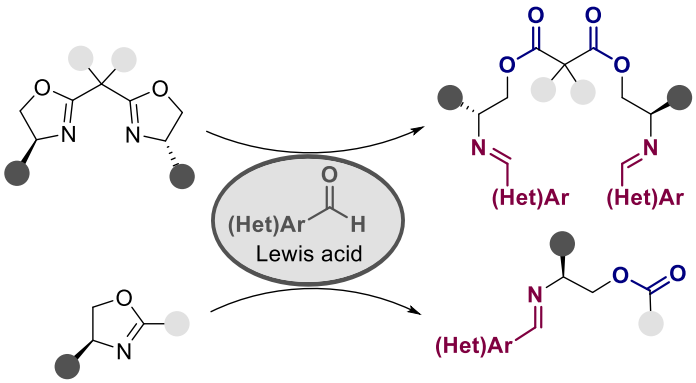

Figure 1: Lewis acid-catalyzed conversion of oxazoline into β-iminoesters.

Although bisoxazolines are useful themselves as chiral ligands, the generation of new β-iminoesters would greatly enhance their synthetic potential. Such a conversion would valorize the chemistry of oxazoline with the possibility of obtaining new molecules with two reactive sites that can undergo further transformation.

Deep Eutectic Solvents for Eco-Sustainable Synthesis of APIs: A Promising Approach

L. Cicco, F. M. Perna, P. Vitale, V. Capriati

Dipartimento di Farmacia-Scienze del Farmaco, Università di Bari Aldo Moro, Consorzio C.I.N.M.P.I.S, Via E. Orabona 4, I-70125 Bari, Italy
filippo.perna@uniba.it

In recent years, increasing environmental awareness has prompted chemists to prioritize the sustainability of chemical processes as a "key driver for innovation" within the pharmaceutical industry. The 12 Principles of Green Chemistry have emerged as the guiding framework for developing greener and more efficient methods to produce active pharmaceutical ingredients (APIs), with the aim of establishing environmentally responsible manufacturing processes.[1]

The selection of solvents during pharmaceutical process development is crucial for ensuring the sustainability of future production lines.[2] Traditionally, toxic and harmful volatile organic compounds (VOCs) have been widely used as solvents by organic and industrial chemists, but their use has been greatly restricted and even blacklisted. Consequently, the entire issue of solvent selection requires re-evaluation and has become a primary focus, particularly in pharmaceutical manufacturing, as solvents contribute to over 80% of the organic waste produced. This "solvent problem" not only pertains to their initial use but also involves considerations regarding containment, recovery, and reuse. Therefore, increasing attention has been paid to the efficient removal of VOCs from manufactured drugs.

Among the non-conventional and environmentally friendly solvents proposed as replacements for VOCs, deep eutectic solvents (DESs) have increasingly been employed for the synthesis of pharmaceutical molecules of interest. The adoption of these non-conventional solvents not only reduces the environmental footprint of synthesis processes, as demonstrated by green metrics calculation, but also enhances reaction efficiency.[3]

Building on our interest in the use of environmentally responsible solvents in API synthesis,[4] in this communication, we report on the sustainable preparation of nitrogen-containing heterocyclic compounds. Specifically, the synthesis of bis(indole) alkaloids, commonly referred to as indigo alkaloids, will be tackled as these compounds have long been recognized for their significant pharmacological properties.

emanuele.pinosa2@unibo.it

During the last decade, the merger of transition metal and photoredox catalysis, termed metallaphotoredox catalysis, has attracted considerable interest due to the mild operational conditions and the possibilities of stereoselective variants.[1] Among all the classes of photocatalysts reported in the literature, Harrit and Lacour introduced stable helical carbenium ions capable of harvesting light in the low-energy portion of the visible spectrum (orange and red light)[2] and Giannetti exploited their peculiar photophysical and redox properties as photocatalysts for organic transformations.[3] More recently, our group reported the use of the carbenium ion dimethoxyquinacridinium ($DMQA^+$) in highly diastereoselective and enantioselective pinacol couplings of aromatic aldehydes promoted by both titanium[4] and vanadium[5] in low oxidation state. In our presentation, we will illustrate the potential and differences between these two approaches, and the problems still unresolved.

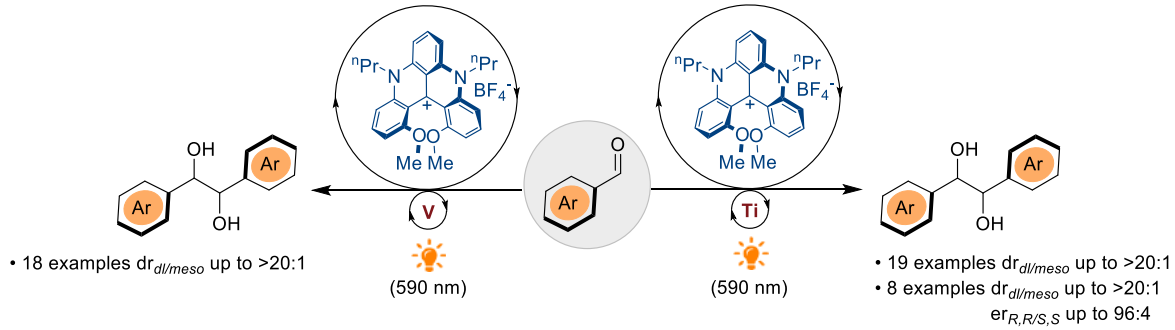

Figure 1: diastereoselective and enantioselective metallaphotoredox pinacol coupling of aromatic aldehydes promoted by titanium and vanadium in low oxidation state.

A microfluidic photo-induced platform to tune the synthesis of functionalized gold nanoparticles

L. Polito, M. Marelli

National Research Council, CNR-SCITEC, via G. Fantoli 16/15, Milan, Italy
laura.polito@scitec.cnr.it

Nanomedicine and the applications of nanomaterials in the life and health sciences have not yet expressed their full potential and kept the promises of their beginnings. In fact, despite the highly interesting and promising properties of nanoparticles (NPs), the full implementation of NPs in the current practice of medicine is still far from being fulfilled. One of the main obstacles is represented by the lack of reliable, reproducible, and scale-up protocols for the preparation of these materials.[1] Flow chemistry is a privileged pathway to synthesize NPs employing reproducible, and scaling-up protocols. Once optimized, the continuous synthesis is more reliable, productive, and less expensive if compared to wet synthesis.[2]

In this context, we have developed an innovative and versatile microfluidic approach to synthesizing functionalized gold nanoparticles (AuNPs).[3] The flow protocol is coupled with a photo-induced reduction promoted by a UV lamp, that avoids the use of any further chemical reductant, templating agent or co-solvent. The use of a 125W lamp allows the one-pot synthesis of functionalized ultra-small AuNPs, a class of luminescent AuNPs with a diameter less than 5 nm. Exploiting this protocol, it was possible to obtain a small library of glyco-AuNPs, checking thoroughly the displacement of the multiple copies of glycans on AuNP surface. The protocol resulted effective for the synthesis of other plasmonic NPs, i.e. silver and platinum NPs. Moreover, preliminary data showed that control over the size of AuNPs is possible by using a 6W UV lamp and tuning the ratio of gold precursor/ligands.

Exploring the fascinating properties of *Bombyx mori* Silk fibroin in catalysis

C. Ricciardelli,[a] G. Rizzo,[a] P. Cotugno,[a] G. M. Farinola[a]

[a] *Dipartimento di Chimica Università degli Studi di Bari "Aldo Moro", Via E. Orabona 4, 70126 Bari, Italy*
carola.ricciardelli@uniba.it

Social and environmental challenges require the continuous development of new materials. Consequently, exploring biomaterials presents a suitable alternative to achieve sustainable use of resources. In particular, the use of biopolymers as catalysts has increased considerably due to their natural availability, remarkable chemical efficiency, and interesting properties such as biodegradability, biocompatibility, and non-toxicity.[1] Within this context, Silk fibroin (SF), an attractive natural fibrous protein extracted from *Bombyx mori* silkworm cocoons, has gained increasing attention because of its natural accessibility, physical-chemical properties, biocompatibility, and adaptability.[2] Besides the traditional use in textile industry, SF is recognized as a versatile material that has been investigated as a promising resource in biomedicine, optoelectronics and many other technological applications. It is known that SF is an efficient support for Palladium, Platinum and Rhodium in hydrogenation reactions.[3]

This study reports the preparation of new heterogenous metal supported on SF catalysts.[4,5] Thus, SF-Palladium catalyst for Suzuki-Miyaura cross-coupling was prepared and optimized, often giving the desired pure biaryl as the only product in mild conditions, avoiding tedious purification steps and chromatography techniques. It is worth noting that Pd/SF showed high recyclability (up to 19 cycles) and it has been demonstrated that the catalyst exhibits a purely heterogeneous catalytic mechanism with no leaching during the reactions.

Regioselective Nitration of Polyaromatic Systems at Room Temperature

D. Yousif,[a,b] L. Vaghi,[b] C. G. Daniliuc,[c] R. Po,[d] A. Papagni,[b] F. Rizzo[a,e]

fabio.rizzo@cnr.it

Nitration of aromatic compounds is one of the most widely studied reactions and an immensely important industrial process due to the pivotal role of nitroarenes as precursors of industrial products and functional materials. Several reagents are available; the most common ones are mixtures of nitric and sulfuric acid, nitronium tetrafluoroborate, and acetyl nitrate. However, nitration reactions are notoriously unselective, leading mixture of isomers. Moreover, they require harsh conditions, by means of an excess of highly corrosive mineral acids at high temperatures. Crivello introduced the use of mixtures of ammonium nitrate and trifluoroacetic anhydride (TFAA) to nitrate a variety of aromatic compounds at room temperature in good yield.[1] However, this procedure has never been applied to polyaromatic compounds and the mechanism of the reaction is not explained to date in the case of nitrate salt.

9,9'-Spirobifluorene is a three-dimensional polyaromatic hydrocarbon compound receiving recently growing scientific and industrial interest due to the application of its derivatives in many technological fields.[2,3]

The nitration of 9,9'-spirobifluorene gives the 2,2′-dinitro-9,9′-spirobifluorene in fair yield (around 65%) under harsh conditions, which allows a very limited control of regioselectivity. Indeed, even working under carefully controlled reaction conditions, the mono-substituted 2-nitro-9,9′-spirobifluorene is recovered in very poor yield (11%).[4] Noteworthily, the formation of side products and the harsh conditions affect dramatically the reproducibility, as underlined by the different yields reported in the literature, ranging from 39 to 65%.

In this contribution we report the regioselective nitration of 9,9'spirobifluorene under mild conditions, that is, by using Menke and Crivello conditions, with very high yield. The presence of two independent fluorene units in one single compound allowed us a novel understanding of the mechanism originally described by Crivello.[5]

Catalyst-free Visible-Light Promoted Thiol-ene Reaction of Alkenes

Marco Rusconi[a], Polyssena Renzi[a], Giovanni Ghigo[a], Annamaria Deagostino[a]

[a] *Department of Chemistry, University of Turin, Via Giuria 7, 10125 Torino*
marco.rusconi@unito.it

The thioether class is renowned among sulfur-containing scaffolds for its chemical versatility and vast applications in the pharmaceutical field as bioactive moieties.[1]

In this context, the thiol-ene reaction is considered to be a core methodology in modern chemistry to access *anti*-Markovnikov thioethers due to its robustness.[2] Traditionally, the straightforward coupling of an unsaturated C=C bond and a thiol requires highly energetic UV light (< 300 nm) to generate the reactive thiyl radicals, arising major challenges related to sustainability and chemoselectivity.[3] Recently, despite the considerable efforts that have been made to accomplish hydrothiolation reactions promoted by visible light,[4] there is still a need for costly photocatalysts and radical initiators to harvest its energy.[5]

In this framework, we unveiled a new activation mode based on the formation of a key photo-active complex between the thiol and its conjugated base, thus developing an innovative catalyst-free approach for the synthesis of *anti*-Markovnikov thioethers employing visible light (390 nm). Depending on the alkene structure, water can be employed either as an additive or as the alternative solvent to dichloromethane, thus increasing the sustainability of this methodology.

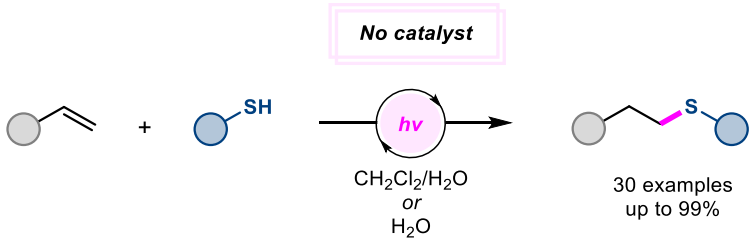

Figure 1: Catalyst-free hydrothiolation reaction of alkenes mediated by purple light for the synthesis of *anti*-Markovnikov thioethers.

e-mail: rsaletti@unict.it

Voltage-Dependent Anion Channels (VDAC1, VDAC2, VDAC3) are mitochondrial outer membrane proteins whose primary function is to allow the communication and exchange of molecules between cytosol and mitochondrion. Despite the high sequence homology and the high structural similarity, the three VDAC isoforms show a different tissue dependent expression pattern, a variable abundance, a difference in cysteine content and are characterized by distinct, specific interactome partner.[1]

The present work is part of a research line concerning the structural characterization of VDAC proteins. We have reported the oxidation pattern of cysteines in rat and human VDACs using "in solution" proteolysis and nanoUHPLC/High Resolution nanoESI-MS/MS, a procedure originally developed by us.[2,3,4] Recently, the position of intramolecular disulfide bonds in the rat VDAC2, using a modification of this procedure to minimize disulfide reshuffling, was investigated.[5]

In the present work, we extended the analysis to the rat VDAC3 protein that contains 6 cysteines. Cys^{2} and Cys^{8} are present in the N-terminal region, which contains the channel voltage sensor; Cys^{165} is the only cysteine exposed to the cytosol, while the other cysteines (Cys^{36}, Cys^{65}, Cys^{122}, Cys^{229}) are located in the loops exposed to the intermembrane space (IMS).

Our results indicate the presence of disulfide bonds both in the N-terminal fragment of the protein and between the cysteines located in the loops exposed toward the IMS.

Here, we also present preliminary results about the possibility that intermolecular disulfide bridges can form between the three VDAC isoforms.

Chirality sensing by chiroptical dithienyl probes

M. Caporale, P. Scafato, S. Superchi,

Department of Science, University of Basilicata, Via dell'Ateneo Lucano 10, 85100, Potenza
stefano.superchi@unibas.it

Chiral sensing and recognition are among the most relevant topics in many fields of chemistry, such as medicinal chemistry, natural product chemistry, material science, and environmental chemistry. In fact, the knowledge of the absolute configuration (AC) and enantiomeric composition of chiral molecules are prerequisites for the study of their properties and behavior both in the environment and in living organisms. One of the most promising approaches for chiral sensing is the use of stereodynamic chiroptical probes *i.e.* either achiral or racemic compounds which, when linked to the chiral analyte assumes a preferred chiral conformation giving rise to electronic circular dichroism (ECD) signal(s) from which the AC and/or the enantiomeric excess of the analyte can be determined. This approach allows the AC assignment in short time, in solution, and requires sub-milligram samples, thus being suitable to treat even not-crystalline natural products. Moreover, such methods constitute a practical alternative to computational chiroptical analyses, when dealing with conformationally flexible and/or UV-transparent (cryptochiral) molecules. In the past, our group described the use of flexible biphenyls probes for the assignment of AC of chiral diols,[1] carboxylic acids,[2] amines,[3] and complex natural products. Herein we report a novel *dithienyl probe* to determine the AC of chiral amines, acids and aminoacids. By transforming amines in the corresponding dithienyl azepines or acids in dithienyl amides, a preferred *M* or *P* twist is induced by the chiral substrate in the *bis*-heteroaromatic moiety, depending on its AC. The preferred twist can be detected by the sign of a diagnostic band in the ECD spectrum or by the Optical Rotation (OR) sign, thus arriving at the AC of the derivatized chiral compound.

Dimethyl carbonate mediated synthesis of 2,5-furandicarboxylic acid esters from galactaric acid

G. Trapasso [a], M. Annatelli [a], B. Chìcharo [a], F. Aricò [a]

[a] *Department of Environmental Science Informatic and Statistics, Ca' Foscari University of Venice, Scientific Campus Via Torino 155, 30170 Venezia Mestre, Italy*

2,5-Furandicarboxylic acid (FDCA) has been extensively studied as monomer for the production of polyesters[1] such as polyethylene furanoate (PEF), considered as one of the most valuable bio-based substitute of the petroleum-derived polyethylene terephthalate (PET).[2] Most of the synthetic processes to FDCA employ glucose and fructose as substrates via the formation of 5-hydroxymethyl furfural (HMF) as key intermediate (Figure 1, top reaction).[1] The main disadvantage of this process regards the intrinsic instability of HMF, together with its high market price and its difficult separation and purification, which ultimately lead to the production of humins, drastically lowering the overall reaction yield.[3] Few studies focused instead on the production of FDCA from alternative substrates. In fact, FDCA can be synthetized starting from aldaric acids, which can be obtained either via oxidation of sugars or directly extracted from citruses peel (Figure 1, bottom reaction).[4] From these premises, the present study reports an alternative synthetic procedure for the production of 2,5-furandicarboxylic acid dimethyl ester (FDME) starting from galactaric acid via dimethyl carbonate (DMC) chemistry. Both sulfonic resins and an iron-based Lewis acid showed to promote the one-pot formation of FDME. The pure product was retrieved as a white crystalline solid with an isolated yield of up to 70 %. Finally, on the basis of the different intermediates identified, a possible reaction mechanism was proposed, which highlights the essential contribute of DMC in the product formation.

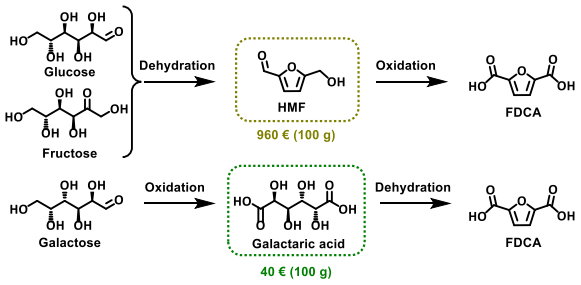

Figure 1: FDCA synthesis via HMF and galactaric acid routes.

[b] *Takis S.r.l., Via Castel Romano 100, 00128, Rome, Italy*

The significance and unique nature of protein interactions in cellular functions and the development of numerous pathological conditions have sparked interest in targeting protein-protein interactions for therapeutic purposes. In cancer, various cell surface protein receptors, including $\alpha_v\beta_3$, $\alpha_v\beta_5$ and $\alpha_5\beta_1$ integrins, are recognized as specific markers of tumor angiogenesis, advancement, and metastasis. We have recently reported the synthesis and the biological evaluation of small molecule drug conjugates (SMDCs) based on the selective $\alpha_v\beta_3$ integrin ligands: *cyclo*(DKP-RGD) and *cyclo*(DKP-*iso*DGR). The conjugates containing *iso*DGR ligands and several cytotoxic agents (e.g. paclitaxel, auristatins and α-amanitin) generally displayed high selectivity towards cells overexpressing integrins, maintaining nanomolar activity.[1] Tumor protein p53, known as "the guardian of the genome", is a critical regulatory protein in vertebrates, crucial for preventing cancer formation by regulating processes like cell cycle progression, apoptosis, and genomic stability. Its levels are typically kept low by the E3 Ubiquitin ligase MDM2, which, along with MDM4, facilitates its proteasomal degradation. However, in certain cancers, MDM2 overexpression leads to p53 inactivation. Recent research has unveiled a negative crosstalk between the transmembrane integrin receptor $\alpha_5\beta_1$ and p53, contributing to chemoresistance in glioblastoma (GBM).[2] Thus, in GBM, the overexpression of both $\alpha_5\beta_1$ and MDM2 leads to the degradation and downregulation of the p53 protein. These findings lay a strong foundation for developing conjugates that can simultaneously target $\alpha_5\beta_1$ integrin and MDM2 protein. In this study, we present the design, synthesis, and *in vitro* evaluation of novel immunomodulating SMDCs incorporating the MDM2 protein inhibitor, SAR405838,[3] and the $\alpha_5\beta_1$ integrin homing peptide, *cyclo*(phg-*iso*DGR-k),[4] for targeted delivery to GBM cancer cells (Figure 1).

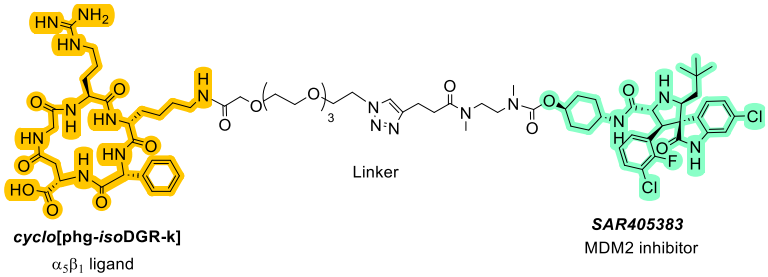

Figure 1: Schematic representation of the synthesized SMDC.

Glioblastoma multiforme (GBM) remains one of the most aggressive and challenging brain tumors to treat with poor prognoses. Understanding the intricate molecular mechanisms driving GBM pathogenesis is crucial for the development of effective treatments. Three-dimensional (3D) in vitro models, reproducing the complexity of the tumor human microenvironment, are promising tools to identify personalized therapies. Addressing the limitations inherent in vivo animal models, which lack human cells and fail to faithfully recapitulate human physiology, underscores the significance of 3D in vitro models. This study aims to produce 3D in vitro models not only to faithfully mimic the extracellular matrix (ECM) but also to precisely replicate cell-ECM interactions crucial for cancer progression[1-3]. For that, we selected gelatin and hyaluronic acid as starting materials to formulate hydrogels upon proper crosslinking. Characterization of functionalized biomaterials was performed via Fourier-Transform Infrared Spectroscopy (FTIR) and Nuclear Magnetic Resonance (NMR) analysis. The physico-mechanical properties of the formulated hydrogels were assessed through swelling tests and rheometry, while the porosity was investigated with Scanning Electron Microscopy (SEM) analysis. Hydrogels were then bioprinted with GBM cell lines and spheroids. Biological experiments were conducted under both static and dynamic conditions, aiming to simulate the tumor microenvironment more accurately and study how the physical and biomolecular stimuli induce the cell behaviour. This comprehensive approach aims to advance our understanding of GBM pathobiology and facilitate the development of models for the validation of novel therapeutic strategies.

Melanins are a group of insoluble dark pigments that are widespread in nature[1]. In mammals, brown-black eumelanins and yellow-red pheomelanins are major determinants of skin, hair and eye pigmentation and play a significant role in photoprotection and many biological functions. Due to their broad spectrum of light absorption, electrical conductivity, paramagnetic behaviour, and biocompatibility, eumelanins represent ideal candidates for biomedical applications. The biogenesis of eumelanins arises from the oxidative polymerization of the key intermediates 5,6-dihydroxyindole (DHI) and related derivatives. In a previous study, a thiogalactoside DHI (S-GAL-DHI) was synthesized that provides a powerful tool to access soluble eumelanins and thus to study eumelanin more thoroughly[2]. The main feature of S-GAL-DHI is its aptitude to undergo spontaneous oxidative polymerization under appropriate conditions, which leads to a biocompatible scaffold for exposing multivalent glycans and makes it a golden candidate for developing advanced protein antagonists/modulators. In this work, soluble eumelanin polymers were synthesized for the purpose of interacting with galectins. The galectins are a family of soluble β-D-galactoside-binding proteins characterized by a highly conserved carbohydrate recognition domain (CRD),[3] involved in several cellular processes, their altered expression or localization is associated with various pathologic conditions. Thus, discovering inhibitors is a critical issue. Within this framework, the synthesis of water-soluble eumelanins was carried out with the aim of studying their interaction with galectins, in order to design eumelanin-based activable galectin inhibition. A combined UV-Vis spectrophotometric/Dynamic Light Scattering approach was adopted to follow oxidation and polymerization over time. Then, the interaction of Galectin-3 CRD with melanins and precursors thereof was assessed by isothermal titration calorimetry.

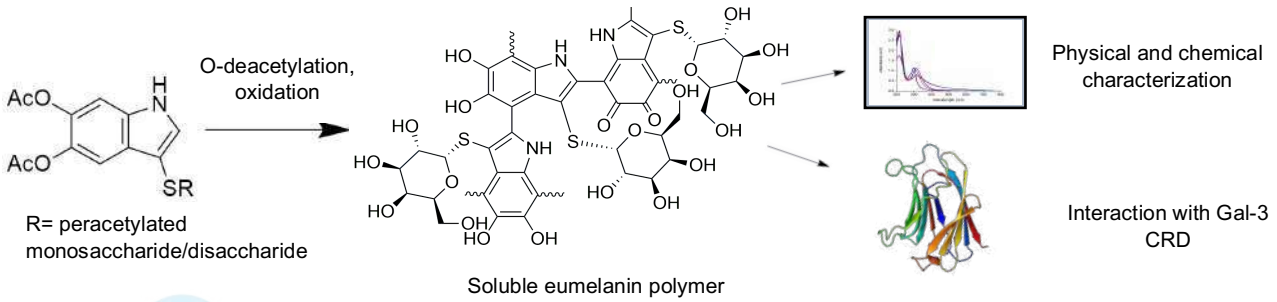

Figure 1: Synthesis and characterisation of water-soluble melanin and its interaction with Galectin-3 CRD.

Type 2 diabetes mellitus (T2DM) is a complex disease characterized by a persistently elevated blood glucose and serious long-term complications. T2DM is an ongoing, risky, and costly health problem which often requires the concurrent administration of several hypoglycemic drugs increasing the risk of side effects[1]. Therefore, the use of multitarget drugs is an emerging strategy to treat this multifactorial disease. Marine Natural Products (MNPs) are a great resource for this purpose since they occupy much of the chemical space with pharmacological value due to their high chemical diversity. Additionally, MNPs may serve as biologically validated starting points for the design of focused libraries for novel ligands with enhanced properties. In this view, we demonstrated that the marine sesquiterpene quinone avarone (Figure 1), isolated from the sponge *Dysidea avara*, is a potent inhibitor of both PTP1B and aldose reductase (AKR1B1), emerging targets involved in the onset and progression of T2DM. The thorough pharmacological characterization revealed that avarone has both insulin-sensitizing and mimetic activity on muscle C2C12 cells[2]. Thus, avarone was selected as a natural hit compound for designing multitarget agents for diabetes. To explore its antidiabetic potential, a focused chemical library of 1,4-benzoquinone-derived compounds was synthesized by a versatile and regioselective protocol (Figure 1). All the simplified and modified synthetic derivatives were screened against both enzymes, and preliminary SARs have been performed. The obtained results highlighted that modification on the alkyl side chains and/or the quinone ring may strongly affect the interaction with enzymatic counterpart underlying different antidiabetic mechanism of action for the synthetic analogues.

Targeting L-SIGN: a potential tool against SARS-CoV-2.

G. Cavazzoli[a], S. Pollastri[a], Clara Delaunay[b], Michél Thepaut[b], Franck Fieschi[b], Anna Bernardi[a]

gianluca.cavazzoli@unimi.it

The C-type lectin receptors (CLRs) DC-SIGN and L-SIGN are known to interact with surface glycoproteins of many pathogens, thus inducing activation of the initial stages of the adaptive immune response. Nevertheless, several deadly viruses - such as HIV, Ebola, hepatitis C viruses - have developed strategies to subvert the natural role of CLRs and use them to promote virus internalization and dissemination.[1] The recent discovery that also SARS-CoV-2 can exploit DC and L-SIGN to adhere to the host and enhance its infection, has stimulated the development of antagonists for these receptors [2,3] and in particular against L-SIGN, which is co-expressed with the viral entry receptor ACE2 in the lungs and in endothelia. However, designing selective L-SIGN ligands is extremely challenging, due to the very high similarity of the two lectins (ca. 80% homology).

We have recently reported the first class of highly selective L-SIGN ligands, whose structure relies on a mannose scaffold modified at position 2 with a methylene guanidine triazole. The first member of this class, **Man84,** displays 50-fold selectivity for L-SIGN against DC-SIGN.[4] Inspired by this molecule, we here present a new set of glycomimetics, able to keep and, in some cases, improve the aforementioned selectivity. All the designed antagonists are based on a mono-mannose scaffold, modified at position 2 with a triazole moiety, decorated with a guanidinium isosteric group. Their synthesis and biological activity will be described and the structure-activity relationship (SAR) of the isosters' set will be discussed.

Acknowledgments: the project is supported by EU funding within the NextGeneration EU-MUR PNRR Extended Partnership initiative on Emerging Infectious Diseases (Project no. PE00000007, INF-ACT). We are grateful to Dipharma Francis s.r.l. for their support in the scale up of crucial intermediates for this project.

Targeting ferroptosis in *Pyricularia oryzae*

M. Christodoulou,[a] A. Kunova,[a] S. Princiotto,[a] C. Pinna,[a] P. Cortesi,[a] A. Pinto,[a] S. Dallavalle[a]

[a]*Department of Food, Environmental and Nutritional Sciences, University of Milan, via Celoria, 2, 20133, Milan*
michail.christodoulou@unimi.it

Rice *(Oryza sativa L.)* is the major staple food for more than 50% of world's population. The rice-blast fungus *Pyricularia oryzae* is the most destructive rice pathogen worldwide, causing globally between 20% and 40% yield losses. The management of the rice blast disease requires a massive application of fungicides, which accounts for more than 8% of total fungicide market.[1]

Diverse classes of fungicides, during the years, have been used against *P.* oryzae,[2,3] including strobilurins and demethylation inhibitors (DMI).[4] Both classes of antifungal compounds have a single-site mode of action and the fungal pathogen populations developed resistance to them. For this reason, the identification of new targets and the discovery of new scaffolds to combat the pathogen is urgently needed.

The modulation of ferroptosis, a form of iron-dependent cell death, has recently emerged as a potential new strategy to control fungal pathogenesis. Ferroptosis, in *P. oryzae*, starts from the terminal conidial cell, and then progresses to the other two cells during the appressorium formation and maturation, and this ferroptotic cell death is required for the infection. Herein, we present the synthesis and biological evaluation of natural (Figure 1) and nature-inspired iron chelators (siderophores), containing the catecholamide moiety, as potential inhibitors of ferroptosis in *P. oryzae.*

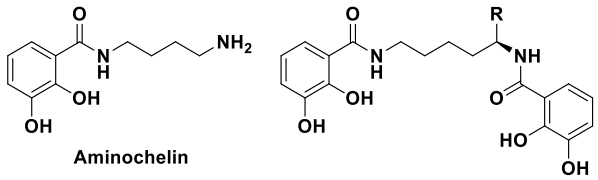

Figure 1. Natural siderophores.

Cancer is one of the most health and socioeconomic disease worldwide. Despite significant progresses have been registered, and several drugs are available to treat cancer, the onset of resistance is a major drawback that often causes the failure of the treatment.[1] Recently, new therapies based on small interfering RNA (siRNA), micro-RNA mimics (miR mimics), and antisense micro-RNA (antagomiR) have been largely exploited to cure cancer, neurodegenerative diseases, and some rare diseases.[2] In the last decade, to circumvent the obstacles imposed by delivery vehicles such as nanoparticles which are composed of potentially toxic exogenous materials, the development of protein-based systems (HumAfFt) as well as chemical modifications of canonical oligoribonucleotides have been considered as promising strategies to improve RNA delivery, stability and efficacy.[3] RNA encapsulation in HumAtFt can be achieved by means of poly-cationic molecules (PCs), which can both specifically bind to the protein and stabilize the oligonucleotide through electrostatic interactions. In order to evaluate a structure-encapsulation relationship between PCs and oligonucleotide, a library of polyamine molecules (PA) (Figure 1) was rationally designed and synthesized featuring a pentafluorobenzene sulfonamine moiety to ensure the anchorage of the polyamines to the cysteine residues of HumAfFt. The first series features cyclic amines which were synthesized by performing subsequent reductive amidation reactions starting from *N*-methyl-4-piperidone and final introduction of the pentafluorobenzene moiety. On the other hand, linear PAs were synthesized by performing subsequent Steglich couplings to join glycine, β-alanine, and methylamine as major building blocks of this series with further introduction of the selective moiety for thiols. Results obtained with cyclic PAs highlighted an efficient siRNA delivery and a good silencing action on glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene expression in three cancer cell lines.

Structural and Immunological characterization of lipopolysaccharide from gut microbe *Prevotella copri*

R. Cirella, E. Andretta, L. De Simone Carone, A. Silipo, A. Molinaro, F. Di Lorenzo

Department of Chemical Sciences University of Naples Federico II, via Cinthia 4, 80126, Naples
Roberta.cirella@unina.it

Prevotella copri is an abundant member of the human gastrointestinal microbiota.[1] Owing to its vast distribution and variable abundance, studies are contradictory about whether it is beneficial or detrimental to human health. As a Gram-negative bacterium, it expresses lipopolysaccharide (LPS) on the external leaflet of its outer membrane. LPSs are amphiphilic macromolecules consisting of a hydrophilic hetero-polysaccharide (formed by the Core oligosaccharide and the O-Antigen) covalently linked to a lipophilic domain termed Lipid A.[2] Besides this general architecture, structural variations potently influence their biological activity. Indeed, LPSs are largely known as potent immunostimulatory molecules able to interact with key receptors of the human innate immune system, leading to potent inflammatory reactions aimed at eradicating the bacterial infection.[2] Nevertheless, LPS immunological properties are strongly dependent on their chemical structures and therefore even the most subtle chemical alteration can dramatically affect the resulting immune response, exhibiting different trends in the induction of an inflammatory reaction.[2]

This acknowledged concept faces the reality of the human gut. Indeed, the intestinal tract is home for more than one thousand billion bacteria, most of which are equipped with LPS, but remain harmless and, in some cases, even beneficial for human health.[3] How LPS is tolerated in the gut is a major unresolved question representing a frontier in our understanding of innate immunity. The answer to this question resides in the peculiar chemistry of LPS from harmless gut microbes that must differ from their pathogenic counterparts. Overall, the elucidation of the structure and the immunological activity of LPS from microbiota will bear new advances in the medicinal chemistry and in the field of search of new molecules able to prevent uncontrolled host immune response against our own microbiota.

In this communication, I will describe the structural and immunological determination of the LPS from *P. copri* which entailed the combined use of chemical analyses and degradations, NMR and mass spectrometry studies, as well as cell culture experiments. A novel LPS structure was disclosed which was reflected in a moderate activator of TLR4-mediated immune response.

andrea.citarella@unimi.it

D-Aspartate oxidase (DASPO) plays a crucial role in the catabolism of D-amino acids, particularly D-aspartate (D-Asp), an activator of *N*-methyl-D-aspartate (NMDA) receptors. Dysregulation of NMDA receptor function is implicated in various mental disorders such as schizophrenia. Thus, inhibiting DASPO could potentially elevate D-Asp levels in the brain, thereby improving NMDA receptors activity and offering therapeutic benefits.[1] Olanzapine, a well-known antipsychotic drug, has been identified as a potent inhibitor of DASPO, increasing extracellular D-Asp levels in the prefrontal cortex.[2]

Building upon this finding, we have employed Proteolysis Targeting Chimeras (PROTAC) technology to target DASPO using bifunctional compounds based on the structure of Olanzapine. The primary aim of PROTACs is to induce the degradation of proteins within cells *via* the proteasomal pathway, leading to an enhancement of intracellular D-Asp levels.[3] This innovative approach holds promise for addressing conditions associated with D-Asp deficiency.

We designed a panel of new bifunctional molecules starting from Olanzapine and incorporating aliphatic, amide-based, or PEGylated linkers (Figure 1). Chosen E3 ligase binders were lenalidomide and VHL ligand. Synthesis of the compounds was achieved through efficient "click" chemistry approaches. Preliminary biological evaluation revealed that MGA26 displayed significant DASPO inhibition (IC_{50} = 4.13 μM) and impacted cellular levels of DASPO.

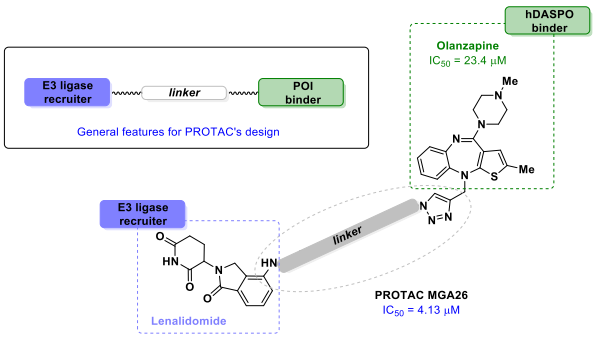

Figure 1: design of novel Olanzapine-based PROTACs targeting DASPO.

email:ecolarusso@unisa.it

Developing compounds targeting multiple pathways is a promising strategy in medicinal chemistry, offering synergistic effects and potential dose reduction. Here, the design, synthesis and biological behaviour of new compounds able to inhibit different targets within the arachidonic acid (AA) cascade are reported.[1] Starting from 1,3,4-thiadiazole based compounds (Figure 1), previously discovered by us as microsomal prostaglandin E_2 synthase-1 (mPGES-1) inhibitors,[2] we decided to modulate the inhibitory activity also against soluble epoxide hydrolase (sEH) and 5-lipoxygenase (5-LO). Therefore, we generated new combinatorial virtual libraries of molecules modifying the phenyl moiety at position 5, while keeping the substituents unchanged in position 2. After *in silico* investigations based on molecular docking calculations, the best-selected compounds were synthesized starting from substituted 2-(4-bromobenzylidene)hydrazinecarbothioamides, obtained by reaction between substituted 4-bromo-benzaldehydes and thiosemicarbazide followed by cyclization reactions with I_2 to give 2-amine-1,3,4-thiadiazoles. The final compounds were obtained using Pd-catalyzed Suzuki-Miyaura cross-coupling and acylation. The effects of synthesized molecules against the three targets of interest were investigated by different biochemical and enzymatic assays, disclosing **2**, **5**, and **7**, as active compounds able to inhibit all the three targets at low micromolar concentrations, while other six compounds showed dual inhibitor activity. Last, MTT assays were performed to evaluate the J774 murine macrophage cell viability, disclosing compound **2** as the most promising one for the *in vivo* and *ex-vivo* experiments of acute peritonitis model.

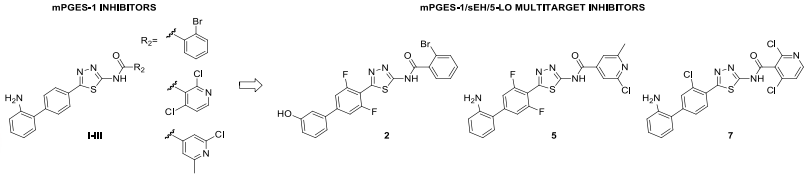

Figure 1: Structure of the initial hit compounds (**I-III**) and the active multitarget inhibitors (**2**,**5**,**7**).

giuseppe.dorazio@unimi.it

Glycoconjugate vaccines, which combine pathogen-associated carbohydrates with immunogenic carrier proteins, are a highly cost-effective strategy for preventing bacterial, viral, and fungal infections. While most licensed glycoconjugate vaccines currently derive their saccharide antigens from bacterial sources, synthetic oligosaccharide antigens offer a promising alternative[1]. These well-defined structures provide homogeneous constructs. *Haemophilus influenzae* (Hi), a significant cause of severe diseases like meningitis, sepsis, and otitis in young children, has recently seen an increased rate of invasive infections caused by Hi serotype a[2,3]. Unfortunately, no vaccine specifically targeting Hia is currently available. The capsular polysaccharide (CPS) of Hia consists of phosphodiester-linked repeating units of 4-β-D-Glucose-(1→4)-D-ribitol-5-(PO_4→) and serves as the antigen for protein-conjugated polysaccharide vaccines[4]. To explore the potential of Hia CPS as an antigen, we synthesized well-defined oligosaccharides with varying chain lengths, containing up to five repeating units (Figure 1). After optimizing the required monosaccharide building blocks synthetically, we assembled them through fine-tuned glycosylation reactions and combined them using the phosphoramidite approach. The resulting CPS-based Hia oligomers were then conjugated to the CRM_{197} carrier protein and evaluated for their immunogenic potential in a rat animal model. The results demonstrated that all prepared glycoconjugates induced antibodies that bound to Hia oligosaccharides; hence, the well-defined synthetic oligosaccharides can potentially mimic Hia CPS and the obtained glycoconjugates could be employed for the development of anti-Hia glycoconjugate vaccines.

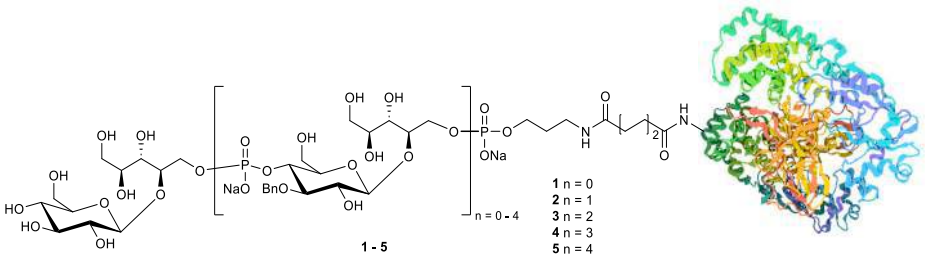

Figure 1: Structure of the synthesized Hia oligomers-CRM_{197} conjugates.

Affinity Enhancement of Protein Ligands by Reversible-Covalent Engagement of Lysine Residues

M. Mason, L. Belvisi, L. Pignataro, A. Dal Corso

Università degli Studi di Milano, Dipartimento di Chimica
Via C. Golgi, 19, 20133 Milan (Italy)
alberto.dalcorso@unimi.it

The design of synthetic small drugs capable of forming a covalent bond with the target protein of interest typically aims at stabilizing the drug-protein complex and to improve the pharmacological effects.

The amino acid Lysine (Lys) is highly abundant in the proteome and one of the most frequent residues on the outer structural layers of proteins. Due to thi s high frequency, the derivatization of synthetic ligands with aldehyde tags capable of imine bond formation with Lys ε-amino groups may represent a general strategy for the discovery of potent small-molecule inhibitors.

Ortho-hydroxy aldehydes such as pyridoxal or salicylaldehyde (SA) derivatives have been used to form imines in aqueous media, stabilized by an intramolecular H-bond between the imine N atom and the ortho-phenolic proton. By virtue of this reactivity, SA derivatives are being installed into various classes of protein ligands, aimed at the reversible-covalent engagement of protein Lys residues.[1,2,3]

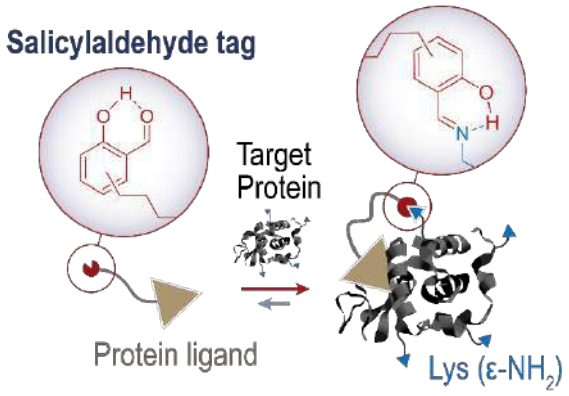

Figure 1: "Dock and Lock" mechanism of small protein ligands bearing the salicylaldehyde tag.

Leukemia inhibitory factor (LIF) is the most pleiotropic member of the IL-6 family of cytokines which plays a prominent role in inflammation, autoimmunity, and cancer. Its receptor is leukemia inhibitory factor receptor (LIFR, also known as CD118) and is expressed in liver, bone, uterus, and the central nervous system. After binding the cytokine, the transphosphorylation of Tyr1034 induces a conformation change which causes JAK1 activation. Thus, JAK1 initiates a cascade of tyrosine phosphorylation that stimulates three distinct signaling cell-type specific pathways. The JAK/STAT, MAP-kinase and PI(3)kinase pathways contribute to cell differentiation, survival and self-renewal; the balance of all these determines the cell fate. Several studies reported the role of LIF/LIFR axis in the cancer progression, even if the mechanism is poorly defined. Thus, the inhibition of LIFR signalling could have beneficial effects on cell growth and tumour progression in several cancers. In 2019, a novel study identified a first-in-class inhibitor of LIFR, EC359, which directly interacts with LIFR to block LIF/LIFR axis[1]. This compound can reduce invasiveness and stemness and promote apoptosis. Furthermore, first results obtained through in silico strategy have shown that mifepristone could act as LIFR antagonist[2]. Computational studies have also revealed that it partially overlapped the LIFR binding site. In view of the antagonistic activity of Mifepristone and EC359 on the LIF-LIFR axis, we focused our attention on the simplification and optimization of the synthetic process[3].

Discovering Cyclic Peptoids: Structures and Bioactivities of a Proteiform Scaffold

R. Schettini, A. De Cicco, G. Pierri, C. Tedesco, G. Della Sala, I. Izzo,[a] **F. De Riccardis**

Department of Chemistry and Biology "A. Zambelli", University di Salerno, Fisciano (SA), 84084, Italy
dericca@unisa.it

The field of peptoids (*N*-substituted glycines oligomers) is one of the most promising in the peptidomimetic arena. However, although hundreds of structures have been reported in recent times,[1] few reports deal with:

1) the interplay between the configurational and conformational ordering;[2]

2) the chelating attitudes of the oligoamide backbone and the biological activities of the metal complexes;[3]

3) their chemical transformation in further chemical entities (such as the azamacrocycles).[4]

In this communication we report studies correlating sequence, structures, and functions of α-cyclic peptoids and describe how crucial intramolecular interactions, cationic hosts, and strategically positioned stereogenic centers forge their morphologic attributes.

The advances in the field of cyclic peptoids represent the first steps for the foundations of a rational design of protein mimetics and a possible model on which to base drug design and supramolecular/biomimetic chemistry. Moreover, the expansion of large-scale monomer assembly and the shift towards water-soluble cyclic oligomers, will certainly enable cyclic peptoids to be used as high-information content structures with unexpected properties.

