The aim of the present work is the optimization of a simple, efficient and green direct C-H amination which avoids the use of any acidic, basic or oxidant additive. The reaction was proved to take advantage from microwave irradiation and excellent results were achieved in presence of a silica supported Cu(I) catalyst. The catalyst allowed a convenient isolation of the final product, and a simple procedure for catalyst regeneration was exploited to reuse the catalyst up to eight times without losing catalytic activity.

Tandem photo-enzymatic catalysis with imine reductase enzymes (IREDs) in the stereocontrolled synthesis of cyclic amines

S. Parisotto,[a] M. Blangetti,[a] C. Prandi[a]

[1] *Università di Torino, Torino, Via Pietro Giuria 7, Italy.*
stefano.parisotto@unito.it

The growing interest in the synergistic use of photocatalysis and biocatalysis, merging the reactivity provided by photocatalysts with the selectivity of enzymes, highlights the potential of photobiocatalysis for achieving novel syntheses of valuable chemicals,[1] for example α-stereogenic amines. Indeed, they are ubiquitous among natural products and active pharmaceutical ingredients (APIs) and are crucial in organic synthesis as chiral auxiliaries and resolving agents. Recently, their preparation via the Dynamic Kinetic Resolution (DKR) of linear and cyclic amines has been improved by the combination of the enzymatic activity of monoamine oxidases (MAOs),[2] and lipases,[3] with different photocatalysts. In this context, our interest in the preparation of cyclic chiral amines has recently brought our attention to imine reductases (IREDs),[4] an emergent class of nicotinamide-dependent enzymes, discovered in 2010 by Mitsukura and co-workers,[5] catalysing the asymmetric reduction of imines. Their use in photobiocatalysis is still unprecedented but given the well-established reactivity of imidoyl,[6] and iminyl radicals,[7] it could provide an original route to *N*-heterocycles.

Here we report the first application of imine reductases (IREDs) in photobiocatalysis in the stereocontrolled synthesis of 2,5-disubstituted pyrrolidines. The presented methodology leverages the photochemical generation of a nitrogen-centred radical which triggers an intramolecular hydroamination of a non-activated alkene. The cyclization is telescoped with the enzymatic reduction of the in situ formed imine, providing the final saturated heterocycle.

e-mail: francesco.pasca@uniba.it

The presence of fluorine atoms in a wide range of pharmaceuticals is well-established, with over 20% of drugs on the market containing at least one fluorine atom.[1] Consequently, the synthesis of complex chemical structures that incorporate fluorine atoms has become a highly sought-after area of research in organic chemistry.[2] The advent of photo(redox)catalysis has enabled the development of new and innovative synthetic methodologies that were previously impossible using traditional ground state pathways. This approach has proven particularly useful in the synthesis of fluorinated compounds. While several strategies have been proposed for generating fluoroalkyl radicals using photocatalytic mechanisms, little research has been conducted on the reactivity of monofluoroalkyl radicals.[3,4,5,6] In this study, we present a novel photocatalytic monofluoroalkylation strategy that employs a decarboxylation of α-fluoro carboxylic acids (Figure 1) in a Giese reaction and in a subsequent multicomponent radical polar crossover reaction for the one-pot synthesis of highly complex chemical structures performed effectively under continuous flow conditions.

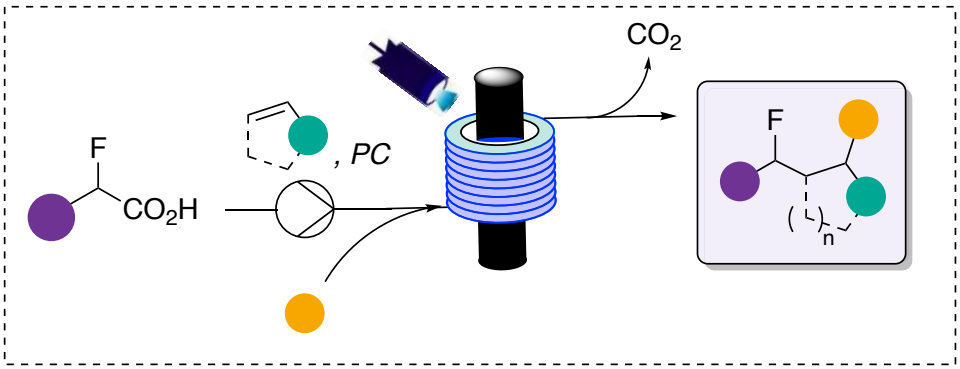

Figure 1: General approach to radical monofluoroalkylation in flow.

Pioneering Low Environmental Impact Methodologies for Polymer Waste Transformation with Deep Eutectic Solvents

A. N. Paparella, V. Capriati, F. M. Perna, P. Vitale

Dipartimento di Farmacia-Scienze del Farmaco, Università di Bari Aldo Moro, Consorzio C.I.N.M.P.I.S, Via E. Orabona 4, I-70125 Bari, Italy
filippo.perna@uniba.it

Polymeric materials play a ubiquitous role in nearly every facet of human activity, thanks to their remarkable chemical and mechanical resilience. However, their exceptional properties come at a cost: most polymers are notoriously non-biodegradable, posing a significant ecological challenge due to their persistent accumulation in the biosphere.

In recent years, significant efforts have been focused on reducing plastic consumption and improving chemical recycling methods.[1] However, there is still a pressing need for innovative green technologies to address the recovery, treatment, and chemical recycling of polymer waste. This would enable their transformation into reusable raw materials or high-value products. Among the myriad thermoplastic polymers utilized in daily life and plastic manufacturing, polyethylene terephthalate (PET) and polyurethane (PU) stand out as both prevalent and environmentally detrimental pollutants.

Our research is committed to developing greener and more environmentally sustainable depolymerization techniques as viable alternatives to conventional processes. To achieve this goal, we are investigating the application of Deep Eutectic Solvents (DESs) or their aqueous solutions as reaction media for plastic depolymerization. These solvents offer favorable chemical and physical properties, ease of production and utilization, and recyclability.[2]

In this communication, we present our findings on the DES-promoted depolymerization of PET and PU chains, enabling the recovery of monomers as new raw building blocks for use in the synthesis of other polymers or fine chemicals. This represents a crucial step towards a more sustainable approach to polymer waste management and resource utilization.