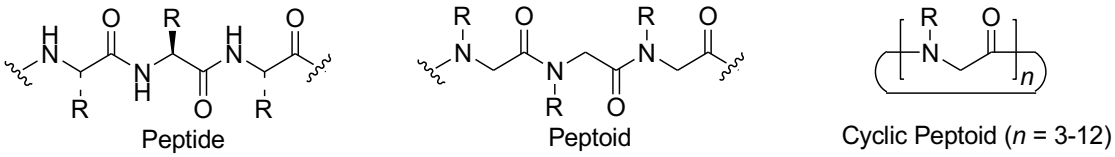

Figure 1: Structural comparison between a peptide, a peptoid and a cyclic peptoid.

Design and antimicrobial activity of short antimicrobial peptides (SAMPs) as promising agents against resilient infections

L. Ferrazzano,[a] T.D. Marforio,[a] S. Rizzo,[a] I. Di Stefano,[a] D. Corbisiero,[a] W. Cabri,[a] G.A. Gentilomi,[b] F. Bonvicini,[b] A. Tolomelli[a]

lucia.ferrazzano4@unibo.it

Concomitantly to the explosion in the development of potent antibiotics, a concerning rise in resistance to targeted drugs has emerged, largely attributable to the dual forces of antibiotic use selective pressure and spontaneous genetic mutations. Recognized as a threat to humanity, antibiotic resistance looms large. Thus, short antimicrobial peptides (SAMPs) emerge as a promising therapeutic alternative to traditional antibiotics.[1] SAMPs, characterized by their widespread occurrence and nonspecific modes of action, exhibit notable efficacy against a broad spectrum of bacteria, while displaying a reduced propensity for resistance development. Their inherent susceptibility to enzymatic degradation necessitates modifications for optimal performance, achieved through the incorporation of modified or unnatural amino acids into the peptide sequence or via C- and N-terminal functionalization, which also confer them hydrophobic and cationic nature, important for selective microbial binding and lysis. Our research was focused on the investigation of novel short peptides and peptidomimetics, starting from the smallest antimicrobial peptide sequence in Phase II clinical trials, LTX-109. Structural refinements to the original peptide sequence led to the discovery of new potent antimicrobial peptides with modulated lipophilicity, steric hindrance and charge, evaluated against both standard bacterial strains and clinical isolates from patients with chronic, non-healing infected wounds. Computational studies elucidated the mechanisms of action, establishing structural correlations with observed antimicrobial efficacy. In a targeted approach towards addressing chronic non-healing wounds, a selected SAMP was integrated into a multi-layered, non-adhesive biomaterial, offering a potential solution for enhanced wound treatment.

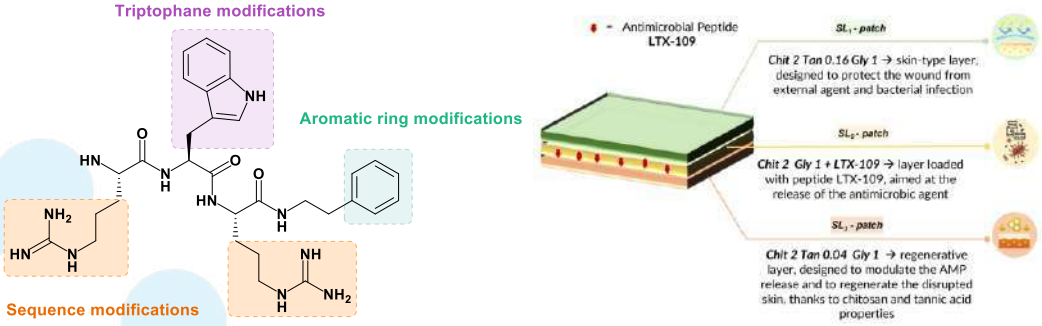

Figure 1. Structural modifications introduced in new SAMPs.

From design to in vitro evaluation, through synthesis: a new way of being an organic chemist.

C.G.Fortuna

Department of Chemical Science, University of Catania, Viale A. Doria, 6 95125 Catania, Italy
cosimo.fortuna@unict.it

Over time, organic synthesis has often been accompanied by paper-based planning and characterized by obtaining, sometimes unpredictably, reaction intermediates that were more interesting than the expected compounds. For a decade, especially in the field of the synthesis of new drugs, the design phase has become important; molecular modeling as well as docking have become tools to support, facilitate and streamline the organic chemist's synthesis work. In this presentation we will take a journey through drug-receptor interaction studies, which will support the synthesis of new heterocyclic compounds and/or the extraction of compounds from Bronte pistachio (FRASTUCA PRIN 2022 project; CUP: E53D2301006 0006) with potential antibacterial[1], anti-inflammatory[2] and anti-tumor activity[3]. In silico studies of the ADME properties and the predictions of in vitro activity which will be confirmed by the relevant in vitro and in vivo assays accompanied by mechanism of action prediction studies.

Analyzing the interaction between RNA and RBPs (RNA-binding proteins) by NMR spectroscopy: the introduction of small molecules as third wheel

I. Gado [a], M. Garbagnoli [b], R. Listro [b], S. Cauteruccio [a], P. Linciano [b], S. Collina [b], F. Vasile [a]

irene.gado@unimi.it

Hu (or ELAV-L) proteins belong to the class of RNA- Binding Proteins (RBPs) whose main role is to form complexes with mRNAs thus modulating the production of specific proteins.[1] HuR is a member of this family, and its target mRNAs encode proteins involved in cell growth, tumorigenesis, angiogenesis, tumor inflammation, invasion and metastasis. HuR overexpression is correlated with high-grade malignancy and poor prognosis in many tumor types.[2]

Previous studies[3] led to the identification of small, drug-like molecules able to interfere with HuR - RNA complexes by applying different approaches (*in silico* studies combined with STD NMR, virtual screening, and fragment-based drug discovery).

We present here the interaction studies between members of the new series of designed and synthetized ligands with HuR obtained by Saturation Transfer Difference (STD) NMR. Moreover, we report on NMR competition studies in presence of RNA fragment, to confirm that the ligands can bind HuR in the RNA binding site.

To overcome the limitations due to RNA handling, that can affect the NMR results, we exploited the use of Peptide Nucleic Acid (PNA) fragments as RNA mimics, using the RNA sequence of TNFα transcript (PDB code: 4ED5). Results clearly show that in STD experiments PNA can be used instead of RNA.

The method herein proposed is a worth alternative for identifying molecules that can effectively modulate HuR-RNA complexes, as potential pharmacological agents.

Furthermore, this approach will support research on more RNA-binding proteins.

Synthesis of stereoisomeric cannabidiols

D. Lanaro,[a] P. Allegrini,[a] A. Gambini,[a]

[a] *Indena SpA, via Don Minzoni 6 - 20049 Settala (MI), Italy*
email: daniele.lanaro@indena.com

(-) trans-Cannabidiol (CBD) is a not narcotic natural phytocannabinoid first isolated from hemp (*Cannabis sativa* L.) in 1940 by Adams. CBD is the active constituent of Epidiolex, a drug used to treat some rare forms of epilepsy otherwise refractory to pharmacological treatment, like the Lennox-Gastaut syndrome. CBD has a broad pharmacological profile, which include anxiolytic and anti-dyskinesic activity.[1] Remarkably, while (-)-CBD has modest affinity for CB1 and CB2 receptors, its unnatural enantiomer [(+)-CBD] is a high-potency ligand for both receptors,[2,3] suggesting that stereochemistry is critical for biological activity. Since both *cis*-enantiomers of Δ^9-THC occur in *C. sativa*, we wondered if the *cis*-isomers of CBD also occurred in the plant, and what their biological profile would be. Inspired by chemistry reported in the proprietary literature, we have developed a total synthesis of both enantiomers of *cis*-CBD starting from phloroglucinol (**2**). The key reaction is the initial Friedel-Craft reaction, which gave the *trans* isomer as the major compound along with ca. 5 % of its *cis*-isomer **3** (NMR quantification). The crude reaction mixture was purified to afford **3**, which then underwent, after phenol activation at the *para*-position and protection at the two *ortho* positions, Negishi cross coupling and reductive deprotection, affording **7** in configuration depending on the chirality of the limonene-derived terpene **1**. The conformation and biological profile of the final products will be discussed.

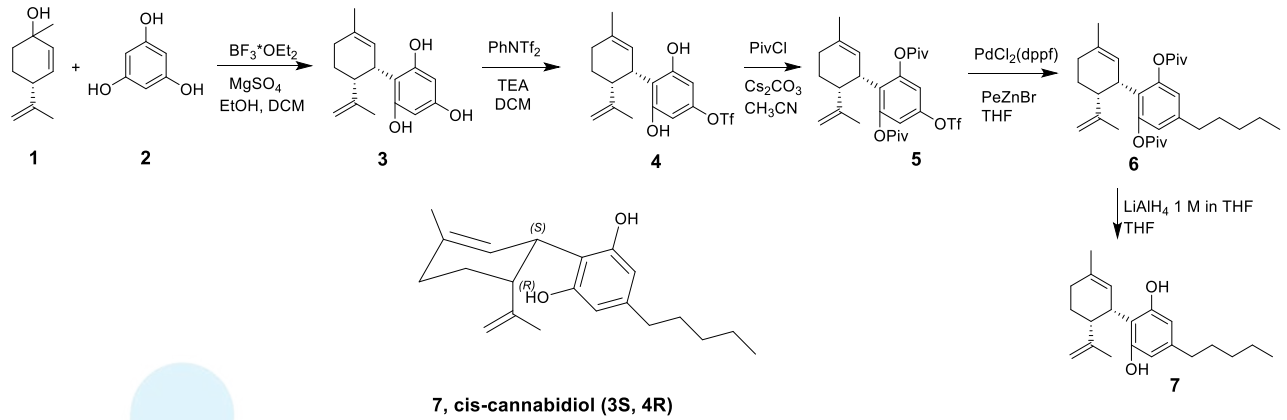

Figure 1: synthetic route to *cis*-cannabidiol **7**.

alberto.minassi@uniupo.it

Natural product chemistry is constantly challenged by newly discovered complex molecules with unprecedented frameworks frequently characterized by interesting biological activity. Unfortunately, they are usually produced in small amounts and, for their total synthesis, a limit of what is considered sensible in terms of steps and yield is frequently reached. As an alternative, semisynthetic approach could be a solution to provide answers to the pressing demand for sustainable, facile and concise routes even to the most complex targets.[1]

Remodelling the carbon skeleton of natural compounds represents a powerful tool in organic chemistry to rapidly generate new natural-like libraries to study different biological processes. Bond breaking, and structure rearrangements are dominant features in the photoreactivity of 4,4-dialkyl-2-cyclohexenones that irradiated undergo to the lumiketone rearrangement giving bicyclo [3.1.0] hexenones as well demonstrated in testosterone like compounds.[2]

In this field, we explored the photoreactivity of Δ^1-3-keto-pentacyclic triterpenic acids and of Δ^1-3-keto-dihydrocholesterol obtaining new *lumi*-derivatives through a stereoselective rearrangement of the A/B rings.

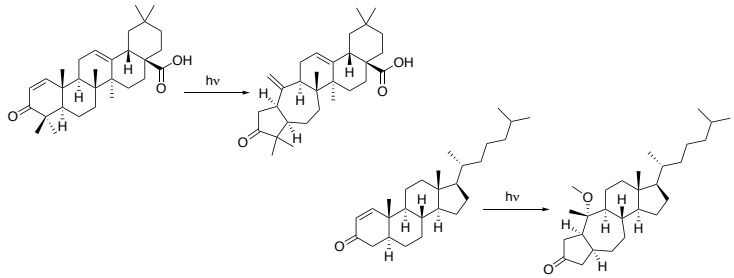

Figure 1: *lumi*-rearrangement of Δ^1-3-keto-triterpenoids

The mechanism of the rearrangement along with the possible applications to the synthesis of complex natural compounds will be discussed.

Synthesis of a novel 4th generation of TKI targeting L858R/T790M EGFR: exploring the reversible drug binding dynamics by plasmonic nanoantenna-based SEIRA structures and atomistic simulations

C. Minnelli,[a] G. Mobbili,[a] E. Romagnoli,[a] E. Laudadio,[a] L. Sorci,[a] G. Birarda,[b] F. Piccirilli,[b] R. Galeazzi,[a] A. Toma[c]

c.minnelli@staff.univpm.it

Targeted therapy with tyrosine kinase inhibitors (TKIs) is the standard of care for patients with non-small cell lung cancer (NSCLC) harbouring mutations of the epidermal growth factor receptor (EGFR) gene. First-line therapy of mutated EGFR forms, such as L858R/T790M, is often osimertinib, a 3rd generation irreversible TKI, but of about 30% of patients develop the C797S mutation, which prevents the formation of the covalent bond with 797 residue[1]. Here, we report the *in silico* design, synthesis, and biological evaluation of a novel chemical entity as a reversible wild-type sparing EGFR inhibitor. Starting from our previous work, the 6-(4-nitrophenoxy)-2-(3-phenoxyphenyl)-4H-chromen-4-one (**FL-4**)[2] was modified to increase the potency and efficacy toward EGFR L858R/T790M mutant. From the results obtained a novel TKI (**FL-28**) was identified with an IC50 120-times lower with respect to **FL-4** for the EGFR L858R/T790M form. Finally, to provide insights on the conformational variations of EGFR induced by **FL-28**, a previous optimized plasmonic nanoantenna-based SEIRA (Surface-Enhanced Infrared Absorption) structures was used. Results suggested variations of helix hydration, ascribable to the ability of compounds to induce the transition of mutant EGFR from the constitutive active to the inactive EGFR conformation. Structurally similar analogues have been synthesized and the following inhibition assays underlined the importance of the presence of acrylamide group and methyl group linked to the A ring of flavone scaffold.

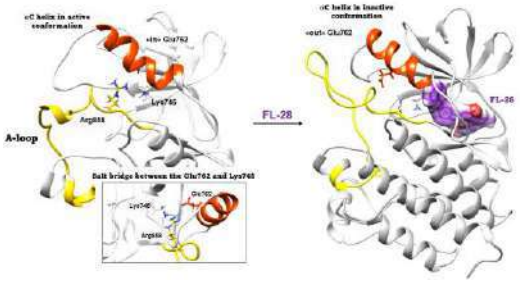

Figure 1: Conformational changes induced by FL-28 to the EGFR L858R/T790M.

A functional proteomics-based multidisciplinary strategy for the Drug-Target Deconvolution of a novel cytotoxic thiadiazolopyrimidone

E. Morretta,[a,b] D. Ruggiero,[b] R. Belvedere,[b] A. Petrella,[b] I. Bruno,[b] S. Terracciano,[b] M. C. Monti.[a]

[a] *Department of Pharmacy, University of Naples Federico II, via Domenico Montesano 49, Naples (NA), Italy*
[b] *Department of Pharmacy, University of Salerno, via Giovanni Paolo II 132, 84084, Fisciano (SA), Italy.*
emorretta@unisa.it and elva.morretta@gmail.com

In recent years, thiadiazol-pyrimidine derivatives have been acknowledged for their attractive poly-pharmacological profile, thus representing excellent candidates for Drug-Target Deconvolution strategies, aiming at the identification of their full spectrum of protein targets. In this scenario, we disclosed the interactome of the lead compound of a small set of cytotoxic thiadiazolo-pyrimidinones, namely compound **1** (i.e., 2-(5'-bromo-2'-ethoxy-[1,1'-biphenyl]-4-yl)-7-methyl-5H-[1,3,4] thiadiazolo [3,2-a] pyrimidin-5-one), through *label-free* functional proteomics strategies based on limited proteolysis. Such approaches are indeed straightforward methods enabling an *in-solution* study of protein/molecule binding through the evaluation of the compound-induced protein conformational changes, either at a protein level (i.e., protein-centred approaches) or at a peptide level (i.e., peptide-centred approaches)[1,2].

Thus, our strategy comprised both protein-centred and peptide-centred approaches, respectively Drug Affinity Responsive Target Stability (DARTS)[3] to identify, in complex mixtures, proteins whose proteolytic response was altered by the interaction with compound **1**, and targeted-Limited Proteolysis coupled to Multiple Reaction Monitoring Mass Spectrometry (t-LiP-MRM)[4] to observe the conformational fluctuation induced at a peptide level, pinpointing compound **1** interacting protein region(s) putatively involved in the binding, either locally or distally.

Thus, DARTS allowed us to disclose Annexin A6 (i.e., ANXA6) as compound **1** main cellular target in HeLa cell lysates, and such interaction was then validated by both Western Blotting, Thermal Shift Assays and Surface Plasmon Resonance. Subsequently, t-LiP-MRM was performed to evaluate compound **1**-ANXA6 interaction features, via the comparison of ANXA6 tryptic profile in samples treated or not with the molecule and submitted to limited proteolysis with subtilisin and then to an extensive trypsinization. ANXA6 conformational changes due to compound **1** interaction were thus identified in the protein C-terminus. To then estimate the consequences of such an interaction, biological assays were performed, proving the ability of compound **1** to inhibit Ca^{2+} transition, as well as HeLa cells migration and invasion[5].

vera.muccilli@unict.it

Biocatalysis, using defined enzymes for organic transformations, has emerged as a tool in organic synthesis, finding widespread application in various industrial sectors. Laccase (EC 1.10.3.2), is a copper-containing protein within its active site. Renowned for its mild and environmentally friendly oxidation, laccase utilizes atmospheric oxygen as a reactant, yielding water as a by-product. The versatile nature of laccase-mediated reactions generates a diverse array of products through radical coupling mechanisms, further augmented by the use of mediators to expand substrate compatibility.

Magnolia species' bark and leaves contain oligomeric compounds derived from two neolignans, magnolol and honokiol, which are renowned for their diverse biological activities.[1,2] However, limited extraction yields and the necessity for extensive purification steps have impeded comprehensive investigations into their biological effects. Overcoming these challenges requires the development of synthetic strategies to facilitate a broader exploration of their biological potential. This work focuses on synthesizing two honokiol oligomeric compounds, Houpulin A and B, utilizing laccase as a catalyst. This approach boasts significant advantages, employing buffer solution and eliminating the requirement for organic solvents and mediators. Employing optimized reaction conditions, we successfully synthesized two additional oligomers: the magnolol dimer and a honokiol-magnolol dimer. These compounds were subjected to in vitro spectroscopic analyses and molecular docking investigation, revealing their potential as novel α-amylase, α-glucosidase, and lipase inhibitors, thus presenting promising candidates for addressing conditions such as type 2 diabetes and obesity.

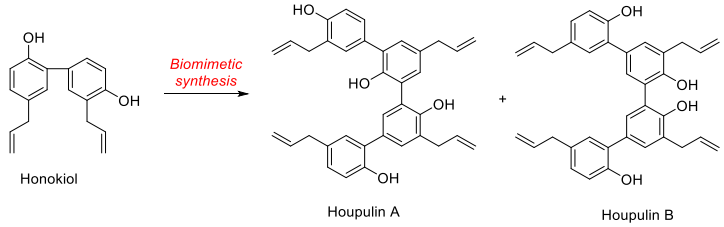

Figure 1. Biomimetic synthesis of Houpulin A and B.

An improved mRNA delivery system for injury repair and regeneration therapy

Li Benhao[1], Ni Qianqian[1*]

[1] *National University of Singapore, 4 Science Drive 2, Singapore*
qqian.ni@nus.edu.sg

The inherent fragility of mRNA poses a significant challenge due to its susceptibility to degradation. Although lipid nanoparticle technology has been validated as an effective route for mRNA delivery, the interaction of certain chemical functionalities, such as oxidation, can destroy the integrity of mRNA structures and lead to translation errors.[1] Enhancing the stability of mRNA becomes paramount to ensure effective translation and therapeutic outcomes of mRNA therapeutics. Our group has been dedicated to address the challenges facing mRNA therapeutics by developing novel delivery systems and RNA modification techniques for enhanced nucleic acids delivery.[2-4] Here, we report an improved lipid nanoparticle (LNP) system to enhance mRNA stability and demonstrate its superiority in mRNA delivery for injured hepatocytes restoration. Briefly, a library of antioxidant lipids (AO-lipid) was obtained successfully through one-step esterification reaction by introducing antioxidant groups including sulfhydryl, phenol, and its derivatives into ionizable lipid (Figure 1). Combinational screening and systemic investigations of these AO-LNPs reveal the importance of structure design in enhancing antioxidation effects. In both acute liver injury and chronic liver fibrosis animal models, hepatocyte-growth-factor (HGF) mRNA delivered by lead AO-LNP could effectively attenuate inflammation and fibrosis via modulation of liver macrophages and hepatic stellate cells as demonstrated by liver damage biomarker detection, single cell sequencing and histologic examination. Overall, our study provides insights into antioxidation LNP for more effective mRNA therapeutics application.

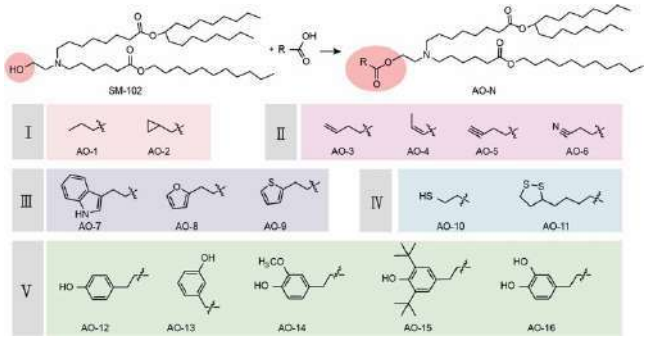

Figure 1: Ionizable antioxidant lipids (AO-lipids) developed for mRNA delivery.

State-of-the-art molecular docking and computer aided methods in the study of natural products, from single molecules to complex matrices

L. Pulvirenti,[a] T. Strano,[a] L. Siracusa,[a]

[a] *Istituto di Chimica Biomolecolare del CNR, sede secondaria di Catania, Via P. Gaifami, 18- 95126, Catania, Italy*
l.pulvirenti@icb.cnr.it

Since ancient times, plant derived natural products have been used as remedies for the treatment of a variety of diseases and phycological disorders. Today, based on modern characterization tools, single molecules isolated from vegetable matrices and natural extracts from plants can be considered as a nearly unlimited source of potential new drugs with less side effects for the treatments of a plethora of affections with high percent of morbility characterized by the appearance of prolonged oxidative stresses, like chronic diseases of metabolic syndromes.

In this context, the exhaustive characterization of vegetable extracts in terms of secondary (specialized) metabolites allows investigating their potential as antioxidants and their compatibility with biological targets imputable to the occurrence of degenerative diseases as single compounds or as complex matrices components through the use of computer based methods.

Exploiting our knowledge both in terms of characterization of complex plant matrices[1], and molecular docking of natural products[2,3], our activity aims to:

1) analyse from a biochemical point of view the metabolic profile of complex plant matrices considered an excellent source of biologically active compounds by means of MS-based tools

2) use computer based investigations on selected biological targets as preliminary biological evaluation tool in the study of potential drugs.

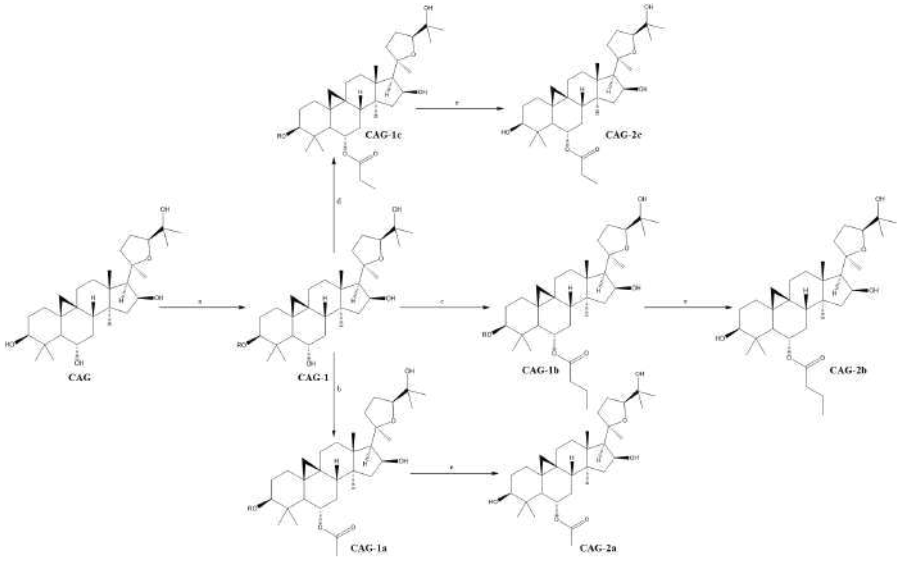
e-mail: mpromano@unisannio.it

Cycloastragenol (CAG) with steroid-skeletal characteristics is a cycloartan saponin of Astragaloside IV (AG-IV) which is one of the main active components of *Astragalus membranaceus*. It is considered as valuable clinical choice for those specific diseases caused by inflammation, oxidative stress, cell senescence, or autophagy. In addition, Cycloastragenol is the only telomerase activator reported in natural products, which is closely related to MAPK and PI3K/Akt signaling pathways[1]. Our group has long been engaged in drug discovery projects using natural compounds as guide structures and considering the above highlighted, the aim of this study was to synthesize a new library of small synthetic modifications to produce semi-synthetic derivatives for enhancing the binding towards the target (**Scheme 1**).



Scheme 1: **a)** Im (6 eq.), TBSCl (4 eq.), DMF, rt, 3h30', 63%; **b)** Ac_2O (18 eq.), Pyridine, 5°C, 24h, 47%; **c)** Butyryl chloride (9 eq.), Pyridine, 5°C, 7h45', 45%; **d)** Propionic anhydride (18 eq.), Pyridine, 5°C, 24h, 98%; **e)** CSA (4 eq.), MeOH, rt.

In *vitro* studies of all synthetic derivatives on HCT 116 and NF-κB reporter (Luc)-HCT-116 cell lines, have been designed to monitor Nuclear Factor Kappa B (NF-κB) signal transduction pathways and evaluate the crosstalk between tumor development and inflammatory processes.

Food industry uses processes involving acid or basic treatments, combined with heat, to extracts proteins both from plant and animal sources. Among the most employed treatments, basic pH and high temperature for long-duration treatments were proven to induce strong amino acids racemization. The presence of D-amino acids inside proteins can obviously change their digestibility and consequently the absorption of essential and non-essential amino acids. Likewise, changes of digestibility may also affect the release of bioactive peptides and the functionality of foods beyond their nutritional aspects. Indeed, during gastrointestinal digestion, proteins are normally cleaved into peptides and amino acids, which can be absorbed by our body. The hydrolysis of food proteins in our gastrointestinal tract is catalysed by specific proteases. However, the molecular details of how much the digestive process is affected by the racemization are still largely unknown. In this work the behaviour of the main stomach and gut digestive enzymes in the presence of D-amino acids in the protein chain was monitored over time using a model peptide where L-amino acids were systematically substituted by D-amino acids. To perform this study, a peptide belonging to β-lactoglobulin was chosen as a model for a protein chain containing diverse amino acids. The model peptide contained cleavage sites for pepsin, trypsin, and chymotrypsin. Several peptides having identical sequence were then also synthesized by systematically introducing a D-amino acid in each different chain position. Then, the hydrolysis of the model peptide, and of all its D-amino acid containing homologues, both by pepsin and by trypsin/chymotrypsin, was monitored by LC-MS, allowing to evaluate the behaviour of the digestive enzymes in the presence of D-amino acids, not only at the cleavage sites, but on all the peptide sequence. The results showed several changes in the behaviour of digestive enzymes, not only when the D-amino acids are inserted at the specific cleavage sites, but in some cases also when in distant positions. Interestingly, the effect seemed more pronounced in the case of pepsin rather than the gut enzymes. The results demonstrated that protein racemization impairs nutritional value by slowing down digestibility and has different effects according to the enzyme/amino acids involved.

A dimeric receptor for the recognition of adenine derivatives via triplex-like interactions.

S. Volpi,[a] N. Rivi,[a] M. Neri,[a] S. Korom,[a] R. Corradini[a]

e-mail: stefano.volpi@unipr.it

The pattern of interaction holding natural T-AT and C^+-GC nucleobase triplets can be artificially reproduced by using tailored nucleobases that recognize both the Watson-Crick and Hoogsteen domains of purine targets.[1] To develop a novel model of this kind of nucleobases, we designed the dimeric receptor **1** (**Figure 1a**), in which two uracil units are arranged on a naphthalene scaffold to bind adenine derivatives by triplex-like base pairing. This compound was tested in the complexation of 9-ethyl adenine (**9-Et-A**) by a series of ^{1}H NMR titrations ($CDCl_3$, 50°C), estimating an association constant (*Ka*) of $4 \cdot 10^5$ M^{-1}. The monomeric control compound **2** (**Figure 1b**), instead, recognized the same substrate with *Ka* = 58 M^{-1}, suggesting a high cooperation between the uracil units of **1**. The chemical shift perturbations observed during the titrations, in combination with NOESY experiments, evidenced a structural rearrangement of **1** in the presence of its target and suggested the formation of triplex-like interactions (**Figure 1a**). Also, a $CDCl_3$ solution of this receptor sequestered 40% of adenosine from D_2O, forming of an insoluble 1/1 complex at the interphase. When a mixture of all the four ribonucleosides was present in the D_2O layer the same 1/1 complex was isolated from the interphase, demonstrating the selectivity of **1** for adenosine. Instead, the monomeric control compound **2** did not cause any precipitation.

Currently, we are evaluating the conversion of **1** into an artificial nucleobase for peptide nucleic acids (PNAs), with the aim of using the resulting oligomers as probes for the direct detection of point mutations on relevant oncogenes (i. e. liquid biopsy).[2]

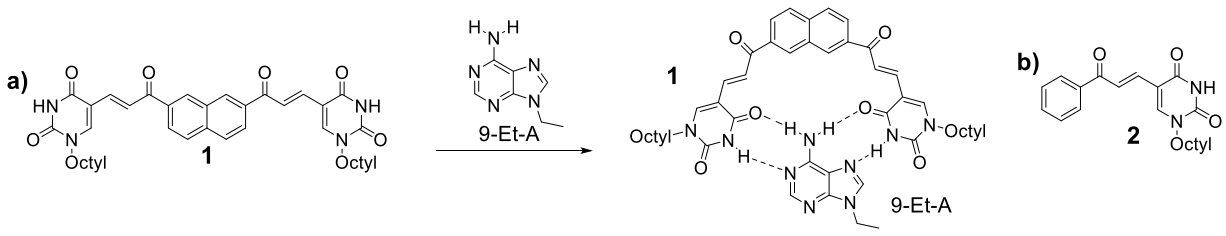

Figure 1: **a)** Complex formation between receptor **1** and **9-Et-A**. **b)** Monomeric control receptor **2**.

alfonso.zambon@unimore.it

Protein Kinase Inhibitors (PKIs) have emerged as a major class of anti-cancer agents, with over 70 approved drugs in 2021. A crucial limit of this therapeutic approach is the frequent development of drug resistance in treated patients, which can occur through several mechanisms such as pathway reactivation and mutation of the kinase domain.[1] Strategies to overcome drug resistance include the development of new tailored inhibitors with alternative binding modes, the identification of drugs with increased affinity towards the target protein and the use dual/multi targeting compounds, able to block simultaneously different signalling pathways.[1,2]

We will present some case studies showcasing each of these approaches, including the rational development of broad-targeting compounds showing efficacy in clinical trials.[3] We will illustrate the use of *in-silico* tools for the design of new compound and the structural elucidation of the mechanisms of resistance (**Figure 1A**),[5,6] and the optimization of *ad-hoc* synthetic routes and methodologies designed to access more efficiently the chemical space of the target inhibitors.[5] These routes were designed to comprise a limited number of high yielding steps with little purification issues and to introduce the main diversity points of the scaffold late in the synthetic line, in order to limit the number of exclusive reactions needed for each analogue (**Figure 1B**).[5]

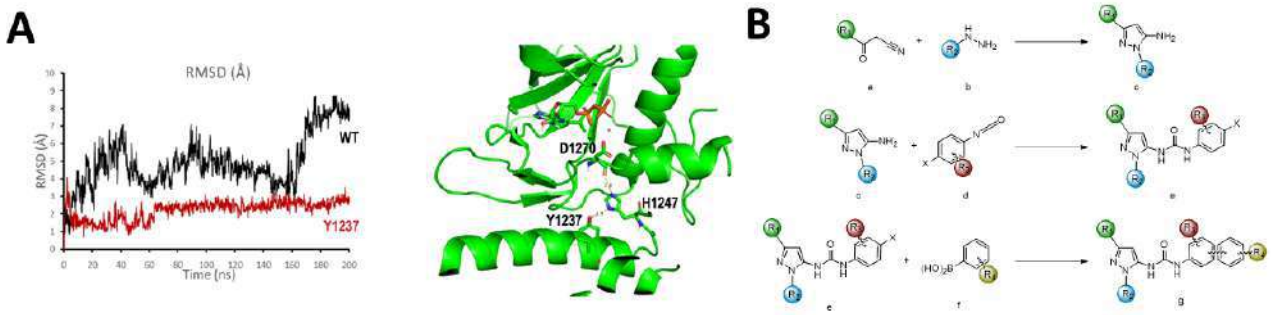

Figure 1 A *in-silico* tools guide design of new compound and structural elucidation of mechanisms of resistance **B** synthetic route to target compounds are designed to access efficiently their chemical space

The encounter between metal-organic cages (MOCs) and gels gives rise to formation of novel nanomaterials. These new materials are characterised by the presence of dual porosities, derived from the cage's cavity and the gel meshes.[1] Advances in this field may contribute to the development of next-generation materials for molecular separation or purification of environmental pollutants.[1] Among the possible gelators, low-molecular weight peptides are very intriguing and are yet applied for different applications as templation of nanoparticle[2] or catalysis[3]. This work reported the formation by sub-component self-assembly (**Figure 1**) of three $Fe^{II}_4L_4$ MOCs containing enantiopure peptides functionalities on the sidechain with sulfur atoms. The use of enantiopure peptides guaranteed the preferential formation of one of the two possible diastereomers, suggesting the chirality transfer exerted by the peptide to the metal vertices. The MOCs gelation has been triggered by coordination between thiol groups of peripherical peptides and the second metal ions, Ag^+, Zn^{2+}, Hg^{2+} (**Figure 1**). The gels displayed the formation of spherical nuclei that interconnect forming the 3D network instead of peptide alone that generally gave rise to formation of fibrils. This gelation in the presence of heavy metals holds promise for the removal of toxic metal ions from the environment.

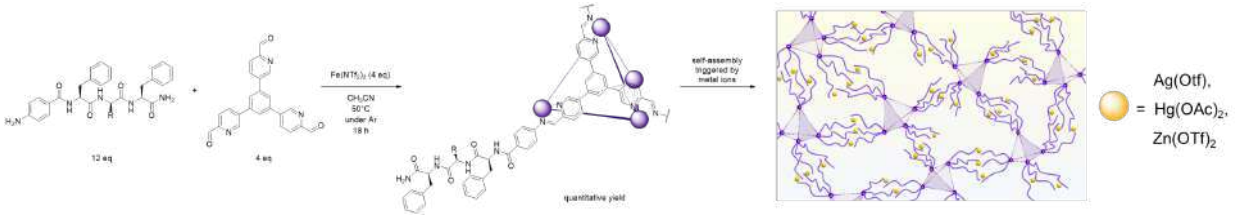

Figure 1: General MOCs synthetical protocol and gelation trigger by metal ions coordination.

A Detailed Investigation of the Sensing Mechanism of an Azocalix[4]arene Chromoionophore

L. Baldini,[a] D. Balestri,[a] L. Marchiò,[a] A. Casnati[a]

[a]*Dipartimento di Scienze Chimiche, della Vita e della Sostenibilità Ambientale, Parco Area delle Scienze 17/A, Parma*
laura.baldini@unipr.it

Calix[4]arenes functionalized with azo groups at the upper rim and cation binding sites at the lower rim are widely used as chromogenic sensors due to their facile synthesis and significant absorption band shifts upon complexation.[1] Despite their popularity, however, a detailed investigation of their sensing mechanism, arising from an azo-phenol – quinone-hydrazone tautomerism, remains unreported.

In this study, we present the synthesis of a novel azocalixarene ligand and investigate its complexation behavior with Ca^{2+} both in neutral and basic conditions. The complete characterization of the metal complexes in solution (by ^1H NMR and UV-vis spectroscopies) and at the solid-state (by X-ray diffractometry), allowed us to elucidate that cation complexation prompts a shift in the tautomeric equilibrium toward the quinone-hydrazone form (Figure 1), while deprotonation of the complex leads to the reversion to the azo-phenol tautomer. At the same time, the hydrazone NH groups provide an anion binding site for the counteranions.[2] Finally, complexation of different chloride salts and of different calcium salts gives rise to different colour changes, allowing naked-eye detection of both metal ions and of anions.

Transparent photovoltaics (TPV) is an emerging and disruptive technology in which the solar cells selectively transmit the visible light to human eyes harvesting UV and/or NIR photons.[1] TPV is attractive as it widens the deployment of PV into new sectors, like building integrated photovoltaics (BIPV), greenhouses, car windows and sunglasses, thus providing an immense potential to generate solar electricity beyond the conventional rooftops and solar power plants. One possible approach to TPV is based on wavelength-selective absorbers where the dye requires an absorption far from the photopic response of the human eye.

Limited classes of dyes possess energetic levels that can ensure an efficient injection while having a bandgap sufficiently narrow to selectively absorb the NIR region.[2] Among these classes, cyanine dyes are promising for their high molar extinction coefficient and easily tunable properties through modification of central core or lateral units and have already been investigated for dye sensitized solar cell (DSSC) devices with promising results in terms of transparency and performance. Fully transparent and colorless DSSC were built reaching 80% transmittance in complete devices.[3,4] The aim of the present work was the development of a library of NIR dyes in order to increase the device's efficiency and stability without losing transparency.

The synthesis of new series of NIR cyanines dyes have been performed in a one or two-step reaction. A simple crystallization of the crude products yielded very low cost and industrially scalable products.

These new sensitizers have been deeply characterized in terms of their optical, photophysical and electrochemical properties, showing interesting structure/property relationships. Finally, photovoltaic performances have been evaluated in lab-scale DSSCs and optimized by different anode modifications and electrolyte formulations.

Tailored Metal-Porphyrin Based Molecular Electrocatalysts for Enhanced Artificial Nitrogen Fixation to Green Ammonia

O. Bettucci,[a] G.Salerno,[a] N.Manfredi,[a] A. Abbotto [a]

[a]*Dipartimento di Scienza dei Materiali, Università degli Studi di Milano-Bicocca, and INSTM Milano-Bicocca Research Unit, Via R. Cozzi 55, 20125-Milano, Italy.*

Electrochemical nitrogen reduction reactions (E-NRR) are one of the most promising approaches to obtain NH_3 sustainably. However, scarce ammonia yield and low Faradaic efficiencies still limit their use on a large scale. For these reasons, efforts focus on studying different E-NRR catalyst structures and formulations. Among all E-NRR catalysts, molecular materials such as metal-porphyrins emerged as an encouraging option due to their planar structures which favour the interaction with the *d* orbitals of the metal, responsible for the adsorption and activation of nitrogen. Nevertheless, the high hydrophobicity of porphyrins limits the aqueous electrolyte-catalyst interaction limiting the NH_3 yield. Following our previous general approach for organic design for solar generation of green hydrogen,[1] in this communication we present our work on the investigation of a series of metal-porphyrins, which have been properly functionalized in order to enhance nitrogen fixation performance. In particular, we have developed two series of hydrophilic triethylene glycol chains (TEG) and hydrophobic ethylhexyl chains (EH) derivatives, able to show different interactions at the interface with the aqueous electrolytic environment of the electrochemical cell, thus affecting the device interface phenomena and, eventually, the final response. [2]

Sustainable Horizons: Unleashing the Power of Earth-Abundant Metal Complexes in Photo-driven CO_2 Reduction

C.Bizzarri,[a]

[a]*Institute of Organic Chemistry, Karlsruhe Institute of Technology, Fritz-Haber-Weg, 6, 76131 Karlsruhe (Germany)*
Claudia.bizzarri@kit.edu

The contemporary scenario of climate change and the rapid depletion of Earth's resources necessitates a shift towards sustainable practices. This imperative accentuates the critical need to harness renewable resources in tandem with renewable energies. Transition metal complexes emerge as promising candidates for enhancing the photocatalytic activity and efficiency in solar energy conversion.[1]

Our research is motivated by the understanding that for these catalysts to be practically viable, they must be readily available and cost-effective, emphasizing the use of earth-abundant materials. Drawing inspiration from nature, we focus on the conversion of carbon dioxide into reactive molecules.

In this context, we introduced novel mononuclear and binuclear Cu(I) complexes, characterized by their favorable photophysical and electrochemical properties as photosensitizers. Their tunable properties, achieved through the modification of their diimine ligands, render them suitable for integration into photocatalytic systems aimed at reducing CO_2 using blue light.[2] Expanding our explorations, we have dedicated efforts to designing new CO_2 reduction catalysts centered on Fe(II) and Co(II).[3,4] The catalytic system, facilitated by a Cu(II)-photosensitizer, has demonstrated remarkable performance, achieving a TON of 576 and a quantum yield of up to 7%. Additionally, we have investigated the formation of syngas through competitive H_2 production.[3] Selective control over CO versus molecular H_2 has been a focal point of our research, leading to the development of a new cobalt complex. Optimization of a complete, earth-abundant photocatalytic system using a copper-based photosensitizer has resulted in an impressive selectivity of up to 99% towards carbon monoxide.[4] This presentation will delve into the latest results,[5] offering insights into ongoing research challenges and the strategies employed to address them.

Chiral-chiral interactions as determining factors in gelation processes

M. Cacioppo,[a] S. Marullo,[a] F. D'Anna,[a]

[a]*Dipartimento di Scienze e Tecnologie Biologiche, Chimiche e Farmaceutiche (STEBICEF), Università Degli Studi di Palermo, Viale Delle Scienze, Ed. 17, Palermo, 90128, Italia*
michele.cacioppo@unipa.it

The design of chiral materials represents an interesting field in chemistry and nanotechnology due to the multiple applications that they could access.[1] In this context, chiral gels represent a feasible material concept and could be obtained by proper chiral precursors, giving the advantage to obtain chiral scaffolds readily employable as chiral media, sensors, catalysts and chiro-optics tools.[2] In the wide panorama of chiral gels, studies are generally focused on hydro- or organogels where organic chiral gelators activate the gelation process in aqueous or organic liquid media.[3] Apart from the widely employed organic molecules as gelators, organic salts resulted in high valuable supramolecular building blocks in the field.[4] Consequently, the use of chiral organic salts could represent an interesting alternative, and advantageous strategy, to access chiral gel materials. With respect to organic medium, we focused on the less investigated Deep Eutectic Solvents (DES) that represent a greener alternative with interesting physico-chemical properties.[5] In the context of chiral gels, this contribution would give first insights into the study of chiral eutectogels through the employment of chiral organic salts, composed of diimidazolium based cations and *L*- or *D*-tartrate anions. Moreover, chiral small molecules have been employed during the gelation process to study the effect on the supramolecular gel structure formation, the related properties, and the feasibility of obtaining multicomponent gels. Our results demonstrate how chiral-chiral interaction could be a useful tool to tune gel properties.

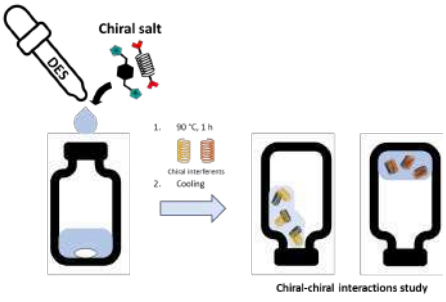

Figure 1: Schematic representation of the chiral eutectogel synthesis study case.

Chiral π-conjugated molecules are attractive starting materials for the preparation of optoelectronic devices such as Circularly Polarized Organic Light-Emitting Diodes (CP-OLEDs) and CP-lasers. Elements of asymmetry in the starting material result in the formation of chiral supramolecular architectures and ultimately affect the electronic properties of the substrate in thin films.[1] Within the framework of our research program on the functionalization of azole nuclei,[2-5] we synthesized four distinct novel chiral chromophores by decorating the imidazole-based π-conjugated systems with enantiopure (*S*)-β-citronellol as the chiral aliphatic moiety (Figure 1). Three general strategies were approached for the preparation of the π-conjugated systems: 1) dehydrogenative alkynylation, 2) direct C–H arylation, 3) one-pot bromination/Sonogashira coupling. (*S*)-β-citronellol was introduced in the last step of the syntheses *via* Knoevenagel condensation. The resulting compounds exhibited CP absorption and emission properties in homogeneous thin films, with consistent chirality on both faces. Interestingly, small structural variations led to significant changes in the origin and magnitude of solid-state chiroptical properties. The introduction of a single acetylene moiety in the π-linker afforded remarkably high dissymmetry g-factors (10^{-1}) in spin-coated film, thus holding significant potential as fundamental component in optoelectronic devices. Finally, tackling the need of a cost-effective and compact device for detecting chiroptical properties, a novel and easy-to use instrument setup was developed.[6]

michele.ciulla@unich.it

Anthropogenic gas emissions and global warming are huge challenges that today's society must face and address by exploiting renewable resources and methods to capture and remove CO_2 from the atmosphere [1]. Carbon capture and storage technologies (CCS) have been proposed to minimize CO_2 emissions during energy production, since they enable the utilization of strategic gas mixtures released during combustion processes, and of potential energy sources like biogas [2]. Currently, most of the CCS technologies adopt systems that pose high risks to the environment and human health, because of toxic chemicals (amine scrubbing), high-pressure processes (pressure swing adsorption), etc [3].

The aim of this work falls within the PRIN 2022 PNRR project CHARYBDIS (Carbon-High AdsoRption bY Bi-functionalizeD solId Sorbents, CUP D53D23016970001, funded by the European Union – Next Generation EU) led by the University "G. d'Annunzio" of Chieti – Pescara, and the University of Messina as a research unit, in which materials based on graphene derivatives will be produced and tested for a highly selective and efficient CO_2 capture in strategic gas mixtures.

In particular, nanoporous graphene oxide (nGO) suitably derivatized with modified tetraethylene pentaamine (m-TEP) containing amide, azide or urea functional groups, are being prepared to be used for CO_2 separation technologies for biogas and syngas gas mixtures.

A set of different preliminary tests on adsorption capacity at different temperatures and pressures were carried out, with particular attention to the capacity of this new compounds to adsorb and release CO_2 in mild condition, a fundamental requirement in terms of eco-sustainability and energy requirements. Cyclability of the whole processes are also tested, followed by a set of several physico-chemical characterization before and after CO_2 adsorption to evaluate the stability of these new sorbent materials. Preliminary results are presented, which are of fundamental importance to set the best absorption P/T conditions in terms of selectivity and gravimetric quantity of adsorbed CO_2, as well as the assessment of the efficiency and the possibility of recycling used sorbents in an optical of environmentally sustainable materials, promising as safe and green alternative to the current separation techniques.

Design and synthesis of new photoactive molecules for Dye-Sensitized-Solar-Cells (DSSCs) operating in low-light conditions

Francesco D'Amico,[a,b] Daniele Franchi,[b] Massimo Calamante,[b] Carmen Coppola,[a] Adalgisa Sinicropi,[a] Alessio Dessì,[b] Lorenzo Zani,[b] Alessandro Mordini,[b] Lucio Cinà,[c] Maurizio Taddei [a] and Gianna Reginato [b]

e-mail: f.damico@student.unisi.it

Among all the photovoltaic technologies**, Dye-Sensitized Solar Cells (DSSCs)**[1] attracted the attention of researchers for their low manufacturing costs, easy availability of raw materials, and short payback times. The latest trend for DSSC applications is moving to **indoor or dim-light environments** because DSSCs have much higher efficiencies than Si-based solar cells (~ 30 %). Thus, indoor photovoltaics are emerging as an important technology suited for IoT (Internet of Things) applications, household, and various electronic applications.[2]

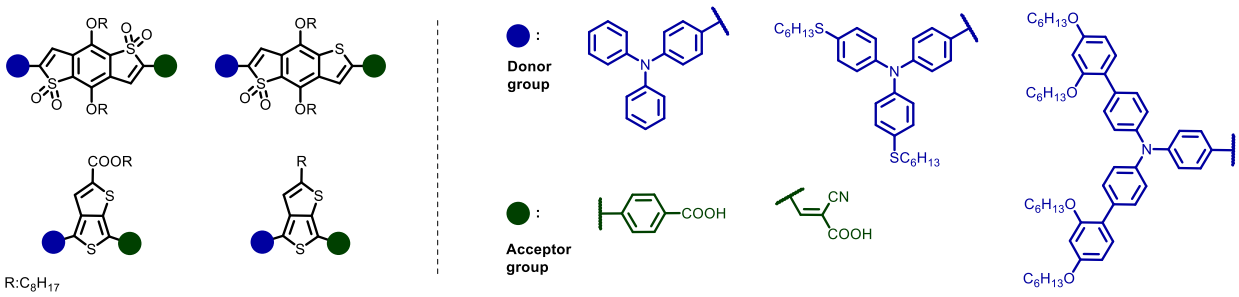

Figure 1: New photosensitizers for indoor DSSCs.

Herein, the design and synthesis of four new families of photosensitizers for indoor DSSCs are presented. The molecules showed properties suitable for this type of application, with broad light absorption in the visible region and redox potentials compatible with the most common organometallic redox couples. First preliminary DSSCs tests afforded promising efficiencies using different light sources.

Catalyzed gas-liquid biphasic (dark or photochemical) reactions, very often are severely plagued by transport phenomena occurring at the interphase, and their full exploitation in terms of efficiency and throughput is thus far to be achieved. Their thermodynamic is regulated by Henry's law, while the corresponding kinetics are governed Fick's and Lambert-Beer's laws,[1] this latter in the case of photoreactions. Mass and photon transfer limitations affecting these reactions are then addressed by increasing the interphases surface to volume ratio,[2] and reducing the thickness of reaction mixture photo-exposure. Aerosols facilitate achieving both goals simultaneously, thus introducing microdroplets reactions as an invaluable paradigm shift. In this scenario, we focused on two model reactions: the photocatalyzed gas-liquid biphasic selective sulfoxidation,[3] of sulfides, and the catalyzes CO_2 fixation on styrene oxide.[4,5] Details of these explorations will be reported, along with our efforts in the ideation, design, implementation and characterization of new reactors and enabling technologies to perform aerosol reactions

The Hexameric Resorcinarene Capsule as Supramolecular Photoacid for the Catalysis in Confined Space

M. De Rosa,[a] G. Ferrino,[a] G. Campanile,[a] P. Della Sala,[a] C. Talotta, [a] A. Soriente, [a] C. Gaeta,[a] P. Neri[a]

[a] *Dipartimento di Chimica e Biologia "A. Zambelli", Università degli Studi di Salerno, via G. Paolo II, I-84084, Fisciano (Salerno), Italy*
e-mail : maderosa@unisa.it

The hexameric resorcinarene capsule **C_6** is a hydrogen-bonded self-assembled capsule obtained in wet solvents (chloroform or benzene) by six resorcinarene units and eight water molecules.[1] Several studies have highlighted the abilities of **C_6** in promoting different types of reactions within its cavity, exploiting its unique catalytic features, such as a cavity large enough to hold several substrates (internal volume of 1375 Å^3), the capability to stabilize cationic intermediates and transition states, the H-bond donating ability, and its mild Brønsted acidity (*p*ka= 5.5-6.0).[3-4] In addition to these, we here show that **C_6**, when exposed to light irradiation, can act as a photoacid exhibiting an enhancement in acidity of 8.8 log units compared to its ground state. The synergistic interplay between the nanoconfined environment of the hexameric resorcinarene capsule and its supramolecular photoacidity paves the way for further developments in unconventional reactivity and selectivity.[5]

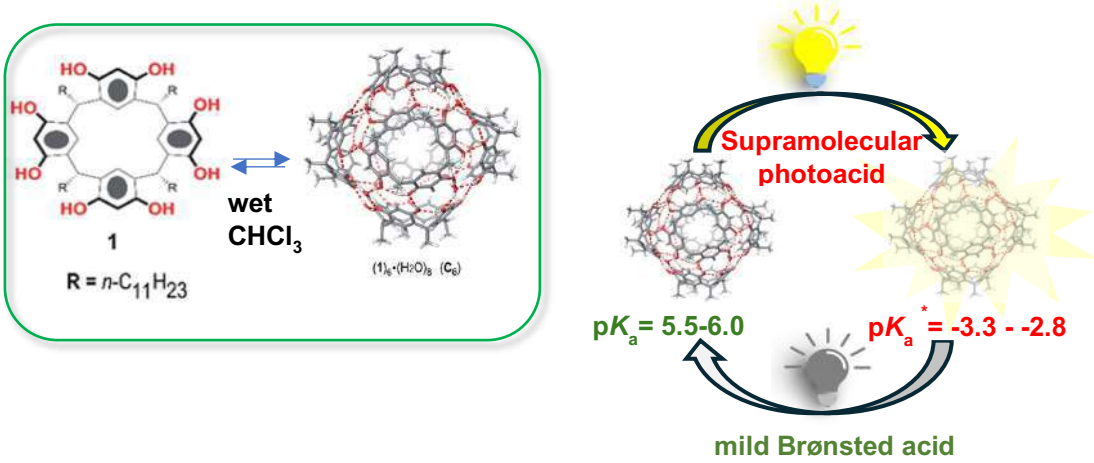

Figure 1: Light-driven pKa switch for the hexameric resorcinarene capsule.

Steroid-fullerene hybrids as promising derivatives with potential application in medicinal chemistry and materials science

R. Lemos,[a,b] Y. Perez-Badell,[a] M. De Nisco,[b] S. Pedatella,[b] M. Suárez[b]

reylemos81@gmail.com

In recent years, fullerenes have gained great interest because their structure enables the development of novel applications based on their chemical and physical properties.[1] With a focus on their small size and special structure, there have been considerable reports on their ability to scavenge free radicals, visualize biological processes, and neuroprotective activity. Furthermore, their ability to capture radicals makes them good antioxidants, for developing potential drugs to treat neurodegenerative diseases.[2] On the other hand, fullerene derivatives have been used as acceptor materials in solar cells for over two decades, following the demonstration of the first proof-of-concept devices at the end of the last century.[3]

This work aimed to obtain structurally novel compounds, based on generating molecular hybrids, with applications as anti amyloid-β (Aβ) peptide aggregates and as acceptor material in organic solar cells. For this purpose, fullerenes were covalently bonded to malonyl conjugates substituted with fragments such as steroids and seleno-sugars. Different strategies were designed for obtaining malonyl-steroids and seleno-sugars, as well as for their coupling reaction. The covalent attachment of the conjugates to [60]fullerene was performed by Bingel-Hirsch cyclopropanation. In addition, theoretical calculations at the DFT level of theory were used to predict the synthesized hybrids' molecular structures and to estimate their physicochemical properties. Theoretical calculations based on CNDOL Fockian together with configuration interaction of single excitations (CIS), as well as the experimental results obtained such as TEM and cyclic voltammetry demonstrated that one can be considered an appealing candidate with applications for photovoltaic devices. Molecular docking was employed to determine the potential application of these fullerene derivatives to treat neurodegenerative diseases, focusing on the interaction of these molecules with the (Aβ) peptide.

CytroCell: A *Citrus*-based micronized cellulose for advanced applications

G. Li Petri, G. Angellotti, M. Pagliaro, R. Ciriminna

Istituto per lo Studio dei Materiali Nanostrutturati, CNR, via U. La Malfa 153, 90146 Palermo, Italy
giovanna.lipetri@cnr.it

CytroCell is a new micronized cellulose derived from industrial waste lemon peel via hydrodynamic cavitation (HC) carried out in water only.[1] Mixed in small amount with fragile pectin-based films, this new bionanomaterial has recently shown its ability to vastly increase the mechanical and thermal properties of the resulting composite films.[2] Dissolved in green, biobased solvent cyrene and mixed a polymerizable ionic liquid (PIL) comprised of a styrene unit functionalized with a triethylphosphonium ion and BF_4^-, CytroCell turns otherwise unstable PIL into a chemically stabilized and mechanically reinforced membrane suitable for producing long-awaited anion exchange membranes for alkaline water electrolysis.[3] In this lecture, I will present the unique structural and physicochemical properties of this new *Citrus*-derived nanocellulose reproducibly produced in large quantity at ultralow cost from lemon processing waste via HC in water only.[4] I will conclude providing arguments for which the HC-based process affording the CytroCell may have solved all main hurdles that so far limited commercialization of nanocellulose on large scale.[5]

Nanocellulose is a versatile biopolymer with excellent chemical and physical properties: high mechanical strength, low density, biodegradability, and biocompatibility. It can be extracted from waste materials such as agricultural biomass or from other sources including plants, bacteria, and algae.[1] Subsequent chemical functionalization increases the properties of nanocellulose and its applicability in medicine, including *drug delivery*. Taking advantage of the modifiable surface of the nanocellulose, carboxyl functions were introduced and used as ligands to anchor Indium Tin Oxide Nanoparticles (ITO NPs). These nanoparticles have an absorption peak in the NIR around 1700-1800 nm, which has recently been exploited to generate heat upon IR irradiation,[2] and is thus promising for photothermal therapy of tumors in the third biologically transparent window. Rose Bengal is another molecule selected for nanocellulose-mediated drug delivery. Rose Bengal has long been used in clinic, but only recently has shown to be effective in photodynamic therapy. Rose Bengal irradiated at 532 nm releases reactive oxygen species (ROS) with distinct antifungal properties.[3] Therefore, an effective synthesis was developed to bind Rose Bengal to nanocellulose and achieve effective antifungal results for the treatment of nail onychomycosis with a lower drug concentration.

Luminescent persistent radicals for photon management applications

S. Mattiello,[a] A. Bionda,[a] M. Sassi,[a] L. Beverina[a]

[a] *Department of Materials Science, University of Milano-Bicocca, 20126 Milan, Italy*
sara.mattiello@unimib.it

Open-shell luminescent molecules are becoming increasingly studied for their unique properties, such as magnetoluminescence and the absence of heavy atom effects. They possess spin ‘‘doublet” ground states, which allows spin-allowed doublet–doublet transition, and do not suffer from quenching via the triplet state typically observable in closed-shell luminescent molecules.[1] The biggest concerns regarding their use in applications has been their stability. From the introduction of perchlorotriphenylmethyl radical (PTM) and tris(2,4,6-trichlorophenyl)methyl radical (TTM), which display room temperature luminescence but decompose under UV light, many progresses have been achieved leading to more stable derivatives, especially from the pyridyl bis(2,4,6-trichlorophenyl)methyl radical (PyBTM) family.

This contribution will describe the preparation of extended conjugation PyBTM derivatives.[2,3] The introduction of further aromatic lateral units allows to increase the materials stability up to the point that their application in luminescent solar concentrators becomes possible. Preliminary results of their use in Organic Light-Emitting Transistors will be discussed as well.

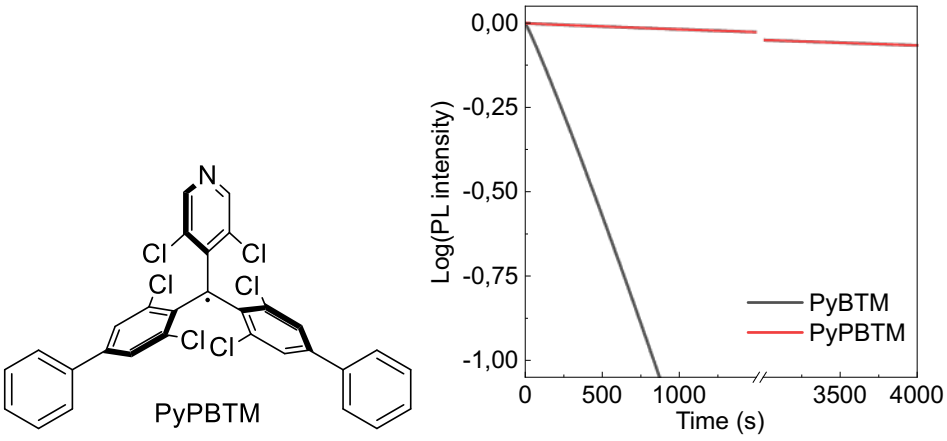

Figure 1: structure of PyPBTM, a derivative of PyBTM with extended conjugation, and its comparative stability in CH_2Cl_2 solution with respect to PyBTM under irradiation at 370 nm.

luigi.menduti@unimi.it

Electrogenerated chemiluminescence, also called electrochemiluminescence (ECL), is the generation of excited states upon recombination of oxidized/reduced species generated at the electrode and reduced/oxidized species produced by a chemical reaction.

In the past decades, ECL-active molecules have been employed in many applications such in systems for the detection of viruses/bacteria.[1] However, despite the increasing demands for accuracy in diagnostics, the sensitivity of ECL in immunoassays, already in the picomolar range, can still be improved by designing emitters with higher emission quantum yields or by thinking of multiple emitter for a single analyte.

As an example, a known strategy to increase the sensitivity of bioassays is the construction of multi-labeled systems, such as the one developed by Roche, PolyRu, consisting of 8 units connected to the same antibody. Such multiple Ru(II)-based emitters are connected to the detecting-platform which in turn binds one equivalent of analyte. This multi-labeled system allows to get considerable signal improvement since each detected analyte can be marked by the ECL-signal produced by several emitters, however the emission intensity is not as expected increased by 8 folds as should be.

Indeed, the maximum signal increase achievable is 30% due to the self-quenching of the (spatially-closed) emitters anchored on the detecting-platform surface. To overcome this problem and improve the signal increase, our strategy is to build systems in which ECL-emitters are anchored on a platform by a suitable linker allowing their release in solution under a certain stimulus . Beyond the tuning of the detecting-platform architecture, the replacement of the commercial ECL emitter $[Ru(bpy)_3]^{2+}$ with more efficient[2] and easily-color-tunable[3] emitters such as water soluble Ir(III)-complexes,[4] represents a promising tool to further improve the signal-to-noise ratio.

enzo.menna@unipd.it

Functionalizing carbon nanostructures (CNS) such as carbon nanotubes (CNT), reduced graphene oxide (RGO) and carbon nanohorns (CNHs) with suitable organic groups is an effective strategy for their inclusion as fillers in a biocompatible polymer phase, to obtain functional materials for tissue engineering applications.

We synthetized and characterized (through TGA, Raman, XPS and electron microscopies) different CNS derivatives, soluble in different organic solvents and in water, and we used them as fillers in different polymer matrices. Resulting composite materials, both in the form of films and electrospun nanofibers, were used as scaffolds for in vitro biological tests, showing that CNS derivatives promote growth and differentiation of different cell lineages, by modulating mechanical and electrical properties of the substrate.

An innovative nanocomposite surgical implant designed for nerve regeneration has been prepared by using water soluble CNT derivatives. In vivo tests show promising results in terms of biocompatibility and effectiveness in restoring.

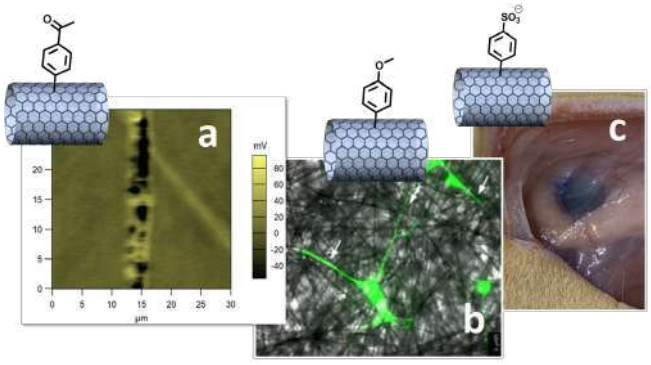

Figure 1: composite scaffolds based on different CNT derivatives: (a) scanning Kelvin probe microscopy of fibers; (b) SH-SY5Y cells extending neurites along the fibers; (c) biocompatibility assessment in vivo.

antonio.monopoli@uniba.it

Ionic liquids (ILs) are salts with a melting point below 100°C that have been established as green solvents for two decades. They offer several advantages, including the ability to recover catalysts and reaction products easily, high thermal and air stability, and negligible vapor pressure. Over the years, we have achieved satisfactory results by performing various organic and catalytic reactions in ILs. Among the various ILs, molten tetraalkylammonium salts have proven to be superior media for many organic and organometallic reactions (see Fig. 1).

In this presentation, we will discuss how different ionic liquids affect catalyst stability, reaction rates, and regio- and stereoselectivity in carbon-carbon coupling reactions. We will focus on the superiority of quaternary ammonium halides over pyridinium- and imidazolium-derived ionic liquids, with a particular emphasis on C-H bond activation.[1,2,3]

In addition, some of us are part of the HOCLOOP[4] European consortium, aiming to explore the viability of non-traditional fluids for heat mining. Our investigation includes the use of CO2 in trans-critical or supercritical states, as well as CO2-based smart fluids (SFs) that contain ionic liquids dissolved in supercritical CO2. These SFs are a groundbreaking concept never been used before in geothermal applications.

Lipid Nanoparticles (LNPs) are constructed with a lipid shell encompassing a core composed of reverse micelles encapsulating drugs, all within a diameter of about 100 nm. The lipid components typically consist of ionizable lipid, phospholipid, cholesterol, and PEGylated lipid.[1]

Recently the interest, as well as the number of approved drugs formulated with LNPs strategy, is increasing due to several advantages, such as the delivery of hydrophobic and hydrophilic drugs, the controlled release, the reduction of drugs adverse effects, the biocompatibility, and the increase of drug lifetime.[1]

Polysaccharides are heterogeneous group of natural polymers, characterized by biocompatibility, biodegradability, and nontoxicity, coupled with wide availability and usually low costs. Numerous studies have demonstrated the biological activities of polysaccharides and particularly of charged polysaccharides, such as anti-tumoral, anti-inflammatory, anti-virals, anti-coagulant, immunomodulatory and antimicrobial properties.[2]

Due to the growing interest towards polysaccharides in pharmaceutical fields, we decided to formulate LNPs containing polysaccharides. The LNPs formulations were obtained using a microfluidic system, which guarantee an excellent size control, a great homogeneity and repeatability, with the possibility to achieve volumes from µL to L and an optimal sample consumption. Furthermore, formulations would allow also to optimize the routes of administration - often a critical point for carbohydrates.

Various polysaccharides and derivatives, characterized by different molecular weight and charge, such as heparin, pentosan polysulphate and hyaluronic acid, have been selected for the encapsulation in LNPs.

Size and Zeta potential, determined by Dynamic Light Scattering, of the LNPs confirmed a size compatible with pharmaceutical applications (< 100 nm), good homogeneity and stability over time. The encapsulation efficiency is determined by Size Exclusion Chromatography. The results are encouraging in terms of efficacy and quantity of encapsulated polysaccharides. LNPs-polysaccharides formulations have been characterized by Nuclear Magnetic Resonance and Fluorescent Spectroscopy. Finally, preliminary structural studies have been carried out using electronic scanning techniques (TEM and SEM) and Small Angle X-Ray Scattering.

2-Benzylideneindan-1-one as Photoswitchable Scaffold for the Design of Light-Driven On–Off AChE Inhibitors

M. Paolino[a]

[a] *Department of Biotechnology, Chemistry and Pharmacy, University of Siena, Via A. Moro 2, 53100 Siena, Italy.*
paolino3@unisi.it

Light-driven molecular switches (LDMSs) are molecules capable of interconverting between at least two different isomeric forms as a result of a light stimulus. In the last two decades different classes of LDMS (e. g. azobenzenes, stilbenes, diarylethenes, indigoids, etc.) have been explored and numerous studies have been conducted to model their photochemical properties (rotational speed, absorption wavelength, isomerization quantum yield, photostability).[1] Among the possible applications of LDMSs, photopharmacology certainly represents a continuously expanding field. Here, light-induced configurational changes are used to alter the interaction of the ligand with the binding-site and thus, modulate the pharmacological activity.[2] In this context, combining our experience in LDMS design and medicinal chemistry,[3,4] we explored the 2-benzylideneindan-1-one as a photoswitchable scaffold of potential bioactive molecules. This nucleus can easily be traced back to numerous active molecules directed towards different targets. Among these, acetylcholine esterase, an enzyme involved in numerous neurodegenerative diseases such as Alzheimer's disease, was chosen as a pharmacological target in our study. By decorating the scaffold with appropriate substituents responsible for the interaction with the enzyme we prepared a library of compounds, all obtained as *E* diastereoisomers. We demonstrated their photoswitcheable ability by inducing the formation of *Z* isomers via light irradiation at 330 nm and restoring the *E* forms using light at 400 nm. Enzyme inhibition studies have shown that, on the basis of the substitutes, *E* isomers have an AChE inhibitory activity (IC_{50}) ranging from sub-micro to sub-nanomolar range. On the other hand, photostationary states constituted of an excesses (75%) of *Z* isomer showed a reduction of the inhibition potency over one order of magnitude, confirming the possibility of modulating their biological activity via light radiation. [5,6]

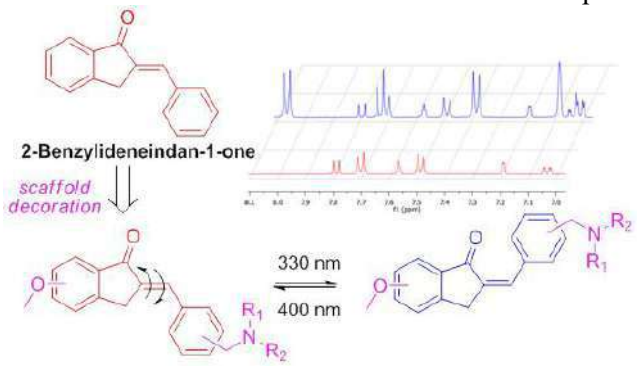

Figure 1: Decoration and photoisomerization of 2-benzylideneindan-1-one scaffold implied in the design of light-driven on-off AChE inhibitors.

The development of systems for the recognition of primary ammonium cations in water is a exciting and timely research area of supramolecular chemistry as several are well-known biomarkers (i.e. cadaverine, putrescine, spermidine) or pollutants (i.e. aromatic amines).[1] Nonetheless, the recognition event of charged species in aqueous media is particularly tricky and limited by the competitive nature of water.[2,3] In this respect, an attractive strategy is the design of receptors based on calix[5]arene macrocycles, which provide an hydrophobic cavity that has proven to lead to strong inclusion complexes with linear alkylammonium guests. The stability of these complexes mainly arises from non-covalent interactions, comprising hydrogen bonding of the ammonium ion inside the cavity with the phenolic oxygens, accompanied by cation-π and C-H-π interactions.[4] A key issue is the obviously poor or incomplete solubility of these receptors in water. To this end, here we report our recent work on a new calix[5]arene ionizable receptor bearing at the lower rim five carboxylic groups able to lend a proton to complementary amines, leading to the formation of a host-guest complex with the linear alkylammonium primary guests thus formed. The complexing capabilities of this system were tested in different environments (organic solvent, water and micelles) through NMR experiments.

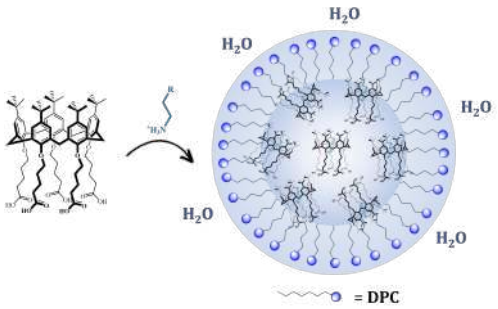

Figure 1: Recognition of primary ammonium in micelles by Calix[5]-pentaacid.

Carbon dots (CDs) are nanomaterials known for their biocompatibility, photostability, and tunable photoluminescence, making them versatile for various applications. With sizes typically below 20 nm, CDs consist of carbon cores with functional surface groups.[1] They exhibit broad absorbance, large photoluminescence, and low toxicity, making them suitable for biomedicine, optoelectronics[2], and environmental applications. Here we outline our activities involving CDs within a sustainable and circular economy framework. We demonstrate the use of CDs as UV protective coatings for food packaging[3], enhancing sustainability. Moreover, we test CDs as charge-regulating layers in organic photovoltaic cells, showcasing their versatility in renewable energy. Additionally, we explore CDs in precision agriculture for enhancing tomato plant growth, drought resistance, and water consumption reduction. Finally, we highlight a circular chemistry approach to synthesize CDs from citric acid sourced from agricultural or biodiesel waste, emphasizing sustainable-by-design principles. These activities integrate innovative nanomaterials within circular economy principles, driving sustainable solutions across diverse sectors.

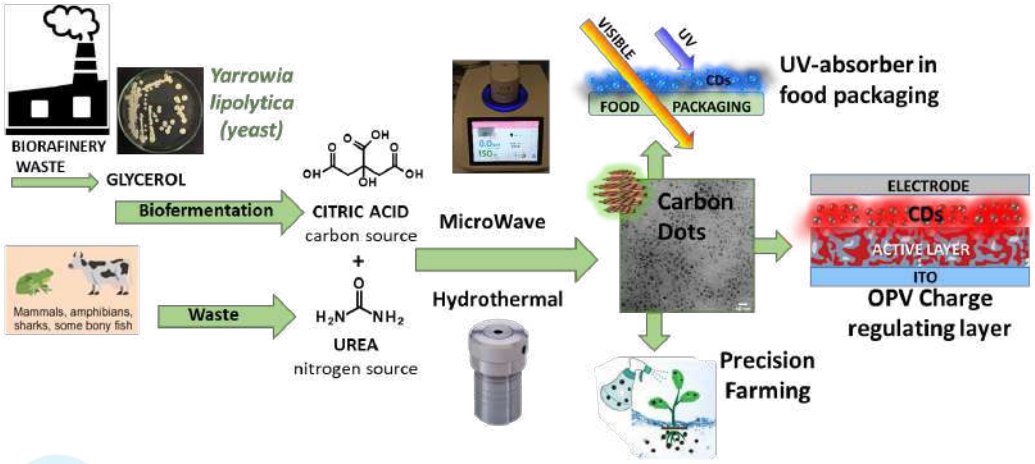

Figure 1: Schematic representation of CDs synthesis and explored applications.

pietro.pecchini3@unibo.it

Asymmetric metal- and organocatalysis rely typically on low molecular weight chiral compounds as enantioinducing elements. However, evoking biocatalysis, examples of inherently chiral natural (e.g. double stranded DNA)[1] and synthetic (e.g. chiral organic frameworks)[2] macromolecules as enantioselective catalysts are rapidly emerging. In this context, we report barium alginate gel beads as heterogeneous, and reusable, catalyst for the benchmark addition of indoles to nitroalkenes, affording the corresponding adducts in moderate to good yields and enantioselectivities (up to 93% ee, Figure 1). This rare example of high enantioinduction offered by a polysaccharide in catalysis was realized thanks to the versatility of the alginates, a family of biopolymers derived from brown algae. After the first promising results,[3] we are expanding to different reactions this versatile catalyst, confirming the wide applicability of our new system to prochiral substrates.

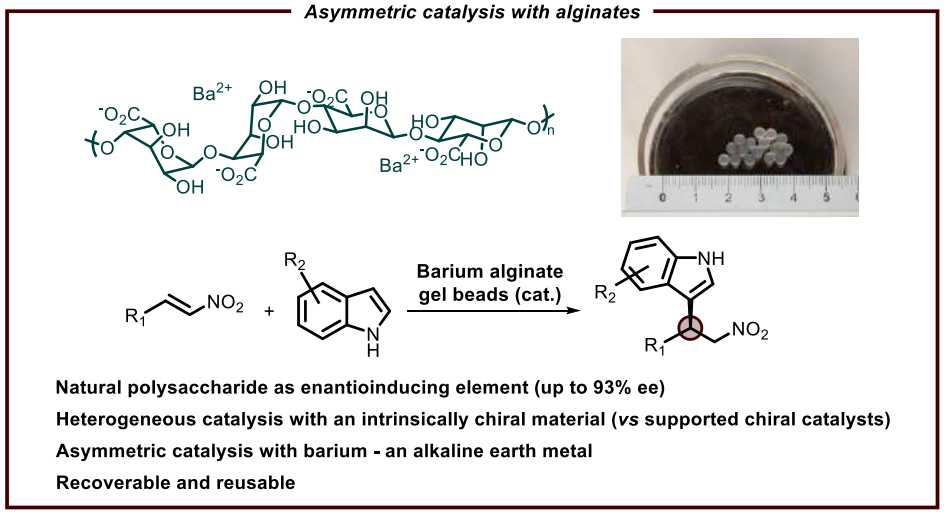

Figure 1: Barium alginate gel beads: a chiral heterogeneous catalyst from brown algae.

The drive for cleaner and more efficient chemical processes has led the scientific community to explore greener synthetic methods, aiming to eliminate or minimize the use of hazardous and expensive chemicals, while maintaining high reaction efficiency. Glycerol, a non-toxic and readily available byproduct of biodiesel production, is emerging as a valuable resource for sustainable organic synthesis. It offers a compelling alternative to traditional organic solvents, potentially making organic synthesis greener and more efficient.[1] In this contribution, we present a sustainable approach to the Sonogashira reaction, utilizing glycerol as the solvent. This alternative strategy was successfully applied to the synthesis of a series of novel triarylamine-based derivatives bearing electron-donating or electron-withdrawing substituents (Figure 1). The structure-reactivity relationship of the starting aromatic halides will be discussed. Furthermore, the characterization of the obtained compounds revealed their suitability for cutting-edge optoelectronic applications, such as hole transport materials (HTMs)[2] in wide-band gap perovskite solar cells (PSCs) and luminophores in Luminescent Solar Concentrators (LSCs)[3].

Hybrid cellulose nanocrystal–gold nanoparticles as a new generation of multifunctional and programmable glyconanomaterial

Giacomo Biagiotti,[a] Barbara Richichi[a]

[a] *Department of Chemistry 'Ugo Schiff', University of Firenze, Via della Lastruccia 13, 50019 Sesto Fiorentino (Firenze, Italy)*

Cellulose nanocrystal (CNC) is a low-cost functional material that has emerged as one of the most appealing natural biopolymeric scaffold for the preparation of advanced nanomaterials in many applicative areas.[1] As such, it has the potential to be exploited as a 'magic bullet' for nanomedicine. In this communication, we discuss on our approach on the design and preparation of a CNC-gold nanoparticles hybrid (CNC-AuNPs),[2] an original, modular, and functional glyconanomaterial that provides a conceptual advance in the field: it combines the complementary physiochemical properties of AuNPs and polysaccharide-based nanomaterials along with preserving the main composition and structure of the pristine CNC. Our CNC–AuNPs surface is easily engineered with different bioactive headgroups under strictly controlled reaction conditions and with high batch-to-batch reproducibility.[2] In particular, the proper arrangement of sugar heads on its surface and the morphological features of this polysaccharide-based glyconanomaterial make our hybrid CNC-AuNPs a unique multivalent scaffold suitable for precision medicine applications.[3] Owing to the support of a multidisciplinary and international network of collaborators[2-3] we studied the specific interactions with lectins, and we explored this programmable glyco-nanotechnology as precision delivery system.

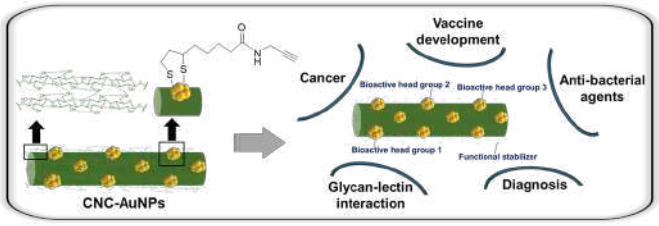

Figure 1: Schematic representation of the hybrid CNC-AuNPs.

From models to Lignin depolymerization. Photocatalysis using V-aminotriphenolate complexes.

Fátima Sanz Azcona,[a] Margarita Escudero-Casao,[a] William Bertoluzzo,[a] Emanuele Cesprini,[a] Giulia Marina Licini.[a]*

fatima.sanzazcona@studenti.unipd.it

The growing shortage of fossil resources leads to the search of a "greener" alternative for high-value chemicals production. The exploitation of biomass waste materials, in particular lignin, is proposed as a valid solution for the replacement of current non-renewable sources. However, the complex and irregular structure of this biopolymer difficult the obtention of target aromatic organic molecules. Recently, photocatalysis in combination with earth-abundant metal catalyst has emerged as a promising methodology for the selective depolymerization of lignin under mild conditions.[1]

In this communication, aerobic oxidative C-C bonds cleavage of Lignin and Lignin models catalysed by aminotriphenolate (TPA) vanadium complexes[2] will be presented. Under visible light irradiation and room temperature, vicinal diols, β-1 and β-O-4 lignin models afforded high-value aromatic products; as carbonyl compounds (aryl aldehydes, aryl carboxylic acids, aryl formates) or phenols with high selectivity. Going ahead, promising results are obtained for depolymerization of lignin itself.

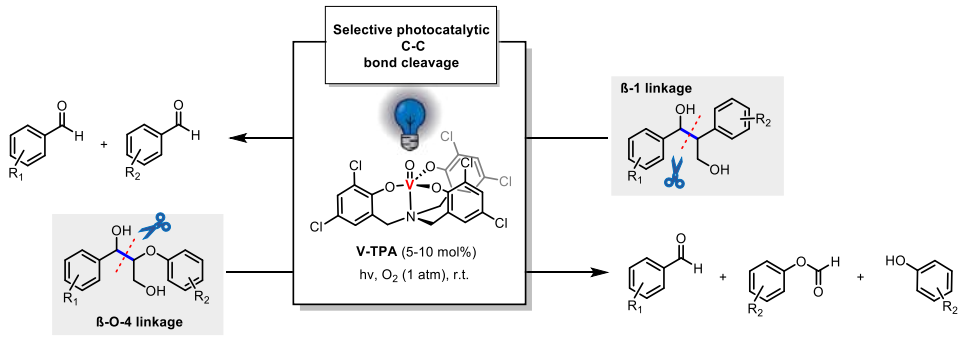

Figure 1: Photocatalytic aerobic oxidative C-C bond cleavage of Lignin models using V-TPA complex.

laura.spagnuolo@phd.unipi.it

Nanostructured materials hold great promise as substrates for immobilization and activation[1] of biocatalysts. Cellulose nanocrystals (CNCs)[2], obtained from waste or renewable sources, are not only sustainable and biodegradable, but also boast a high specific surface area, making them ideal for anchoring a substantial number of enzyme units. They also exhibit high thermal and mechanical stability. In this communication, we present a comprehensive mechano-enzymatic approach to produce CNCs from cotton linters[3] and the development of antibacterial materials through the immobilization of enzymes, including lysozyme and lipase, on mechano-enzymatic CNCs. The antibacterial property is a much sought-after feature in water-dispersible materials, which makes CNC composites suitable for applications in sustainable paper and textile coatings.[4] Initially, we discuss the use of *Aspergillus niger* endoglucanase[5] for the enzymatic hydrolysis of Avicel. This environmentally friendly approach, compared to hydrolysis with mineral acids, successfully produces neutral CNCs. Next, we delve into the enzymatic self-assembly process, involving chicken egg white lysozyme and lipase from Candida rugosa, with neutral or negatively charged sulfated cellulose nanocrystals.[6] Lysozyme shows interesting protective properties against the proliferation of *Candida albicans*, *Aspergillus niger*, *Staphylococcus aureus* and *Escherichia coli*,[7] while lipase contributes an additional layer of enzyme functionality, enhancing the versatility of nanostructured materials.

sara.viggiano@unina.it

Polyphenols, including lignin and tannins, are natural organic compounds characterized by several interesting properties that make them exploitable in many different fields. In addition, they can be extracted by green and sustainable procedures from a wide variety of waste biomasses. In this context, , the present study was focused on the extraction and characterization of phenolic compounds from pine needles (PN), a largely available and still not fully exploited waste material. Several extraction techniques were compared, aiming to achieve the efficient use of this feedstock while ensuring the sustainability of both the extraction process and of the resulting product.[1] A combination of spectroscopic (UV-Vis, NMR, and EPR) and chromatographic (HPLC) analysis revealed that PN extract mainly consists of phenolic polymers, in particular condensed tannins, identified as propelargonidin/prodelphinidin tannins (Figure 1).

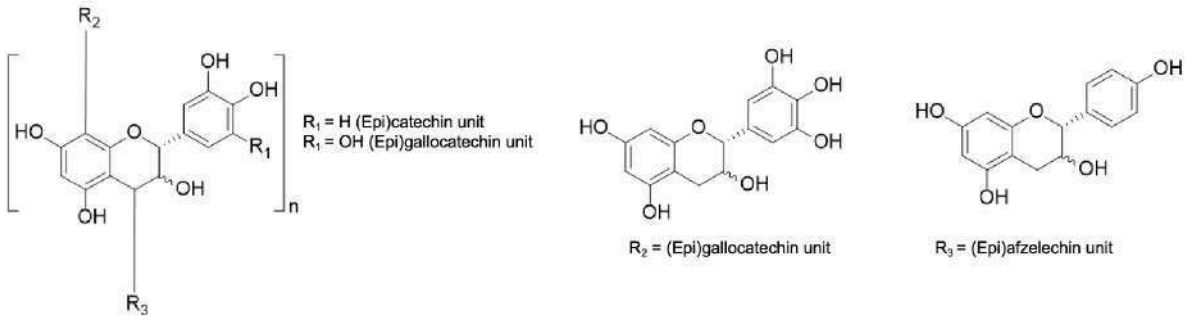

Figure 1. Proposed exemplificative structure for condensed tannins in the PN extract.

These compounds exhibited promising activity as a green alternative to the traditional corrosion inhibitors for the protection of aluminium alloys.[2] Therefore, the obtained results contribute to expand the knowledge of the structure-property relationships of complex phenolic compounds, particularly concerning those derived from largely available and underexploited biomasses.

Environmental remediation often requires technology at the interface between material science, chemistry and biology, aiming to cheap materials with low environmental impact themselves.[1] Artificial sources or non-Nature derived matrices should be optimized to avoid delivery of toxic side metabolites, produced with eco-compatible chemical conversion, and possibly imply resorption or recycle. Here we present two different time-cost efficient, environmentally friendly, sustainable, and effective biohybrid systems produced *via* various approaches. The first exploits the naturally porous eggs capsules produced by *Hexaplex trunculus* (known as the banded dye-murex), a well-known marine gastropod mollusks, in the Muricidae family. After the eggs release, these porous capsuled structures exhibit a sponge-like, biomineralized, proteinaceous bulk whose sacculae are considered here as a powerful natural, unexplored matrix to be used for removing pollutants from water, due to its rehydratable property. The bioorganic chemistry tool here helped to improve the selectivity of this material towards the adsorption of specific organic pollutants, introducing poly-phenolic moieties as additive chemical functions. In a second tale, exhausted polyurethane elastic foam has been valorised and utilized as a polymeric bulk to chemically immobilize *Pseudomonas fluorescens* bacteria for soil bioremediation purposes. The exploited chemistry here consisted of a hydroxy-indole-based polymer, processable in water with strong sticky properties [2] and biocompatibility, bearing methyn-aminophenyl boronic units [3] for linking the bacterial external glycocalyx. This biomimetic, melanin like polymer resulted efficient also in decreasing the delivery of microplastics from polyurethane foam structures. Both the investigated materials efficiently bioremoved *via* adsorption inorganic and organic model pollutants from contaminated waste water sources and soils. These works refer to Agritech National Research Center funding from the European Union Next-Generation EU and "Dipartimenti di Eccellenza-progetto MAR.V.E.L. (MARginal areas: Valorization of Ecosystem resources for fair and sustainable Livelihood, ICT-2018-20)".

In the search for sustainable approaches to energy great interest has been given to DS-PECs, mimetics of natural photosynthesis, where O_2, H_2 and carbon-based chemicals are produced from cheap and abundant sources (water, carbon dioxide) and solar radiation[1]. In DS-PECs for *water splitting*, the photoanode combines visible light-absorbing photosensitizers for light harvesting and charge separation and a water oxidation catalyst (WOC). Due to the pivotal role of the dye in the device's operation, the development and synthesis of new sensitizers with broad optical responsiveness, suitable energy levels, and robust stability stand as crucial aspects[2]. Here we report the design and synthesis of three new quinoxaline-based organic dyes featuring a D-π-A architecture. As a result of a specific bottom-up synthetic strategy, we were able to finely tune HOMO energy level by varying the substituents of the donor moiety. Furthermore, dyes **1a-c** (*Figure 1*) have been fully characterized from a photo-electrochemical point of view and employed in combination with the WOC Ru(bda)(pyP)$_2$ for the successful assembly of a photoelectrochemical cell.

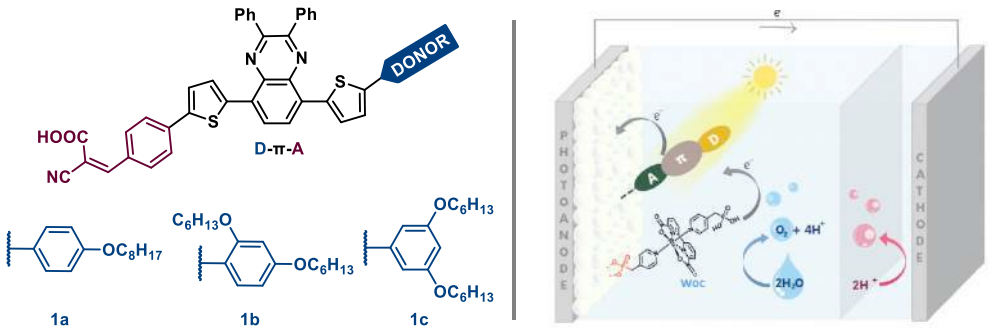

Figure 1: Quinoxaline-Based Dyes (left); schematic representation of a DS-PEC for water splitting (right).

The Csp^2–N bond is crucial in the synthesis of active pharmaceutical ingredients. The Buchwald–Hartwig coupling emerges as a preeminent and extensively utilized method for introducing nitrogen-containing functionality into molecules.[1] Despite its wide applicability, the pressing need to enhance energy efficiency and environmental sustainability remains paramount. In response to these imperatives, we report herein a Buchwald-Hartwig Coupling catalysed by commercially available Pd/C as a recoverable catalyst, thereby facilitating the synthesis of di- and triarylamines through waste-minimized protocols. This strategy employs a recoverable and low-energy-consuming azeotropic mixture of CPME: water.[2] The synergistic interplay between heterogeneous catalysts and recoverable reaction media enables application under flow conditions, addressing concerns associated with the solubility of inorganic species involved.

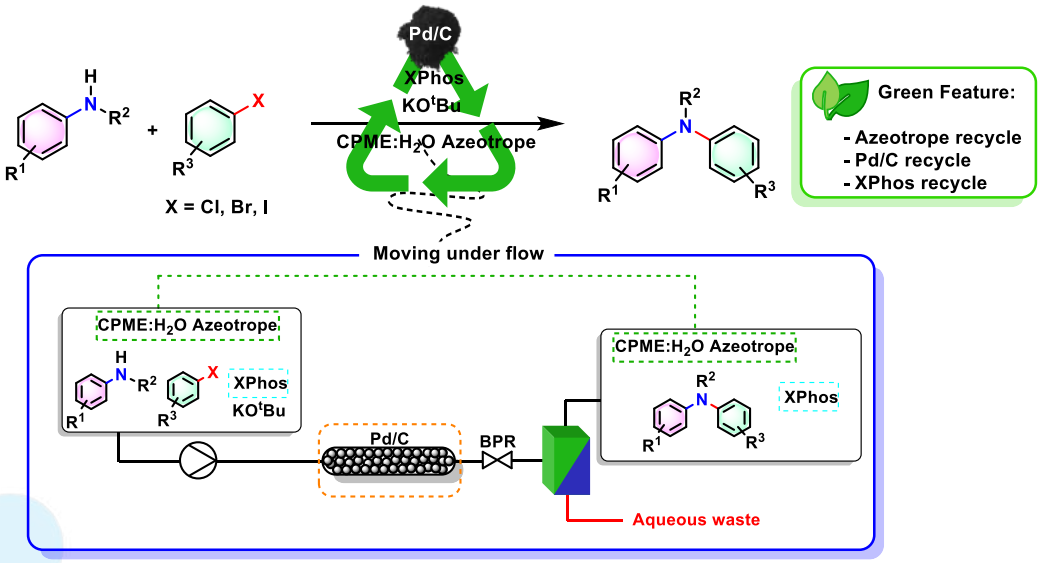

Figure 1: Schematic representation of the heterogeneous Buchwald-Hartwig coupling to access di- and triarylamines in a waste-minimized approach under batch and flow conditions.