New approach for the development of Streptococcus pneumoniae 6A and 6C vaccine

Laura Petrosilli[a], Laura Morelli[b], Federica Compostella[b], Luigi Lay[a]
[a]*Department of Chemistry, University of Milan, Via Golgi 19, Milan (20133), Italy*
[b]*Department of Medical Biotechnology and Translational Medicine, Via Saldini 50, Milan (20133), Italy.*
laura.petrosilli@unimi.it

The control of *Streptococcus pneumoniae* (SPn) infections is a dynamic and evolving field, particularly in developing vaccines that can provide broad protection against different serotypes. The first pneumococcal polysaccharide conjugate vaccine (PCV7), which covered only a few of the many serotypes of SPn, has been expanded over the years to cover more serotypes due to the serotype replacement phenomenon[1], whereby an increase in cases of infection by serotypes not present in available glycoconjugate vaccines (NVTs) is observed. An example is serogroup 6, where serotypes 6A and 6B are included in PCV13 vaccine, but 6C[2] has subsequently shown serotype replacement, highlighting the need for continuous innovation in vaccine design. The use of molecular dynamics simulations[3] represents a novel approach in this regard, allowing researchers to explore conformational differences between serotypes within the group 6. Particularly the study of conformations on capsular polysaccharide (CPS) fragments, allows critical data to be collected to predict cross-protection between serotypes. This information is invaluable in synthesizing the most effective vaccine candidate, particularly for serotypes with similar epitope structures, such as 6A and 6C, and provides an opportunity to hypothesize the structure that will achieve a total cross-reactivity. The CPS repeating units of SPn 6 serotypes have minimal structural differences: 6A and 6C have the same glycosidic linkages, but they differ in their monosaccharide composition, with glucose replacing galactose in 6C[4]. The tetrasaccharide fragments of SPn 6A (Target 1) and 6C (Target 2) serotypes are the primary synthetic goals of this project (Scheme 1). In addition, we designed the 4-deoxy derivative of both tetrasaccharides (Target 3), where the only structural difference between 6A and 6C CPS is removed. According to the retrosynthetic approach, compound **4** was synthesized from a suitable rhamnose derivative, which can be used both as an acceptor for the synthesis of disaccharide **8** and as a donor for the glycosylation of ribitol **9**. Finally, target tetrasaccharides **1**, **2** and **3** have been assembled using the phosphoramidite derivatives **5**, **6** and **7**. The synthetic tetrasaccharides will be eventually conjugated to a carrier protein, and the glycoconjugates obtained will be subjected to in-depth immunological studies. The results will help to identify protective epitopes to be employed for the development of an effective anti-SPn 6A/6C glycoconjugate vaccine. A new approach to pneumococcal vaccine design is needed to stop serotype replacement and consequently the phenomenon of antimicrobial drug resistance, which is estimated to cause 10 million deaths annually by 2050[5].

Outright DFT method for determining pKa and pKb of small organic compounds.

S. Pezzola,[a] V. Conte,[a] M. Venanzi F. Sabuzi[a], P. Galloni,[a]

[a]*Dipartimento di Scienze e Tecnologie Chimiche, Università di Roma Tor Vergata, via della Ricerca Scientifica, Roma*
silvia.pezzola@uniroma2.it

We have developed a method characterized by exceptional reliability, for determining the pKa of a wide panel of organic acids, such as phenols[1] and carboxylic acids[2]. Our "easy to use methodology" returned minimum average error (MAE) lower than 0.3 for phenols pKa, and 0.5 for carboxylic acids. Further, it can predict with great reliability the pKa of difficult to model compounds (i.e. trichloroacetic acid) with a simple level of theory[2]. It exploits CAM-B3LYP as functional, the solvation model based on density (SMD) and 6-311G+(d,p) as basis set[1-3]. In our approach, we draw the very first solvation shell, adding two explicit water molecules at the reaction centre. The pKa is calculated applying the ionogenic equation, without the usage of experimental energy values for H^+ nor *ex post facto* correction. Recently, we explored the possibility of applying this methodology in predicting the pKb of primary aromatic and aliphatic amine, obtaining impressive results, *i.e.* MAE=0.3. Such striking result strengthens the reliability of our approach[1-3] providing, for the first time, the possibility to predict the pKa and pKb of small organic compounds with the same methodology, always ensuring trustworthy outputs.

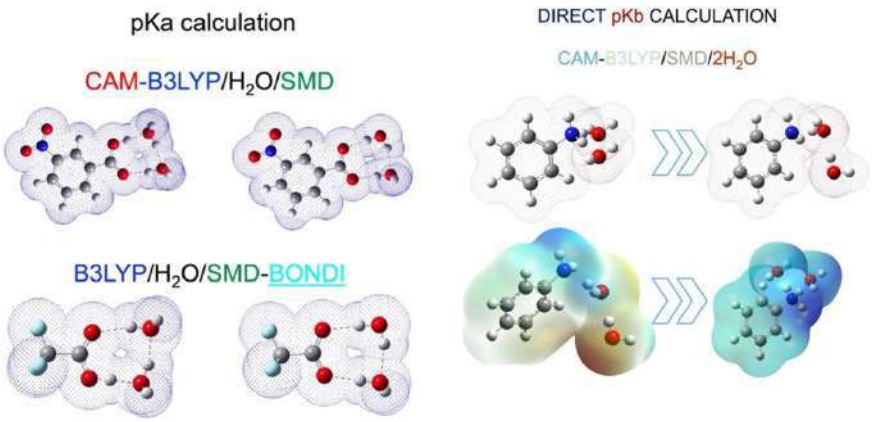

Figure 1: Accurate prediction of the pKa and pKb of small organic compounds in ***one-pot method***. Geometry optimization CAM-B3LYP/SMD/2H_2O/6-311G+(d,p) or B3LYP/SMD-BONDI/2H_2O/6-311G+(d,p).