Molecular interaction between heparan sulfate mimetics and the recognition spike protein of SARS-CoV-2 virus

Mandalari Marco [a,b], Civera Monica [a], Stefano Elli [b], Michela Parafioriti [b] , Guerrini Marco [b]

[a] *Università degli Studi di Milano, Dipartimento di Chimica, Via Golgi 19 20133 Milano, Italy.*

e-mail: marco.mandalari@unimi.it / mandalari@ronzoni.it

Heparan sulphate (HS) is a linear highly sulphated polysaccharide, belonging to the glycosaminoglycan (GAG) family. Its repeating unit is the disaccharide of uronic acid (D-glucuronic or L-iduronic) β(1→4) linked to D-glucosamine (GlcN) residues and characterized by a variable degree of sulfation.

In the extracellular matrix, HS is organized in proteoglycans (HSPGs) or glycoproteins and forms long chains, that covers the entire external surface of cells. HS is polyanion and its negative charges, allow it to bind viral and/or bacterial recognition proteins.

SARS-CoV-2 is a single-stranded RNA virus whose recognition glycoprotein (S or spike) decorates the outer surface of the viral capsid, forming the characteristic *crown*. The distal tip of the spike (receptor binding domain S1-RBD) specifically binds the angiotensin-converting enzyme 2 (ACE2) and activates the internalization of the virus. Early evidence suggests that HS acts as the first anchor point for the virus particles and as a co-receptor, mediating the interaction between S1-RBD and the ACE2 [1] which is located on the cell surface hidden by HS chains.

Our study focuses on characterizing the interaction between HS oligosaccharides and S1-RBD of the Omicron, Delta, and WT variants of SARS-CoV-2 to understand how the viral genetic evolution affects the co-receptor role of HS. Both saturation transfer difference (STD) NMR and MD simulation were used to achieve this goal. Two hexasaccharides, referred to here as IAGAIA [2] and PPS [3], were selected as mimetics of HS and a poly-xylane-sulfate, respectively. Both compounds have been shown to inhibit the SARS-CoV-2 infection of cells in vitro.

Complexes between the S1-RBD variants and IAGAIA, or PPS were generated using a docking procedure, in which the ligand is treated as semi-flexible (Glide SP - Schrödinger). A selection of top-ranked poses has been further refined by molecular dynamics simulations in explicit solvent (Amber18), using the force fields: Glcycam06 and Amber ff14SB for the glycan and protein description, respectively. This allows us to estimate their binding free energy (MMGBSA) and to identify key ligand-protein interactions. In parallel, STD-NMR interaction experiments between S1-RDB (Omicron) and IAGAIA have been performed to determine the glycan epitopes binding. The experimental STD initial slope (STD_0 values) measured in this experiment have been compared with the corresponding simulated STD using selected MD simulation trajectories of the IAGAIA-S1-RBD complex (RedMat)[4] allowing the validation of the predicted glycan-S1-RBD epitope binding.

matteo.martina@uniba.it

The use of non-conventional energy sources versus traditional thermal heating has recently gained significant attention due to the possibility of minimizing reaction times, enhancing product yield and avoiding undesired by-products. In this frame, infrared (IR) irradiation is very appealing, as a highly efficient form of heating emitted from an inexpensive lamp, with high heat transfer rate, good heating homogeneity, low energy consumption and short heating time [1]. IR irradiation potential in transition metal-catalyzed organic reactions has not been yet extensively investigated. We have recently demonstrated its suitability in solvent-free Pd-catalyzed (hetero)aryl-aryl reactions via Csp^2-H bond activation [2,3].

Here we report our preliminary studies proofing the high efficiency of IR irradiation in promoting (a) transition-metal catalyzed direct arylation reactions between Csp^3-H bonds and aryl iodides in the presence of transient directing groups and (b) Buchwald type arylation reactions of indoles with aryl iodides.

Biofilms consist of microbial cells living as a community with a very high intrinsic tolerance and resistance to abiotic and biotic stresses, severely impacting human health.[1] In marine environments, biofilm-coated surfaces facilitate the attachments of macro-organisms such as algae, barnacles, and mussels with consequent material erosion, reduction of vessel speed, and increased fuel consumption. Furthermore, fouled ships can spread marine organisms in new environments, increasing the chances of biocontamination.[2]

Here, we focused on developing greener antifouling coatings known as contact-killing surfaces. In these systems, non-leaching biocidal motifs, such as superficial quaternary ammonium compounds (QASs), can ensure long-term protection since featuring fouling release properties.[3]

In the synthesis of QASs, the number and type of cationic heads (aliphatic or aromatic), the anion, and substituents on nitrogen have been systematically changed to obtain a set of molecules with antimicrobial activity against a Gram-negative bacterial strain highly resistant to environmental stresses.

The antibacterial silane **1** was used to design crosslinked polydimethylsiloxanes and siliceous materials **2** which resulted in materials capable of preventing the onset of microbial biofilms.

Finally, we explore the synthesis of more hydrophobic ionic liquids as antibacterial additives for base oil in super-repellent and contact-killing slippery liquid-infuses porous surfaces (SLIPS).[4,5]

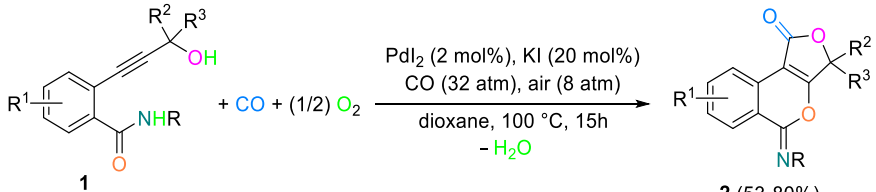
Pd-Catalyzed Carbonylative Double Cyclization to a New Class of Tricyclic Heterocycles

I. Ziccarelli,[a] R. Mancuso,[a] and B. Gabriele[a]

[a]*Laboratory of Industrial and Synthetic Organic Chemistry (LISOC), Department of Chemistry and Chemical Technologies, University of Calabria, Via Pietro Bucci 12/C, 87036 Arcavacata di Rende (CS), Italy*
ida.ziccarelli@unical.it

Carbonylation reactions are known to play a major role in the direct synthesis of carbonyl compounds of industrial interest as well as for the sustainable preparation of fine chemicals.[1] In particular, carbonylative double cyclizations are powerful synthetic methodologies that allow the construction of two new cycles in one synthetic procedure with formation of carbonylated polycyclic structures starting from suitably functionalized substrates.[2,3]

We report here a new carbonylative oxidative double cyclization process which leads to the formation of 5-imino-3,5-dihydrofuro[3,4-*c*]isochromen-1-ones **2** in one step starting from readily available 2-(3-hydroxyprop-1-yn-1-yl)benzamides **1**, CO and O_2 (from air) under the catalytic action of PdI_2 in conjuction with an excess of KI. Products are obtained in chemo- and regio-selective manner under relatively mild conditions (at 100 °C for 15 h under 40 atm of a 4:1 mixture CO–air) and with 53-80% isolated yields (Scheme 1).



1 **2** (53-80%)

(R = H, alkyl, aryl; R^1 = EWG, EDG; R^2, R^3 = H, alkyl)

Scheme 1

Tricyclic heterocycles **2** represent an interesting new class of polyheterocycles, with potential applications in different fields, including medicinal chemistry and material science. The structure of a representative product has been confirmed by X-ray crystallographic analysis.

Predicting PROTAC-mediated ternary complex structures through *in silico* approaches

M. Aliberti,[a] M. G. Chini,[b] G. Bifulco,[a] G. Lauro[a]

[a]*Department of Pharmacy, University of Salerno, Via Giovanni Paolo II 132, Fisciano, Italy*

mialiberti@unisa.it

Degradation of proteins by PROteolysis TArgeting Chimera (PROTAC) technology has recently emerged as a promising new approach with more advantageous over occupancy-based inhibitors. PROTACs are heterobifunctional compounds featuring two binders connected by a chemical linker: one binds the protein of interest (POI) and the other recruits an E3 ubiquitin ligase[1]. Hijacking POI in close proximity to E3 ligase, a PROTAC molecule promotes the degradation of the target protein by the ubiquitin-proteasome system (UPS). In this mechanism, the formation of a stable ternary complex is essential to have an efficient POI ubiquitination and therefore, the knowledge of its 3D structure is a key aspect for the rational design[2]. To date, structural data (e.g., by X-ray) of few ternary complexes are available and they are limited to small number of target proteins, e.g., BRD4, SMARCA2/4, BTK, and WDR5.

We here propose an innovative computational methodology to predict PROTAC-mediated ternary complex structures. Our method uses protein-protein docking experiments to determine all possible interactions between POI and E3 ubiquitin ligase, then inserts the PROTAC molecule so that each ligand reproduces its binding mode in the respective target binding pocket. Finally, the obtained ternary complex models are refined by multiple rounds of metadynamic simulations, which show the conformational changes of the two proteins and PROTAC occurring until they converge to a thermodynamically favoured state (Figure 1). The applicability and the accuracy of this approach is evaluated reconstructing a series of experimentally determined ternary structures, which differ by both target protein and E3 ubiquitin ligase. This computational methodology could be a useful tool to guide and accelerate the rational design of new PROTACs related to proteins undruggable or not extensively studied. In addition, it could elucidate the mechanism of actions of already developed PROTACs whose 3D structures have not been resolved, aiding the design of novel derivatives with improved pharmacological features.

Figure 1: General workflow of new computational methodology

andrea.aloia@uniba.it

Recent dramatic geopolitical situations have shown that the only winning strategy for an industrially competitive country is to diversify energy sources to resist any asymmetries in the supply chain. In this context, biofuels can be crucial in achieving the right energy supply mix. Among them, fatty acid methyl esters (FAMEs) are certainly the most studied, being ideal substitutes of petro-diesel as they can be used without any engine modification, giving also reduction of emissions of SO_x, NO_x, particulate matter, dangerous aromatic compounds, and sulfur derivatives into the environment[1]. The major drawbacks of biodiesel production are the threatening of food storages, due to the lands use changes, the high energy costs of the transesterification process and the use of strongly acidic or alkaline homogeneous catalysts, often employed under stoichiometric conditions and hard to be recycled[2].

In this work, a novel supported catalyst was prepared starting from calcium chloride and chitosan flakes using a very mild approach in an aqueous medium without final calcination. The catalyst was fully characterized and proved to be very efficient in biodiesel production. The catalyst was also recycled ten times without any loss of activity.

Expanding the scope of a new bio-orthogonal templated reaction

M. Amariglio, A. Manicardi
Department of Chemistry, Life Sciences and Environmental Sustainability, Parco Area delle Scienze 17/A, University of Parma, Parma
e-mail: mattia.amariglio@unipr.it

The desire to explore biomolecules and biological processes within their natural contexts has driven the development of reactions that are compatible with such environments. This pursuit presents a substantial challenge owing to the complexity of cellular systems. Reactions capable of proceeding within a biological system without disrupting native biological processes are termed "bioorthogonal reactions". Components involved must exhibit rapid and selective reactivity in water under phisiological conditions, in contexts of high molecular crowding.

Despite the remarkable advancements in bioorthogonal chemistries, so far very few ligation reactions have proven to be efficient at cellular level. Within current methodologies, challenges related to interference amidst the numerous functionalities present in vivo, and the requirement to remain non-toxic to the biological system, persists.

Our aim is to improve a recently discovered bio-orthogonal templated reaction which requires "proximiy" as sole trigger and expand his reactivity, ultimately extending its applicability to cellular studies.[1,2] The chosen reaction involves the ligation between 2,5-dioxopentanyl (DOP) moiety and an alpha nucleophile, resulting in the formation of piridazinium or pyrrole linkage (Fig.1). This reaction, which has been successfully tested in cell lysate, has demonstrated its ability to proceed exclusively under the guidance of a template, such as (peptide) nucleic acids or coiled-coil system formation, with high specificity and without off-target reactivity.

Here, we will present preliminar results regarding the synthesis of various alpha nucleophiles building blocks and preliminary ligation experiments performed on peptide nucleic acids (PNAs) models.

Electrochemical enantioselective α-chlorination of aldehydes

S. Andolina,[a] S. Resta,[a] S. Rossi,[a] M. Benaglia[a]

[a] *Università Degli Studi di Milano, via Golgi 19, 20133, Milano*
stefano.andolina@unimi.it

Organic electrochemistry offers several advantages over traditional chemical oxidation methods, such as the possibility to avoid the use of stoichiometric oxidizing agents and toxic or hazardous reagents[1]. Typically, organic electrochemistry transformations require milder reaction conditions compared to traditional oxidation approaches, since electrons are used as traceless redox equivalents to perform the process without the need for additional redox reagents[2]. In this context, we focused our attention on the development of a stereoselective synthesis of α-chloroaldehydes by organo electrochemical approach, taking advantage of linchpin catalysis.

α-chloroaldehydes have been synthetized with high level of enantioselectivity starting from unactivated aldehydes using a chiral amine as organocatalyst in the presence of a cost-effective and environmentally friendly Cl^- source. The α-chloroaldehydes could be rapidly converted (in-situ) into several significant building blocks such as aziridines, epoxides, and amino acids.

Desired products were obtained in good yields (from 75 % to 95 %) and up to 97% ee (determined on the corresponding chlorohydrin derivatives) (**Figure 1**). The methodology was also investigated under flow conditions, to enhance productivity and space-time yields for gram-scale production.

aurora.antonello@scitec.cnr.it

The current developments of optoelectronics and bionanoscience (including electrochemiluminescence -ECL- technology) take great advantage from the ability of organic, organometallic and hybrid compounds to fulfill specific needs and requirements. Phosphorescent transition-metal complexes, in particular octahedral iridium(III) ones, have been the target of intense researches given their high thermal and chemical stability and the excellent photophysical properties, such as high luminescence quantum efficiency and short radiative lifetime[1]. Furthermore, due to the potential of Ir(III) complexes to emit in the whole visible (from blue to red) and near-infrared (NIR) range there is a growing interest in their use in ECL applications, which today mostly rely on orange/red emissive Ru(II)polypyridine complexes[2,3].
In this contribution, we present the synthesis of a family of cyclometalated heteroleptic Ir(III) complexes with emission centered in the blue, green and NIR spectral regions according to the nature of the C^N ligand (Figure 1a) while carrying an ancillary N^N ligand that enables to anchor the complex to an electrode surface or to a particle. Moreover, we present the synthesis of a new CN-functionalized ligand, accomplished exploring an innovative palladium-free cross-coupling reaction that allows to reduce the number of steps from three to one (Figure 1b)[4].

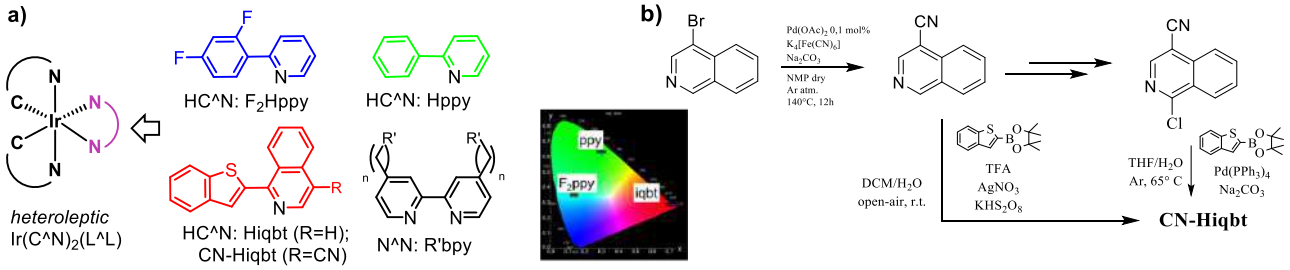

Figure 1. a) general structures of the heteroleptic Ir(III) complexes and their corresponding emission colors. **b)** Palladium-free synthetic pathway for the preparation of CN-Hiqbt ligand.

The opportunistic Gram-negative pathogen *Burkholderia cenocepacia* is a globally spread multidrug-resistant bacterium that causes severe lung infections in immunocompromised or cystic fibrosis patients.[1] This bacterium employs lectins as virulence factors to target host tissues through recognition of and adhesion to the glycoconjugates on the host cells' surface. Among these lectins, the *superlectin* BC2L-C has been proposed as a major player in the adhesion process and in the formation of bacterial biofilm.[2] In particular, its N-terminal fucose-binding domain (BC2L-C-Nt) represents an interesting target for the design of new antimicrobials that may prevent lectin-mediated bacterial adhesion to the host cells.

Recently, we reported the development of a first generation of synthetic ligands targeting BC2L-C-Nt, based on fragment- and structure-based design studies.[3,4] Despite the promising results shown by these ligands, the affinity for the N-terminal domain of the target lectin remains in the sub-millimolar range.[4,5]

With the aim of improving the binding affinity, a new generation of ligands was designed to covalently target specific nucleophilic amino acid residues (Cys72 and Lys108) located near the fucose binding region of BC2L-C-Nt. The new glycomimetics, which contain a L-fucose scaffold connected through a linker to a spacer bearing an electrophilic warhead, were screened in silico through non-covalent and covalent docking protocols, and the most interesting ones were synthetized and subjected to biophysical studies displaying promising results.

In particular, the new ligands showed up to a 100-fold affinity gain over the parent monosaccharide resulting in the first synthetic BC2L-C-Nt ligands that reach the micromolar affinity of the fucosylated histo-blood oligosaccharides.

Acknowledgments: the project is supported by EU funding within the NextGeneration EU-MUR PNRR Extended Partnership initiative on Emerging Infectious Diseases (Project no. PE00000007, INF-ACT).

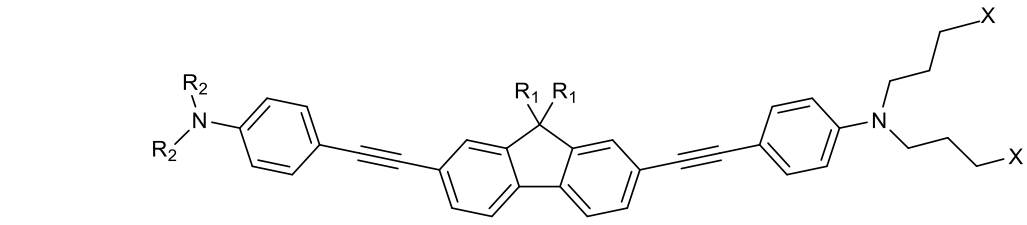
davide.baccelli@unipr.it

Fluorescent potential-sensitive probes (voltage sensitive dyes) are widely used in mapping myocardial contraction. Most of the commercially available systems exploit two mechanisms: electrochromism or photoinduced electron transfer. Despite the great time resolution provided by these systems, they are affected by a low signal to noise ratio. Our project aims to overcome this problem by developing a non-linear optical method to study cardiomyocytes contraction with four-dimensional resolution (in space and time). We decided to use quadrupolar fluorescent molecules[1] that can stain the phospholipidic bilayer of cardiac cells. These molecular sensors are based on a double mechanism: first, a variation in the potential of the cell should result in a different fluorescent response. Second, the cell contraction should lower the symmetry order, with the consequence that the resulting non-centrosymmetric system would be able to generate non-linear second order responses, such as second harmonic generation.[2]

In this poster presentation, we report the synthesis and spectroscopic properties of a selected library of quadrupolar dyes. They all contain a central fluorescent core, asymmetrically functionalized via a statistical Sonogashira coupling, with two electron-donating arms, one bearing a lipophilic and the other a polar end, to ensure a homogeneous orientation of the probe within the cell membrane.



R_2= CH_3; $(CH_2)_5CH_3$ R_1= $(CH_2)_7CH_3$; $(CH_2)_2CH_3$; CH_3 X=$CH_2OSO_3^-$;COO^-, Py^+

The introduction of a trigonal boron atom into polyaromatic hydrocarbons is an extremely powerful tool to provide organic scaffolds with enhanced spectroscopic and electrochemical features as well as optimal packing in the solid state.[1] As a drawback, such flat polyaromatics often display low processability due to their poor solubility in common organic solvents. The distortion of the molecular scaffold represents a suitable strategy to improve the solubility and stacking properties of boron-doped polyaromatics while maintaining good electronic interactions. Extreme structural distortion can be achieved in helical-shaped compounds such as helicenes,[2] which are inherently chiral polycycles, formed by ortho-fused aromatic or heteroaromatic rings. The introduction of boron in these compounds represents a topic of huge interest since borahelicenes show intriguing physico-chemical properties[3] promising for manifold applications in material science. However, the borahelicene structural diversity is still limited to a reduced number of molecules, mainly consisting of tetracoordinate boron-based carbohelicenes.[4]

Our innovative contribution to this field concerns the synthesis of the first doubly BO-doped tetrathia[7]helicenes **1**[5] and **2** (Figure) incorporating two oxaborine rings into the parent tetrathia[7]helicene scaffold. The two structures are isomers characterized by the inversion of the B-O bonds in the oxaborine rings. Spectroscopic measurements, electrochemical characterization and theoretical calculations carried out on **1** and **2** showed that their properties are strongly affected by the orientation of the BO bonds into the scaffold. In addition, the enantiomers of **1** and **2** were separated by chiral HPLC and their chiroptical properties as well as racemization kinetics were investigated.

Samarium complexes have attracted significant attention across various fields due to their diverse applications and unique properties. Research has demonstrated the synthesis and characterization of different samarium complexes, showcasing their potential in catalysis, luminescence, biological studies, and materials science.[1] The luminescent properties of samarium(III) complexes, characterized by an orange-reddish emission, make them particularly attractive for bioimaging and optoelectronic applications.[2] Despite the modest luminescence quantum yields, typically not exceeding 5%, samarium complexes have shown unexpected efficiency for combined visible and near-infrared biphotonic microscopy.[3] In fact, these complexes exhibit emission bands in both the visible ($^4G_{5/2} \rightarrow {}^6H_{5-11/2}$) and NIR ($^4G_{5/2} \rightarrow {}^6F_{1-11/2}$) spectral ranges, making them valuable for imaging purposes.[4]

Here we report on the design, synthesis, chemical and photophysical characterization of a large series of samarium(III) β–diketonate complexes of general formula $[Sm(hfaa)_3(L)_n]$, where hfaa is 1,1,1,5,5,5-hexafluoroacetylacetone and L is a polypyridine co-ligand.

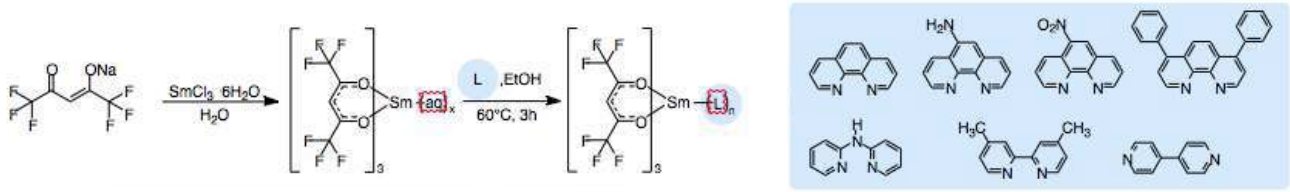

Figure 1: Scheme of the synthetic pathway and the poly-pyridine co-ligands.

baptiste.charrier@unito.it

Th With the development of the Internet of Things and the emergence of self-powered devices operating under ambient light conditions, indoor photovoltaics (PV) have been developed to meet these new energy requirements. Among the various PV technologies developed thus far, Dye Sensitized Solar Cells (DSSCs) have quickly emerged as one of the most efficient and practical solutions[1]. Consequently, there is now significant industrial-scale development of DSSCs, with considerable effort dedicated to achieving optimal efficiency and stability under low illumination.

SL9 and SL10 are two recently published dyes[2] that have shown high Power Conversion Efficiency (PCE) in co-sensitized devices. In this study, these dyes were synthetised and characterized using NMR, HRMS, UV-Vis absorption and cyclic voltammetry. They were then integrated in industrially processed DSSCs to evaluate their long-term stability and performance under white LED light. As a result, co-adsorbed SL9 and SL10 displayed high PCE at 1000 lux of more than 25% after 2000 hours, making them comparable to benchmark dyes. Even at 130 lux, more than 22% PCE was recorded, exceeding most of other commercialized technologies.

Additionally, the effect of bufexamic acid on cell stability was investigated, since it has been shown to improve the dense packing of the dye monolayer at the surface of the titania mesoporous film[3]. Consistently with previous findings, BPHA pre-adsorption contributed to enhance the Jsc, with no detrimental effect on other PV parameters[2]. Furthermore, a noticeable increase in electron lifetime was also observed by using intensity modulated photovoltage spectroscopy (IMVS), suggesting that bufexamic acid has an interfacial passivating effect toward charge recombination. Finally, the long-term stability of the cells under harsh light soaking and temperature conditions is being monitored. Preliminary results show that bufexamic acid has a beneficial effect regarding fill factor retention under stressing conditions, which contributes to slow down the decrease of cell performance.

ismaele.barbetta@scitec.cnr.it

Nanofabrication of long-ordered structures displaying specific functional properties is extremely relevant in nanotechnology and electronics miniaturization. The intense scientific research on this subject is driven by new potential applications, especially in organic electronic devices and sensors. The peculiar properties of a molecular system can be enhanced at monolayer level, where the control on the spatial arrangement and orientation of the molecules is of fundamental importance. We present new molecular systems able to be used in bottom-up nanofabrication of long-range ordered monolayer surfaces through a two-step approach: a first in-plane pattern of metal porphyrins that coordinate a second out-of-plane monolayer of functional organic molecules guided by metal-ligand interaction. A linear and planar conjugated BDT (benzo[1,2-*b*:4,5-*b*']dithiophene) unit will be used to mimic the structure of the DPNDI (naphthalene diimide derivative) already exploited by the proponents,[1] while a chiral tetrathia[7]helicene core[2] will be chosen for the preparation of homochiral surface. The two scaffolds have been asymmetrically functionalized at the α-positions of the thiophene rings to fulfil the specific requirements: i) the head of the molecule has been engineered to guarantee axial coordination at the metal atom of the porphyrin, ii) the tail has been decorated with functional groups able to provide information on molecular orientation by X-ray and photoemission spectroscopies.

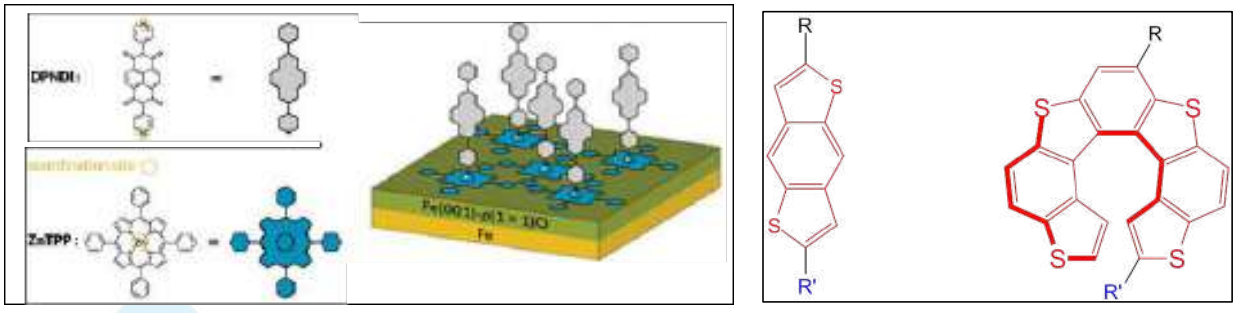

Figure 1: (left) bottom-up growth of organic monolayer on metal porphyrin, (right) newly synthesized molecular systems.

lucia.battistini@unipr.it

In the vast family of integrin receptors, the αvβ6 and αvβ8 integrins are members of high clinical interest.[1,2] These integrins are mainly expressed in epithelial cells and fibroblasts, and both belong to the RGD integrin subfamily, and recognize, among others, the matrix ligand fibronectin and the ECM-bound latent TGFβ complex. Their overexpression and dysregulation have been recognised as valuable prognostic biomarkers of pathological conditions: αvβ6, for example, binds and activates the pro-TGFβ1 promoting deposition of collagen in chronic pulmonary inflammation, lung cancer and fibrosis, while αvβ8 integrin dysfunctions in neuronal cells are associated to brain pathologies. Compounds that can discriminate between homologous αvβ6 and αvβ8 and other RGD integrins, could have considerable utility in the development of new therapeutic agents or diagnostic probes according to the modern paradigm of precision medicine.

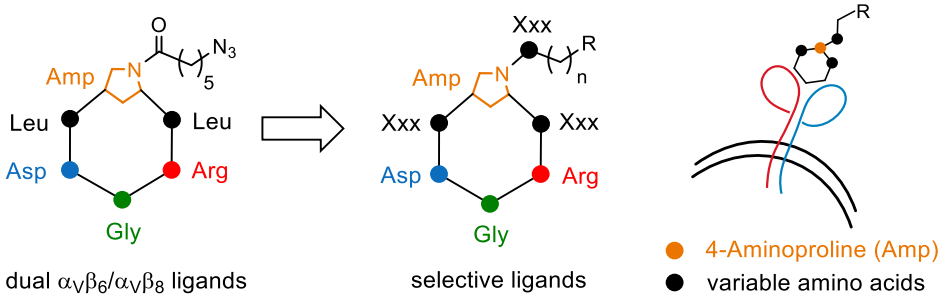

Figure 1: Design of RGD-Amp-based cyclopeptides selectively targeting αvβ6 and/or αvβ8 integrins.

Starting from our previous results on αvβ6 integrin-targeting ligands,[3] guided by in-solution NMR-based conformational analyses and molecular modeling studies, we designed the structural features within the RGD-Amp-based cyclopeptide family (Figure 1) to gain the desired high affinity and selectivity profile.

The decrease in the availability of oil resources, combined with the increase in demand for oil from emerging economies and environmental concerns regarding the use of fossil fuels,[1] has led to the need for the development of efficient processes to produce fuels and chemicals from renewable resources. In this context, plant biomass, particularly lignocellulosic biomass, is currently the best sustainable source of organic carbon.[2] Lignin, one of the constituents of lignocellulosic biomass, can be seen as a renewable source of functionalized aromatic units and, above all, phenols.[3] Phenols are present as structural motifs in a wide variety of molecules of both natural and industrial origin. Whitin aromatic starting materials and phenols are simple precursors for the synthesis of other value-added chemicals.[4] Consequently, the synthesis of site-specifically substituted phenols is challenging, and the development of new methods for this purpose would be highly desirable. Herein, we present an acid- or basic-[5] catalyzed *ortho*-alkylation of phenols strategy using primary alcohol and a Pd catalyst.

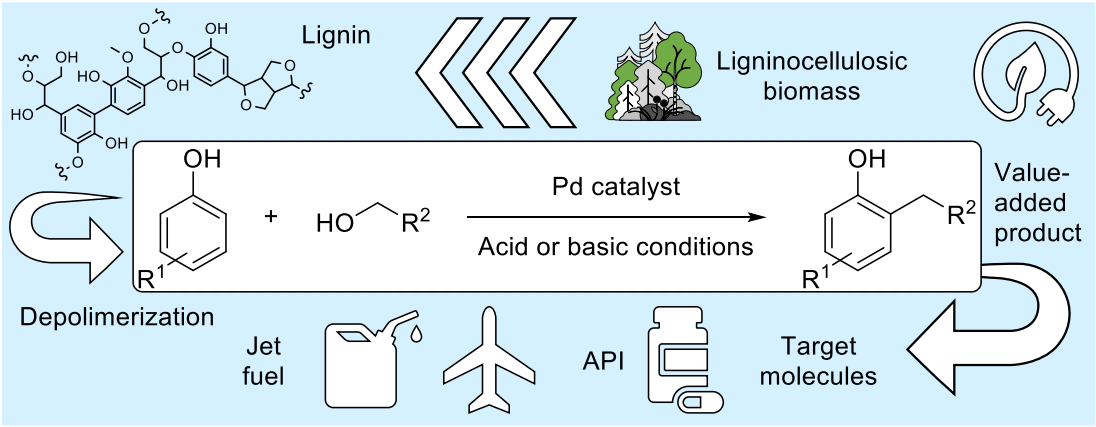

Figure 1: *ortho*-alkylation of phenols strategy as a tool for the valorization of waste biomass.

Carbon nanomaterials including carbon nanotubes (CNTs), reduced graphene oxide (rGO) and carbon nanohorns (CNHs) possess exceptional mechanical, electrical and thermal properties, and for this reason, they can be inserted into biomaterials for tissue engineering applications, improving the mechanical properties and conductivity of the resulting materials.[1] The properties of carbon nanostructures can be tuned by chemical functionalization. The functionalization allows them to be dispersible in the matrix, introduce biocompatibility, and reduce the toxicity issues related to unfunctionalized carbon nanostructures.[2]

The purpose of this project is the compatibilization of different carbon nanostructures with hydrogel phases through surface functionalization with different moieties. Hydrogels are ideal matrices for biomedical applications due to their biocompatibility and ability to mimic natural tissue.

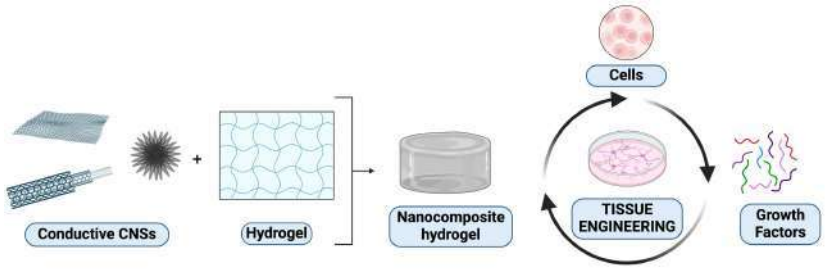

Figure 1: schematic representation of the application of carbon nanostructures for tissue engineering.

Carbon nanostructures have been functionalized with different functional groups by diazotation reaction and characterized through TGA, IR, Raman, DLS and Z potential measurements; the resulting derivatives have been successfully inserted into different types of hydrogels based on self-assembling peptides and on gelatin/chitosan. The obtained materials have been characterized by rheometric measurements and TEM. On the basis of these promising results, tests for cell adhesion and growth shall be taken into consideration.

valentina.benazzi01@universitadipavia.it

Photoacid generators (PAGs) are compounds designed to generate acid upon exposure to light. In the last decades, PAGs have gained importance in different fields as photolithography, 3D printing, chemistry and material science. They play an important role in the fabrication of microelectronic devices, in microfluidics, and to generate acids that can promote different chemical reactions. PAGs are classified into two different groups, according to their characteristics: ionic, and non-ionic. The first are sulfonium, iodonium, phosphonium or diazonium salts, they have excellent PAG properties but restricted application due to the limited solubility in organic media. On the other hand, non-ionic PAG have been extensively used as their high solubility in organic solvents and polymer matrices, especially for polymer initiation and surface curing[1]. In this work Arylazo Sulfones have been employed as non-ionic PAG, for their ability to generate sulfonic acid after visible-light absorption in presence of oxygen[2,3], to catalyze one of the most renowned reactions employed in organic synthesis: Fischer Esterification. Different carboxylic acids were tested, including aliphatic and aromatic derivatives, dicarboxylic acids and amino acids, as well as saturated and unsaturated long-chain fatty acids and esterification proceeds efficiently in the presence of a wide range of differently substituted alcohols.

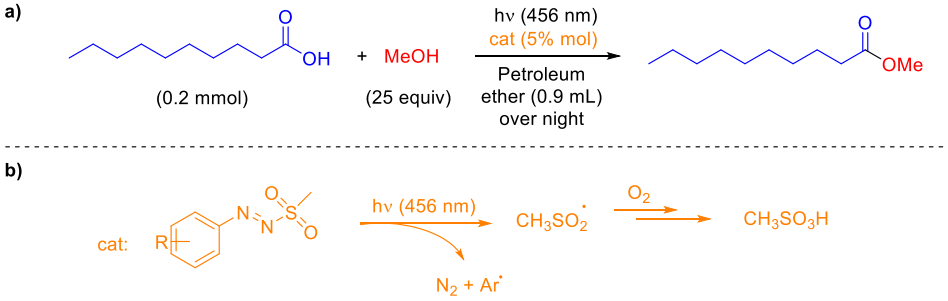

Figure 1: a) Model reaction employed for optimization of reaction conditions b) Proposed reaction mechanism for the photochemical generation of methanesulfonic acid from arylazo sulfones.

Metal complex polymers as hole conductors for perovskite solar cells

I. Benesperi[a]

[a]*Università di Torino, Dipartimento di Chimica, via P. Giuria 7, 10126 Torino, Italy*
iacopo.benesperi@unito.it

Perovskite solar cells (PSCs) have surged in the past 12 years as the most promising third generation solar cell technology, capable or rivaling with silicon solar cells in lab-scale devices and only requiring a fraction of the energy for their fabrication. Although several companies are nowadays conducting research on them and larger-scale modules and panels are being manufactured, commercialisation of this technology is still impeded by the poor long-term stability of the perovskite light absorber. The hole transporting layer is one of the main causes of this instability. Organic small molecules, which allow PSCs to reach top performances, require hygroscopic additives that degrade the perovskite material to reach the desired conductivity, and can migrate into the light absorbing layer.[1] Polymeric materials are intrinsically more conductive and can avoid the use of dopants. Although they can work efficiently in PSCs, their synthesis remains complex, which reflects into their commercial prices.[2] Metal complexes are a viable alternative to organic molecules, as their energy levels can be fine-tuned by tweaking the ligand environment or changing the metal centre.[3] They can be intrinsically doped by adding two different oxidation states of the metal centre to the hole transporting layer, being able to overcome state-of-the-art organic small molecules both in efficiency and stability.[4]

In this work, I developed covalent polymers based on metal complex monomers to use as hole transporters in perovskite solar cells. These materials take advantage of the higher conductivity of metal complexes compared to organic compounds and couple them with the greater stability of polymers compared to small molecules. Careful design of the ligand environment allows the formation of robust macromolecules that can be dissolved in perovskite-compatible solvents and that present a good degree of hydrophobicity, to help with the preservation of the light abosrbing layer over time.

LIGHT-DRIVEN REGIOSELECTIVE [2+2] CYCLOADDITION OF ARYL-ENONES BY EOSIN Y

T. Benettin,[a] S. Resta,[a] A. Puglisi,[a] M. Benaglia[a]

[a] *Dipartimento di Chimica, Università degli Studi di Milano, Via Golgi 19, Milano*
e-mail: tommaso.benettin@unimi.it

The use of light as energy source for organic synthesis has been emerged as a powerful tool to both explore new reactivity and have environmentally friendly processes.[1] In the same way, the development of flow chemistry in combination with light-driven processes allows to enhance the efficiency and the scalability of the reaction.[2] In this context, photocyclization of aryl-enones promoted by visible light in the presence of photocatalysts provides an innovative strategy for the synthesis of cycloalkanes, through radical intermediates.[3] After exploiting reactivity of different substituted aryl-enones to effort the [2+2] photocycloaddition by the use of Eosin Y as photocatalyst using visible light irradiation, we decided to transport this reaction under flow conditions in order to have a more efficient process.

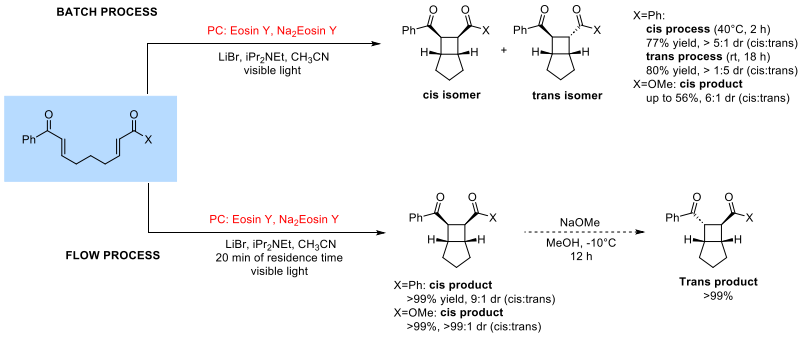

Figure 1: [2+2] photocycloaddition of aryl-enones in batch and in flow.

Different reaction conditions have been tested using symmetric and asymmetric substrates to achieve the bicycle products in good yields as a mixture of isomers. With our delight, for the symmetric aryl-enone, it was possible to find the conditions to selectively drive the cycloaddition towards one or the other isomer. Also, the best reaction conditions have been used in flow leading to reduced reaction time, increased productivity and selectivity towards the *cis* isomer preferentially, both for symmetric and asymmetric substrates. The *cis* isomer can be quantitatively converted into the *trans* isomer under basic conditions.

Development of supramolecular catalysts containing *N*-hydroxyphthalimide for the selective functionalization of C-H bonds

Marianna Bernardini, Tommaso Braghetti, Marika Di Berto Mancini, Giorgio Olivo, Osvaldo Lanzalunga,

Dipartimento di Chimica e Istituto CNR per i Sistemi Biologici (ISB-CNR); Sezione Meccanismi di Reazione, Università di Roma "La Sapienza", P.le A. Moro, 5, 00185 Roma, Italia.

Selective functionalization of C-H bonds in hydrocarbons represents an outstanding challenge in synthetic organic chemistry. In this contest, N-hydroxyphthalimide (NHPI) has attracted increasing interest as an effective organocatalyst for C-H activation by hydrogen abstraction (HAT) [1]. NHPI acts as a precursor of the phthalimide N-oxyl (PINO) radical, which is the effective catalyst promoting hydrogen abstraction processes. C-H bonds with similar electronic and steric environments exhibit a comparable intrinsic reactivity making selective functionalization extremely difficult [2]. This is particularly true for the positions located far away from other functional or directing groups (remote sites). A supramolecular, geometric approach can provide a way to overcome these challenges. In this context, we developed two catalysts based on *N*-hydroxyphthalimide with a crown or aza-crown ether as a supramolecular recognition site (figure 1).

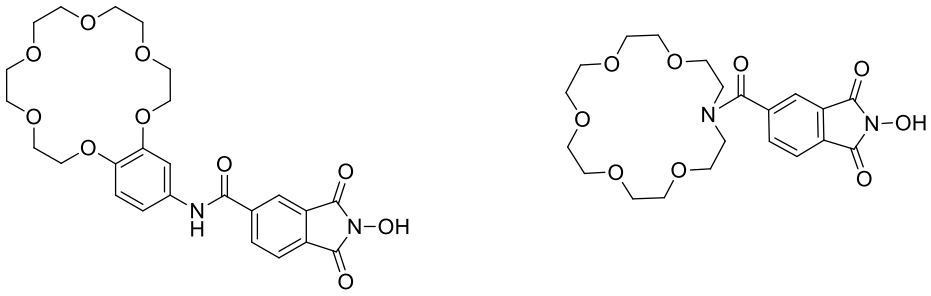

Figure 1

The 18-crown-6 or the 1-aza-18-crown-6 receptors recognize the heads of primary, linear alkylammonium chains and, when coordinated to Ba^{2+} ions, can also establish electrostatic interactions with substrates containing carboxylates, sulfates and sulfonates functional groups. In this way, by an intramolecular HAT, it will be possible to selectively abstract H atoms from specific C–H bonds that are properly oriented towards the in situ-generated *N*-oxyl radical (figure 2).

william.bertoluzzo@phd.unipd.it

This research group has developed a new methodology for the aerobic oxidative cleavage of 1,2-diols based on homogeneous catalysis employing vanadium aminotriphenolates.[1,2] In this communication we will report results obtained in the aerobic C-C-bond cleavage of 1,2-diols yielding bis-carbonyl derivatives under photo-induced conditions at room temperature. The influence of different reaction parameters (temperature, solvent, wavelength, substrate) on the reaction course will be reported as well as the scope of the reaction.

Preliminary results on mechanistic studies on the photoactivated mechanism of the reaction will be also reported. Radical trapping experiments confirmed the radical nature of the reaction, and the role oxygen is playing in the conversion of the substrates, while computational methods are being used to shine light on the photoactivation process of the catalyst-substrate adduct.

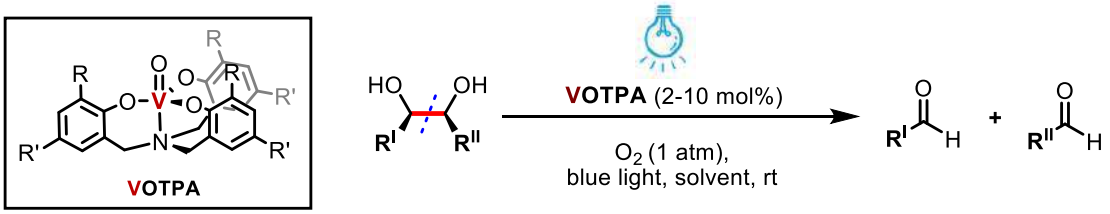

Figure 1. Photoinduced aerobic oxidative C-C bond cleavage of 1,2-diols catalysed by **VOTPA**.

elisa.bianchi1@unifi.it

Cellulosic nanomaterials have stimulated interest in the scientific community thanks to their properties that make them particularly promising among nanostructured materials. Nanocellulose-based materials are naturally available, from waste materials, at low price and are, generally, characterized by a high biocompatibility.[1] Moreover, nanocellulose can be easily functionalized to produce materials with new properties and applications. In this work we focused on materials with antimicrobial properties. Actually, the antibiotic resistance in the treatment of chronic infections related to the chirurgical introduction of medical devices, generates in Europe almost 25.000 thousand deaths per year.[2] The develop of medical devices, such as catheters, coated with nanocellulosic materials with antibacterial properties, may prevent the formation of biofilms, a kind of aggregation of bacteria that makes them insensitive to antibiotic treatments.

Our project aims to the production of a multilayered material composed by differently functionalised nanocellulose to obtain an efficient antibiofilm device. Finally, we developed a catheter prototype made with a base in polydimethylsiloxane (PDMS) covered by a plastic polymeric layer made of Evatane® 40-55 and two nanocellulosic layers kept together by electrostatic interactions.

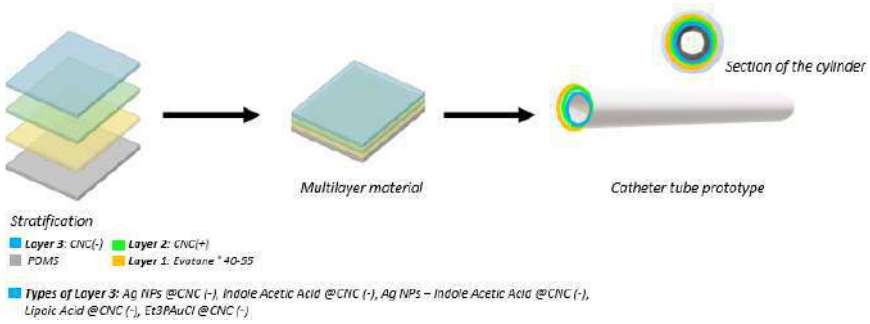

Figure 1: Stratification and formation of the catheter prototype.[3]

Synthesis of original open-shell luminescent derivatives

A. Bionda,[a] S. Mattiello,[a] M. Sassi,[a] L. Beverina[a]

[a] *Department of Materials Science, University of Milano-Bicocca, 20126 Milan, Italy*
a.bionda1@campus.unimib.it

Open-shell molecules possessing doublet ground states such as organic radicals have attracted growing interest as a unique class of molecular emitters. They can exhibit properties which are difficult to achieve with conventional closed-shell molecules. Improvement of luminescence efficiency, electroluminescence with nearly 100% electron–photon conversion, absence of heavy atom effects, magnetoluminescence are the principal characteristics of these type of systems. Therefore, these emitters have great potential to expand the variety and design strategies of luminescent molecules to broaden their utility for photofunctional applications.[1]

Perchlorotriphenylmethyl radical (PTM) and tris(2,4,6-trichlorophenyl) methyl radical (TTM) are typical examples of stable radicals that show distinct photoluminescence in solution at r.t. By fine tuning the substituent groups, it is possible to change the photochemical properties of the system and lower the energies of the frontier molecular orbitals, increasing their photostability over time. For example, pyridyl bis(2,4,6-trichlorophenyl) methyl radical (PyBTM) family shows a significantly increased stability.[1]

This contribution will describe the preparation of selected derivatives in order to expand the spectrum of open-shell emitters.

Ultrasound-assisted iodination of anilines

F. Bocerani,[a] F. Ferlin,[a] L. Vaccaro [a]

[a]*Laboratory of Green S.O.C. – Dipartimento di Chimica, Biologia e Biotecnologie, Università degli Studi di Perugia, Via Elce di Sotto 8, 06123 – Perugia – Italy, web: greensoc.chm.unipg.it, filippo.bocerani@studenti.unipg.it*

Aromatic iodination plays a significant role in the realm of synthetic organic chemistry. Iodo compounds find frequent application in cross-coupling reactions, copper-catalyzed reactions, and Grignard reactions, where C-C bonds are formed. Due to this versatility, they hold immense utility across various chemical disciplines.[1] Additionally, these compounds assume an important role in medicine, either as integral components of pharmaceuticals or as radioactive diagnostic markers.[2] Throughout history, multiple methods have been developed for conducting electrophilic iodination. A large number of electrophilic iodinating agents have been devised and implemented in organic synthesis, including *N*-iodosuccinimide[3] or iodochloride (ICl).[4] In our current study, we present a novel approach to electrophilic iodination. Our focus lies in waste reduction and the adoption of reaction conditions aligned closely with the principles of green chemistry. Our aim is to maintain a sufficiently high concentration (1 M), employ a non-toxic solvent derived from biomass (2-MeTHF), and utilize a non-toxic acid additive (AcOH). Furthermore, we seek to minimize energy consumption by employing sonication instead of temperature control.

Down-color converters, also known as down-conversion materials or phosphors, are substances that absorb light of shorter wavelengths, such as ultraviolet (UV) or blue light, and re-emit it at longer wavelengths in the visible spectrum. These materials play a crucial role in various lighting applications, including solid-state lighting, display technologies, and fluorescence-based sensing. Organic chromophores have emerged as promising candidates for down-conversion color converters in various optoelectronic applications, owing to their tunable optical properties, cost-effectiveness, and environmental friendliness.

This study explores the synthesis and characterization of naphthalene-based chromophores tailored for their potential application as down converters in hybrid white light-emitting diodes (LEDs). The design and synthesis of these chromophores were thoroughly carried out to optimize their photophysical properties, aiming at efficient energy absorption and subsequent emission at longer wavelengths. Through a systematic approach, the photophysical properties of the synthesized chromophores were thoroughly investigated employing various techniques, including UV-Vis absorption spectroscopy, fluorescence spectroscopy, and quantum yield measurements. The results unveil successful tuning of absorption and emission wavelengths, alongside enhancements in fluorescence quantum yields, achieved through strategic structural modifications of the naphthalene core and its substituents. However, challenges such as photostability, aggregation-induced quenching, and limited thermal stability still need to be addressed to realize the full potential of naphthalene-based converters. The findings underscore the promising potential of naphthalene-based chromophores in bolstering the efficiency and color quality of hybrid white LEDs, thereby fostering advancements in energy-efficient lighting technologies. This research lays a foundation for further exploration and development of novel chromophores for next-generation lighting applications.

kateryna.bondar@unito.it

This study focuses on the synthesis and characterization of cyanine dyes derived from carboxy indole, featuring cyclopentene and cyclohexene central moieties. These dyes exhibit notable differences in their absorption properties, with the cyclopentene-based dye showing a pronounced red shift and higher extinction coefficient compared to its cyclohexene counterpart[1]. Our research aims to elucidate the structural influences on the optical properties of these dyes and explore their potential application as sensitizers in dye-sensitized solar cells (DSSCs). By leveraging the distinctive absorption characteristics of these cyanine dyes, we seek to optimize their performance for enhanced light harvesting and photovoltaic efficiency in DSSC devices. DSSCs offer several benefits, including low production costs, ease of fabrication, and flexibility in design and integration[2]. Furthermore, DSSCs exhibit excellent performance under low-light conditions and have the potential for use in a wide range of applications, including portable electronics, building-integrated photovoltaics, and off-grid power generation in remote areas. This investigation contributes to the development of efficient and cost-effective solar energy conversion technologies, with implications for sustainable energy production and expanded access to clean energy solutions.

Water-soluble photosensitizers for application in X-ray promoted photodynamic therapy

Marco Bormetti, Nicola Rivi, Giorgia Gullo, Paolo Minessi, Franca Bigi

Department of Chemistry, Life Sciences and Environmental Sustainability, University of Parma, Parco Area delle Scienze 17/A, 43124, Parma, Italy
marco.bormetti@unipr.it

Photodynamic therapy (PDT) is a clinical approach to treat cancer by activating a photosensitizer (PS) through light exposure ranging from UV to near-infrared. This activation induces the production of reactive oxygen species (ROS), particularly singlet oxygen ($^1O_2$), well known for its cytotoxic impact on cancer cells. Studies reported in the literature highlighted the possibility to enhance singlet oxygen production by combining photosensitizers with metal nanoparticles under laser irradiation. The principal drawback of conventional PDT lies in the limited penetration of visible light in biological tissues, impeding effective photosensitizer excitation in deeper tissues. Consequently, substantial efforts have been directed towards overcoming this limitation through X-ray irradiation. Metal nanoparticles with elevated Z values exhibit efficient X-ray absorption, facilitating energy delivery to surrounding tissues[1]. It has been reported that the presence of photosensitizers and metal nanoparticles (NPs) enhances singlet oxygen and ROS generation. Gold nanoparticles (AuNPs) have gained prominence due to their biocompatibility, making them widely used as contrast agents.

This study presents the synthesis of new water-soluble nanosystems achieved by conjugating either a porphyrin derivative or a rose bengal (RB) derivative to AuNPs. The water soluble porphyrin was synthesized by modifying tetra(4-hydroxyphenyl)porphyrin (THPP) with three PEG chains and a short linker terminating with a thiol or disulfide group. The RB derivative was prepared by reacting a thiol or disulfide ending linker with the carboxylic moiety of RB. The thiol or disulfide moiety is needed for effective binding to the water-soluble AuNPs due to the strong affinity between sulfur and gold. A preliminary investigation was conducted to evaluate singlet oxygen and ROS production by the nanosystems under X-ray irradiation, using different probes.

Figure 1: THPP and RB based nanosystems

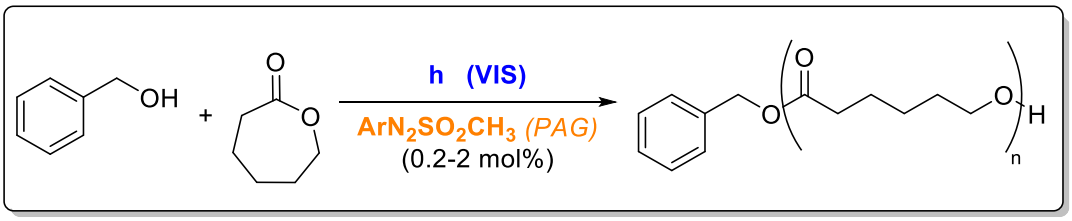
giulia.borsatti01@universitadipavia.it

Photopolymerization offer several advantages over classical thermal polymerizations such as rapidity of execution, solvent-free conditions and thus reduced emission due the room temperature used. Photopolymerization is currently dominated by non-degradable UV-curable resins based on acrylates, methacrylates and epoxides that are usually polymerized by radical or cationic pathways, mainly due to their fast reaction rates. In the last decade, biodegradable polymers such as poly(ε-caprolactone) (PCL), polylactic acid (PLA) and polyaminoacids (PAA) have found applications in several fields including, among the others, nanomedicine, tissue engineering and 3D printing.[1] In this context, ring-opening polymerization (ROP) of the cyclic monomers in the presence of an initiator (usually an alcohol or amines) and a Bronsted/Lewis acid as the catalyst may induce a spatial and temporal control, and controlled polymerizations in term of polymeric architectures and polydispersity indexes.[2]

Arylazo sulfones are thermally stable derivatives of aryl diazonium salts previously used as photoinitiators in free-radical polymerization of methacrylates,[3] as well as visible light Photoacid Generators (PAGs) in organic synthesis.[4] Herein, we present an efficient protocol for the ring-opening polymerization of different cyclic monomers (eg. ε-caprolactone) upon visible light irradiation, initiated by various alchools and using differently substituted arylazo sulfones as the PAGs (an example is illustrated in Scheme 1). The efficiency of the designed procedure will be discussed in terms of polymerization yields, dispersity and degree of polymerization.



Scheme 1: Light driven ring-opening polymerization of ε-caprolactone using arylazo sulfones as PAGs.

Epothilones are 16-membered macrolides that can act as microtubule-targeting agents to tackle cancer[1-6]. Many synthetic analogues have been investigated for their activity, yet often based on macrolide structures. A notable exception is Ixabepilone, an azalide representing the only epothilone-like molecule approved by the FDA as a chemotherapeutic[7]. Exploiting the amide-triazole bioisosterism[8], in this work we report the synthesis of the first generation of epothilones lacking the macrolide or azalide structure, with the ester or amide linkage replaced by a triazole unit. Together with the synthesis of this new analogue, computational and biological evaluations have been performed too.

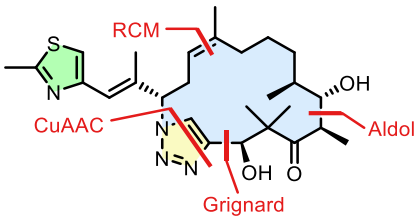

Figure 1: Target Epothilone analogue and synthetic strategy involved.

The menisci are crescent-shaped fibrocartilaginous cushions found in the knee articulation between the femoral condyles and the tibial plateau which main function is weight distribution[1]. Their extracellular matrix is highly hydrated and mainly composed of collagen, glycosaminoglycans (GAGs), adhesion glycoproteins and elastin. They are composed of three distinct regions with different cell populations, extracellular matrix (ECM) components and morphological features[2].

Here in this work, bioprintable hydrogels were formulated using the horseradish peroxidase phenol coupling to crosslink gelatin and hyaluronic acid both functionalized with tyramine. The effectiveness of the oxidative coupling was checked with NMR, UV-VIS and FTIR analyses. Then, different formulations of the hydrogel were compared with a SEM analysis to investigate the morphology and the porosity and with an amplitude sweep test to determine the storage modulus (G'), the loss modulus (G''), yield and flow points. FTIR (Fourier-transform infrared spectroscopy) was then performed to confirm the hydrogels formation.

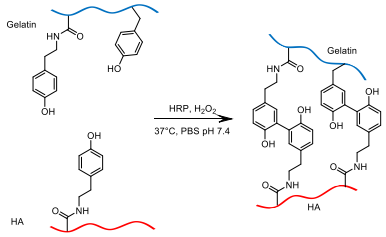

Figure 1: horseradish peroxidase phenol coupling between hyaluronic acid and gelatin

Comparing these results, the most suitable hydrogels for meniscal regeneration were determined to mimic the outer and inner zones of the tissue: a viability test was finally performed with mesenchymal stem cells on them to investigate their interaction and cytocompatibility.

Chemo-enzymatic approaches for recovery and valorization of stilbenoids from agri-food waste

G. Brioschi,[a] F. Annunziata,[a] C. Pinna,[a] S. Princiotto,[a] M.L. Contente,[a] A. Pinto,[a] S. Dallavalle,[a] and G. Borgonovo[a]

[a] *Department of Food, Environmental and Nutritional Science, University of Milan, via Celoria 2, 20133-Milan, Italy*
giulia.brioschi2@unimi.it

Food loss and waste (FLW) currently represent one of the most pressing public and economic challenges, since negatively impact food security and nutrition and significantly contribute to greenhouse gas emissions.[1] Agri-food industries produce significant amounts of FLW, especially from fruit and vegetable processing,[2] including peels, seeds, leaves, and stems which are known for their high content of bioactive molecules. The development of extraction and processing procedures of these high value natural products for different industrial sectors (i.e., nutraceutical, cosmetic and pharmaceutical industries) is a valid solution to the social and environmental issue represented by agri-food waste.

Resveratrol, a stilbenoid found in grapes, is a natural phytoalexin.[3] It has been intensively studied for its variety of biological activities, together with its metabolites. However, these biological investigations have to deal with the scarce quantity and difficult isolation of pure compounds present in the natural matrices.

In this context, we focused our attention on the development of sustainable chemical processes ("green" extractive chemical approaches and/or enzymatic bioconversions) for the recovery, valorization and production of high value-added molecules starting from vine-wine supply chain. The proposed strategy aims to the search and chemical characterization of active antimicrobial and antioxidant stilbenoids in a "circular economy" approach,[4] allowing at the same time a stable and consistent source of supply.

Covalent functionalization of reduced graphene oxide improving its dispersibility in P3HT to obtain composite Hole Transporting Materials for Perovskite Solar Cells

Linda Maria Brun,[a] Claudia Longo,[a] Luca Lazzarin,[a] Elena Iannibelli,[b] Luigi Vesce,[b] Aldo Di Carlo,[b] Enzo Menna[a]

Enhance the efficiency and device's reproducibility of perovskite solar cells (PSC) is a largely pursued goal. Improving the long-term stability of hole transporting materials (HTM) is a key strategy to bring PSC closer to their practical application.

We synthesized and characterized reduce graphene oxide (RGO) derivatives with the aim of increasing the stability and homogeneity of their dispersion within a poly(3-hexylthiophene) (P3HT) HTM. In principle, RGO and P3HT have the potential to establish π–π stacking interactions between their individual delocalized π electrons clouds, which can make their composites highly stable, but unfortunately this does not often occur due to the stronger tendency of pristine nanostructures to self-aggregate compromising the homogeneity of their dispersion within a polymer matrix.

Goal of chemical functionalization of RGO is therefore to promote interactions with P3HT, by choosing appropriate functional groups, while avoid an excessive disruption of the RGO native electronic structure.

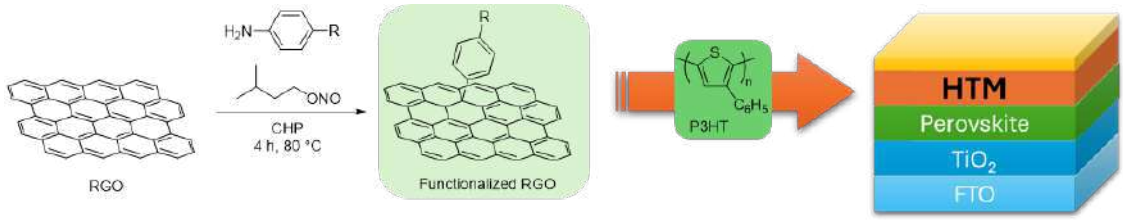

Figure 1: Schematic illustration of functionalization reaction of RGO to obtain derivatives to be used as fillers in P3HT-based composite HTM.

Pirfenidone-Containing Dual Conjugates Targeting $\alpha_V\beta_6$ Integrin as New Potential Antifibrotic Agents

K. Bugatti,[a] L. Battistini,[a] F. Zanardi,[a] F. Bianchini,[b] A. Sartori[a]

kelly.bugatti@unipr.it

Idiopathic Pulmonary Fibrosis (IPF) is a rare, chronic, and fibrotic lung disease, characterized by a median survival after diagnosis around 3-5 years. Pirfenidone is one of the two drugs approved for the treatment of IPF, although *i)* its mechanism of action is not completely clear; *ii)* it just slows down the disease progression; *iii)* it causes several off-target side-effects.[1] Thus, research in finding new drugs against IPF is widely active, and several biological targets are currently under investigation as new markers. The $\alpha_V\beta_6$ integrin is one of these targets, as it is overexpressed in IPF being involved in activation of the principal pro-fibrotic mediator, TGFβ, and it may be exploited both for the selective delivery of an antifibrotic drug, and as therapeutic target.

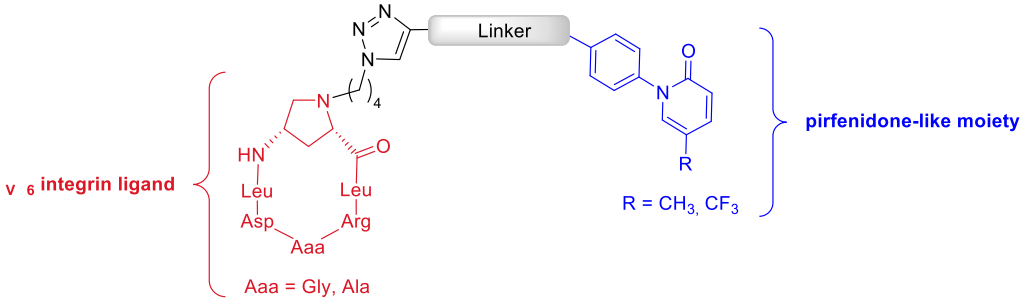

Figure 1: Generic representation of covalent conjugates embedding an $\alpha_V\beta_6$ integrin-targeting ligand and a pirfenidone-like moiety.

Based on this evidence and on the promising results of our previous work on integrin-based conjugates as antifibrotic agents,[2] the aim of this project is the construction of new covalent conjugates embedding an $\alpha_V\beta_6$ integrin-targeting ligand and a pirfenidone unit. Three covalent conjugates (Figure 1) were designed and synthesized, constituted by a pirfenidone-like moiety (depicted in blue), which is linked to the integrin-targeting aminoproline-based cyclopeptide (depicted in red) by means of a robust triazole-based linker (depicted in black). The synthesized compounds will be tested towards activated fibroblasts, also with the aim of better elucidating the mechanism of action of pirfenidone, paving the way to the development of potential targeted antifibrotic drugs.

Gaucher disease (GD), the most prevalent lysosomal storage disorder, arises from a genetic anomaly in the *GBA* gene, causing misfolding of acid-β-glucosidase (GCase) enzyme. The mutation in GCase perturbs its trafficking to the lysosomes leading to substrate accumulation which in turn determines severe systemic symptoms. A promising therapeutic approach is the Pharmacological Chaperone (PC) Therapy[1], which utilizes enzyme inhibitors, such as iminosugars, as folding templates to restore GCase trafficking and thus endogenous enzyme activity. The affinity of the PC to the enzyme should be higher in the endoplasmic reticulum (pH = 7) and lower in the lysosome (pH = 4.5) to allow the natural substrate entering the catalytic site, thus maximizing the therapeutic efficacy. Aim of this study is to develop innovative PCs for GD based on smart host-guest systems responsive to the physiological pH fluctuation (Figure 1). In this context, the synthesis of mono and bis-alkylated-iminosugars with piperidine and pyrrolidine skeletons was carried out, starting from cost-effective carbohydrates. The alkylation was carried out either on the nitrogen atom, on the alpha carbon neighbouring the nitrogen atom, or on both positions (bis-alkylated) to guarantee the affinity with GCase. The *endo*-cavity complexation of these bioactive compounds with water-soluble prismarenes[2] will be studied at different pH values by NMR or Fluorescence titration experiments.

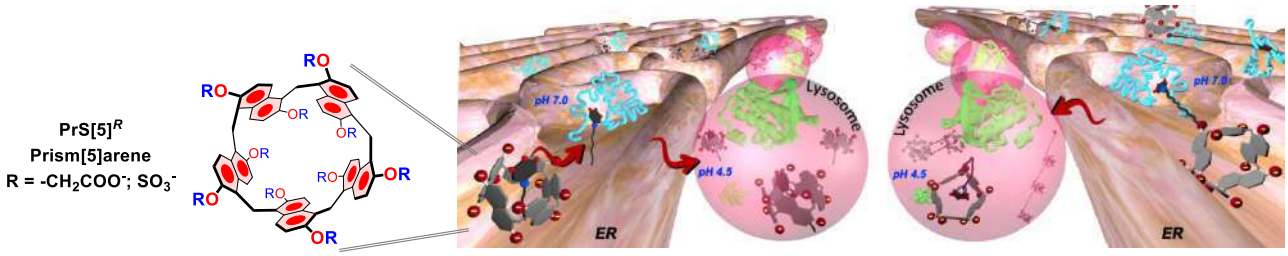

Figure 1: Schematic representation elucidating the rationale behind pH-responsive PCs.

The aim of moving towards a sustainable global economy and a future without fossil fuels has driven researchers to seek new methods for producing and storing energy. Harnessing solar energy to generate power through photovoltaic technology is an economical, stable, and clean method. However, currently available photovoltaic panels are black or blue and therefore not suitable for all environments. In this work, we report the synthesis of new organic fluorophores with LDS properties, which once dispersed in PMMA can be used as Luminescent Solar Concentrator (LSC), colored optical devices that can be used in alternative contexts to traditional photovoltaics. With this in mind, a series of quinoxaline emitters was designed for maximum absorption wavelength between 500 and 600 nm.[1] The emitters were expeditiously prepared following a direct arylation protocol and extensively characterized by spectroscopic analyses and computational studies. They present high light harvesting ability in the green region of the visible spectrum and good emission properties, which were fully retained in the solid state when embedded into a PMMA matrix. Devices constructed with these materials could thus be used in greenhouses because they are transparent in the radiation used by plants and they can convert the remaining visible radiation into electrical energy. The tailored properties of these materials allowed us to prepare LSC devices with promising efficiencies, η_{dev} up to 0.43%. More broadly, this study highlights the use of organic emitters as a convenient strategy in the development of green-light selective LSC devices for their integration into agrivoltaic technologies.

umberto.calice@unibas.it

Chiral recognition is gaining significance across multiple fields such as biochemistry, clinical and medicinal chemistry, natural product chemistry, and environmental chemistry. Identifying the structure and enantiomeric composition of chiral molecules is crucial for their detection and comprehension of their behaviour in both the environment and living organisms. One of the most promising methods for chirality sensing and detection is the use of stereodynamic chiroptical probes.[1] These probes consist of achiral or racemic compounds which adopt a preferred chiral conformation when interacting with a chiral analyte, thereby generating a CD signal from which the absolute configuration and/or enantiomeric excess of the analyte can be determined.[2] Some of us recently introduced prismarenes,[3] a novel class of macrocycles able to form inclusion complexes with cationic guests. These macrocycles can assume enantiomeric chiral conformations and it has been shown that inclusion of chiral enantiopure guests induces formation a preferred host enantiomer, as evidenced by characteristic CD spectrum features.[4] The presence of numerous aromatic chromophores on the macrocycles facilitates the detection of UV and CD silent chiral compounds, termed "cryptochiral", due to their ability to produce easily detectable CD signals. We report herein the study of the chiral induction in the host-guest complexes between different chiral compounds and prismarenes PrS[5]^{Me} and PrS[6]^{Et} using CD spectroscopy, eventually applying this approach to determine the enantiomeric composition of scalemic mixtures.

Applications of carbon nitride-perovskite composite materials as heterogeneous photocatalysts in C-C bond formation and oxidation processes

Camilla Callegari,[a] Emanuele Bosetti,[a] Alessia corbo,[a] Costanza Tedesco,[a]
Giulia Giovilli,[a] Lorenzo Malavasi,[a] Davide Ravelli[a]

[a] *Department of Chemistry, University of Pavia, viale Taramelli 12, 27100 Pavia, Italy*

e-mail: camilla.callegari01@universitadipavia.it

Grafitic carbon nitride-based materials (general formula: g-C_3N_4) are commonly used as photocatalyst (PCs) working via *single-electron transfer* (SET) in several applications, ranging from fuels production to synthesis due to their ease of preparation, low cost and light absorption in the visible light range.[1] Heterojunction design can improve the redox properties of g-C_3N_4 (in particular, the carrier lifetime) and metal halide perovskites (MHPs) resulted to be effective semiconductors to be coupled to g-C_3N_4 in composites.[2] Herein, we devised and prepared the g-C_3N_4/$Cs_2AgBiCl_6$ and g-C_3N_4/$CsPbCl_3$ composite systems, considering the good energy alignment between the two semiconductors and the efficient photocatalytic activity of $Cs_2AgBiCl_6$ and $CsPbCl_3$.[3,4] In this work, we have tested the prepared composites (including the parent derivatives) in the role of heterogeneous photocatalysts for synthetic purposes under visible light irradiation. Specifically, we have tested their competency in the 1,2-difunctionalization of olefins via *Atom-Transfer Radical Addition* (ATRA; see Figure 1, left part)[5]. Moreover, we have placed our attention on different kind of benzylic oxidation processes (see Figure 1, right part).

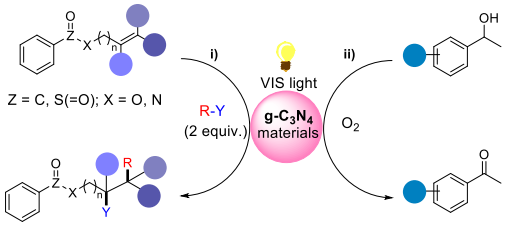

Fig.1 Carbon Nitride-perovskite composites as heterogeneous photocatalysts under visible light irradiation in synthetic applications for: i) ATRA processes between olefins and alkyl halides (left part) and ii) benzylic oxidation (right part).

Bromodomains (BDs) are protein modules of ~110 amino acids that recognize acetylated lysine, particularly in histones, and thereby they have important roles in the regulation of gene expression. Following the most recent structure-based classification, the human BRDs are grouped into eight families that span all 61 domains.[1] Bromodomain-containing protein 9 (BRD9), an epigenetic reader, has received increasing attention in the scientific community for its role in gene regulation and its overexpression in many human tumours highlighting it as an attractive target for cancer therapy.[2,3]

The identification of selective BRD9 inhibitors could disclose new epigenetic chemical probes useful to elucidate its biological function, as well as for discovering new anti-cancer drugs.

Following a multidisciplinary protocol that involves virtual combinatorial screening, chemical synthesis and preliminary pharmacological assay, we afforded to the identification of a new chemotype of BRD-9 inhibitors, endowed with an indolyl 2-pyrazole scaffold.

These outcomes pave the way toward a medicinal chemistry optimization campaign of the disclosed hits in order to obtain new BRD-9 inhibitors endowed with high affinity and selectivity.

Agriculture faces a significant challenge in safeguarding crops against weed competition while minimizing their spread. To this end, natural biopesticides like phytotoxins offer promising traits, having low persistence in the environment and highly targeted modes of action, thus minimizing pest resistance issues and environmental impact. Ascaulitoxin and its aglycone (**AscA**), derived from the *Ascochyta Caulina* fungus[1], stand out as potent phytotoxins with potential for controlling weeds[2]. The absolute configuration of natural **AscA** was unknown and its relative configuration uncertain. Therefore, aim of this work was the total synthesis of stereoisomers of ascaulitoxin aglycone to both determine its absolute configuration and provide quantities necessary for large-scale applications and structure-activity relationship studies. **AscA** can display up to 16 possible stereoisomers, but initially, we assumed an (*S*) absolute configuration of the terminal amino acid moieties, thus limiting the search to four of them. Therefore, this report details the approach to the diastereo- and enantioselective synthesis of four ascaulitoxin aglycone stereoisomers. The synthesis of *anti* isomers of the central amino and hydroxy groups was carried out by an asymmetric dihydroxylation-Mitsunobu azidation sequence, while the *syn* isomers were obtained through direct asymmetric aminohydroxylation. Both methods originate from the same olefin, readily prepared from commercially available Boc-L-allylglycine through self-metathesis. Furthermore, the phytotoxic activity of the synthetic intermediates of ascaulitoxin aglycone diastereomers was tested on host and non-host weed plants.

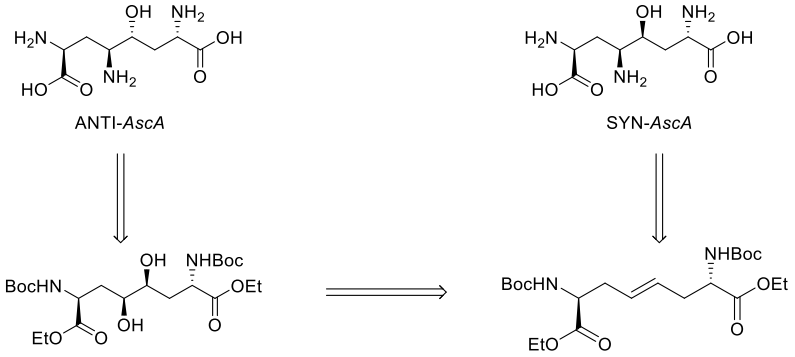

Figure 1: Retrosynthetic approach for the synthesis of the *anti* and *syn* stereoisomers of AscA

New molecular cages for chiroptical sensing

F. Carnio,[a] F. Begato,[a] G. Licini,[a] C. Zonta[a]

[a] *Dipartimento di Scienze Chimiche, Università degli Studi di Padova, Via Francesco Marzolo 1, 35131 Padova*

francesco.carnio@phd.unipd.it

Metal complexes of tris(2-pyridylmethyl)amine (**TPMA**) ligands have gained interest in sensing applications due to the seminal contributions of Canary[1,2] and Anslyn.[3] Recently, these complexes have been exploited by our research group as building blocks for the synthesis of novel molecular cages.[4] These architectures are obtained through imine bond formation from the self-assembly of a modified **TPMA**-based metal complex bearing three aldehyde groups and diamine linkers.[4,5]

The present work illustrates the synthesis of new **TPMA**-complexes and the corresponding novel molecular cages. Furthermore, the synthesis of new chiral hydrolytically stable cages, exploiting a method recently published by our research group,[6] is described. The goal of this project is to obtain new chiroptical properties like, for example, an amplification of circular dichroism (CD) and circularly polarized luminescence (CPL) signals. In order to achieve these aims, chiral cages could be employed together with fluorophore guest molecule appropriately functionalised. Otherwise, the fluorophore could be embedded in the chiral cage structure as in the case of the 9,9-dihexylfluorene unit (Figure 1).

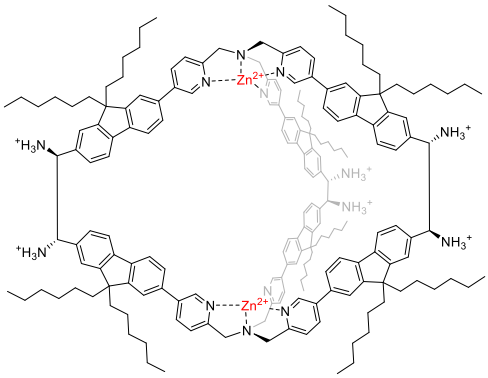

Figure 1: New hydrolytically stable **TPMA**-based molecular cage bearing six 9,9-dihexylfluorene units.

emanuele.carrella@unina.it

Eumelanins are dark insoluble pigments,[1] arising by oxidative polymerization of 5,6-dihydroxyindole (DHI) and DHICA 5,6-diacetoxy-indole-2-carboxylic acid, involved in important biological functions (*e.g.,* photoprotection, homeostasis). Due to their natural origin and peculiar physical-chemical properties, eumelanin can play a key role in biomedical applications and bioelectronics[2]. In a previous study, the first water-soluble eumelanin monomer 3-thiogalactoside-DHI (S-GAL-DHI) allowed noteworthy insights in structural investigations of DHI melanin[3]. In the view of the emerging interest of soluble glycosylated eumelanin in materials science and in glycobiology, the synthesis of new glycosylated melanins involving diverse saccharide precursors represents a field of research of high relevance. In this work, a series of 3-selenoglycosylated eumelanin derivatives (figure 1) were prepared through a practical and efficient approach exploiting a metal free, simple, and scalable synthetic route. The strategy is feasible for installing both mono- and disaccharide units for the first time on both O-protected eumelanin precursors and relies on the exploit of easily accessible glycosyl diselenides[4] as selenium source.

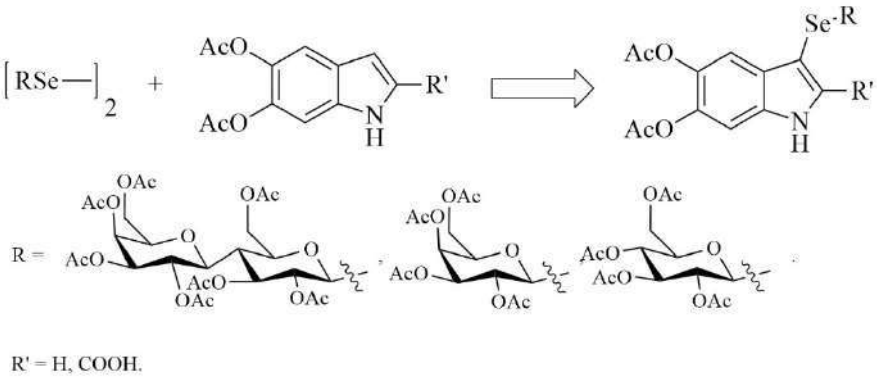

Figure 1: Synthesis of 3-selenoglycosilated eumelanin monomers.

π-Conjugated Functionalized Wood towards Sustainable Optoelectronics

F. Casti,[a] G. Sforazzini[a]

[a] *Dipartimento di Scienze Chimiche e Geologiche, University of Cagliari, Monserrato, Sardinia, Italy*
e-mail: federico.casti@unica.it

Highly transparent materials are pivotal for the development of energy saving budling.[1] Among these materials, transparent wood (TW) offers exceptional optical properties, UV blocking and low thermal conductivity,[2] in combination with a rapid fabrication process and impressive mechanical strength, reducing building energy consumption and construction industry's environmental impact. Transparent wood is made in a two-step process. First, delignification using an oxidant solution of hydrogen peroxide and sodium hydroxide in combination with heat, resulting in bleached wood that has empty channels (lumens) deprived of chromophore molecules.[3] The second step involves the filling of these channels with of thermo- or photocurable polymer resins.

In this work, we introduce a novel approach to enhance the optical and optoelectronic properties of these materials. Lumen filling is done utilizing three methods: 1) chromophore adsorption followed by polymer infiltration, 2) covalent chromophore anchoring to the lumen wall followed by polymer infiltration, and 3) synthesis of monomers inclusive of pendant chromophores for a single-step infiltration and polymerization. Two types of class of compounds were investigated: light-responsive azobenzene and electron-rich arylamine derivatives. The resulting wood-optoelectronic materials were characterized through UV-vis and IR spectroscopy, X-ray diffraction (XRD), SEM, TEM, moreover tensile strength and fracture mechanics tests were carried out to complete the mechanical investigation of the new material.

Nowadays the responsiveness of supramolecular entities toward applied stimuli is fuelling a compelling area of research. Being inspired by the reactivity of living cells to encountered inputs, the interest of researchers has rapidly spread towards the development of systems able to accomplish complex and specific tasks upon a controllable stimulus.[1] Mirroring the features of living cells might potentially be the key to shaping new future technologies, widening from groundbreaking strategies for **pollution remediation** to novel **therapeutic tools** in the frame of drug delivery.[2]

In this work, a library of artificial **azobenzene-based amphiphiles** was designed and synthetized, further to their incorporation in the bilayer of giant unilamellar vesicles (GUVs). Given the photo-triggered *E-Z* isomerization of the azobenzene moiety, unconventional behaviours were highlighted on the supramolecular scale via microscopy experiments. Remarkable shape and size alteration were confirmed upon light exposure in our engineered GUVs, as well as the **opening of pores** through the bilayer. All the observed phenomena were readily reverted by interrupting the irradiation.[3] In light of the positive results attained, novel amphiphilic molecules were developed further on by integrating the **photo-switch** feature with **fluorescence**.

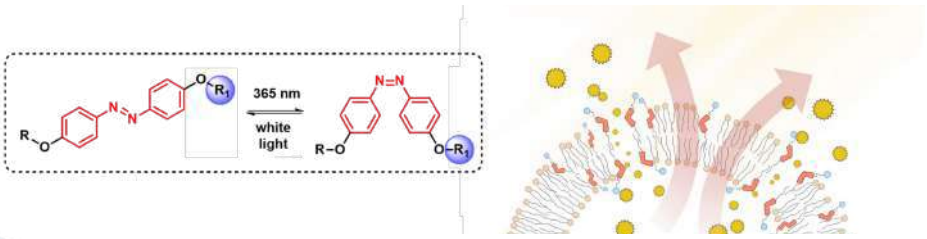

Figure 1: on the left, E-Z isomerization of the light-responsive amphiphiles; on the right, representation of the cargo release for the engineered GUVs

Hydrochars as soil amendments for heavy metals removal from soil

E. Cerza[a], A. Poderini[a], L. Vaccaro[a], A. Marrocchi[a]

[a] *University of Perugia, Department of Chemistry, Biology and Biotechnology, Via Elce di Sotto 8, Perugia, Italy*
elisa.cerza@studenti.unipg.it

In the last years, mankind faced problems associated to depletion of non-renewable resources and the rise of demand for raw materials; lignocellulosic biomass and circular economy principles can help to solve this issue. Biomass is a renewable and carbon neutral resource, that can also be exploited starting from its waste form; according to circular economy waste biomass valorisation is a better option than waste disposal. Biochars are carbonaceous materials that can be derived from waste lignocellulosic biomass. They are often employed in several fields, such as electrochemistry, water, soil purification, and as catalytic support[1,2]. Biochars are usually obtained from pyrolysis, which requires deep drying, which is energy-intensive, particularly for biomass with high-moisture content. A more sustainable thermochemical process is hydrothermal carbonization (HTC), which operates in water-rich environment under autogenous pressure generated from water and at moderate temperature conditions, about 200-260°C[3]. The final solid product is called hydrochar, a particular class of biochars, that retains volatile organic matter and functional groups that are crucial for adsorption. This study investigates the effectiveness of hydrochars from different biomass waste sources in the adsorption of lead, zinc, and cadmium from soil, both as single metals and simultaneously.

Figure 1: Waste biomass valorisation into hydrochar for heavy metals adsorption from soil

Unlocking the Potential of Lignin: Integrating Extraction and Depolymerization Strategies for Sustainable Biomass Valorization

E. Cesprini[a], W. Bertoluzzo[a], F. Sanz Azcona[a], and G. Licini[a]

[a]*Department of Chemical Sciences, University of Padova*
emanuele.cesprini@unipd.it

Lignin, the second most abundant natural polymer, holds immense value in the biorefinery sector, offering diverse opportunities for innovation and sustainability across industries. However, the complex and irregular structure of this biopolymer presents challenges in achieving specific target molecules. Firstly, the focus is on obtaining unaltered lignin, known as "lignin first," which closely resembles its natural composition. Protective agents like aldehydes and ketones have been explored to mitigate lignin denaturation during extraction processes[1]. Additionally, lignin depolymerization often relies on harsh catalytic methods with limited selectivity. However, recent advancements in photocatalysis with earth-abundant metal offer a promising avenue for gentler lignin depolymerization.

This study integrates those approaches to enhance lignin's suitability as a natural feedstock for obtaining target aromatic molecules such as aryl aldehydes, carboxylic acids, and formates. Therefore, formaldehyde is chosen as a protective agent to stabilize α,γ-diols, such as β-1 and β-O-4, during the 1,4-dioxane extraction process, facilitating acetal formation. Subsequently, acetals are removed to recover formaldehyde and restore vicinal diol functionalities. Indeed, the presence of α,γ-diol is essential for the vanadium(II) aminotriphenolate complex in order to catalyse aerobic oxidative cleavage of C-C bonds under ambient conditions and visible light [2,3]. In summary, this study provides a comprehensive perspective on biomass utilization, focusing on enhancing lignin as a platform for aromatic derivatives.

Buckwald-Hartwig goes greener. An effective heterogeneous protocol to access the synthesis of Csp2 – N bond under microwave irradiation.

M. Ciani,[a] G. Brufani,[a] L. Vaccaro[a]

[a]*Laboratory of Green S.O.C. – Dipartimento di Chimica, Biologia e Biotecnologie, Università degli Studi di Perugia, Via Elce di Sotto 8, 06123, Perugia, Italy*
e-mail: marta.ciani@studenti.unipg.it

Buchwald-Hartwig coupling is a powerful tool allowing the formation of Csp^2-N bonds. Compared to traditional synthetic strategies,[1] offers the advantages of being a one-step reaction, using relatively mild reaction conditions and having greater tolerance to functional groups. This versatile method has a strong impact in both academic and industrial sectors: agrochemicals, natural products, sensors, ligands, polymers, and e Active Pharmaceutical Ingredients (API) heavily rely on this type of bond.[2] Despite its applicability, improving energy efficiency and environmental friendliness remains an ongoing endeavour. To address these challenges, the use of recoverable, low-energy-consuming, biomass-derived 2-MeTHF,[3] presents a promising solution. Herein, a comparison between traditional and microwave heating is reported in combination with Pd/C as a recoverable catalyst. To the best of our knowledge, there are few examples of applying this technology in this field. The synergy between microwave technology, heterogeneous catalysts, and recoverable reaction media enhances the accessibility of diversely functionalised arylamines, key intermediates in API synthesis.

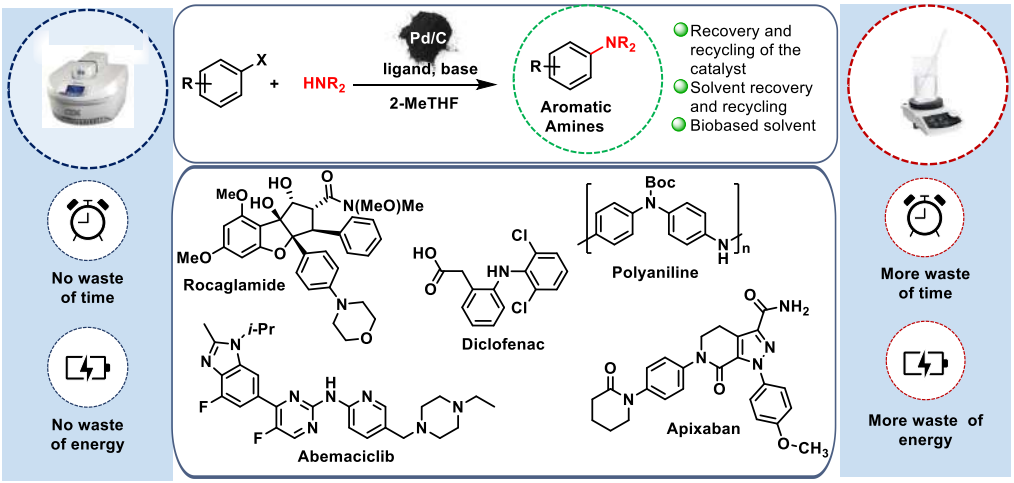

Figure 1: Buchwald-Hartwig reaction and some of its applications.

Prostate cancer is the second most common tumor and the fifth cause of cancer death in men. Recent studies showed that different types of human tumors, as for example prostate cancer, present an overexpression of a protein kinase, c-Src, which downregulation could be a useful strategy for their treatment. Over the years several c-Src inhibitors have been developed that possess in their structure some heterocyclic rings, such as pyrazolo[3,4-d]pyrimidine derivatives. However, these molecules present a very poor aqueous solubility that requires high dosage to be efficient worsening the patience compliance. Halloysite, a clay mineral belonging to kaolin group with a typical hollow tubular structure, because of its biocompatibility and low cost represents a valuable carrier system for the local delivery of such drugs.[1,2] Herein, we report the design of halloysite based nanomaterials covalently or supramolecular modified with some pyrazolo[3,4-d]pyrimidine derivatives ad hoc synthetized. The obtained nanomaterials were thoroughly investigated from a physico-chemical point of view to assess the successful modification and their morphology was imaged by transmission electron microscopy. Furthermore, their antiproliferative activity was also assessed by *in vitro* studies on RT112, UMUC3 and PC3 cell lines as model of bladder and prostate cancer cells.

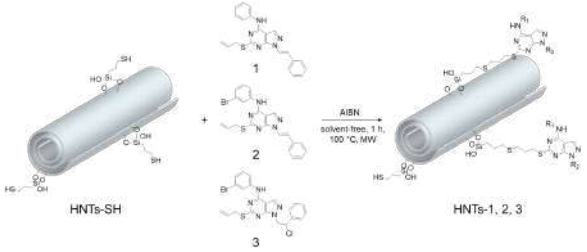

Figure 1. Halloysite/Pyrazole[3,4-d]pyrimidine nanomaterials.

Study of methods, enviromentally sustainable abatement of organic fraction responsible for Chemical Oxygen Demand in wastewater of industrial plants

[a]Riccardo Ciciriello,[a] Pietro Cotugno,[a] Gianluca Maria Farinola

[a]*Dipartimento di Chimica, Università degli Studi di Bari, Via Edoardo Orabona 4, Bari*
riccardo.ciciriello@uniba.it

This research aims to conduct a comprehensive large-scale analysis, focusing on exploring advanced and sustainable methods to reduce the presence of the organic component associated with Chemical Oxygen Demand (COD) in industrial effluents. The main objective is the identification, evaluation, and implementation of innovative protocols, with particular emphasis on the application of the Fenton reaction as an Advanced Oxidation Process (AOP)[1].