Preliminary evaluation of new bicyclic chelators for Ac-225 targeted α-therapy

P. Piacenza,[a] L. Tei[a]

[a]*Università del Piemonte Orientale, Dipartimento di Scienze e Innovazione Tecnologica, V.le Teresa Michel 11, Alessandria, Italy*
pietro.piacenza@uniupo.it

^{225}Ac is an α-particle emitting isotope studied in nuclear medicine for α-therapy applications. The isotopes generated by radioactive decay of ^{225}Ac have different physico-chemical characteristics compared to the parent nuclide, that can lead to the release of the free isotopes during the in vivo application. One of the chelators most suitable for the stable complexation of ^{225}Ac is the 4,13-diaza-18-crown-6 macrocycle functionalized with picolinic arms (Macropa).[1] Unfortunately, one of the main problem of such ligand for the ^{225}Ac radiolabelling is the possible release of ^{221}Fr or ^{213}Bi after radioactive decay of the parent radionuclide.

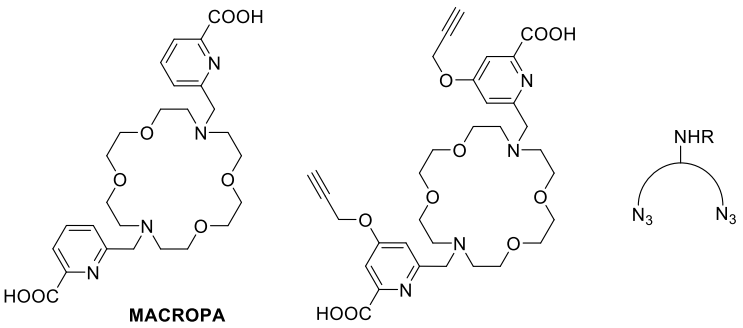

Figure 1: Macropa, funzionalized macropa and the bis-azide containing element

In this work we synthetized the bis-alkyne ligand in Fig.1 through the alkylation of the 4,13-diaza-18-crown-6 macrocycle with methyl 6-(chloromethyl)-4-(prop-2-yn-1-yloxy)picolinate as already reported in literature[2]. Two bis-azide-functionalized amines are then synthetized with different lengths with the aim to obtain a macrobicyclic structure able to create a cage around the isotopes preventing the release of both parent and daughter isotopes. The Cu(I) catalyzed Azide-Alkyne reaction has been carried out on the La(III) complex that is considered the non-radioactive surrogate of Actinium. The bicyclic La(III) complex has been characterized via ^{1}H NMR and the its kinetic inertness evaluated in acidic conditions.

After these preliminary studies, the amino groups on the closing molecules will be used for the bioconjugation of the radiopharmaceutical with biomolecules for targeting purposes.

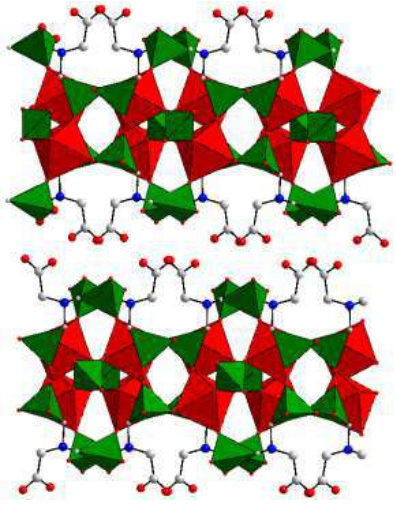
Efficient Catalytic Reduction of Nitroarenes Using Zirconium Carboxy-Aminophosponate Nanosheets Loaded with Nickel Nanoparticles

M. Pancotto,[a] M. Nocchetti,[b] O. Piermatti[a]

[a]*Università degli studi di Perugia, Dipartimento di Chimica Biologia e Biotecnologie, Via Elce di Sotto 8, 06123 Perugia,*
[b]*Università degli studi di Perugia, Dipartimento di Scienze Farmaceutiche, Via del Liceo 1, 06123 Perugia*
oriana.piermatti@unipg.it

Supported metal nanoparticles are widely explored for their sustainability, activity and recyclability. Among metal nanoparticles, nickel nanocatalyst is the preferred choice due to its availability, minimal toxicity, and low cost.[1] As known, a careful choice of the support plays a pivotal role in designing stable and high active supported metal NPs catalysts. In this context, layered zirconium phosphate and phosphonates with high surface area offer an attractive support for metal nanoparticles because of their chemical and thermal stability, along with a facile tunability of their structural features.[2-5]



Polyhedral representation of ZrPGly

Zirconium phosphate carboxy-aminophosponates (ZrPGly) possess a layered structure with exposed phosphonate and carboxylic groups on the surface, allowing efficient interactions with cations. To increase the accessibility, the solid was completely exfoliated in water by adding n-propylamine, resulting in a stable dispersion of zirconium phosphonate nanosheets. The ion exchange with a solution of nickel acetate provides zirconium carboxy-aminophosponate nanosheets loaded with nickel as a green pale solid (**Ni@ZrPGly**). The resulting Ni-catalysts were fully characterized and tested in the reduction of nitroarenes with $NaBH_4$ at room temperature. The catalytic system proved its efficiency as it was reused for five cycles with a negligible loss of catalytic activity and with a very low Ni leaching.

Characterization of the protein fraction by high resolution mass spectrometry reveals specific post translational modifications in extracellular vesicles secretes by astrocytes

M.G.G. Pittalà,[a] L. Leggio,[b] A. Di Francesco,[a] V. Cunsolo,[a] A. Lanzoni,[a] N. Iraci,[b] R. Saletti[a]

[a] *Laboratory of Organic Mass Spectrometry, Department of Chemical Sciences, University of Catania, Via S. Sofia 64, 95123, Catania*

e-mail: mariagaetana.pittala@unict.it

Parkinson's disease (PD) is characterized by the progressive loss of dopaminergic (DAergic) neuronal cell bodies in the ventral midbrain (VMB) and their terminals in the striatum (STR). Astrocytes (AS) play a crucial role in maintaining the homeostasis of DAergic neurons, and extracellular vesicles (EVs) secreted by astrocytes (AS-EVs) can have either destructive or beneficial effects [1]. To identify the mechanisms involved in the neuroprotective effects of AS-EVs, we have characterized their protein fraction and specific post translational modifications (PTMs), comparing vesicles secreted by astrocytes from the VMB vs. the STR, both in basal conditions (AS-EVs CTRL) and activated by the pre-treatment with the neuroprotective chemokine CCL3 (AS-EVs CCL3) [2].