The Fenton reaction, based on the generation of highly reactive free radicals through the interaction between hydrogen peroxide and iron, emerges as a promising perspective for wastewater treatment, also mediated by other metals such as copper, cobalt, and manganese. This approach is particularly important in the context of treatment using activated sludge, a traditional methodology that employs microorganisms to simulate purification processes observed in nature in water bodies. However, an intrinsic limitation of this approach lies in its inefficacy in treating toxic pollutants, as microorganisms may not completely degrade them[2].

In the presence of toxic pollutants challenging the efficacy of activated sludge treatments, advanced oxidation processes such as the Fenton reaction emerge as an alternative and complementary solution. These processes, characterized by their ability to generate highly reactive free radicals, offer a more robust and efficient oxidation mechanism. Therefore, the integration of innovative approaches in industrial wastewater management aims to overcome the limitations of conventional treatments, more effectively addressing the presence of recalcitrant contaminants[3].

A distinctive aspect of this research lies in the synthesis of metallic catalysts employed in the Fenton reaction, obtained through the recovery of metallic waste from various industrial sources. This synergy between the power of the Fenton reaction and the recycling of waste materials highlights a sustainable approach that not only aims to reduce COD but also seeks to transform waste into valuable resources through the production of metallic catalysts[4].

The studied reaction conditions include the concentration of hydrogen peroxide (0-0.2 mol/L), pH (1-8), quantity of metallic waste (0-15 mg/mL), temperature (25-80 °C), and reaction time (0-24 hours). Decolorization tests using methylene blue and methyl orange were conducted, showing complete decolorization and dye removal at room temperature after 5 hours. Subsequently, decolorization tests were carried out on industrial wastewater samples, also showing complete decolorization at short reaction times.

Biomedical science has long been looking for innovative systems for diagnostic and therapeutic applications. In the last years, particular interest has been given to heteroaryl ethylene molecules, which have both anti-tumor and antibacterial activity, as well as excellent pH-sensitive fluorescent properties, useful in the diagnostic field.[1,2] However these molecules show a very low aqueous water solubility and short lifetime that hamper their use. Halloysite nanotubes (HNTs), a phyllosilicate clay mineral, represent appealing nanomaterial because of their high biocompatibility, low cost and the peculiar capability to cross cellular membrane, localizing themselves in the perinuclear area, that together the presence of an empty lumen, make them excellent systems for the loading and delivery of different biologically active species.[3,4]

Herein we report the synthesis and characterization on HNTs based nanomaterial loaded with 2,6-Bis{(E)-2-[4-(Dimethylamino)phenyl]vinyl}-1-methylpyridinium iodide (HNTs/PB_4). Furthermore, the luminescent properties of HNTs/PB_4 were also studied by fluorescent spectroscopy both in solution and in solid state. The data obtained show the potentiality of the obtained nanomaterial for future application in biomedical field.

Direct enantioselective photocatalytic α-functionalization of aldehydes with nitrogen-lactam radicals

E. Colombo,[a] M.F. Boselli,[a] A.Puglisi,[a] M. Benaglia[a]

[a] *Dipartimento di chimica, Università degli Studi di Milano, via Golgi 19, 20133 Milano, Italy*
eleonora.colombo2@unimi.it

Lactams can be considered some of the most significant heterocycles in medicinal chemistry and drug discovery. They are a privileged structure common to a large variety of natural products and drugs, to which they lend a potential therapeutic effect for the treatment of different disorders, spanning from cancer, diabetes, and infectious diseases.[1] Typically, lactam rings are introduced in organic molecules by ring-closure reactions, while no example of direct introduction is reported.

In this context we report the development of a photocatalytic strategy that enables the direct stereoselective introduction of lactam rings, via nitrogen radicals. In the last decades, light emerged as one of the most powerful synthetic tools to assist the organic synthesis, enabling challenging transformations under mild conditions, via radical intermediates. Its combination with organocatalysis allowed us to point out a stereoselective version of the reaction, that opened the door to the synthesis of chiral molecules of synthetic interest.

To the best of our knowledge, no example of nitrogen lactam radical is reported in the literature, therefore we first studied the development of a *N*-aminopyridinium salt as radical precursor.[2] Inspired by a work of MacMillan and coworkers, we tested the reactivity of the radical with the nucleophilic enamine of aldehydes, obtaining good results in the α-functionalization of a wide range of substrates (**Figure 1**).[3] The scope of lactam rings and of the substrates was studied, obtaining the desired products in moderate to good yield and with good enantiomeric excess. In the end, the strategy was exploited for the synthesis of an orphan drug, Levetiracetam, to demonstrate the synthetic applicability of the method.

Para-aminomethyl calixarenes as ligands for biologically relevant G-quadruplexes

M. Cremonini,[a] B. Antolini,[a] A. Casnati,[a] F. Sansone,[a] S. Volpi[a]

[a]*Department of Chemistry, Life Sciences and Environmental Sustainability, University of Parma, Parco Area delle Scienze 17/A, 43124 Parma, Italy*
maria.cremonini@unipr.it

G-quadruplexes (G4s) are DNA and RNA four-stranded secondary structures generated by the stacking of guanine tetrads. Due to their presence in key regions of the human genome, such as telomeres and gene promoters, and their association with cancer and neurodegenerative diseases, several classes of ligands have been developed to study and modulate their biological functions.[1]

Here, we present a small library of calix[n]arenes, which were synthetized as potential new ligands for G4s (Fig. 1). The upper rim of these compounds was decorated with various amines to promote their association with the negatively charged surfaces of their targets, while their aromatic scaffold was expected to provide hydrophobic and stacking interactions. Also, we tuned the size and conformational mobility of the tested compounds through a different valency of the macrocycles (n = 4, 6, 8) and the functionalization of their lower rim (free vs methylated phenolic OHs).

The binding features of these compounds were assessed via Förster Resonance Energy Transfer (FRET)-melting assays, using the human telomeric G4 as a substrate. In this assays, the target DNA sequence was labelled with a FRET couple of fluorophores, and ligand-induced variations of its melting temperature were monitored through fluorescence measurements.[2] This approach enabled the automated screening of the tested ligands, evidencing the ability of some of them to affect the stability of their target. Then, the interaction between the tested G4 and the most promising calixarenes was further characterized via CD spectroscopy.

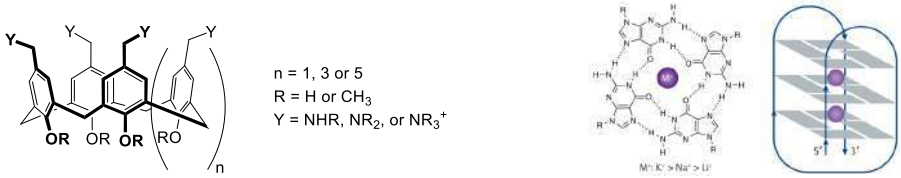

Figure 1: general structure of the tested calix[n]arene ligands (left) and a possible G4 topology (right).

Design and synthesis of chimeric antitumoral compounds Nutlin-DCA

V. Cristofori,[a] C. Trapella,[a] A. Fantinati, G. Turrin, D. Illuminati

[a]*Department of Chemical, Pharmaceutical and Agricultural Science, University of Ferrara, via Luigi Borsari, 46-44121 Ferrara (FE)*
virginia.cristofori@unife.it

Chimeric compounds are used in cancer research for the treatment of distal pathways that integrate several concurrent signals responsible for tumour growth. Their structure comprises of two or more pharmacophores connected through suitable chemical linker. This dual or multi-functional drugs have the ability to interact with different biological targets for a more pronounced therapeutic effect upon administration.

In this work we designed and built novel multifunctional molecules DCA and (-)-Nutlin-3, focusing on two important pathways linked to the predominant survival and proliferative aggressiveness of malignant cells: the Warbug effect and the suppression of "the genome guardian", p53.

Dichloroacetic acid and in particular dichloroacetate (DCA) showed to unlock cancer cells from anti-apoptosis state due to Warburg effect, via inhibition of mitochondria pyruvate dehydrogenate kinase (PDK) restoring oxidative phosphorylation metabolism.

The substitute *cis*-imidazolines, also known as Nutlins are potent antitumoral compounds studied in several types of cancer in clinical trials for their ability to restore the protective function of p53, by blockage of its antagonist oncoprotein MDM2.

Chimeric compounds derived from the connection of dichloroacetic acid (DCA) and the cis-imidazoline (-)-Nutlin-3 through suitable biodegradable linkers, could simultaneously inhibit mitochondrial pyruvate dehydrogenase kinase (PDK) and restore p53 function, inducing cell cycle arrest to impede tumor development and harboring normal cells.

Hence the final intent of this work is the selection of new multitargeting drugs with enhanced antitumoral efficacy given by a synergistic activity

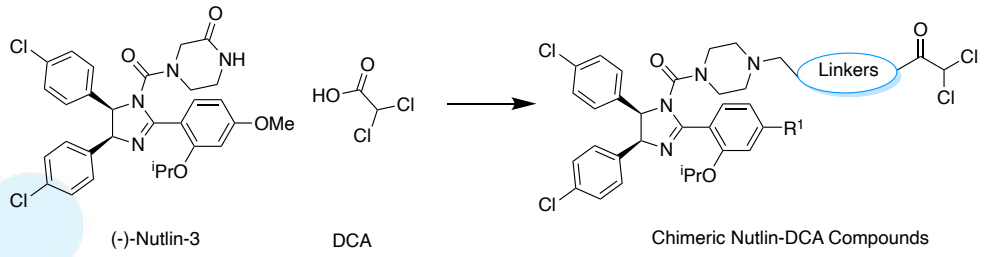

Figure 1: Schematic preparation of chimeric Nutlin-DCA compounds.

Carbon-doped Ionic Liquid Gels for simultaneous removal of emerging pollutants from water

F. D'Anna, S. Marullo

Dipartimento STEBICEF, Università degli Studi di Palermo, Viale delle Scienze Ed. 17, Palermo (Italy)
francesca.danna@unipa.it

Contamination of water bodies is a pressing issue of present-day society, exacerbated by their wide structural variety. It is therefore necessary to develop systems able to remove multiple pollutants simultaneously. In this context, we prepared and characterized supramolecular hybrid ionic liquid gels of 1,3:2,4-dibenzylidene-D-sorbitol (DBS), doped with carbon materials such as graphite, carbon nanotubes, graphene and graphene oxide. We employed these gels as sorbents for the simultaneous removal of pollutants of different classes, such as dyes and emerging pollutants like drugs and bisphenol A.

We firstly characterized the gels in terms of thermal stability, rheology and self-healing ability. Then, we tested them as sorbents for pollutants in aqueous mixtures, observing high removal efficiency and high recyclability, especially in the case of the graphite-doped gel, which achieved adsorption capacities as high as 117 mg/g and 66 mg/g for rhodamine B and bisphenol A in mixture, with a distinct preference towards cationic contaminants.

QM/MM investigation and rate constant evaluation of long-range electron transfer pathways in Bacteriorhodopsin and Bacteriorhodopsin-sensitized TiO_2 hybrid systems

A. d'Ettorre,[a] C. Roldán-Piñero,[b] L. A. Zotti,[b] A. Sinicropi[a,c,d]

alessio.dettorre@student.unisi.it

Bacteriorhodopsin (bR) is a protein present in the purple membrane of *Halobacterium salinarum*. Due to its favourable chemical and photochemical properties, it has been used in photocatalysis, photoelectrochemistry, and bioelectronics fields as a sensitizer for TiO_2.[1,2] It has been widely employed to improve the efficiency of solar energy conversion in technological devices such as photovoltaic and photoelectrochemical cells. Nevertheless, the mechanism of the Electron Transfer (ET) from the Retinal Protonated Schiff Base (RPSB) to the surface of the protein is not yet fully understood. In this work, Quantum Mechanics/Molecular Mechanics (QM/MM) methods were applied to investigate the most probable long–range ET pathways in the isolated bR and four different bR/TiO_2 hybrid systems. The goal of this work is to acquire knowledge about the intramolecular ET mechanism that leads the electron to be injected into the semiconductor conduction band. The bR/TiO_2 hybrid systems were previously generated in our laboratory.[3] Mulliken Population Analysis (MPA) and Spin Density (SD) values were computed to investigate the active redox amino acids involved in the long–range ET. Marcus's equation for ET rate constant (K_{ET}, eq. 1) was also solved for the isolated bR and the four bR/TiO_2 hybrid systems, involving the RPSB and the amino acids identified based on the SD delocalization map.

$$K_{ET} = \sqrt{\frac{4\pi^3}{h^2 \lambda RT}} \boldsymbol{H}_{\boldsymbol{AB}}^2 exp\left\{-\frac{(\Delta G^\circ + \lambda)^2}{4\lambda RT}\right\}, \qquad (1)$$

The electron coupling, $\mathbf{H_{AB}}$, was unraveled from the off-diagonal terms of the Hamiltonian corresponding to the donor D and the acceptor A of the ET reaction and treated through the Green's function ($H_{D,A}\mathbf{g}H_{A,D}$) under perturbation theory principles.[4] The driving force ($\mathbf{\Delta G^o}$) and the reorganization energy ($\boldsymbol{\lambda}$) were also computed. Since the models are treated in the gas phase, $\boldsymbol{\lambda}$ was estimated to be the internal nuclear rearrangement and calculated as half contribution from donor rearrangement and half from the acceptor.[5]

Such understanding would drive the design of novel punctual mutations for bR to produce potentially more efficient bR–variants/TiO_2 hybrid models with enhanced ET properties.

PharmaCore: automatic 3D structure-based pharmacophores development and its applications in drug discovery and repositioning

S. De Vita,[a] E. Colarusso,[a] M.G. Chini,[b] G. Bifulco, [a] G. Lauro[a]

sdevita@unisa.it

In the last few years, the development and application of 3D structure-based pharmacophores in routine virtual screening procedures led to an improvement in the quality of the results, creating a robust selective method.[1-3] However, the development of the procedure is highly time-consuming, and the time/benefit ratio was still very unfavourable. Prompted by these findings, we generated PharmaCore[4]: a completely automated workflow that can create 3D structure-based pharmacophores for any protein that meets specific requirements. In brief, this method is based on available experimental protein-ligand complexes, guaranteeing that the pharmacophoric hypotheses are developed, considering each molecule's binding orientation. The reliability of this method was recently extensively tested by us on well-known systems returning predictions that are in line with the biological data. Here we show the development of pharmacophore hypotheses for all the bromodomain for which more than 4 protein-ligand complexes with biological data were available (477 structures for 16 bromodomains) and for tankyrase 2 (60 structures). A retrospective study was also carried out using know inhibitors (AM879 for bromodomains and Pur1-3 for tankyrase) and the results were in line with what reported, with interesting new targets discovered for AM879. Moreover, considered the importance of the target, the same evaluation was performed considering the pharmacophores developed for SARS-CoV-2 M^{Pro} (1084 structures). PharmaCore, therefore, provides highly reliable pharmacophores that can be used for drug discovery or target identification. A web application and further details are available at www.computorgchemunisa.org/pharmacore.

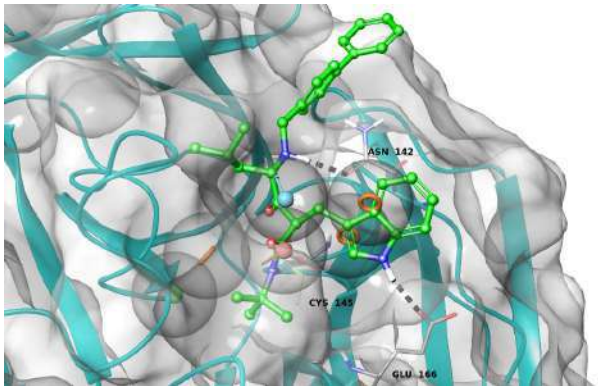

Figure 1. Example of virtual screening using a 3D structure-based pharmacophore.

G-quadruplexes (G4s) have received considerable attention in recent years, due to evidence of their occurrence in living cells. [1]Formed by stacks of guanine quartets, G4s belong to the wide class of non-canonical nucleic acid structures. Putative G4 forming sequences are distributed in genomic regions relevant for a number of pathologies, spanning from cancer to viral infections, where they can act as regulators of genetic information transfer.[2] In this context, G4-targeting is regarded as a novel potential therapeutic approach for the treatment of associated diseases.[3] Taking inspiration from the recent literature on G4 ligands[4] and relying on the scaffold hopping strategy,[5] we selected three different heterocyclic frameworks, potentially able to bind G4s by stacking the external G-tetrads. We functionalized these scaffolds with proper polar or positively charged flexible groups for binding to G4 loops/grooves, and/or with alkylating warheads for more selective covalent targeting. To investigate the G4 binding properties of the new molecules, *in vitro* biophysical studies were performed employing both telomeric and oncogene promoter G4-forming sequences. Interestingly, the investigated compounds showed potent G4-stabilizing properties and a certain preference for G4 over duplex DNA. Under preliminary *in vitro* studies, some ligands proved to inhibit cancer cells proliferation, not affecting healthy cells used as control.

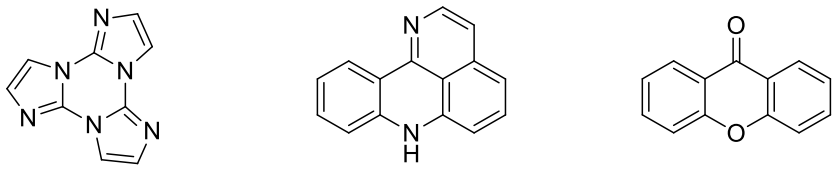

Figure 1: Heterocyclic scaffolds.

alessandro.dimasi@unimi.it

Caerulomycins, natural pyridine-based alkaloids, have been previously synthesized starting with highly pre-functionalized starting materials or requiring many functional group interconverions.[1–3] In this work,[4] we exploit recent C-H activation methodologies of N-heterocycles for the first total synthesis of Caerulomycin K, a diversely tri-functionalized pyridine readily assembled in three steps. Starting from mono-functionalized pyridines, the first strategy looked at a double C-H activation by means of phosphonium chemistry.[5] However, this strategy revealed unsuccessful. A better alternative was represented by a radical approach, achieved *via* Minisci chemistry. Firstly, an ortho-arylation on 4-chloro pyridine occurred, followed by an ortho-alkylation using trioxane.[6] In conclusion, a one pot S_NAr, trioxane deprotection and oxime formation occurred to obtain the desired final product. Compared to already reported Caerulomycin syntheses, this novel approach requires only three step and a mono-functionalized starting material.

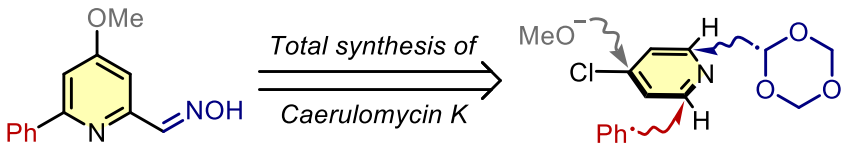

Figure 1: The first total synthesis of Caerulomycin K has been reported exploiting Minisci-type chemistry. Compared to previously reported Caerulomycin syntheses, this novel approach does not require highly pre-functionalized starting materials

Base metal-mediated cross couplings represent one of the fields in which photocatalysis can unfold its potential. In this area, for example, it has been shown that it is possible to carry out Ni-catalytic C-O and C-N cross couplings with Ni under irradiation with visible light in the presence of several types of photocatalysts.[1] In these reactions it would be highly desirable to lower the loading of Ni, considering in particular its toxicity. As a possible strategy to achieve this goal, our group envisaged the use of bifunctional photocatalysts featuring a covalent linkage between the photoactive moiety and the nickel complex. Although in visible light photocatalysis the bifunctional approach has been exploited much less than in other subareas of catalysis,[2] there are some examples in which this approach has been used to increase the catalytic performance in terms of stereoselectivity[3] and activity.[4]

Our research group synthesized and tested a bifunctional ligand for C-O cross coupling reactions between aryl bromides and aliphatic alcohols, created by linking a bipyridine moiety to a donor-acceptor cyanoarene dye similar to **4CzIPN** (**1**). By comparison of the bifunctional photocatalyst with a reference dual catalytic system involving **2** as dye, it is possible to observe the beneficial effect given from the proximity of the Ni metal centre to the light absorbing moiety.

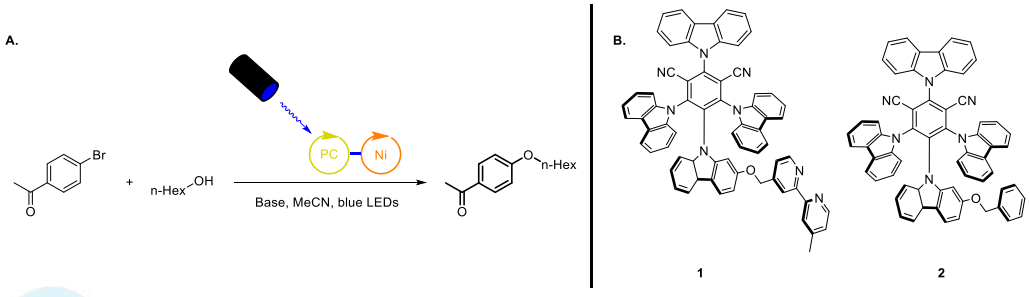

Figure 1: A. C-O coupling model reaction; B. Photocatalysts tested in this work.

denise.dozio@unimi.it

Plant secondary metabolites play a pivotal role in defense mechanisms both as antimicrobial compounds and as substrates for cell wall reinforcement. Their accumulation is often observed after pathogen infections and wounding. Cinnamoylamides are phytoalexins containing a cinnamic acid unit coupled with biogenic amines[1] and are involved in dimerization reactions under biotic or abiotic stress conditions triggered by oxygen radical species. Dimers are often endowed with higher antimicrobial activity, as reported for the ferulic acid dimer poacic acid and for hordatines[2]. To deepen the investigation of their biological activity, high amounts of the compounds are needed, but their recovery from the natural matrices is often laborious and low yielding. The development of efficient synthetic strategies could overcome this limitation, finally opening the possibility to enrich this collection of compounds with new analogues.

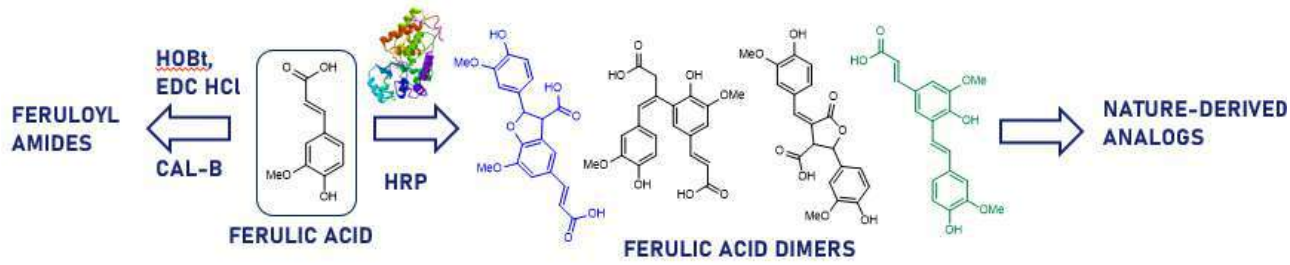

Figure 1: Ferulic acid derivatization pathway. In blue the hordatine precursor, in green poacic acid

A small library of feruloyl-amides was obtained by chemical condensations and enzymatic amidations using the lipase B from *Candida antartica* (CaL-B) in the green solvent *tert*-amyl alcohol. In parallel, to obtain ferulic acid dimers, radical reactions were performed employing the horse radish peroxidase (HRP) in presence of H_2O_2. Starting from the carboxylic intermediates shown in Figure 1, a series of natural and nature-derived analogues was synthesized. Preliminary results about their antibacterial and antifungal activities suggest the possible application of new synthetized natural compounds for a wide range of different sectors.

Recently, energy generation has become a crucial scientific and technological issue. Given the increased global demand for energy, there is an urgent need to find new strategies to get energy from renewable sources.[1] In this field, among the new generation of photovoltaic systems, dye-sensitized solar cells (DSSCs) are devices that stand out for their simplicity of fabrication and peculiarities of functioning. For these reasons, those devices have recently received considerable attention with the focus on optimizing their components to improve efficiency.[2]

The same aim can be found in this work in which we present a novel organic photosensitizer (DYAD) designed to improve light-harvesting efficiency (LHE) containing an antenna moiety to enable the well-known Förster Resonance Energy Transfer (FRET) effect, often used to increase the LHE.[3] The novelty of the compound lies in its structure containing a dye with the classical D-π-A sequence used in DSSCs and a covalently bonded antenna (donor). To achieve this purpose, two compounds were designed in order to have complementary spectroscopy properties and they were prepared to be joined together by a "click" reaction as a late-stage connection. Moreover, a model dye was synthetized to verify the increased properties and the FRET effect.

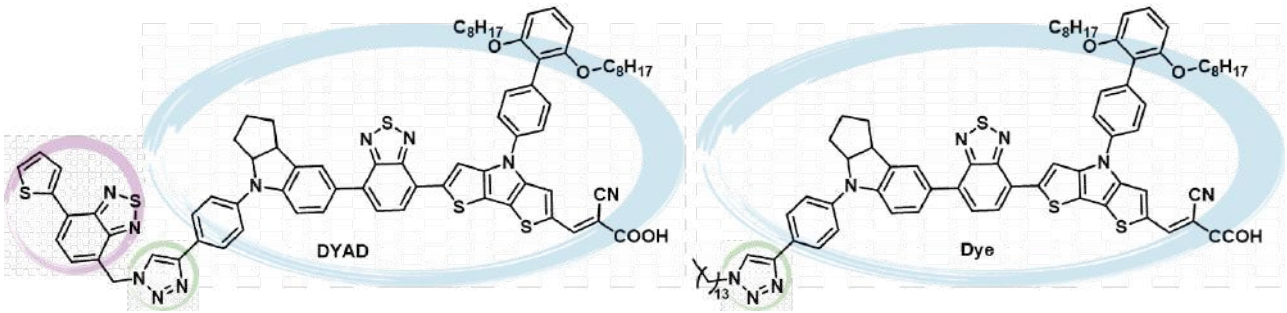

Figure1: structure of the new DYAD and the model dye

Precise control of substrate positioning and orientation (its proximity to the reactive unit) is often invoked to rationalize the superior enzymatic reaction rates and selectivities when compared to synthetic models. Artificial nonheme Fe(IV)=O complexes react with C(sp^3)-H bonds via a biomimetic Hydrogen Atom Transfer/Hydroxyl Rebound mechanism,[1] but rates, site-selectivity and even hydroxyl rebound efficiency (ligand rebound versus substrate radical diffusion) are smaller than in oxygenases.[2,3] Herein, we quantitatively analyze how substrate binding modulates nonheme Fe(IV)=O reactivity by comparing rates and outcomes of C-H oxidation by a pair of Fe(IV)=O complexes that share the same first coordination sphere but only one contains a crown ether receptor that recognizes the substrate (Figure 1). Substrate binding makes the reaction intramolecular, exhibiting Michaelis-Menten kinetics and increased reaction rates. In addition, C-H oxidation occurs with high site selectivity for remote sites. Analysis of Effective Molarity reveals that the system operates at its maximal theoretical capability for the oxidation of these remote sites. Remarkably, substrate positioning also affects Hydroxyl Rebound, whose efficiency increases only on the sites placed in proximity by recognition. Overall, these observations provide evidence that control of substrate positioning via weak interactions is an effective tool to modulate the reactivity of oxygenases and its models.

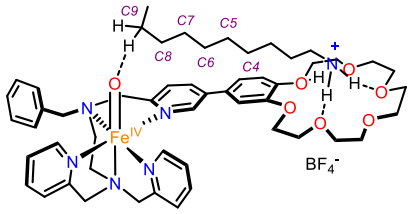

Figure 1: representation of a supramolecularly guided C-H oxidation by a Fe(IV)=O complex. Crown ether receptor interact with primary ammonium function of oxidable substrate.

Caerulomycins, natural alkaloids with antineoplastic and antibiotic properties, have been previously synthesized starting with highly pre-functionalized building blocks or requiring many functional group manipulations.[1–3] In this work,[4] we report the first total synthesis of caerulomycin K, a diversely tri-functionalized pyridine readily assembled in three steps exploiting the recent advancements in the C-H activation of N-heterocycles. Starting from mono-functionalized pyridines, we attempted as first strategy a double C-H activation by means of phosphonium chemistry.[5] We succeeded in the mono-functionalization of *para*-position, whereas a poor conversion of the second *ortho*-C-P bond formation prompted the search for a better approach. This was achieved by sequential Minisci *ortho*-arylation and *ortho*-alkylation,[6] with the latter converted in one pot into the desired oxime. Compared to previously reported caerulomycin syntheses, this innovative strategy involves shorter synthetic route and does not demand highly pre-functionalized starting materials.

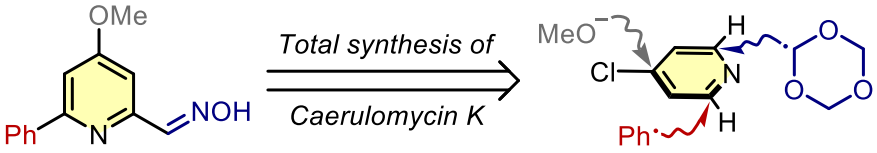

Figure 1: first total synthesis of caerulomycin K *via* Minisci-type chemistry.

This study centres on the field of natural product chemistry, specifically aiming to analyse and describe the structure of secondary metabolites obtained from plants. These secondary metabolites have been evaluated as potential "new drugs" because of their fascinating pharmacological effects shown in both laboratory and animal experiments[1]. The features of this substance encompass anti-inflammatory, antioxidant, anticancer, antiviral, and antibacterial actions.

The perennial Mediterranean shrub *Laurus nobilis* L., also referred to as bay laurel, has an extensive historical background of customary utilisation in culinary practices and traditional medicine owing to its beneficial effects on health. These features are currently being scientifically clarified through a range of biological activities.

Specimens of *L. nobilis* were gathered from three distinct areas in central-southern Italy. The leaves underwent hydro-distillation, and essential oils (EOs) were examined using gas chromatography (GC/FID) to quantification volatile chemicals and gas chromatography/mass spectroscopy (GC/MS) to identify them. The multivariate analysis of the principal components examines the relationships between various chemical substances and their respective antioxidant and anti-inflammatory effects.

The antioxidant activity was assessed using various methods (DPPH, ABTS, FRAP assay) *in vitro*. Additionally, the ability to reduce inflammation was evaluated by measuring its inhibition of specific enzymes involved in the production of eicosanoids through three metabolic pathways: cyclooxygenase (COX), 5-lipoxygenase (5-LO), and cytochrome P450 (CYP450)[2].

In more detail here, the simultaneous targeting of several enzymes, specifically COXs and Soluble Epoxide Hydrolase (sEH) of the EOs, in a more detailed manner. Moreover, the *in silico* investigations were used to explain the biological activities in inflammatory events that were observed for the primary secondary metabolites of the various types of *L. nobilis* essential oils at the molecular level.

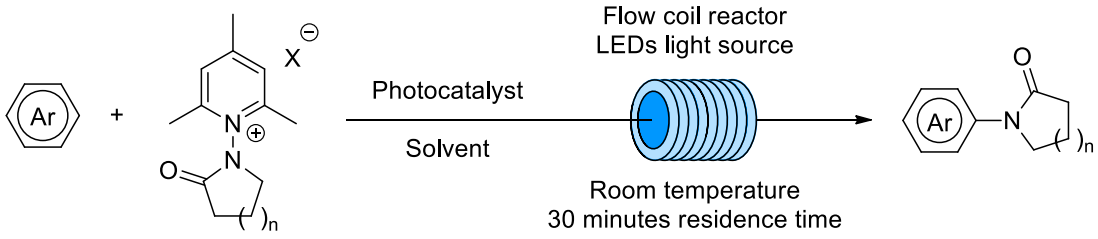
Light-induced *N*-Lactam radicals generation under continuous flow conditions

M. Fattalini,[a] E. Colombo,[a] M.F. Boselli,[a] M. Benaglia,[a]

[a]*Dipartimento di Chimica, Università degli Studi di Milano, Via Golgi 19, Milan, Italy*
e-mail: marco.fattalini@unimi.it

Nitrogen-containing structures are widespread in both natural and synthetic organic compounds, including pharmaceutical products. Finding novel synthetic approaches for forming C-N bonds in a mild, sustainable, and potentially stereoselective way is a subject that captivates synthetic organic chemists.
Over the past twenty years, photoredox catalysis[1] and flow chemistry[2] emerged as powerful methods for generating radical species in such conditions. The possibility to use light as traceless reagent plays a pivotal role in the development of green synthetic strategies, and flow setups can further enhance the performances of light-induced reactions. Additionally, the characteristics of flow reactors offers advantages in terms of both process scalability and safety, making flow chemistry an indispensable tool for organic chemists.

Among the various nitrogen radical species, amidyl radicals[3] have interesting properties for synthetic purposes. The light-induced generation of *N*-lactam radicals, which are not know in literature, and their reactivity with aromatic substrates under flow conditions are the focus of this work (scheme 1).



Scheme 1: General reaction scheme for the reaction under study.

The *N*-radical precursor was synthesized by taking inspiration from the literature.[4] Different indole derivatives were successfully tested. The reaction proceeds in mild conditions, and the use of an organic photocatalyst makes this approach interesting since the use of expensive and polluting metal-based catalysts is avoided. The development of a flow setup permitted to achieve better results compared to a conventional batch reactor, significantly reducing the time required to complete the reaction.

Oxazolidinone-Derived *N*-Centered Radicals: Unlocking Bioactive Compounds by Photoredox Catalysis

S. Ferrario,[a] N. Intini,[a] S. Rossi,[a] M. Benaglia.[a]

[a] *Dipartimento di Chimica, Università degli Studi di Milano, Via Camillo Golgi 19, 20133 Milano, Italy*
sara.ferrario@unimi.it

The recent advancements in radical chemistry have paved the way for new opportunities in synthesis, solving challenges that more conventional methodologies have historically encountered. Traditional approaches used to build C-N bonds often rely on high temperatures and pre-functionalized coupling partners, such as Cu-catalyzed Ullman type coupling or Pd-catalyzed Buchwald-Hartwig amination.[1] However, in the last few years, some of these issues have been solved by the use of *N*-centered radicals generated by photoredox catalysis. These radicals have proven effective for building C-N bonds under mild reaction conditions. The use of *N*-centered radicals, when combined with flow chemistry, have proven to be effective also for large-scale productions, overcoming issues related to limited light penetration associated to batch processes.[2]

In this context, we focused our attention on the development of novel synthetic methodologies for the synthesis of products of pharmaceutical interest such as Linezolid and Eperezolid[3] (**Figure 1a**), involving the use of *N*-oxazolidinone radicals generated by photocatalytic approach. An easy protocol for the generation of *N*-oxazolidinone radicals have been developed (**Figure 1b**), which were successfully employed in amidation reactions of various aromatic substrates performed under traditional batch and continuous flow conditions. These initial investigations mark a significant step toward devising efficient and sustainable methods for the synthesis of APIs.

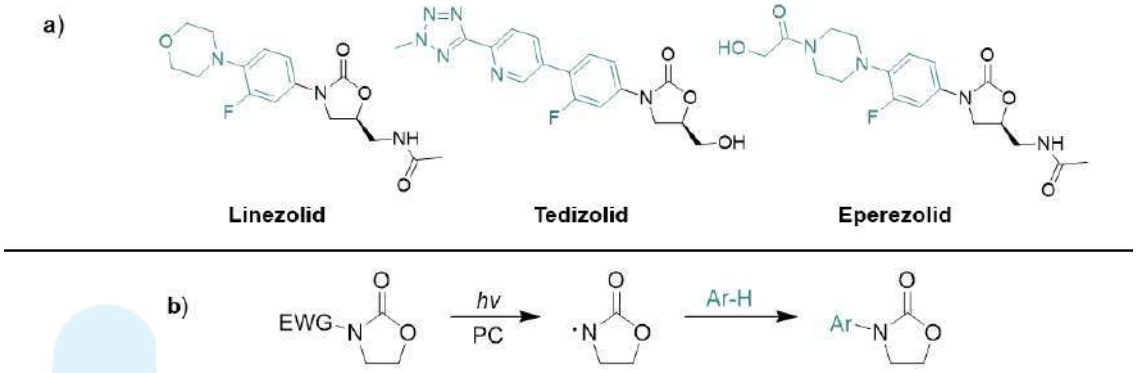

Figure 1: **a)** Exemplary chemical structures of the APIs and **b)** Synthetic approach

Jacopo.ferro@uniupo.it

Although Pb is known to be a highly toxic element at concentrations above 0.1 ppm, the existence of Pb radioisotopes makes it of great interest for biomedical applications. ^{212}Pb decay chain includes ^{212}Bi, which decays mainly through the emission of β^--particles and secondarily by emitting α-particles. In order to exploit the properties of the ^{212}Pb/^{212}Bi pair in therapy, it is necessary to identify polydentate ligands that form with both the radioactive cations complexes with high thermodynamic stability and kinetic inertness. Unfortunately, the literature often focuses exclusively on the stability properties of the complexes formed with the parent radiometal (^{212}Pb), as in case of $[Pb(DOTAm)]^{2+}$ (DOTAm = DOTA tetraamide, Figure 1) which presents several problems such as instability in basic environment and the tendency of primary amides to hydrolysis. In addition, the $[Bi(DOTAm)]^{3+}$ complex is not stable enough to prevent dissociation of the complex once ^{212}Pb has decayed to ^{212}Bi.[1] This work aims to evaluate the stability constants and the kinetic inertness of the Pb(II) complexes of a series of macrocyclic and linear polydentate chelators such as DOTA, DOTAm, DOTP and DTPA (Figure 1 and Table 1). Among them neither the macrocyclic DOTA, DOTAm and DOTP nor the linear DTPA are able to form stable and inert complexes with Bi^{3+}/Pb^{2+} pair.

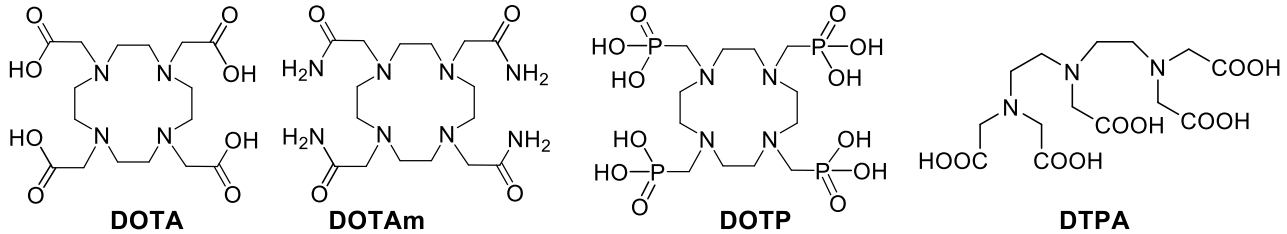

Figure 1. Chemical structures of the ligands used in this study

Table 1. Conditional stability, selectivity, dissociation half-life of Pb(II)-complexes with ligands shown above

	Conditional Stability at pH=7.4 ($\log K_{PbL}^{Cond}$)	Selectivity of the ligand for Pb^{2+} over Ca^{2+}, Zn^{2+} and Cu^{2+} ($\log K_{Pb}^{sel}$)	Diss. half-life at pH=7.4 and 25°C, $\log t_{1/2}$ (h)
DOTA	18.50	6.35	6.16
DOTAM	15.25	5.21	–
DOTP	12.41	0.10	2.21
DTPA	15.18	0.21	–

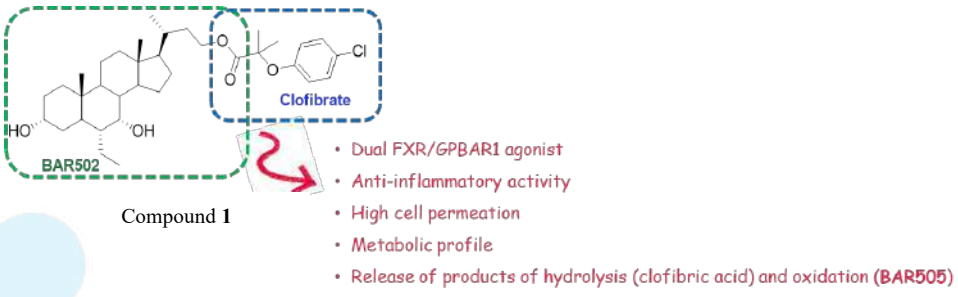
NASH is a hepatic manifestation of metabolic syndrome characterized by accumulation of fat, inflammation, and fibrosis in the liver. If untreated, it could irreversibly progress to liver cancer or liver cirrhosis.[1] New potential therapeutic agents were developed and introduced in the market but at present, there are no approved drugs and satisfying pharmacological treatment. Therefore, there is an urgent need to discover new biological active lead structures useful for the pharmacological treatment of this disease. One of the best approaches in the fight against NASH remains the combination of different agents, that target multiple pathways involved in this pathology.[2]

In this poster, we propose the development of hybrid compounds, obtained by conjugation, through high-yield condensation reaction, of **BAR502**[3,4] with three different fibrates.[4] The aim was to evaluate the ability of these hybrid derivatives to be hydrolyzed in physiologic fluids releasing two active chemical entities, with synergistic action in treating NASH. Within the library of hybrids, compound **1**, obtained by conjugation of **BAR502** with clofibric acid, showed an interesting activity, maintaining a similar **BAR502** dual behaviour towards FXR and GPBAR1 receptors. Compound **1** showed also anti-inflammatory activity, reducing the expression of IL-1β, IL-6 and CXCL2, and was able to reduce the expression of all markers of adipocyte differentiation in 3T3.L1 cells. Furthermore, we have proved by LC-MS analysis that compound **1** is hydrolyzed in mice releasing clofibric acid and **BAR505**, the oxidized metabolite of **BAR502**, endowed with retained dual FXR/GPBAR1 activity. In addition, compound **1** showed a high cell permeability in HepG2 cells and a better ability to release clofibric acid compared to clofibrate. These data suggested that compound **1** could be considered a promising pro-drug, achieving higher plasmatic concentrations of clofibric acid and **BAR505**.



Compound **1**

Hydrophilic emissive NDIs and DNA: a tale of love and hate

F. Cardano[a], G. Volpi[a], P. Quagliotto[a] and A. Fin[a]

[a] *Department of Chemistry, University of Torino, Via P. Giuria 7, 10125, Torino*

andrea.fin@unito.it

Naphthalenediimides (NDIs) are versatile fluorophores developed throughout the last century.[1] The first synthetic report on substituted NDIs dates to 1937 and useful synthetic strategies to modify the chemical structure and photophysical properties have been published in the early 2000s. [2,3] NDIs have been investigated for several applications spanning from supramolecular chemistry, catalysis through anion−π interactions, organic electronics and chemical biology. [1] NDIs in biological chemistry have been mainly used for targeting biomolecules as well as for cell imaging. [4,5] NDIs have been proposed as DNA intercalators: their small size and flat morphology allow the allocation between base pairs in DNA duplexes (Figure 1).[4]

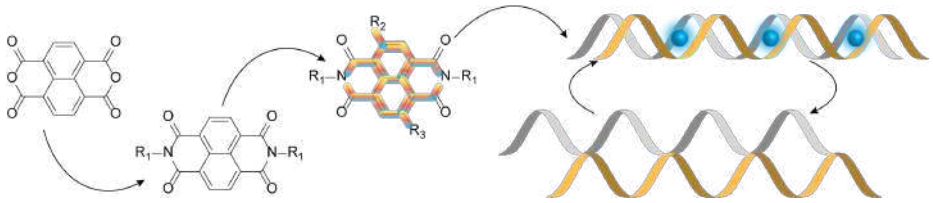

Figure 1: NDI interactions with DNA.

Here, we present the synthesis of a small library of substituted NDIs and preliminary evaluations as emissive probes for nucleic acids visualization. NDI's ability to intercalate in different DNA duplexes was monitored by fluorescence and related to their molecular variations on the core, as well as, on the imide edges to point out the best candidate for the visualization of nucleic acids.

paola.fornarini@student.unisi.it

The deployment of renewable energy sources is a critical strategic lever for decarbonizing the energy sector and mitigating the effects of climate change[1]. Solar PV and wind power are the main tools for reducing emissions from the electricity sector, and the IEA predicts that the growing competitiveness of solar PV could lead its installed capacity to surpass that of wind power before 2025 and coal before 2040[2].

Perovskite solar cells are emerging as a promising photovoltaic technology due to their outstanding power conversion efficiency (PCE) and low material costs. Since the first report of a solid-state solar cell with a PCE of 9.7% in 2012, progress has led to a certified PCE (NREL) of 26.1%. A prevalent material for the hole transport layer (HTM) is Spiro-OMeTAD, often doped with metal salts of bis(trifluoromethyl-sulfonyl)imide ($M(TFSI)_n$). These dopants play a crucial role in generating radically active cationic species within the HTM[3].

In the first part of the work, carried out at Uppsala University in Professor Gerrit Boschloo's research group, perovskite solar cells were prepared and the effect of metal cations (M= Li, Zn, Mg, Cu) on the doping of Spiro-OMeTAD was analyzed by a combination of techniques, including Electron Paramagnetic Resonance (EPR), UV-Visible and photoluminescence, complemented by analysis of fabricated photovoltaic devices.

In the second part, carried out in the R²ES research group of the University of Siena, DFT (Density Functional Theory) calculations were performed on the Spiro-OMeTAD radical cation in different environments, which confirmed the good hole-transport capacity of the above-mentioned material due to the broad delocalization of the spin density over the entire molecule in all cases considered. Moreover, calculations of $(Spiro\text{-}OMeTAD)^{\bullet+}$ on $CH_3NH_3PbI_3$ surface's paramagnetic properties are ongoing.