Intact EVs were purified from primary cultures of postnatal VMB and STR astrocytes. EVs were lysed using 0.1% RapiGest SF and proteins were reduced with DTT, alkylated with iodoacetamide and digested using trypsin. Analysis was conducted in triplicate by a shotgun approach and nanoUHPLC/High-Resolution nanoESI-MS/MS [3].

The results showed a different protein content and a different pattern of PTMs in AS-EVs CTRL and AS-EVs CCL3 extracted from VMB and STR. In particular, we focused the attention on PTMs related to protection and degradation pathways of proteins as ubiquitination, SUMOylation, oxidation, phosphorylation and deamidation. The assignment of functional roles to these PTMs will be a further step towards the full understanding of the impact of EVs on neurodegeneration.

Overall, our study suggests the existence of a molecular machinery capable of organizing the sorting of specific proteins towards EVs, in nigrostriatal astrocytes. Furthermore, it implies the possibility that secreted proteins with specific PTMs may have specific functions when transferred to target cells and thus the reprogramming of AS-EVs as a novel strategy for brain repair. Finally, the knowledge generated within this study may pave the way for the development of innovative therapeutic approaches to tackle PD.

Synthesis of Bivalent Natural Products-Based Inhibitors of SARS-CoV-2 Spike Protein

Luca Pozzi[1], Martina Pedrini[1], Dr. Andrea Citarella[1], Dr. Valerio Fasano[1], Prof. Daniele Passarella[1]

[1] *Dipartimento di Chimica, Università degli Studi di Milano, Milan, Italy.*

SARS-CoV-2 is a virus responsible for COVID-19 pandemic, which caused more than 6.7 million deaths worldwide. Viral mutations could compromise the efficacy of vaccines, so developing drugs capable of suppressing viral replication to treat COVID-19 remains an open therapeutic challenge. In SARS-CoV-2 morphology, a crucial region is the receptor-binding domain (RBD), located in subunit S1 of Spike glycoproteins, since it is involved in the binding with Angiotensin-Converting Enzyme 2 (ACE2)[1] receptor of human cells in the early internalization step. Through virtual screening of the RBD active recognition region, several natural products (NPs) capable to bind in two different portions of the RBD were identified. Triterpenoids were reported as pocket 1 binders, while bile acids derivatives should bind to pocket 5.[2] In this work, bivalent compounds formed by a triterpenoid and a bile acid linked by a spacer were developed, with the aim of obtaining more potent and selective antiviral molecules capable of blocking the fusion between SARS-CoV-2 and host cell. Computational studies have guided the synthesis, providing indications on the size and flexibility of the compounds. Azide-alkyne cycloadditions and amide couplings were used as synthetic strategies to connect the selected triterpenoids (betulinic acid and glycyrrhetinic acid) and bile acid (obeticolic acid). Neutralization assays using pseudotyping lentiviral particles with specific SARS-CoV-2 Spike proteins were performed to evaluate the antiviral activity of these bivalent compounds, demonstrating a higher ability to reduce SARS-CoV-2 infection than single natural products.

α,β-Unsaturated esters represent a class of organic compounds commonly encountered in nature and utilized in various applications. They are frequently found as components in essential oils for perfume production and also serve as key substrates for synthesizing pharmacologically active compounds.[1] Among various synthetic methodologies, the Horner–Wadsworth–Emmons (HWE) reaction is commonly employed for the synthesis of (E)-α,β-unsaturated esters.[2] In this work, we present a straightforward, scalable and environmentally friendly protocol for synthesizing (E)-α,β-unsaturated esters via the HWE reaction.[3]

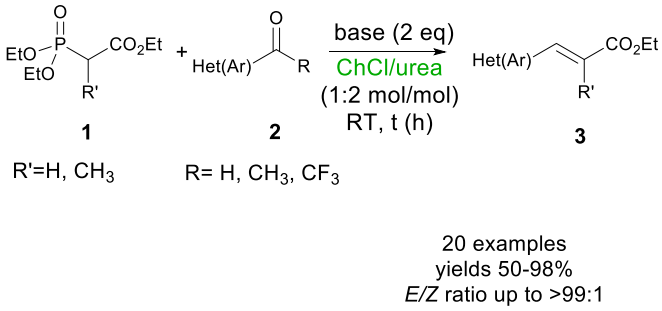

Figure 1: Stereoselective syntheses of α,β-unsaturated esters by HWE.

This innovative method employs deep eutectic solvents, known for their non-toxic, biodegradable, and cost-effective properties, thereby eliminating the need for volatile organic compounds. Highly efficient HWE reactions were successfully conducted using choline chloride/urea (1:2 mol/mol) as a solvent, under mild conditions at room temperature. The reactions exhibited excellent yields (50-98%) and *E*/*Z* ratios (up to 99%). Notably, this protocol demonstrates remarkable stereoselectivity in synthesizing (*E*)-α,β-unsaturated esters **3** from **1** and (hetero)aromatic aldehydes and ketones **2** containing halogens, electron-withdrawing, and electron-donating groups (**Figure 1**).

martina.ridino@unina.it

GPBAR1 and FXR have been found to be the two most involved receptors in inflammatory liver conditions. Currently, the only semi-synthetic steroid derivative to have been successfully employed in human therapy for primary biliary cholangitis (PBC) is obeticholic acid (OCA).[1] Its only drawback is the induction of a moderate to severe itching in treated patients. To identify a safer alternative to OCA, my research team performed extensive modifications to the bile acid scaffold and was able to identify several selective or dual FXR/GPBAR1 agonists.[2] Among these, BAR502 emerged from the pharmacological studies were carried out as the most active without inducing itching. It is a double FXR/GPBAR1 agonist and has a shortened side chain. It is a 3,7,23-triol that shares the same stereochemistry as the substituents on rings A and B with OCA. BAR502 was also tested in several *in vivo* tests such as HFD and CCl_4 induced damage models. The excellent results from all of these tests prompted the start of phase I clinical trial: safety, tolerability, pharmacokinetics, and pharmacodynamics of BAR502 in healthy subjects.[3] Subsequent *in vitro* studies were executed by incubating the molecule in two well-known enzymatic systems and then analysed by LC-MS. To this end, conceivable metabolites both identified in our enzymatic assays or hypothesized as plausible by rational biotransformation prevision were synthesized and used as analytical standards.[4] Obtained analyses and fragmentations spectra perfectly overlap with the authentic standard assuring high confidence in the identification.