The study also delved into the criticality of raw materials and hazardous chemicals for the advancement of renewable and sustainable technologies, focusing particularly on perovskite solar cells. Several raw materials used in these cells were evaluated for their criticality and potential risks, considering their roles as electrode materials, components of electron-carrying layers, photoactive materials, and p-dopants. Some of these materials, such as indium, magnesium, and lithium, were identified as critical due to factors such as availability, import/export dynamics, price, widespread industrial use, and recycling challenges. However, it was noted that alternatives to these materials are readily available. In future research, the use of alternative materials that don't pose human health risks or supply chain issues will be explored.

Deep Eutectic Solvents (DESs) represent a sustainable alternative to common organic solvents complying with green chemistry requirements.[1] In this work, DESs have been employed for the first time for a Miyaura borylation and Suzuki-Miyaura cross-coupling one-pot protocol.[2]

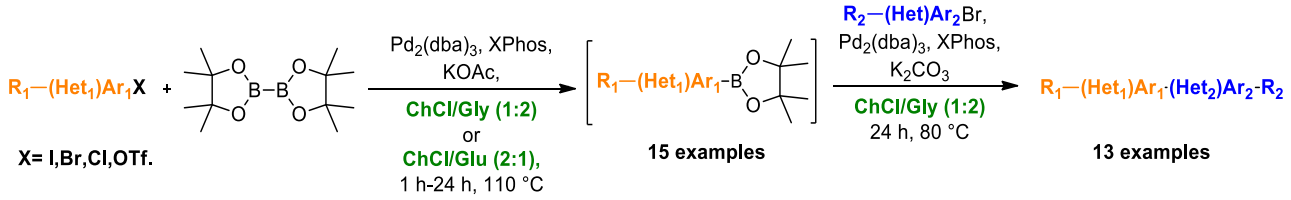

Figure 1: Generic scheme of Miyaura borylation and one-pot Suzuki-Miyaura cross-coupling in DES.

Starting from a precedent work on direct arylations in DES,[3] the protocol was optimized for borylation and coupling of (hetero)aromatic iodides, bromides, chlorides, and triflates in choline chloride/glycerol (1:2) and choline chloride/glucose (2:1) DESs. Robust and efficient conditions were found for electron-poor and electron-rich (hetero)aryl substrates. The boronic esters were isolated and characterized or directly exploited for cross-coupling in a one-pot fashion. The optimized protocol was successfully applied for preparing conjugated organic compounds with potential application in optoelectronics. The protocol sustainability was assessed through green metrics and compared with the literature when possible.

Sustainability is an important concern for the development of new organic materials. Synthetic procedures should become simpler, more efficient and less resource-intensive. Furthermore, waste must be avoided as much as possible. Hence, the combination of heterogeneous catalysis and micellar approaches can have a major impact on this field. Micellar catalysis helps in getting rid of organic solvents replacing them with water and in creating nanometric environments having enhanced reagent local concentrations to assure higher reaction rate and selectivity[1]. Easy recovery, reuse, and lack of toxic ligands make heterogeneous catalysts preferable with respect to homogeneous ones, although several challenges have yet to be faced: heterogeneous catalysts have lower activity, selectivity, and stability with respect to homogeneous ones, beside suffering from metal leaching phenomena. Undoubtedly the need for high surface area, reactant compatibility and homogeneous active sites distribution are the starting point for further studies[2]. Having all these challenges in mind, we developed a new heterogenized catalyst having π-conjugated organic colloidal nanostructures obtained through micellar polymerization as active sites support. They are designed to be intrinsically stable, water-dispersible and to embed the Pd catalyst involved into their own synthesis so that they could be directly reused as heterogenized catalyst in further micellar cross-coupling reactions. As a proof of concept, we synthetised a first-generation heterogeneous catalyst through deposition of Pd metal nanoparticles (Pd-NPs) on reprecipitated Poly(9,9-dioctyl)fluorene (PFO) nanospheres, then we tested its catalytic activity in in-water micellar Suzuki-Miyaura reactions. The efficiency of such catalyst was compared to that of the benchmark heterogeneous palladium catalyst Pd/C (Evonik hydrogenation catalyst). The initial findings show higher conversion associated to the use of the polymer-supported Pd catalyst. Furthermore, recycling of the catalyst is also possible thanks to the development of a straightforward workup procedure. The second-generation heterogenized catalyst requires the synthesis of conjugated polymer nanoparticles (CPNPs) by direct miniemulsion Suzuki polymerization. Literature examples of CPNPs synthesis always contemplate a purification step, to get rid of surfactants[3]. However, in this case, their entanglement within the colloidal structure is a crucial advantage: they constitute a template in which the polymeric nano-object can grow having a controlled morphology, and they make it suitable for its final application as catalyst. The synthesis produces dispersed spherical Pd-embedding polymer-surfactant semi-interpenetrated networks (sIPN). Such dispersion was then used as heterogenized catalyst showing the highest conversion rate. Encouraged by preliminary results both catalyst generalities are currently under investigation as well as the fine tuning of the structure of the polymeric support. The final big picture foresees the study and understanding of how the presence of

Dihydrobenzofurans and 2,3-dihydrobenzofurans are known for their important biological properties like anticancer, anti-inflammatory and antioxidant [1]. Many of them are naturally produced by the dimerization of polyphenols as resveratrol, one of the most important stilbenes. Among them, gnetin C (figure 1) is particularly interesting as it is currently in III phase of clinical studies of prostate antitumor compound [2]. Up to now no synthesis of gnetin C has been performed.

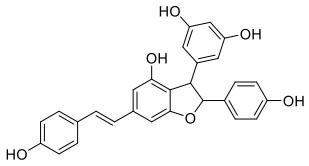

Figure 1. Structure of gnetin C

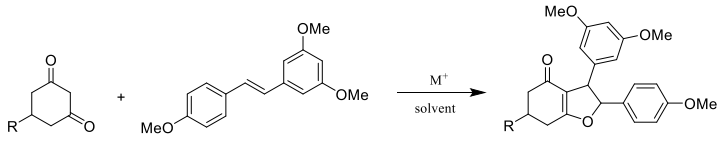
To this challenging end we are investigating a strategy to synthesize it. A preliminary attempt has been conducted using a 1,3-dicarbonyl compound and an internal olefin in a [3+2] addition promoted by an oxidating agent (scheme 1), in order to obtain the dihydrofuran [3], which has been aromatized to the corresponding dihydrobenzofuran.[4,5]. A regioisomeric mixture has been obtained deriving from different reactivity of the two possible sites of attack to the olefin (Scheme 1).



1. R = Me;
2. R = (p-OMe-Ph)$CHCH_2$

Electrochemical di-oxygenation of quinolines

D. Gariboldi,[a] F. Franco,[a] A. Puglisi[a]
[a] *Dipartimento di Chimica, Università degli Studi di Milano*
davide.gariboldi@unimi.it

Electrochemical methods for the synthesis and transformation of organic compounds have recently received increased interest by both academic and industrial research[1]. Electrochemistry represents a mild and green way to obtain useful molecules, avoiding the stoichiometric use of harsh and often hazardous or waste-generating oxidating and reducing agents, that can limit large-scale applications. Moreover, the highly selective nature of this method allows to avoid the sometimes tedious protection/deprotection steps. The renaissance of organic electrochemistry has been accompanied by an increased attention to flow electrochemistry, that, thanks to the small interelectrode gap, reduces the resistance and improves the mass transport of the substrates from the bulk to the electrode surface, with the advantage of reducing the reaction time[2].

Di-oxygenation of olefins is generally achieved with several methods including the use of transition metals, for example Sharpless reaction[3]. In very recent years, electrochemical approach has emerged as an alternative method to perform di-oxygenation not only of olefins, but also of heterocycles, like indoles and thiophenes[4].

In this context, we envisioned the possibility to perform the di-oxygenation of activated quinolines. Dihydroquinolines, that can be pre-formed by classic chemical activation, are subjected to electrochemical transformation, opening new frontiers in the synthesis of highly functionalized tetrahydroquinolines. Alternatively, the one-pot procedure will be attempted.

Synthesis of trifluoroborates derivates for the preparation of theranostics in Boron Neutron Capture Therapy

Arianna Garzulino,[a] Daniela Imperio,[a] Luigi Panza [a]

[a] *Department of Pharmaceutical Science, Università del Piemonte Orientale, Largo Donegani 2, 28100, Novara, Italy*
E-mail: arianna.garzulino@uniupo.it

Boron Neutron Capture Therapy (BNCT) is a binary therapeutic treatment based on the nuclear fission reaction of ^{10}B. When irradiated with neutrons, ^{10}B produces the isotope ^{11}B in an excited state, which spontaneously decays generating a high-energy α particles and recoiling a ^{7}Li ion. [1] The required neutron beam is nowadays generated by proton accelerators containing a lithium or beryllium target and a beam shaper to produce epithermal neutrons. [2] These neutrons have enough penetrating power to reach cancer tissues where they become thermalized reaching the right energy for the capture by ^{10}B nuclei. [3]

In perspective, this therapy will be used in addition to conventional cancer treatments such as radiotherapy or surgery and is mainly focused to treat tumours that are resistant to other types of therapy, such as glioblastoma multiforme (GBM), but also metastatic melanoma, head and neck tumours and malignant mesothelioma.[4]

Agents containing boron atoms, such as carboranes (clusters of ten boron atoms and two carbon atoms), boronic acids or trifluoroborate groups, are under investigation in order to deliver enough boron atoms to tumour cells. It was decided to synthesise compounds containing either a carborane or a trifluoroborate group because the last one has a dual function: it allows boron to be delivered to cancer cells and the replacement one of the fluorine atoms of the trifluoroborate group with the ^{18}F isotope, allows its detection by PET, so generating a potential theranostic compound. Finally, it was planned to conjugate the boron-containing agent to structures that would further enhance its concentration in cancer cells exploiting known features of these cells such as overexpression of specific transporters. The strategy followed for the conjugation of the boron containing moiety and the tumour recognizing structures exploits the copper-catalysed Huisgen reaction.

beatrice.gatti@unipr.it

Friction is the force that hinders the movement between sliding or rolling surfaces, and it is caused mainly by microscopic contact points between mechanical parts, that can cause adhesion and deformation. About 25% of the energy provided by an engine is lost due to friction; therefore, lubricants are crucial to reduce the energy waste and to ensure the optimal functioning of the machine.

To maximize the lubricating properties of an oil, friction reducing additives are needed. The typical structure of a friction reducer (FR) consists of a polar head, that allows the additive adsorption on metal surfaces in the engine, and long alkyl chains to ensure the solubility in oil and the formation of a protective multilayer matrix. The most common functional groups that can be found in friction reducers are carboxylic acids, amides, imides, amines, and phosphoric or phosphonic acid derivatives. These functionalities lead to the formation of absorbed layers anchoring the additive to the metal surface, while the hydrocarbon tails align to each other and favour the layers formation thanks to van der Waals forces.[1]

Macrocycles can be suitable candidates for the synthesis of FRs, thanks to their synthetic versatility and stability. Moreover, their scaffold can provide preorganization of the matrix layers, facilitating the film formation. To investigate and exploit these properties, we synthesized various resorcinarene- and calixarene-based additives with different polar functionalities.[2] The products that showed the best solubility and stability in oil formulations were tested to evaluate their tribological properties.

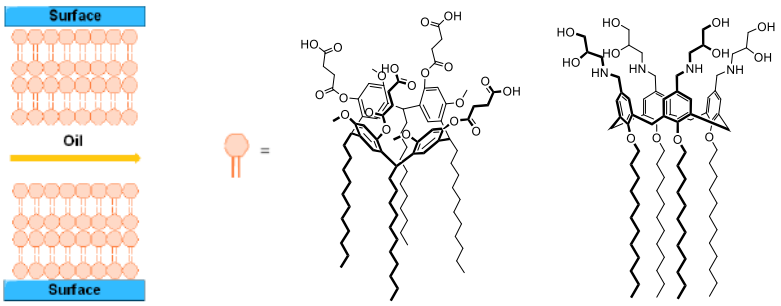

Figure 1: left: multilayer matrix structure; right: examples of macrocyclic FRs.

Development of new sterically hindered chiral phosphoric acids: synthesis and catalytic applications

M. Gazzotti,[a] S. Rossi,[a] M. Benaglia[a]

[a] *Dipartimento di Chimica, Università degli Studi di Milano, Via Golgi 19, 20133 Milano, Italy*
margherita.gazzotti@unimi.it

In the broad field of stereoselective synthesis, Chiral Phosphoric Acids (CPAs) have recently found widespread application in several and crucial chemical transformations, considered powerful tools for the synthesis of pharmaceuticals and natural products. Due to the important applications of chiral phosphoric acids in organic synthesis, in the last few years the design and the synthesis of new chiral phosphoric acids have attracted much attention.[1] A new class of chiral phosphoric acids, with a two-carbon-atom-spacer between the aromatic rings bearing the acidic functional group and a decahydroquinoxaline scaffold derived from the *trans*-1,2-diaminocyclohexane through a diastereoselective pinacol-type coupling reaction, has been developed. Decahydroquinoxaline-based chiral phosphoric acids have been successfully applied in the model stereoselective Friedel-Crafts addition of indoles to *N*-tosylimines with good to excellent yields and enantioselectivities (**Figure 1**).[2]

leonardo.gelati@unimi.it

High efficiency and selectivity, mild operational conditions and low toxicity are some of the main features that make enzymes efficient catalysts and important tools in making chemical processes greener[1]. However, to render the process economically viable, enzymes should be recovered and reused and sometimes their operational stability should be improved[2]. A common strategy to tackle these problems is the immobilization of the enzyme on a solid support[3]. Hydroxyapatite (HAP) is a biocompatible inorganic material which is suitable for this task thanks to its structural stability, non-toxicity, large surface area and ease of surface modification. Moreover, it can be obtained from waste such as ashes from waste-to-energy plants, the fish supply chain, the avian supply chain, etc., in agreement with circular economy principles.

γ-Glutamyl transferases from both *Bacillus subtilis* (BsGGT) and *Escherichia coli* (EcGGT) were chosen as model enzymes to study the immobilization process on HAP. HAP was synthesised according to a literature-reported wet procedure of coprecipitation of calcium nitrate and ammonium phosphate under basic conditions. Enzyme immobilization was carried out through adsorption, simply by mixing an enzyme solution and a hydroxyapatite suspension under controlled conditions (pH, temperature). Different particle sizes and experimental set-up were investigated and, after assessing that the enzyme did not desorb under reaction conditions, the supported GGTs were tested as biocatalysts in the γ-glutamylation of L-methionine. Moreover, the enzyme reusability was tested in five consecutive reaction cycles and its storage stability was verified.

The introduction of a single hydroxyl group can dramatically influence the drug−receptor binding affinity through the formation of an extensive hydrogen bond network.[1] Moreover, the -OH group can serve as a handle for further derivatizations. In the polar domain, hydroxyalkylations can be accomplished via different reaction pathways. However, retrosynthetically, the possibility to obtain γ-hydroxy substituted derivatives is precluded from polar mechanisms due to a polarity mismatch. α-hydroxyalkyl radicals have emerged as suitable intermediates to promote radical hydroxyalkylations.[2] Despite extensive research into the chemistry of ketyl radicals, we hypothesised that a more direct approach to access these intermediates was feasible using readily available feedstocks. Naturally occurring and readily available α-hydroxy carboxylic acids (AHAs) can be utilized as a platform for visible light-mediated oxidative CO_2-extrusion furnishing α-hydroxy radicals which proved to be versatile C1 to Cn hydroxyalkylating agents. In particular, we developed a photoredox-based γ-hydroxyalkylation via the coupling of α-hydroxy radicals with various SOMOphiles. Furthermore, flow technology facilitates the scaling of this photochemical methodology.[3,4]

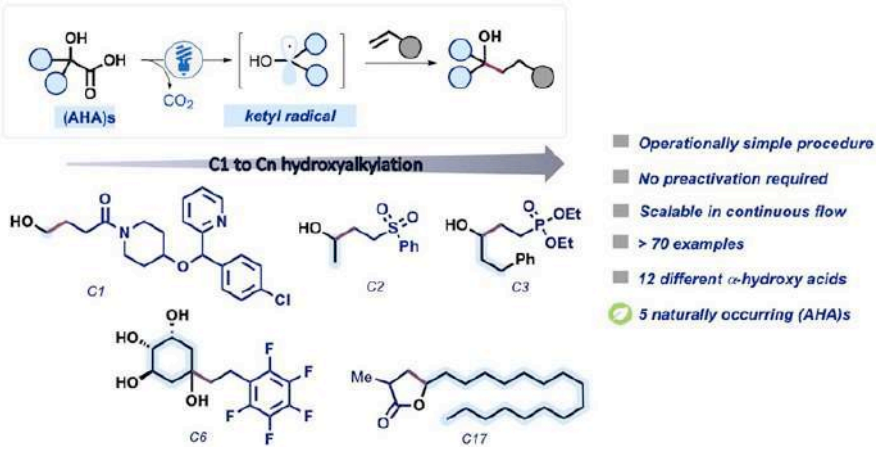

Figure 1: Photoredox hydroxyalkylation leveraging ketyl radicals generated from AHAs.

Sustainable approaches for Sonogashira coupling reactions in water and under air atmosphere

E. Ghiglietti,[a] E. Incarbone,[a] S. Mattiello,[a] L. Beverina[a]

[a] *Department of Material Science, University of Milano-Biccoca, Via R. Cozzi 55, Milan, Italy*
erika.ghiglietti@unimib.it

Metal-catalysed cross-coupling reactions hold a pivotal role in organic chemistry, enabling the construction of carbon-carbon bonds. Among them, the Sonogashira coupling stands out as a transformative tool for synthesizing substituted and/or conjugated alkynes. Recently, noteworthy advances have been achieved from the standpoint of health, safety and environmental concerns, leading to the development of Cu-free methodologies. However, some challenges still persist.[1]

Within this context, our project aims to address the worldwide demand for sustainable and straightforward chemical processes, focusing on reducing the catalyst loading and ensuring mild reaction conditions. Experiments are initially conducted via homogeneous catalysis using water in the presence of surfactants to enhance the dispersibility of organic substrates in aqueous environments.[2] Synthetic procedures are easy, mild and reproducible. Additionally, the use of low amounts of commercially available and cost-effective palladium acetate addresses the challenges associated with low metals availabilities and their high costs. Simultaneously, the project explores the assembly of bio-based core-shell nanocapsules loaded with various palladium(II) sources by originally modifying the solvent evaporation encapsulation technology. In an aqueous environment, the bio-polymer selected for the external shell of our capsules, ethylcellulose, reorganizes its chains to orient the hydrophilic components towards the bulk aqueous medium, thereby creating a central hydrophobic cavity where the catalytic species localize.[3] These innovative nanoreactors exhibit remarkable catalytic activity, operating directly in heterogeneous aqueous environments with minimal metal loadings and without additional organic cosolvents. The synergy between surfactants and our synthetic nanocapsules is essential, creating nano-confined spaces which offer enhanced control and increase local reactant concentrations at the interface of EC structures due to the hydrophobic effect.

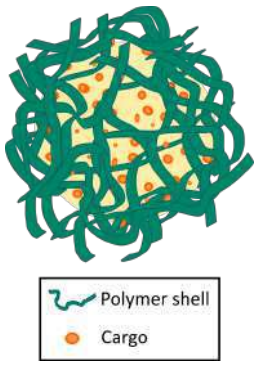

Figure 1: cartoon of EC nanocapsules produced with our methodology.

Overall, the methodologies here presented are completely aligned with the Green Chemistry principles, representing a significant step towards more environmentally-friendly and efficient chemical processes in the field of metal-catalysed cross-coupling reactions.

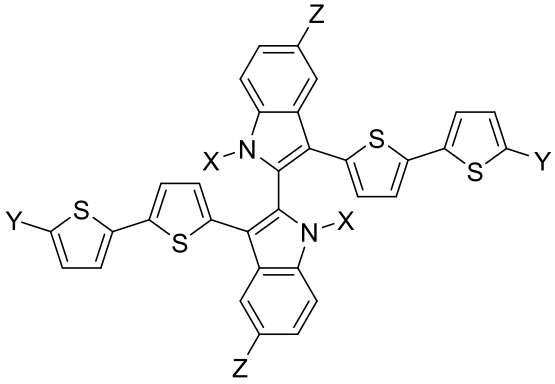
sghirardi@uninsubria.it

The research for replacing classical organic solvents (which are unhealthy VOCs) with greener media represents an increasingly urgent scientific challenge. Water represents a safe and sustainable alternative, with the obvious problem that lipophilic organic reagents typically do not dissolve in it. Surfactants are amphiphilic molecules characterized by a hydrophilic and hydrophobic domain and give great opportunities to perform reactions in aqueous medium[1] making the process clean, fast and efficient with consequent remarkable overall benefits for sustainability.[2]

A family of conjugated 2,2'-biindole derivatives **1a-c** functionalised in position 3,3' with bithienyl units and bearing hydroxylic groups in different positions of the heteroaromatic scaffold was synthesized as precursors for an innovative class of surfactants.



1a X = CH_2CH_2OH; Y, Z = H
1b X = Pr; Y = H; Z = CH_2OH;
1c X = Pr; Y = CH_2OH; Z = H

Figure 1: The family of the 2,2'-biindole derivatives

The hydroxy groups of compounds **1a-c** were functionalised with PEG derivatives of different length and, taking advantage of the design of the 2,2'-biindole scaffolds, which allows to introduce the hydrophilic chains in different position, a wide series of amphiphilic molecules was prepared. Their aqueous solutions were successfully employed as non-conventional media in Suzuki-Miyaura coupling reactions. The different catalytic performances of the surfactants as a function of their structural features are discussed.

Regio- and stereoselective arylation of *L*-proline

I. Giussani[a], G. Antonini[a], L. Belvisi[a], A. Bernardi[a], S. Mazzotta[a]

[a]*Università degli Studi di Milano, Dipartimento di Chimica, via Golgi 19, 20133-Milano, Italy*
ilaria.giussani@studenti.unimi.it

The five-membered pyrrolidine ring and its derivatives are heterocyclic scaffolds widely used in medicinal chemistry and drug design.[1] Among this vast class of compounds, *L*-proline is of particular interest, and is often employed for the synthesis and optimization of lead compounds.[2] Among the many derivatizations that can occur to the *L*-proline scaffold, the stereoselective functionalisation of position 5 proves particularly challenging.

We are currently exploring this problem in an effort to obtain novel glycomimetic ligands for the *N*-terminal domain of the bacterial lectin BC2L-C from *Burkholderia cenocepacia*[3]. The desired ligands (general formula **1**) consist of N-fucosyl amides carrying a functionalized proline residue either in the *cis* or *trans* configuration. For the synthesis of compounds with *cis* configuration, we are pursuing classical synthetic pathways for the preparation of *cis*-5-arylproline **2** starting from *L*-pyroglutamic acid **4**.[4] The preparation of *trans* diastereomers is significantly more challenging. For these, we are examining a photoredox-mediated hydrogen atom transfer (HAT) process described by MacMillan *et al* as a single example starting from proline **5**.[5]

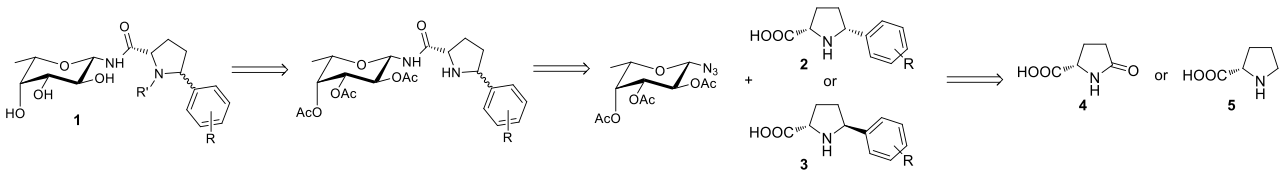

Figure 1: Synthetic strategy for glycomimetic fucosides with arylated *L*-proline

claudia.gonzalezcastro@unina.it

Selenium (Se) is recognized as a trace element essential for human health; low Se levels are actually associated with several diseases.[1] Many natural occurring Se compounds show redox and biologically capacities, thus stimulating synthesis of new molecules with the aim to spread antioxidant effects in biological systems.[2] Most of these bioactive Se-containing molecules showed a strong therapeutic and biological relevance.[3]

In the framework aimed at discovering new efficacious antioxidants, the synthesis of new seleno-glycoconjugates, consisting of monosaccharaides containing selenium bound to polyphenols, is of our interest with the aim to overcome the poor (poly)phenol bioavailability and to provide a synergistic antioxidant effect at once.

The results herein reported open new and long- term perspectives in the seleno-sugars like antioxidants in biological medium.[4]

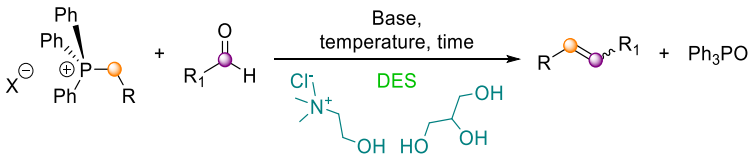
Wittig Reaction in Deep Eutectic Solvents: Expanding the DES Toolbox in Synthesis

F. De Nardi,[a] G. Gorreta,[a] C. Meazzo,[a] S. Ghinato,[a] M. Blangetti,[a] C. Prandi[a]

[a]*Dipartimento di Chimica, Università di Torino, via P. Giuria 7, 10125 Torino, Italy*
giulia.gorreta@unito.it

The Wittig reaction[1] is a reliable strategy that allows the chemo-, regio- and stereoselective preparation of alkenes from carbonyls and it is widely used both in academia and on industrial scale.[2] This transformation requires the use of a phosphorus ylide that can react with a carbonylic compound via an oxaphosphetane intermediate. Traditionally the Wittig olefination is carried out in dry and aprotic solvents, under homogeneous conditions, using an organometallic base to generate a phosphonium ylide.[3] In order to improve the sustainability of the reaction, in recent years many variations of the Wittig reaction have been studied, including catalytic versions and processes carried out in an aqueous environment.[4] However, many organic molecules are not soluble in water or may undergo undesired chemical transformations in a protic environment.

In this context, owing to our interest in the development of sustainable synthetic strategies,[5] we decided to investigate Deep Eutectic Solvents (DESs) as green reaction media to promote the Wittig olefination. It emerged that it is possible to carry out Wittig reactions using weak bases, at room temperature and in air. The procedure allowed us to synthesize alkenes with good to quantitative yields, starting from a wide range of non-enolizable aldehydes. In addition, experimental attempts to separate the alkenes from the phosphine oxide byproduct and from the excess of reagents without the use of chromatographic columns will be presented.



Scheme 1: Wittig olefination in Deep Eutectic Solvents.

asia.grattagliano@uniroma2.it

Aqueous Organic Redox flow batteries (AORFBs) offer several advantages over other types of batteries in energy storage such as scalability, safety, long cycle life and cost-effectiveness, making them an exciting frontier to explore[1]. For this scope, the family compound of porphyrins was considered thanks to their well-defined redox processes. In fact, porphyrins go through four electron reactions which can be exploited to develop the redox couple. Particularly, as water-soluble electroactive species for AORFB application, the tetra-(4-sulfonatophenyl) porphyrins (H_2TPPS) and nickel-tetra-(4-sulfonatophenyl) porphyrin (Ni-TPPS) were prepared and tested. The disadvantage related to these compounds is their tendency to aggregate, so a preliminary Density Functional Theory (DFT) study on H_2TPPS and NiTPPS was performed. It revealed that the introduction of a metal atom inside the porphyrinic core can twist the molecular skeleton resulting in saddle structure that can reduce the normal tendency of porphyrins to aggregate (Fig.1a). This result was confirmed by a UV absorption study (Fig.1b). Efficient redox reactions within the electrolyte are essential for AORFB performance[1]. Improving the kinetics of charge transfer and minimizing energy losses during cycling are key objectives to enhance the overall system efficiency. One of the challenges related with these concepts concerns that the redox processes of electroactive species must occur within the stability potential window of water[2]. Ionic liquids (ILs) are fascinating compounds that for electrochemical applications, show good ionic conductivity, wide electrochemical potential window and high thermal stability[3]. For these reasons, different ILs were considered to be investigated for use as supporting electrolyte to improve stability and electrochemistry. Among the different ILs electrochemically characterized, 1-butylpyridinium tetrafluoroborate ([$Bupy^+$][BF_4^-]) showed the largest water potential stability (-1.3 an +1.5 V) and was chosen as candidate to test the electroactive species.

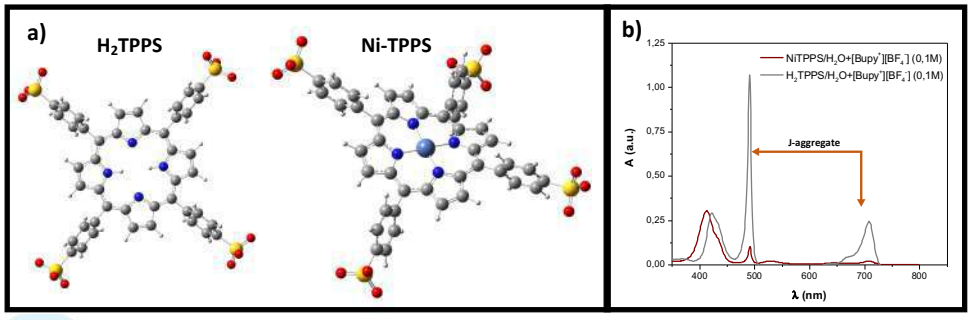

Figure 1 a) DFT calculation of the molecular structure of H_2TPPS (left) and NiTPPS (right); b) UV-Visible aggregation study on H_2TPPS and NiTPPS revealing the highest formation of J-aggregates at 490 and 700 nm for H_2TPPS.

alessandra.gritti@unimi.it

Oxygen-containing molecules represent an indispensable class of heterocyclic compounds, due to their physicochemical properties. In particular, two of the most studied scaffolds are benzofurans and chromenes, widely present in natural compounds (flavonoids, alkaloids, etc.) and synthetic drugs (antiarrhythmic, dermatological and anticancer therapy).[1]

Due to their importance, chromene and benzofuran core have gained enormous attention in the development of different synthetic pathways, involving a plethora of methods and types of reactions.[2] In this context, Divergent Synthetic Strategy emerges as a promising tool, in order to obtain a variety of products under different reaction conditions, starting from similar simple and affordable substrates.[3]

Herein, we report our recent results in the development of a divergent regioselective synthesis of benzofuran and 4*H*-chromene nuclei. Specifically, we describe the reactivity of substituted *o*-propargylphenols under two different reaction conditions, both supported by microwave heating: using a catalytic amount of base we were able to selectively obtain substituted benzofuran, while in the presence of a metal catalyst, the reactivity shifted to the formation of chromenes. We also investigated the limitations and the mechanism of our approach.

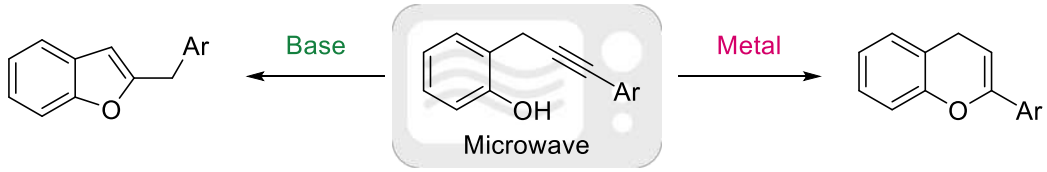

Figure 1: Divergent synthesis of benzofurans and chromenes.

Synthesis of enantioenriched carbocycle-fused uracils as SARS-Cov-2 RdRp inhibitors

Debora Guazzetti,[a] Claudio Curti,[a] and Franca Zanardi[a]

[a]*Department of Food and Drug, University of Parma, Parco Area delle Scienze 27/A, 43124, Parma, Italy*
debora.guazzetti@unipr.it

During a previous work,[1] we developed a new asymmetric methodology to access chiral enantioenriched (5*S*,6*R*)-5-hydroxy-6-nitro-5,6,7,8-tetrahydroquinazoline-2,4(1*H*,3*H*)-diones[2] of type **3** through an organocatalyzed [4+2] cycloaddition between remotely enolizable uracil carbaldehyde **1** and nitroolefins **2** (Figure 1). Using this strategy, a "first generation" set of compounds were synthetised and tested in preliminary *in-vitro* assays assessing a "hit compound",[3] showing a low micromolar activity as inhibitor of SARS-CoV-2 viral protein RNA dependent RNA polymerase (RdRp).

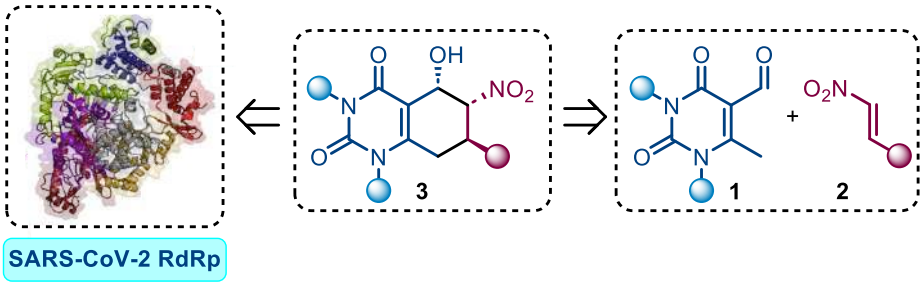

Figure 1

Molecular docking studies were then performed[3] to identify probing interactions between the "hit compound" and the crystal structure of viral RdRp: based on these observations, a "second generation" set of molecules was designed and here presented. Structural modifications involved the nitrogen appendages within pronucleophiles **1** (blue dots in Figure 1) and differently functionalized substituents within dienophiles **2** (purple dots). The design and synthesis of properly functionalized starting materials **1** and **2**, and their use in a series of asymmetric [4+2] cycloaddition reactions will be described, along with the isolated chiral products **3** which were accessed in good yields, complete diastereocontrol and good enantioselectivity.

Human antigen R (HUR) is a master post-transcriptional regulator mainly involved in messenger RNA (mRNA) translation and turnover. HUR over-expression and cytoplasmic accumulation is well correlated to several diseases, including cancer, inflammation, cardiovascular, muscle, kidney, and liver diseases, making HUR an attractive therapeutic target.[1] Reported HUR targeting strategies include the use of small interfering RNAs (siRNAs) and small molecule inhibitors.[2] Regarding the latter, although several compounds have been reported,[2] they still face major issues, such as limited solubility and bioavailability, as well as off-target effects against other RNA-binding proteins (RBPs). Therefore, targeting HUR remains a major challenge in biomedical research.

Based on the screening of a large, small molecule library, a hit compound has been identified as a potential HUR inhibitor with promising biochemical properties. Docking studies performed on this hit showed more insights about its interactions with HUR, giving us more room for SAR elucidation and structural optimization for analogues endowed with better affinity and pharmacokinetic profile.

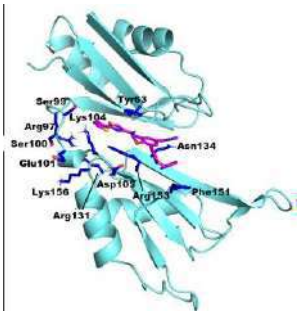

Figure 1: Molecular docking of the Hit compound and HUR

Our attempts towards the rational design and synthesis of novel HUR inhibitors aimed at improving their pharmacokinetic profile will be presented together with their preliminary biochemical evaluation.

In the last decades, light mediated processes have emerged as a new way to access novel and unparalleled transformations due to the implementation of photocatalyst in light mediated protocols, which allows for functional group tolerance and selectivity.[1] Between all photocatalyst, Iridium organometallic complexes stands out due to their unique photophysical features,[2] allowing challenging transformations and achieving high molecular complexity through streamlined protocols. Recently, our research group reported that the tedious formation of an open-shell intermediate can benefit form the presence of stochiometric amounts of naphthalene thanks to the stabilization of the transient triplet states through radical-π dispersion interactions.[3] Herein we report the first class of iridium-based photocatalysts featuring pendant radical-stabilizing groups aimed to enhance the EnT-based transformations via generation and stabilization of the biradical species trough the pendant naphthyl or binaphthyl moieties.

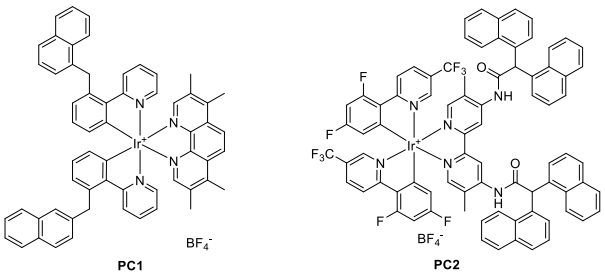

Figure 1: Iridium photosensitizers bearing naphthyl-radical stabilizing moieties.

Different degree of substitution with naphthyl pendants were explored, isolating a family of 8 new photosensitisers. Their catalytic activity was studied in isomerization, cyclization and dearomatization reactions. The results showed diradical stabilization thus achieving high reaction yields, typically only attainable in the presence of stochiometric amounts of naphthalene.

Borazine, a heterocyclic analogue of benzene, is isoelectronic and isostructural with benzene. For this reason, borazine is sometimes referred to as "inorganic benzene". Owing to the substitution of B−N bonds, the electron donation of nitrogen to boron centers contributes to the strong polar character of the B–N bonds, which makes borazine and its derivatives good UV emitters and peculiar reactivities. Based on its properties, borazine and its derivatives have wide applications including, optoelectronic organic materials, self-assembly, H_2 storage, and ceramics since it was reported in 1926.

This work aims to explore more borazine derivatives about the C–H functionalization of borazine and expand the applications of borazine derivatives. In this work, the C–H functionalization of tri-substituted and hexa-substituted borazines between heterocycles and aromatics has been explored, which enables to diversify the variety of borazine derivatives and enlarges the scope of their application.

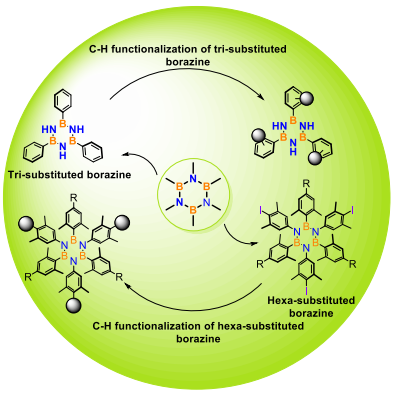

Figure 1: C–H functionalization of tri-substituted and hexa-substituted borazines.

Harnessing light energy: photoresponsive surfactants for enhanced micellar catalysis

E.A. Incarbone,[a] R. Rapone,[a] S. Mattiello,[a] L. Beverina[a]

In the context of green chemistry, minimizing waste and energy consumption is crucial in chemical processes. Organic solvents, known for their toxicity and hazards, pose a significant waste issue, prompting the search for non-toxic alternatives like water for organic reactions. Despite the hydrophobic nature of many organic compounds in aqueous environments, self-assembling surfactants enable "micellar catalysis", overcoming this challenge by hosting reagents in their lipophilic pockets, offering conditions for high-yield, efficient, and sustainable reactions, if appropriately chosen.[1]

The chemical nature of surfactant-formed interphases significantly influences products distribution in competitive reactions. Within the micelle, an interfacial dipole induces selectivity between the hydrophilic and hydrophobic portions of the surfactant.

Introducing selectivity in surfactant-enhanced reactions requires controlling the non-covalent interaction between surfactant and substrates, considering: 1) regioselectivity in competitive transformations induced by the preferential orientation of reaction intermediates due to interface dipoles at the hydrophilic/lipophilic interphase; 2) product selectivity induced by specific surfactant/substrate interactions; and 3) product selectivity due to compartmentalization effects between the water and oil phases.

To enhance selectivity, we propose a novel surfactant design with a photochromic compound, specifically a spiropyran. The photochromic residue is incorporated at the boundary between the hydrophilic and the lipophilic portion of the amphiphilic molecule, which consists respectively of a PEG moiety and an alkyl chain. Responsive to UV light, it switches between a neutral-low polarity and a zwitterionic-high polarity state. This tuning ability, rooted in the concept of photostatic equilibrium, determines the relative population of open (polar) and closed (nonpolar) forms of the photochromic molecules.[2] Adjusting irradiation conditions in terms of intensity, pulse duration and temperature, tunes the interfacial dipole and the Hydrophilic-Lipophilic Balance (HLB) of the surfactants used. This innovation holds promise for improving reaction selectivity in surfactant-enhanced processes.

BAG3, or Bcl-2-associated athanogene 3, is a multifunctional protein involved in critical cellular processes such as protein quality control and cell proliferation and survival. As part of the BAG protein family, it interacts with the molecular chaperone Hsp70, working as a co-chaperone to regulate protein folding, functioning, and degradation. BAG3-HSP70 interaction is crucial for maintaining cellular homeostasis under stress conditions like those experienced by malignant cells. Interestingly, both BAG3 and Hsp70 are overexpressed in different types of cancer, where they are connected to tumor progression and resistance to chemotherapy.[1] For this reason, targeting BAG3 and HSP70 represents a promising approach in cancer therapy.

Continuing our research in the field of protein quality control system regulation using small molecules, we decided to investigate the indolizine scaffold as a new promising moiety for the design of new Hsp70-BAG3 modulators, taking advantage of innovative MCRs procedures for the synthesis.

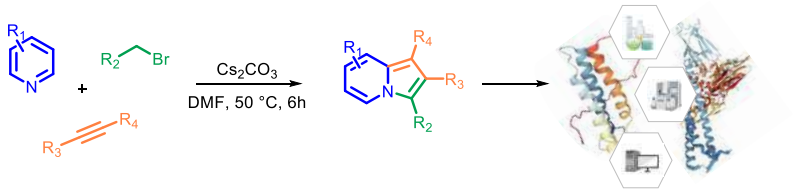

Figure 1: Synthetic approach and application to BAG3-HSP70 modulators identification.

We investigated several experimental conditions for the synthesis of indolizines through the 1,3-dipolar cycloadditions of pyridine, bromide derivatives, and alkynes, and finally, we succeeded in optimizing the procedure using the caesium carbonate as base in DMF as solvent.[2] Hence, we designed and synthesized a first set of compounds that have been tested against the targets of interest using an SPR-based assay. The results obtained allowed us to identify a compound with an interesting binding profile, being able to bind both BAG3 and HSP70 that can be considered as a starting point for further optimization process.

RNA-based drugs increasingly appear to represent the therapy of the future and the search for methodologies to control gene expression by external stimuli is one of the open challenges in the years to come.[1] Here, we lay the foundations for building photomodulable RNA systems through the use of chromogenic molecules and unnatural nitrogenous bases. An acetylated Morita-Baylis-Hillman adduct[2,3] (compound **1**) was tested in the functionalization reaction of the four RNA bases and two unnatural nitrogenous bases (5-aminomethyl uracil, **5-AMU**, and 5-methylaminomethyl uracil, **5-MAMU**) revealing a high selectivity towards the latter. The obtained conjugation products (compounds **2** and **3**) were investigated from a photophysical and photochemical point of view with experimental and computational methods. The investigation revealed the efficient abitilty of monoadduct **2**, containening only one generated cinnamic structure, to act as light-driven molecular switch, while diadduct **3** under light irradiation lead to photoinduced reactions such as a 2+2 cycloaddition. The results of this study push us to apply this chemical strategy to the creation of photomodulable RNA systems.[4]

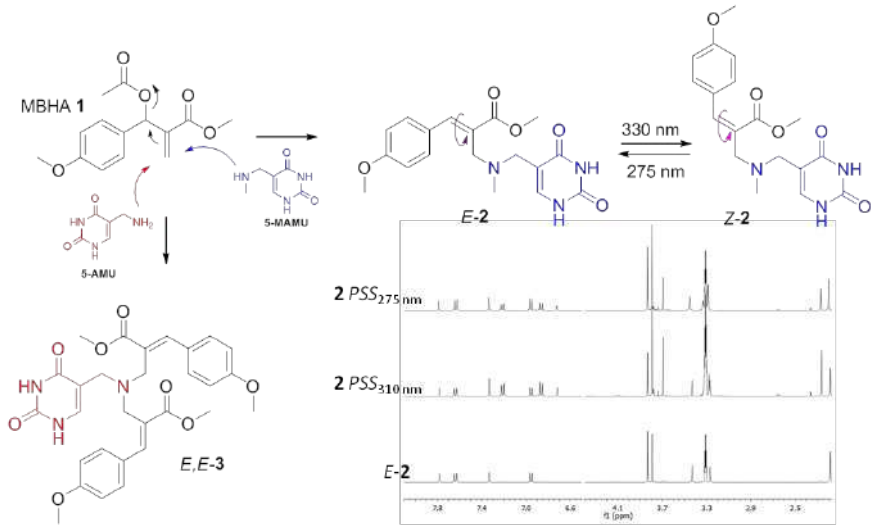

Figure 1: Reaction of MBHA derivative **1** with the unnatural nitrogen bases **5-AMU** and **5-MAMU** and photointerconversion of the monoadduct **2** monitored by ^{1}H NMR.

Due to the higher cost of living and climate change, nowadays, legumes represent one of the most important sources of human food after cereals.[1] Particularly, chickpea (*Cicer arietinum L.*) is considered one of the most popular legumes crops worldwide. To date comprehensive studies on agronomic and genetic influences on chickpea protein composition are lacking. This work reports a comparative proteomic analysis via shotgun approach and label-free quantification (LFQ) of two chickpea samples of the Italian genotype Pascià, grown under two different water conditions, namely rain fed and irrigated.[2,3] Proteomic analysis allowed the identification of about 1100 different proteins. Most of them are common to the two samples (about 78%), whereas 9% of the total and 12% appear exclusively revealed in the rain fed and the irrigated sample, respectively. This comparison revealed a similar qualitative distribution of protein composition in both samples, although some differences have been detected. As expected, in both samples the most abundant components belong to the storage protein family (i.e., legumins, vicilins, and albumins), although the rainfed sample globally contains a little higher content of both legumins and vicilins, and also shows a little higher ratio between vicilins and legumin (V/L ratio). Moreover, a label-free quantification (LFQ) analysis allowed the identification of twenty-three differential abundant proteins (DAPs) that resulted significantly more abundant in the rain fed sample. Most of them are storage proteins or components belonging to the family of the late embryogenesis abundant proteins (LEA), a group of proteins that are upregulated during dehydration stress and show a high abundance during the later stages of seed development, giving the seeds the ability to tolerate drought. Taking into account that legumins and vicilins belong to the cupin superfamily, a group of proteins already identified as legumes allergens,[4] these results, although preliminary, suggest that a balanced water regime might promote a reduction in allergenic potential in chickpea. In the future, this investigation will be extended to another chickpea genotype, to study the impact of different water regimes and nitrogen supply on the qualitative and quantitative protein composition.