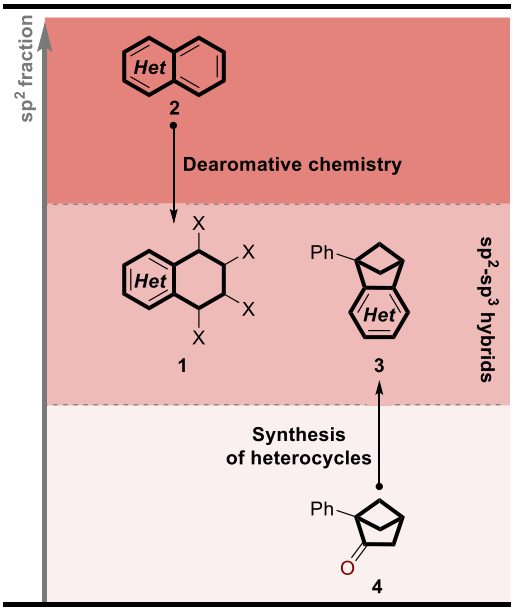

Figure 1: Two approaches to sp^2-sp^3 hybrids, increasing and decreasing the sp^2 fraction.

Over the past years, sp^2-sp^3 hybrids are emerging as medicinal chemistry relevant building blosks[1–3] attracting the interest of the synthetic community. In this communication two different strategies to reach sp^2-sp^3 hybrids will be discussed (**Figure 1**). The first one relies on the development of a dearomative platform for the synthesis of (amino)cyclitols-aryls sp^2-sp^3 hybrids **1**,[4] this approach allows to reduce the sp^2-fraction of polynuclear aryls and (hetero)aryls **2**, giving access to aryl condensed cyclohexane rings.
In the second approach the sp^2-fraction of the ketone **4** has been increased exploiting the ketone chemistry to get (hetero)aryls-bicyclo[2.1.1]hexanes sp^2-sp^3 hybrids **3**. Those scaffolds represent an attractive class of benzene rings bioisosteres.[5]

Hit-to-lead optimization of flavone-based tyrosine kinase inhibitor inhibiting L858R/T790M EGFR activation in NSCLC

EGFR is one of the most molecular targets in non-small lung cancer (NSCLC) where the mutant forms of EGFR are expressed. The efficacy of tyrosine kinase inhibitors (TKIs) could be compromised by additional mutations in EGFR. Since several flavonoid have been reported to possess protein kinase inhibitory activity [1-2], a flavone core was used as a scaffold for the design of novel ATP-competitive inhibitors. The core is modified by introducing several chemical groups able to interact with the key regions of the ATP-binding pocket. A homemade virtual library was generated, and a three-track virtual screening was made to identify compounds with a higher affinity toward both mutated forms with respect to the wild type one. This process allowed us to select two novel flavone-based TKIs (FL4 and FL5), that were then synthetized and tested in kinase enzyme assay. One of these two hits compound (FL4) shows effective selectivity against both $EGFR^{L858R/T790M}$ and $EGFRL^{858R/T790M/C797S}$ while sparing the wild type ones [3]. At this point, our goal was to optimize this hit compound to obtain a lead compound with a better efficacy profile. We also aimed to improve its lipophilicity profile. The LogP of compound FL4 is 6.9, a value that does not comply with one of Lipinski's 5 rules (LogP<5). Starting from this hit compound, novel TKIs are therefore designed to obtain molecules with nanomolar inhibitory activity. Molecular Docking approach was used for the identification of the most promising compound (F2) which was then synthetised and tested in the enzyme-based assay. This novel flavone compound showed an IC50 of 0.1 μM against EGFRL858R/T790M form, 120-times lower with the respect to compound FL4 and it did not inhibit the phosphorylation of wild type EGFR. Finally, it can be stated that the new lead compound also has a better lipophilicity profile compared to compound FL4, with a LogP value of 4.

Structural Identification of the main Impurities of Voclosporin, a semisynthetic API with immunosuppressant Activity

V. Rositano,[a] M. Molinari,[a] L. Arnoldi,[a] O. Taglialatela-Scafati,[b] L. Senaldi,[a] F. Peterlongo,[a] P. Allegrini.[a]