Cancer theranostics represent a valuable tool for successful treatment and ease patient care. To achieve efficient medical care, nanoparticle-based therapeutics are commonly used for different biological purposes. Natural inorganic carriers such as halloysite nanotubes (HNTs) are attracting considerable attentions thanks to their capability to penetrate cellular membranes and localizing itself in the perinuclear region.[1] Recently, the modifications of HNTs with different biological active species allowed to synthetize valuable carrier systems, capable of selective detection of cancer cells.[2] In last years, naphthalene diimides, have emerged as versatile compounds able to span the whole visible spectrum upon simple structural modifications and they can be used for fluorescence tissue imaging. Furthermore, they can generate singlet oxygen acting as photosensitizers for photodynamic therapy.[3] Herein we report synthesis of HNTs modified on the external surface with different NDIs derivative to develop new nanomaterials that can be used as theranostic agents. The obtained nanomaterials were characterized by different physical-chemical techniques, their morphology was examined by TEM and the photophysical properties were investigated both in dispersion and solid state. The generation of singlet oxygen by these nanomaterials was also evaluated by recording the absorbance value of 1,3-diphenylisobenzofuran, a singlet oxygen scavenger, after its irradiation with a 650 nm laser. Finally, as proof of concept, the HNTs-NDI nanomaterials were used as carrier for the loading of a PNA derivative to develop a nanomaterial that could selectively target cancer cells.

Melanin hybrids with transition metal ions: new sustainable strategies in heterogeneous catalysis

P. Lioniello,[a] M. L. Alfieri,[a] E. Mazzotta,[b] C. Malitesta,[b] P. Manini[a]

[a]*Dept. Chemical Sciences, Univ. Naples Federico II, via Cintia 4, I-80126 Naples*
[b]*Dept. Biological and Environmental Sciences and Technologies, Univ. Salento, Via Monteroni, I-73100 Lecce*
p.lioniello@studenti.unina.it

In the last decade, several attempts have been made to develop innovative materials provided with tunable nanometer-scale porosity for innovative applications in heterogeneous catalysis.[1,2]

With respect to the general interest for even cheaper and easier to prepare materials, in the last years the focus has been moved toward the research for other and less investigated materials as heterogeneous catalysts such as: carbon nanostructures (*e.g.*, carbon nanotubes) and graphene[3] with high surface area and thermal stability, agri-food waste materials characterized by low-cost and easy availability,[4] and materials inspired by biopolymers that are fully biocompatible and eco-sustainable. In this context, recently special attention has been given to the use of melanins as potential catalysts. Melanins are pigments widely diffused in nature that, due to the unique physicochemical properties, have been used as a multifunctional material in various sectors ranging from (bio)electronics[5] to nanomedicine, energy storage and conversion, and tissue engineering.[6] Moreover, because of their ability to interact with metal ions, melanins have also found applications as chelating agents and in the design of polyfunctional hybrids nanoparticles.

Starting from this evidence herein we report the main results of a research activity aimed at the development of melanin-based catalysts by designing novel metal-melanin hybrid materials.

Calixarene-based RAFT polymers: synthesis and supramolecular properties

M. Longo,[a] E. Tosi,[a,c] S. Volpi,[a] P. Tecilla,[b] P. Gobbo,[b,c] A. Casnati,[a,c]

matteo.longo@unipr.it

Calixarenes are considered the third generation of supramolecular macrocycles after cyclodextrins and crown ethers.[1] Thanks to their supramolecular properties, calixarenes have been included into polymers to develop chemical sensors, selective membranes, heterogeneous catalysts, microelectronic devices, and drug delivery systems.[2]

In this work we concentrated our efforts on the synthesis and characterization of calixarene-based RAFT polymers, that have never been reported in the literature. RAFT polymerization is a highly reproducible and reliable reversible deactivation living radical polymerization that ensures the synthesis of polymers with low molar mass, dispersity, and uniform chemical composition.[3] We synthesized and characterized different calixarene-polymer hybrid macromolecules based on N-isopropylacrylamide (Figure 1) and having a different number of polymer arms at the calixarene lower rim. The preliminary thermoresponsive and supramolecular properties of such hybrids were also investigated together with their possible future applications in material science.

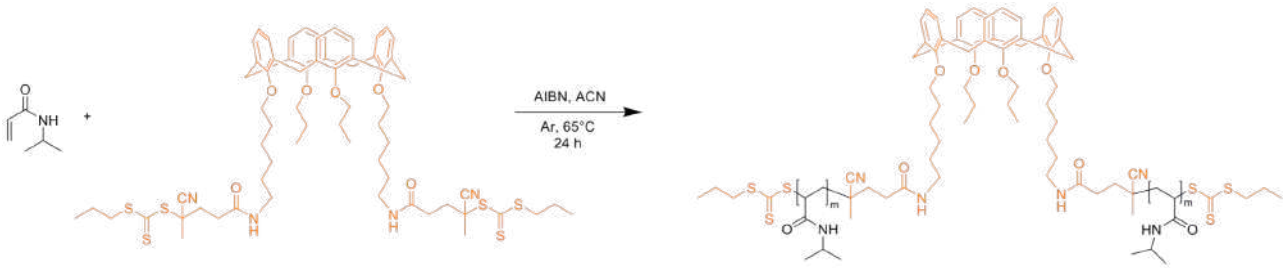

Figure 1. Synthesis of calixarene-based RAFT polymer having two arms at the lower rim.

A multi spectrophotometric approach for the comprehensive study on α –glucosidase, α–amylase and tyrosinase inhibitory activity of anacardic acids

Anna Elisabetta Maccarronello,[a] Nunzio Cardullo,[a] Vera Muccilli[a]

[a]*University of Catania, Department of Chemical Sciences, Viale A. Doria 6, 95125 Catania (Italy)*
anna.maccarronello@phd.unict.it

Anacardic acids are 6-alkylsalicylic acids with varying alkyl chain lengths and degrees of unsaturation, which have demonstrated strong antibacterial and anti-inflammatory properties.[1] In our recent studies, anacardic acids were for the first time discovered in *Pistacia vera* and *Juglans regia* shells extracted in hydroalcoholic solutions by an optimized microwave-assisted method.[2,3] Both extracts showed remarkable hypoglycemic properties by inhibiting key carbohydrate-hydrolysing enzymes (α-amylase and α-glucosidase). Additionally, the *P. vera* shell extract efficiently inhibited tyrosinase, an oxidase enzyme involved in dermatological disorders. According to HPLC-MS/MS analysis, anacardic acids were the most abundant components of the extracts. However, their role towards α-glucosidase, α-amylase, and tyrosinase has not been deeply explored to date.

Herein, (C15:0)-anacardic acid and (C17:1)-anacardic acid (Fig. 1) were selected to investigate the inhibitory behaviour of such class of phenolic lipids towards α-glucosidase, α-amylase and tyrosinase. Notably, tested compounds resulted superior metabolic enzyme inhibitors than the anti-diabetic drug acarbose. In addition, (C15:0) and (C17:1) anacardic acids exhibited a higher anti-tyrosinase activity (IC_{50} of 26.55 and 29.36 μM, respectively) than kojic acid (IC_{50} = 34.96 μM), used as a reference standard. Kinetics analyses uncovered these compounds as competitive inhibitors, while fluorescence experiments allowed the determination of the dynamic quenching (K_{sv}) and binding (K_a) constants. Altogether, these results introduce anacardic acids as interesting natural hypoglycaemic and anti-melanogenic agents.

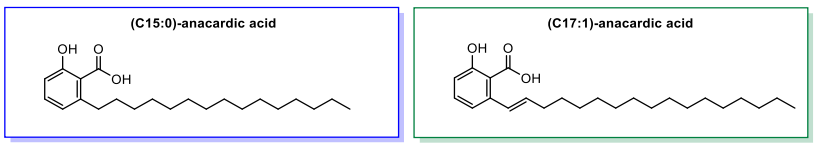

Figure 1: Chemical structures of anacardic acid constituents from *P. vera* shells

Developing a Sustainable Method for Taming Short-lived Cyclopropenyllithium in Flow

I. Mahdi, M. Colella, P. Natho, L. Degennaro, and R. Luisi

FLAME-Lab, Flow Chemistry and Microreactor Technology Laboratory, Department of Pharmacy –Drug Sciences, University of Bari "A. Moro" Via E. Orabona 4 -70125 Bari, Italy

e-mail:iktedar.mahdi@uniba.it

Functionalized cyclopropenes are highly strained reactive molecules, widely used in numerous reactions,[1] showing metabolic stability when incorporated in bioactive molecules,[2] and used as bioorthogonal chemical reporters.[3] Additionally, substituted cyclopropenyllithium compounds are also valuable synthetic reagents, serving as reactive intermediates for synthesizing diverse organic molecules.[4,5] However, the reported synthetic batch protocols for accessing cyclopropenyllithiums present practical challenges, requiring a cooling-heating-cooling process in the range of -78 °C to -20 °C to -50 °C within one hour. This poses reproducibility issues, especially on a larger scale. Furthermore, the utilization of flash chemistry in flow microreactors enables the control of short-lived organolithiums at higher temperatures compared to batch processes, ensuring reproducibility and precise control. In this presentation, we introduce a sustainable and reproducible protocol for generating and utilizing cyclopropenyllithium intermediates using a continuous flow microreactor for the first time. This reaction can be conducted under more practical conditions without compromising the selectivity and reactivity of the employed cyclopropenyllithium. [6,7]

In this presentation, we report, for the first time, a sustainable and reproducible protocol for the generation and use of cyclopropenyllithiums intermediates using a continuous flow microreactor. The reaction can be conducted under more practical conditions without compromising selectivity and reactivity of the employed cyclopropenyllithium.

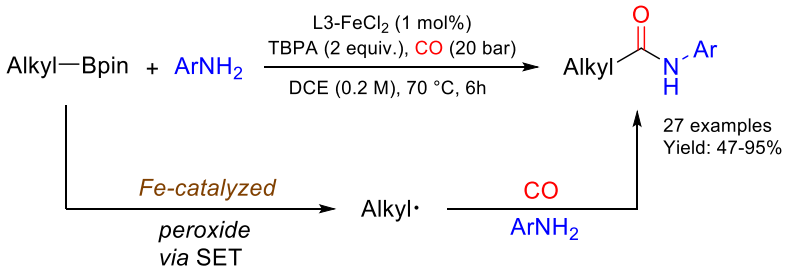
raffaella.mancuso@unical.it

The amide bond is an essential linkage in organic chemistry and, represent the key functional group in peptides, polymers and many natural products and pharmaceuticals [1]. Furthermore, alkyl-boronic acid or esters have attracted much attention due to their high stability, low toxicity, simplicity of preparation and the wide applicability [2]. For this reason, the aminocarbonylation of alkyl-boronic pinacol esters toward amides has been developed. The reactions took place in presence of L3-$FeCl_2$ (L3: 4,4'-di-tert-butyl-2,2'-bipyridine), TBPA (tert-butylperoxiacetate), under 20 bar of CO in DCE at 70 °C for six hours (eq 1).



Eq. 1: aminocarbonilation of alkylboronic pinacol esters via radical generation.

27 examples have been reported with yields up to 95%. The reaction radical mechanism has been confirmed through tests by using BHT as radical inhibitor, a free-radical compound (TEMPO) and a chemical able to react with free-radicals: the 1,1-diphenylethylene.

The inverse electron demand [4+2] hetero Diels-Alder reaction allows to easy access to tetracyclic fused glycomimetics as precision tools in cancer settings

Chiara Mangini[a], Giacomo Biagiotti[a], Laura Legnani,[b,c] Maria A. Chiacchio,[c] Barbara Richichi[a]

e-mail chiara.mangini@unifi.it

Glycomimetics, molecules that mimic the structural and functional features of native carbohydrates, possess vast therapeutic potential and are emerging within the drug development market.[1] It is well established that by proper modulation of their structure, researchers can overcome the inherent limitations of native carbohydrates leading to molecules with enhanced selectivity/potency for the target and improved drug-like properties. With this in mind, straightforward synthetic strategies that allow to access to such compounds have emerged at the frontier of drug design thus making glycomimetics more and more available tools for advancing our understanding of the glyco-code and as therapeutics for a great variety of diseases.[1b, 2]

In this framework, the use of glycals as electron-rich dienophiles in the [4+2] inverse electron-demand hetero-Diels-Alder (ihDA) reaction allows as easy access of an array of glycomimetics with a high degree of structural diversity. In this communication, we describe our last contribution in the field in providing a new class of electron-poor heterodienes, the N-substituted-3-thioxo-benzo[c][1,2]thiazin-4-one-2,2-dioxides.[3] The use of such heterodienes in the ihDA allows either to further widen the structural diversity of the glycomimetics and to foster the understanding of the mechanistic details and the reactivity of some glycals in the ihDA. The implications of our recent insights in the development of precision therapeutics in cancer settings will be also described.

Synthesis and characterization of Gadopiclenol bifunctional derivatives

A. Marcotrigiano,[a] L. Tei[a]

[a]*Università del Piemonte Orientale, Dipartimento di Scienze e Innovazione Tecnologica, V.le Teresa Michel 11, Alessandria, Italy*
angelo.marcotrigiano@uniupo.it

Due to its optimal thermodynamic stability, kinetic inertness and efficiency (in terms of relaxivity), Gadopiclenol has been proved to be a valuable GBCA (gadolinium based contrast agent) for Magnetic Resonance Imaging (MRI) applications[1]. In this work we performed the synthesis of a bifunctional Gadopiclenol analogue bearing an amino group on the pyridine moiety (Figure 1); this scaffold could be used in order to link the complex to a molecule with high affinity with human serum albumin (such as adamantane group) or to build a dimeric derivative.

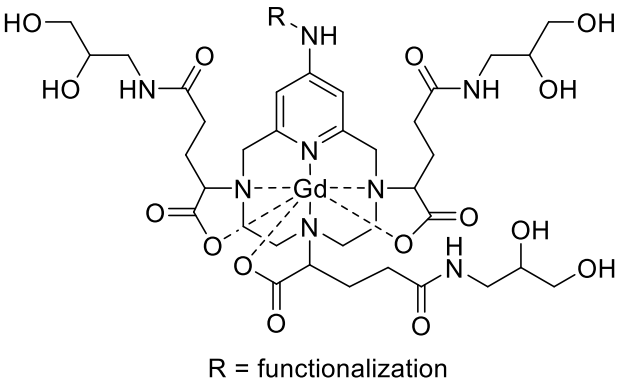

Figure 1: Bifunctional Gadopiclenol amine derivative.

These paramagnetic contrast agents show improved efficiency because of their higher molecular weight (which leads higher rotational correlation time values). In addition, Gadopiclenol and its derivatives are neutral complexes, so they are suitable for MRI-guided therapeutic applications based on the administration of sonosensitive liposomes co-encapsulating the anticancer drug doxorubicin and the paramagnetic agent[2].

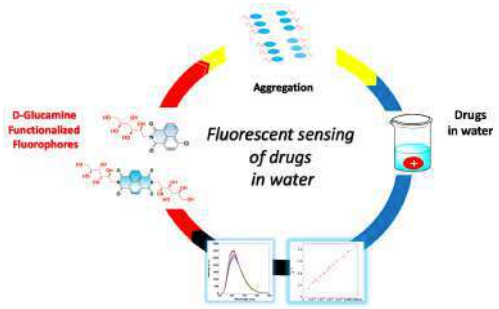
salvatore.marullo@unipa.it

Fast and sensitive quantification of drug residues in water is increasingly required, due to the relevant presence of such pollutants in water bodies. This explains the rising interest in fluorescent sensing probes for this purpose. In this context, we synthesized two D-glucamine functionalized fluorophores bearing self-assembling cores, as 1,8-naphthalimide and naphthalene diimide. We studied their self-assembly in water solution, and characterized the aggregates formed by determining their stability constant, their morphology and size by scanning electron microscopy, resonance light scattering and dynamic light scattering. Then, we studied their sensing ability, in water, towards pharmaceutically active compounds such as ciprofloxacin, nalidixic acid, carbamazepine and diclofenac sodium salt, by fluorescence investigation.



Data collected show that the self-assembling ability is significantly affected by the fluorophore structure, which in turn also determines sensing ability. In particular, the naphtalene diimide-based probe was the most sensitive, with LOD as low as 0.01 μM in the presence of nalidixic acid, which is in line and competitive with more complex sensing systems, recently reported in the literature.

alessandro.maselli@dottorandi.unipg.it

In the last years, the interest in the synthesis of heterocycles is largely increasing for their wide range of industrial application[1], from the pharmaceutical industry to the agricultural[2]. Between the numerous types of molecules studied, some of the most interesting are probably the Benzofurans; these are in fact really useful in pharmaceutical industry, because they are found as scaffolds in a large amount of API, with different applications, such as antitumorals[3],anti-infiammatory[4], antiarrythmic[5] and many more.

To answer to the high demand for this scaffolds, a great number of synthetic pathways were created and can be easily found in literature; most of them, however, present problematics, mainly for the expensive chemicals and catalysts applied, but also for safety and sustainability reasons, such as the use of dangerous solvents and the generation of wastes. To try to achieve better and more sustainable processes for these compounds of great industrial relevance, this work tried to optimize their synthetic paths, applying the principles of Green chemistry. To achieve this, we selected a process form literature between diphenylacetylene and phenol[6], in which was used the C-H activation reaction, that is highly desirable for a more sustainable process since it doesn't require any prefunctionalization steps. We then started to apply safer solvents, heterogeneous catalysis and different type of bases and oxidizing agent to decrease the wastes.

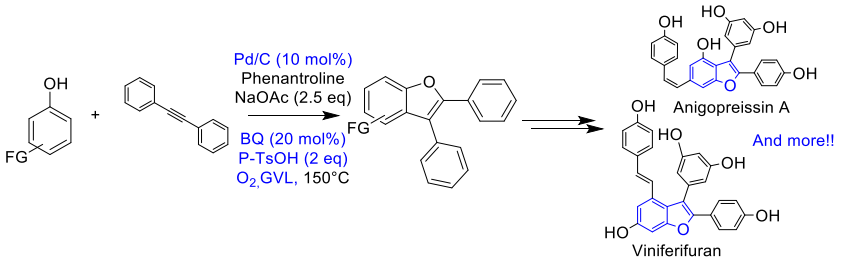

Figure 1: Optimized protocol for the synthesis of Benzofurans

Enzyme immobilization is a powerful tool for the design of green and sustainable production processes. Given the diversity of methodologies and carriers, the proper approach for the specific requirements of a given process can be pinpointed. Enzyme immobilization helps to maintain the catalytic activity and stability under a range of pH, temperatures, and inhibitors, along with maintaining their recyclability over successive catalytic cycles. Also, the immobilization of enzymes to solid supports ensures highly purified products by easily removing the biocatalyst from the medium.[1] The high expense associated with the support systems hinders the commercial applicability of immobilized enzymes. In this light, clay minerals being natural and low-cost, represent valuable candidates to be used as support for enzyme immobilization.[2]

Herein, we report the covalent grafting of laccase and, collagenase, on clay minerals' surface to develop functional nanomaterials for different purposes. The obtained nanomaterials were thoroughly characterized by different physical chemical techniques, aiming to confirm the successful grafting. Furthermore, UV-vis experiments were performed in order to validate that the enzymes can retain their enzymatic activity after the covalent grafting on clay surface.

Currently, since immobilized enzymes seem to have immeasurable prospects in all areas of science from targeted drug delivery to the development of sensor and bioremediation to develop functional materials that can be used in different fields.

stefania.mazzini@unimi.it

Quadruplex-Duplex (Q–D) junctions are unique structural motifs garnering increasing interest as drug targets, due to their frequent occurrence in genomic sequences. The viral HIV LTR-III sequence was chosen as a Q–D junction model to study the affinity of the selected compounds BMH-21, namitecan, and doxorubicin, all containing a planar polycyclic aromatic moiety, linked to either one short aminoalkyl or an aminoglycosyl group. A multidisciplinary approach that combines NMR spectroscopy, molecular modelling, circular dichroism (CD) and fluorescence spectroscopy was employed to investigate the interactions of BMH-21, namitecan and doxorubicin with the Q–D junction LTR-III. In particular, the binding of BMH-21 and namitecan to the LTR-III target was not associated to a significant stabilizing effect. However, doxorubicin was found to be the best Q–D junction binder, as evidenced by the complex denaturation curve, which showed higher melting temperature values. Interestingly, the removal of the aminoglycosyl group significantly changed the pattern of the interactions, indicating that highly polar substituents have a stronger affinity with the exposed regions of the Q–D junction, particularly at the level of the interfacial tetrad. Our chemical investigations, supported by biophysical data and molecular modeling studies, provide guidelines for the identification of new scaffolds for selective Q–D recognition. Since CPTs and doxorubicin have been found to inhibit HIV virus with unknown mechanisms of action, the results may be useful to extend the search for potential antiviral agents in the management of HIV infections.

C-1 and C-5 quaternarization of β-fucosides by HAT reactions

S. Mazzotta[a], I. Giussani, G. Antonini, L. Belvisi, A. Bernardi

[a]*Dipartimento di Chimica, Università degli Studi di Milano, Milano, Italy*
sarah.mazzotta@unimi.it

The functionalization of C-H bonds gives access to complex molecules in fewer steps relative to classical methods. However, the modification of polyfunctionalized structures like carbohydrates is very challenging and still underdeveloped. The challenge arises from the unreactive nature of carbohydrates' C–H bonds and from the regioselectivity problems associated to the presence of many similar functionalities.[1]

Hydrogen atom transfer (HAT) reactions enable a direct activation of C-H bonds, without the need of pre-functionalization or the presence of a directing group. As such, they are synthetically attractive and have been used on carbohydrates mostly to obtain regioselective inversion of stereocenters of unprotected sugars.[2]

In the context of glycomimetic design, we are interested in the potential of HAT reactions to modify desired ligands while maintaining the sugar structure intact. This allows to target secondary binding sites in proteins and/or create multivalent ligand presentations, thus expanding the toolbox for glycomimetic development.

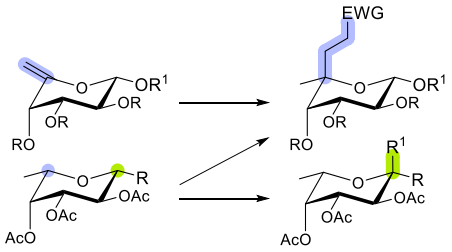

Figure 1: C-1 and C-5 functionalization of β-fucosides.

Here we report on the functionalization of the C-1 and C-5 position of β-fucosides (Figure 1) that we are exploring for the synthesis of antimicrobial antiadhesive agents targeting the *N*-terminal domain of the bacterial lectin BC2L-C.[3]

Robust, reproducible, low waste and large scale procedure for high quality $CsPbBr_3$ nanobricks synthesis for scintillation.

S. Mecca,[a] A. Fappani,[a] F. Pallini,[a] A. Erroi,[a] L. Beverina,[a] S. Brovelli[a]

sara.mecca@unimib.it

Research interest in all inorganic lead halide perovskite nanocrystals (LHP-NCs), described by the general chemical formula of CsPbX3, has recently grown fast thanks to their outstanding and highly tunable chemical and physical properties that make them optimal candidates for a wide range of technological applications[1]. Amidst this rapidly expanding and diverse landscape, we present a robust, reproducible, and easily scalable synthetic method that enables the production of high-quality CsPbBr3 NCs on an unprecedented scale, reaching up to 8 grams. To achieve this, we modified the synthetic procedure originally outlined by Akkerman et al.[2], introducing a turbo emulsifier (Ultra Turrax Homogenizer) for the first time. This emulsifier, typically used in formulating large batches, enhances the homogenization of the reaction mixture, addressing concentration gradients and reproducibility issues that commonly impact liter-scale reactions of LHP-NCs. Additionally, we employed tetrabutylammonium bromide (TBAB) as an extra bromide precursor to ensure the correct stoichiometry. Operating in a halogen-rich environment is known to reduce defectivity, and the bulkiness of this specific quaternary ammonium salt prevents it from competing with other cations in the perovskite crystal lattice. Our results indicate that the amount of recovered solid material is directly proportional to the solution volume used at every scale, affirming the well-controlled nature of the process even at larger scales. There are also evidences that increasing the scale, magnetic stirring becomes insufficient where turbo-emulsifier remains reliable. Furthermore, the procedure is easy extendable to CsPbCl3 and mixed phase and other acid and amine ligands. We pushed the boundaries by demonstrating that our approach allows for the recovery and reuse of low-boiling solvents and excess reactants, particularly lead bromide, without compromising the final product's quality. This not only reduces the environmental impact associated with waste production but also represents a significant step toward eventual industrial applications. We finally tested radioluminescence properties and radiation hardness in polymer matrix, confirming their competitiveness in scintillation field[3].

Dissipative Dynamic Covalent Chemistry (DDCvC) Based on The Transimination Reaction

Daniele Del Giudice, Matteo Valentini, Gabriele Melchiorre, Emanuele Spatola and Stefano Di Stefano

[a]*La Sapienza University of Rome, Aldo Moro Square 5, Rome*
gabriele.melchiorre@uniroma1.it

This work reports the possibility to control over time the composition of a dynamic library (DL) of imines that interconvert among them through reversible equilibria of transimination.[1] These transimination equilibria studied in organic media involve the conversion of one or more *N*-aliphatic imines to *N*-aromatic ones, and the composition of these libraries is strongly shifted toward the *N*-aliphatic imines, that have attached the more basic amines. A representative situation of these systems is the first minimal DL studied, between *p*-brome-*N*-benzylidenebutylamine and *p*-brome-*N*-benzylidenetoluidine (Figure 1A).
Since this kind of DL is sensitive to acid-base stimulus, by adding an acid to the environment we can subtract from the equilibrium the most basic substance (the aliphatic amine) in order to overexpress its protonated form and the *N*-aromatic imine through Le Chatelier's principle. By adding a decarbossilative acid fuel like the 2-cyano-2-(4'-chloro)-phenylpropanoic one instead, this dramatic change of composition can be realized temporarily (with the creation of a dissipative dynamic library, DDL, Figure 1B), because then through the decarboxylation of the fuel coniugate base (the rate determining step) a strong carbon base would be generated *in situ* in order to revert the starting situation back:[1]

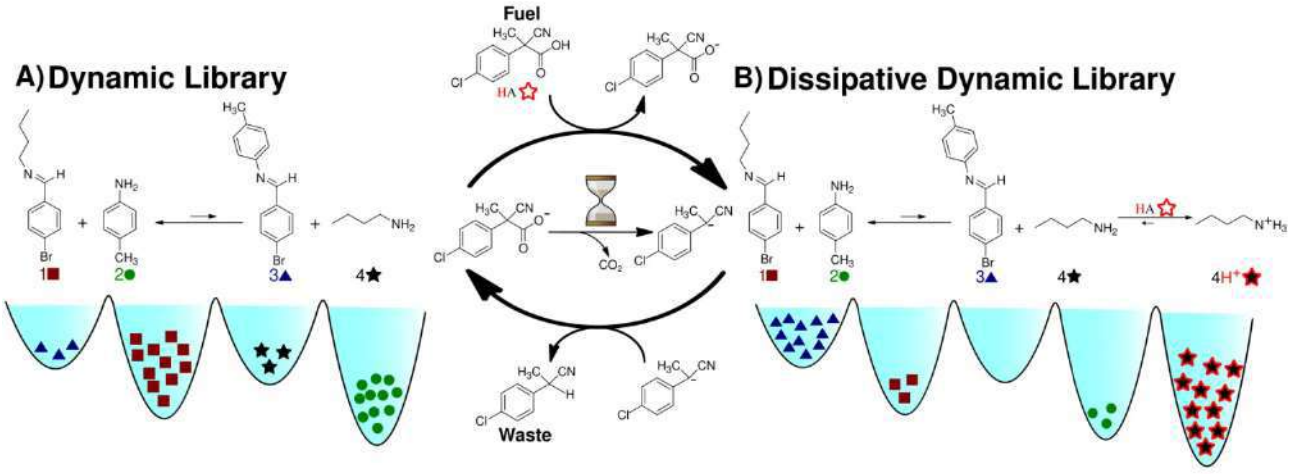

Figure 1: A) A minimal DL that consists of *p*-brome-*N*-benzylidenebutylamine (1) in equilibrium with *p*-brome-*N*-benzylidenetoluidine (3), and the relative amines. A qualitative free energies profile of the substrates is shown for representing the composition of the system. B) The addition of the fuel shifts the equilibrium toward the imine 3 and the butylammonium, and this state persists until the fuel consumption.

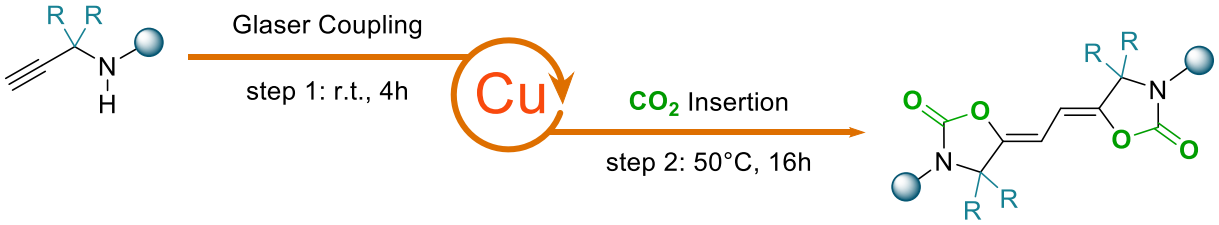
Francesco.mele@unipr.it

With the continual increase in atmospheric CO_2 levels, scientists globally have undertaken research to develop innovative methods for the effective capture and utilization of this well-known greenhouse gas. To tackle this challenge, the Carbon Capture and Utilization (CCU) strategy is designed to capture CO_2 from emission sources and transform it into valuable products[1]. The carboxylic cyclization of propargylic amines to produce 2-oxazolidinones stands out as a highly appealing chemical approach for trapping carbon dioxide. One of the possible reactions of propargylamine is the Glaser coupling on terminal alkynes, that enables easy access to 1,3-diynes, essential intermediates for polymers, macrocycles, and complex scaffolds[2].



Scheme 1. Inexpensive copper catalyst for sequential Glaser coupling and carboxylation of propargylic amines.

As a part of our research on catalytic conversion of carbon dioxide into novel and useful compound utilizing CO_2[3,4], we embraced the task of integrating the copper-catalysed reaction of terminal alkynes with the carboxylation of propargylamine (Scheme 1). As far as our knowledge extends, a comprehensive synthesis of bis(2-oxazolidinone)s has not been documented. We try to investigate the Cu/DBU catalytic system, observing a manifold role of copper salt, which acts as a catalyst both for the Glaser coupling and the carboxylative cyclization. We successfully devised a straightforward and efficient one-pot two steps procedure that can be used for a vast range of propargylamines, resulting in a substantial collection of products with excellent yields. Importantly, the purification of the resulting products can be easily accomplished by directly precipitating them from the reaction medium. Finally, we observed a spontaneous polymerization of these butadiene-containing monomers leading to the formation of a category of specialized polymers, accomplished through a solid-state Single Crystal to Single Crystal transformation.

Gold catalyzed asymmetric synthesis of axially chiral indole-fused diazocines.

S. Meraviglia[a], V. Pirovano[a], E. Brambilla[a], G. Abbiati[a]

[a]Dipartimento di Scienze Farmaceutiche, Sezione di Chimica Generale e Organica "A. Marchesini"
Università degli Studi di Milano, Milan
e-mail: silvia.meraviglia@unimi.it

Atropisomerism, also called axial chirality, is a particular kind of chirality in which the rotation of a σ bond is constrained because of the steric or electric effects of bulky substituents. The main difference between classical stereoisomers and atropisomers is that classical stereocenters are often stable and racemize via a bond-breaking, while racemization for axially chiral compounds is possible through an intramolecular dynamic process that simply involves bond rotation.[1] This time-dependent chirality shows great potential for drug development and has been observed in natural products. In addition many chiral catalysts and ligands that are frequently used in asymmetric synthesis are axially chiral compounds.[2] Among these substrates, axially chiral indole derivatives have been recognized as an important class of five-membered heterobiaryls, because of their presence in some natural alkaloids, chiral phosphine ligands and bioactive molecules.[3] Taking into account these premises, this poster will deal with our recent developments in the gold catalyzed asymmetric synthesis of axially chiral indole-fused diazocines. In particular, optimization of catalytic conditions and preliminary substrate scope of the reaction will be presented together with a mechanistic proposal.

francesco.minio@dottorandi.unipg.it

Over recent years, there has been a growing interest in the exploitation of transition metal-catalyzed C-H bond activation for the synthesis of natural products and biologically active compounds.[1] While the activation of C(sp^2)-H bond benefits from a higher acidity and effective reactant-catalyst interactions, the activation of C(sp^3)-H bonds remains a more challenging process yet very useful for making carbon-carbon or carbon-heteroatom bonds.[2] In addition, considering the increasing importance of environmental issues, the attention of the scientific community is shifting towards the use of processes employing safer solvents and recoverable, reusable catalytic systems.[3]

In this contribution, we report our study on the definition of sustainable C-H activation methods to synthesize indolines both in batch and/or flow conditions.[4] In addition, we report our exploration towards the development of enantioselective protocol.[5]

2-aminobenzaldehydes are versatile building blocks in organic synthesis enabling a variety of bond-forming strategies.[1] These molecules are also well-known for their high reactivity in self-condensation reaction.[2] Indeed, for over 80 years, this domino reaction has garnered interest due to the variety of nitrogen-containing polyheterocycles it can produce.[3] In addition, the process plays a considerable role in synthesizing macrocyclic ligands using transition metal ions as templates (figure 1a).[4]

Despite being intrinsically straightforward, controlling the chemoselectivity of the self-condensation presents a significant challenge, as it is strongly influenced by the stereo-electronic effect of the substituents and the reaction parameters such as solvent, temperature and nature of the acidic catalyst.

Herein we present a systematic study on transition metal ions at various oxidation states aimed to address the selective synthesis of trimer derivatives **A**, using non-innocent alcoholic solvents (figure 1b).

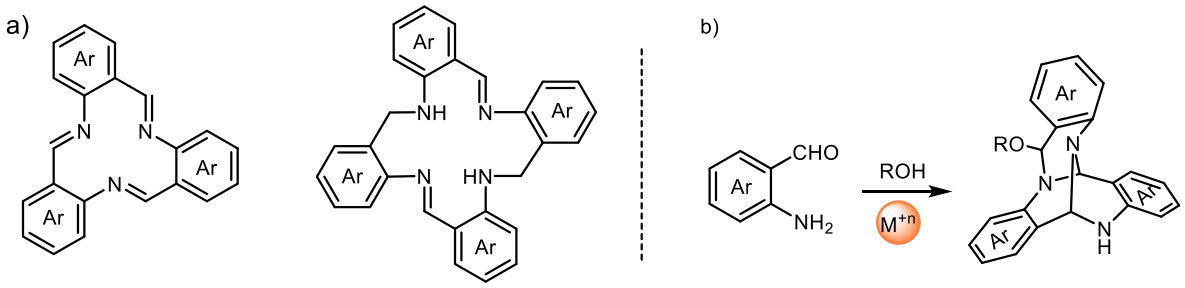

Figure 1. a) Nitrogen-containing macrocycles. b) Self-condensation products addressed in this study.

Mechanistic Insights Into The Base-Mediated Deuteration Of Pyridyl Phosphonium And Ammonium Salts

A. Montoli,[a] A. Dimasi,[a] S. Rossi,[a] D. Passarella,[a] V. Fasano.[a]

[a] *Università degli Studi di Milano, Via Golgi 19, Milan*
arianna.montoli@unimi.it

The past decade has witnessed great progress in the field of "deuterium switch", a strategy based on the replacement of hydrogen with deuterium. Due to the greater activation energy for the cleavage of the C-D bond, the metabolic stability and safety of a drug containing deuterium atoms can improve compared with the non-deuterated counterparts. Given the importance of pyridines in drugs, novel methodologies to access diverse selectivity patterns in their deuteration are highly desirable; inspired by its reported base-mediated *meta*, *para*-deuteration[1,2], we wondered how the deuteration of model compound 2-phenylpyridine (**1**) could be modified to allow for a different labelling selectivity. We envisaged that the temporary installation of an electron-withdrawing group on the pyridine could promote the deuterium switch and alter the deuteration pattern, and in particular that phosphonium salt **[2]**$^+$ or ammonium salt **[3]**$^+$ could promote *ortho*/*meta*-deuteration by increasing the corresponding acidity in these positions while blocking the *para*-position. A phosphine ligand was then installed on the Ph_3P^+ moiety as a directing group (compound **[4]**$^+$) to facilitate the approach of the base by pre-coordination of its cation. In this work, we evaluated, computationally and experimentally (including by in situ NMR analysis) the deuteration of compounds **[2]**$^+$ to **[4]**$^+$.

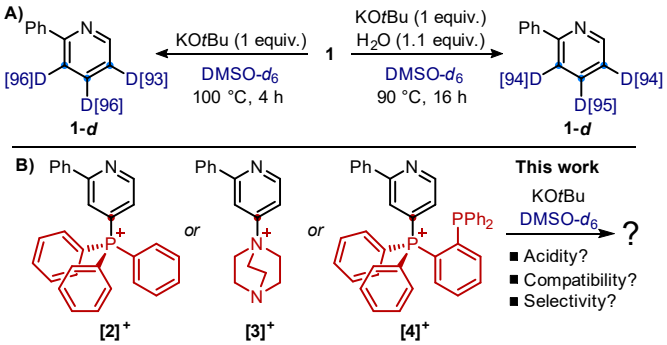

Figure 1: **A)** Base-promoted deuteration of 1-*d*. **B)** Phosphonium and ammonium salts used in this work.

The design and synthesis of multitarget directed ligands represents one of the most attractive and challenging fields in medicinal chemistry research. Nitrogen-containing glycomimetics, such as iminosugars, have proven to be inhibitors of glycosidases and glycosyltransferases. More recently, these compounds have been introduced as therapeutic agents towards lysosomal storage disorders (LSDs), acting as pharmacological chaperones (PCs)[1]. PCs are small molecules able to rescue the activity of mutated enzymes. In the context of LSDs, they favor the correct folding of the enzymes and facilitate their translocation to the lysosomes when used at subinhibitory concentration. In this work, we report a series of trihydroxypiperidine iminosugars bearing different antioxidant or anti-inflammatory moieties as potential bifunctional agents for the treatment of Gaucher disease (GD) (Figure 1), starting from low-cost D-mannose. GD is the most prevalent LSD, caused by mutation in the *GBA* gene encoding for lysosomal β-glucocerebrosidase (GCase), which is responsible for the hydrolysis of glucosylceramide[2]. The new compounds are potentially able to mend GCase dysfunction while reducing the severe oxidative stress/inflammatory state observed in GD patients. Since *GBA* mutations are also known as the most recurrent genetic risk factors for Parkinson disease (PD)[3], these novel compounds are interesting for the treatment of PD as well. The synthesis of the new bifunctional compounds and their biological evaluation towards GCase will be presented.

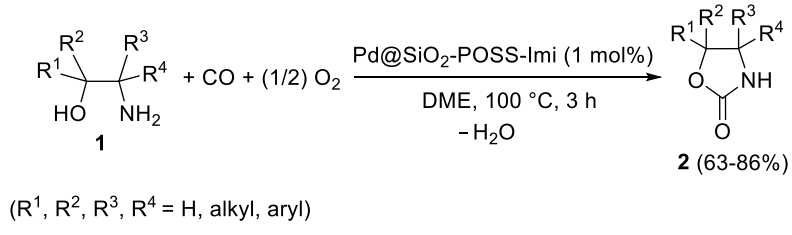
novello.mariangela@gmail.com

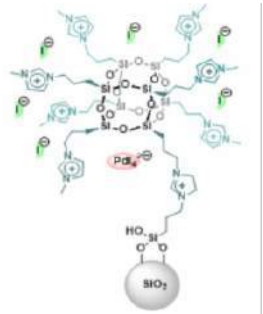
The direct synthesis of 2-oxazolidinones by the oxidative carbonylation of *β*-amino alcohols[1] allows obtaining high value added molecules with several biological applications. 2-Oxazolidinones are known, in particular, to possess significant antibacterial[2] and antitumor activities.[3]

We have now found that it is possible to perform this kind of transformation by supporting our PdI_4^{2-} catalyst (already widely applied in the development of oxidative carbonylation processes under homogeneous catalysis conditions)[4] on a hybrid material based on imidazolium modified polyhedral oligomeric silsesquioxanes (POSS-Imi) grafted on amorphous silica (SiO_2).

The newly developed heterogeneous catalyst was proved effective with a wide range of *β*-amino alcohols **1** to give the 2-oxazolidinone derivatives **2** in fair to high isolated yields (63-86%) as shown in Scheme 1.



Scheme 1



The recyclability of the catalysts has been successfully verified for three consecutive runs.

Visible-light-driven splitting of water into oxygen and hydrogen, often referred to as "artificial photosynthesis", is an attractive way to convert solar energy into fuels. In this context, dye-sensitized photoelectrochemical cells (DS-PECs) have been deeply investigated as a promising technology to convert solar energy into renewable hydrogen fuel. A crucial strategy to increase the efficiency of DS-PEC is the optimization of the dye used in the sensitization of nanostructured TiO_2 photoanodes, whose electrochemical properties must match those of the ruthenium complex used as water oxidation catalyst (WOC).[1] We designed metal-free sensitizers having a D(donor)–π–A(acceptor) structure (**Figure 1**) according to the photoelectrochemical requirements for applicability in DS-PEC.

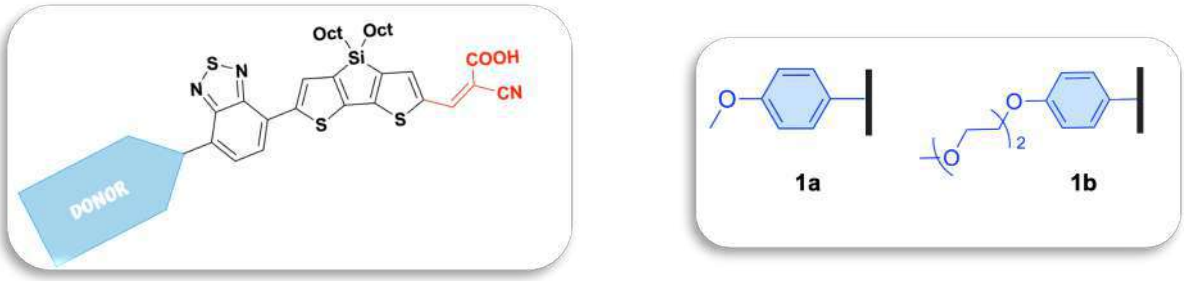

Figure 1: Structures of the designed D–π–A Sensitizers

Taking advantage of the modulation of HOMO energy through the insertion of different donor groups, we synthesized molecules **1a-b** by means of a short sequence featuring a direct arylation reaction as the key step. In this communication, the optimization of the synthetic conditions and the characterization of the final compounds will be described.

In Antarctica, ice-free areas can be found along the coast, on mountain peaks, and in the McMurdo Dry Valleys, where microorganisms well-adapted to harsh conditions can survive and reproduce. Metabolic analysis can shed light on the survival mechanisms of Antarctic soil communities from both coastal sites, under different plant coverage stages, and inner sites where slow-growing or dormant microorganisms, low water availability, salt accumulation, and a limited number of primary producers make metabolomic pro-filing difficult. Here we report, for the first time, an efficient protocol for the extraction and the metabolic profiling of Antarctic soils based on the combination of NMR spectroscopy and mass spectrometry (MS)[1]. This approach was set up on samples harvested along different localities of Victoria Land, in Continental Antarctica, devoid of or covered by differently developed biological crusts.
NMR allowed the identification of thirty metabolites (mainly sugars, amino acids and organic acids) and the quantification of just over twenty of them. UPLC-MS analysis identified more than twenty other metabolites, in particular flavonoids, medium and long chain fatty acids, benzoic acid derivatives, anthracenes, quinones.
Our results highlighted the complementarity of the two analytical techniques. Moreover, we demonstrated that their combined use represents the "gold standard" for the quali/quantitative analysis of very little explored samples such as those collected from Antarctic soils.

Solid supported Cu(I): an efficient catalyst for additive free C-H amination of benzoxazole

Andrei Paraschiv, Katia Martina, Giancarlo Cravotto

Department of Drug Science and Technology, University of Turin, Via Pietro Giuria 9, 10125, Turin
andrei.paraschiv@unito.it

Among nitrogenous heterocyclic compounds 2-aminoazoles, especially 2-aminobenzoxazoles, possess high relevance due to their biological and pharmaceutical activities.

Selective C-N bond formation of benzoxazoles is usually performed by reactions as Buchwald Hartwig or Ullmann and Goldberg couplings but still some disadvantages are needed to be solved for better agreement with green chemistry criteria. Thus, developing greener and simpler methodologies, the direct amination of aromatic C–H bonds is regarded as a more powerful alternative.

Many transition metals had been exploited as catalysts, however Copper use has risen thanks to its low cost, high functional group tolerance, high environmental abundance and safety, and low overall toxicity.[1, 2]

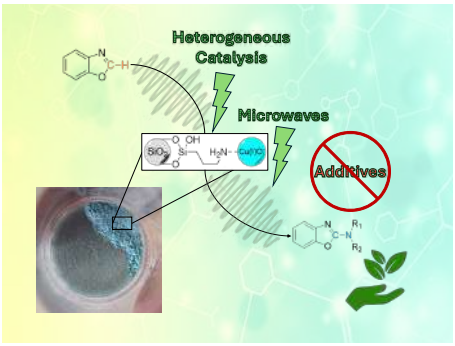

Figure 1: Graphical representation of microwave assisted C-H amination of benzoxazole

Successfully examples of benzoxazole selective C-H amination are reported in literature, however they usually show limits such as the use of stoichiometric amount of an acid or base as a promoter, non-greener peroxide oxidants or solvents, pre-functionalised amino-reactants as well as high temperature.