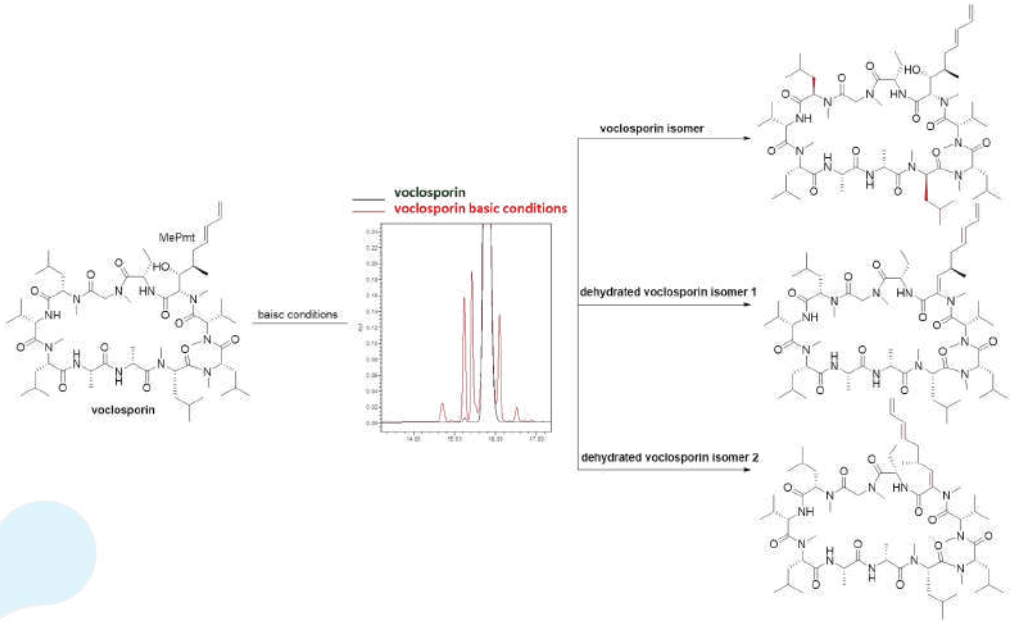
vincenzo.rositano@indena.com

Voclosporin (tradename: LUPKYNIS) is a semisynthetic immunosuppressant drug derived from cyclosporin A. The presence of a diene system instead of a single double bond, at the noncoded amino acid methyl-pentadienyl-*N*-methylthreonine (MePmt1), gives higher activity and lower toxicity than cyclosporine A,[1] enough to be approved by FDA in 2021 for the treatment of Lupus nephritis.

In the development of the API process, the study of the potential impurities which could arise during the synthesis, purification and storage, is a key aspect.[2] The most critical impurities of voclosporin are generated due to the instability of this API in basic conditions.

Three main impurities were synthesized, isolated and their structures were elucidated by orthogonal analytical techniques such as LC-MS, mono and bi-dimensional NMR. One of them was identified as an isomer of voclosporin, produced by epimerization of specific stereogenic centres in the cyclic undecapeptide, while the other two impurities are dehydrated voclosporins, generated by elimination reaction of the hydroxyl group at the noncoded amino acid (MePmt1).



Scheme 1: voclosporin impurities generated in basic conditions.

Plant diseases are caused by pathogenic microorganisms, mainly fungi, which affect the quality and the yield of produced crops, causing losses up to the 30% at all stages of crop production. Pathogen control has been effectively performed mostly by synthetic fungicides. However, nowadays only a few of them are allowed worldwide, and their continuous use has resulted in resistance emergence and spread of several pathogenic fungi.[1] Furthermore, synthetic pesticides have created a high environmental impact over the years, also causing bioaccumulation. To address the growing urgency in managing fungal diseases, there is the need to find novel compounds able to effectively inhibit pathogens, with lower human and environmental impact. In this context, the development of natural and nature-derived agrochemicals is a promising strategy.

In the last decades phlorotannins emerged as an important class of polyphenols. They are isolated from various brown seaweeds as a very complex mixture of phloroglucinol oligomers. In the present work, given the promising antifungal activity showed by the phlorotannin crude extracts,[2] phloroglucinol dimers, namely diphenylethers and biphenyls (Figure 1) were synthesized. The potential antifungal activity of the single pure compounds and their methylated/acetylated analogues (Figure 1) was investigated. Furthermore, Differential Scanning Calorimetry (DSC) experiments were designed to study the potential interaction of the bioactives with the phospholipidic membrane[3] of pathogenic fungi.

Tailored Metal Porphyrin-Based Electrocatalysts for Artificial Nitrogen Fixation to Ammonia

G.Salerno,[a] O.Bettucci,[a] N. Manfredi, [a] A.Abbotto.[a]

1Dipartimento di Scienza dei Materiali, Università degli Studi di Milano-Bicocca, and INSTM Milano-Bicocca Research Unit, Via R. Cozzi 55, 20125-Milano, Italy.

giorgia.salerno@unimib.it

Ammonia is an essential raw ingredient for fertilizers, a carbon-free hydrogen carrier, and an alternative fuel. The over one-century old Haber-Bosch process is still used today for the synthesis of ammonia, from nitrogen and hydrogen, but it is strongly energy demanding (ca. 2% of global energy demand) and generates massive greenhouse gases (ca. 2% of global emissions). It is therefore mandatory to develop clean access to ammonia to match the net zero decarbonation targets for 2050. Recently, research has focussed attention on alternative routes and, among those proposed, the electrocatalytic reduction from nitrogen to ammonia is the most accredited. The strongly inert N_2 molecule can be activated thought an electrocatalytic approach under mild conditions. However, so far, the use of organic-based electrocatalysts is very rare in the literature and systematic studies are almost absent.

Following our previous general approach for organic design for solar generation of green hydrogen,[1] in this communication we present our recent preliminary work on the investigation of a series of metal-porphyrins, which have been properly functionalized to enhance nitrogen fixation performance (**Figure 1**). We have developed two series of hydrophilic and hydrophobic derivatives, able to show different interactions at the interface with the aqueous electrolytic environment of the electrochemical cell, thus affecting the device interface phenomena and, eventually, the final response.

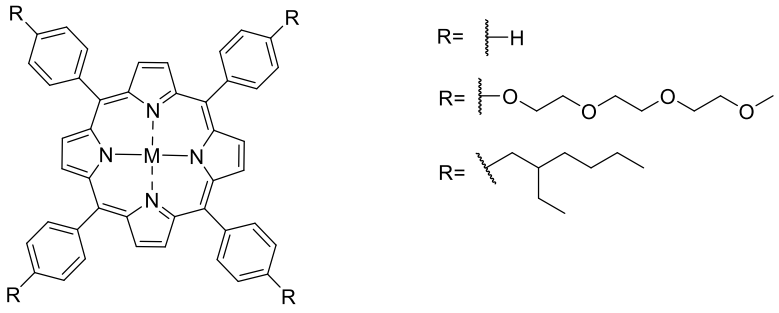

Figure 1: metal-porphyrins functionalized to enhance nitrogen fixation performance.

Apples (*Malus domestica* Borkh.) are one of the most extensively produced and consumed fruits worldwide[1] and represent an important source of bioactive compounds like polyphenols which are responsible for their antioxidant and anti-inflammatory properties and possess a role in the prevention of degenerative diseases[2]. The proposed project is based on the valorization of the Molise region, exploiting specific autochthonous cultivars belonging to *Malus domestica*: although the nutritional characteristics of these species are well known, knowledge of the Molise products is still incomplete compared to other Italian regions (e.g., Annurca apple of Campania region). Thus, the comprehensive phytochemical investigation of metabolomes of these cultivars represents a partially unexplored research field that could be helpful to trace and/or complete their fingerprint. The metabolomic profile will be assessed through a quali-quantitative determination of the constituents of each selected variety by 1D and 2D NMR Spectroscopy for the polar extracts while UHPLC coupled to Mass Spectrometry will be applied to identify fatty acids in the apolar extracts. Chemometric analysis with the PCA and PLS-DA techniques will be performed in order to observe differences among the varieties. Moreover, LC-MS/MS will be applied to identify polyphenols obtained with a specific extraction protocol with the aim to disclose active secondary metabolites that can be used for nutraceuticals, cosmeceuticals, food supplements and cosmetics. Furthermore, the total phenolic, flavonoids, and condensed tannins content will be assessed, and in vitro antioxidant activity will be evaluated by using DPPH scavenging activity, the ABTS scavenging assay, and ferric-reducing antioxidant power (FRAP).

Waste-minimized C(sp3)-H activation for the preparation of fused N-heterocycles

A. Tian Sang [a] B. Tommaso Scarabottini,[a] C. Francesco Minio,[a] D. Luigi Vaccaro [a]

[a] *Laboratory of Green Synthetic Organic Chemistry, Dipartimento di Chimica, Università di Perugia 1, Via Elce di Sotto, 8 – 06123 Perugia*
tian.sang@studenti.unipg.it

One of the most effective strategies for reducing environmental pollution associated with chemical production is the use of efficient catalytic reactions. Transition-metal-catalyzed C–H functionalization technologies have emerged as a valid alternative to traditional cross-coupling reactions for the effective formation of carbon-carbon and carbon-heteroatom bonds. Particularly, heterogeneous palladium catalysts have received widespread attention because they can be easily separated from the reaction mixture and reused.[1]

Nitrogenous heterocyclic compounds, such as oxindoles and pyrrole derivatives, are important structural motifs in many molecules of biological and pharmaceutical interest.[2] Herein we present the development of a waste-minimized protocol for the synthesis of oxindoles using cyclopentyl methyl ether (CPME) as a safe and green reaction medium and palladium on carbon (Pd/C) as a reusable catalyst, up to at least 4 reaction runs, with negligible loss of reactivity and stability, with low values of palladium leaching in solution. Meanwhile, the E-factor calculated for this protocol is very low demonstrating its validity from a sustainable point of view.[3] Then we developed an effective waste minimized approach for the intramolecular Pd-catalyzed C(sp3)-H activation of methyl pyrrole derivatives, by using of a heterogeneous recyclable palladium(II)-bis(N-heterocyclic carbene) catalyst and CPME, the heterogeneous catalytic system could be recovered and reused up to representative five runs without any loss in efficiency. The target products have been obtained selectively and with excellent isolated yields and the approach leads to the definition of a protocol with a very good E-factor.[4]

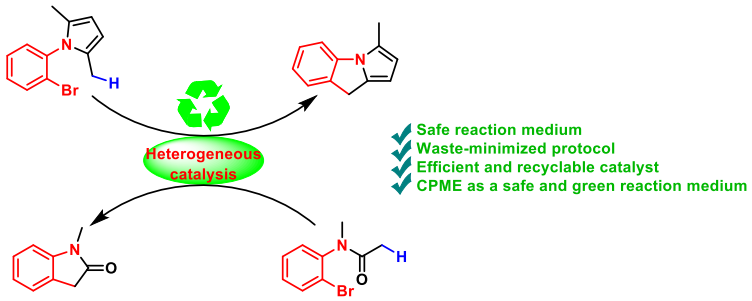

Figure 1: Waste-minimized C(sp3)-H activation for the preparation of fused N-heterocycles.

Pentaerythritol Tetra Esters: a Novel Spiro DiKetal Mediated, Water Catalyzed Synthetic Method is Presented

F. Sangiovanni

e-mail: isoclaboratory@gmail.com

Pentaerythritol tetra esters are widely used as additives in the lubricant oils industry.[1] A novel two step one pot convenient method for the preparation of these molecules will be presented. Pentaerythritol is a notoriously problematic molecule because of its poor solubility in almost all organic solvents. This characteristic makes the synthesis of its esters very difficult, resulting in the creation of synthetic procedures over the years that are characterized by high solvent consumption, long reaction times and the use of dangerous reagents like thionyl chloride.[2] This new method unlocks the possibility of preparing larger amounts of esters in smaller reaction mixture volumes thanks to the key intermediate 3,3,9,9-Tetramethyl-2,4,8,10-tetraoxaspiro[5.5]undecane. The reaction proceeds in 3 major steps: first, the spiro diketal is prepared; then, it react in the presence of a catalytic amount of acid with trace amounts of water in the solvent that act as initiator, hydrolysing one ketal. The two hydroxyl groups liberated are then able to undergo esterification, yielding water that continue the cycle. The method will be tested on other polyalchols to increase its applicability

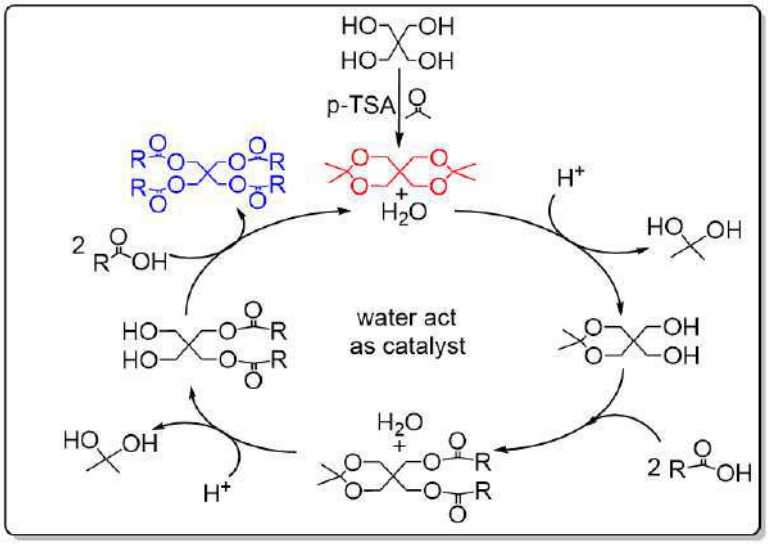

Figure 1: : spiro diketal mediated, water catalyzed pentaerythritol esterification.

Calixarene derivatives reduce α-synuclein-induced toxicity in a Parkinson's disease model

D. Dell'Accantera,[a] G. Piccinini,[a] S. Anzellotti,[a] R. Ruotolo,[a] F. Sansone[a]

[a]*Department of Chemistry, Life Sciences and Environmental Sustainability, University of Parma, Parco Area delle Scienze 17/A, 43124 Parma, Italy*
francesco.sansone@unipr.it

Parkinson's disease (PD) is one of the most common neurological disorders, with a growing trend and a heavy impact on persons and public health systems, in particular in developed countries with elderly populations. A PD molecular hallmark is the accumulation of intracellular inclusions (Lewy bodies) containing misfolded and aggregated α-synuclein (AS) in oligomeric form. AS is a small protein abundant in the brain, primarily found in nerve terminals, involved in the regulation of vesicle trafficking network. Targeting lysine in AS, especially in its partially conserved motif KTKEGV, could prevent its aggregation due to the role of this amino acid in stabilizing toxic oligomers.[1] Starting from the well-known ability of negatively-charged calix[4]arenes to complex lysine side chain,[2] we prepared different anionic calix[4]arenes as potential ligands of AS. These were tested (Fig. 1) in a yeast model of PD that overexpresses AS leading to the formation of toxic oligomers associated to intracellular foci, causing global cellular dysfunction. We observed that some of the calix[4]arenes indeed counteract AS-induced toxicity, through the reduction of oligomer formation, restoring different metabolic pathways impaired by AS and hindering other damaging events such as oxidative stress.

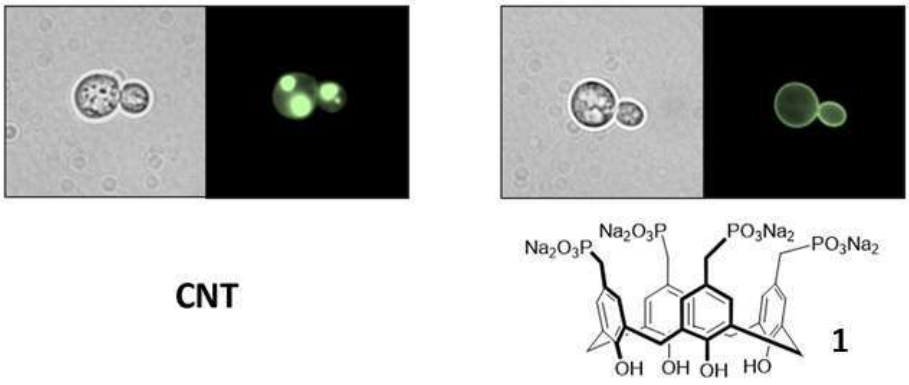

Figure 1: Calix[4]arene **1** affects AS localization and toxic inclusion accumulations. AS oligomers in intracellular foci are observed in untreated yeast cells (CNT; *left*), but not in cells treated with **1** (*right*).

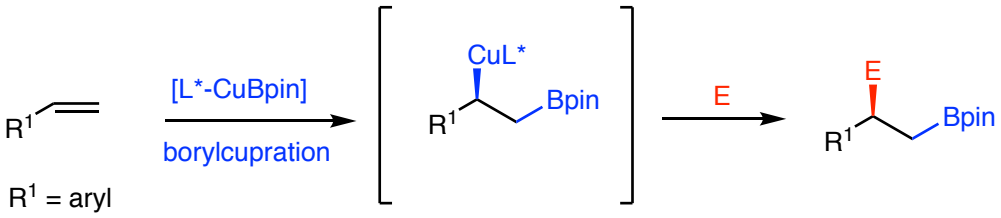
Development of copper-catalyzed regio- and stereoselective tandem functionalizations using strained heterocyclic rings

F. Sardelli,[a] B. Baldini,[a] L.M. Comparini,[a] S. Di Pietro,[a] M. Pineschi*[a]

[a] *Department of Pharmacy, University of Pisa, Via Bonanno 33, 56126 Pisa*
francesca.sardelli@phd.unipi.it

The synthesis of complex molecules through efficient and streamlined processes represent one of the most coveted goals in organic synthesis. In this sense, multicomponent reactions represent nowadays a fascinating as well as challenging method that provide access to variously functionalised building blocks, starting from readily available reactants with a higher atom and step economy.[1,2] In this context, three-component copper-catalysed borylative difunctionalization of olefins has become a powerful method for a concomitant installation of a C–C bond and a boryl group.[3] These procedures pave the way for an easy access to borylated building blocks, of great interest in organic chemistry due to their exclusive reactivity and divergent synthetic capability. As shown in **Scheme 1**, a boryl-copper species formed *in situ* undergo an insertion an alkene and the resulting alkyl-copper intermediate is then intercepted by an electrophile (E) to generate the desired product bearing a boryl group.[3,4] On these bases, we developed some novel three-component stereoselective copper-catalysed tandem procedures, consisting in an overall assembly of a styrene molecule, a pinacol-borane (BPin) unit and strained heterocyclic rings as the electrophilic partners.



Scheme 1: General mechanism for three-component borylative difunctionalisation of alkenes.

The generation of (bi)radical intermediates under mild conditions has opened broad synthetic opportunities during the last century, but these reactive intermediates are present in solution in tiny concentrations, and they require a tailored tuning of experimental parameters to efficiently convert substrates into desired products. Here, we report a general approach that can overcome those limitations using bi-naphthyl derivatives. These species can act catalytically in energy-transfer mediated processes, showing a dramatic effect on the efficiency of several visible-light promoted reactions,[1] such as the E/Z isomerization of conjugated alkenes, and a [1,5]-HAT/cyclization[2] or an arene para-cycloaddition of functionalized allenamides[3] (Figure 1). These results show that this family of bi-naphthyl derivatives represent a new class of catalysts, which might become widely used for several photocatalytic applications.

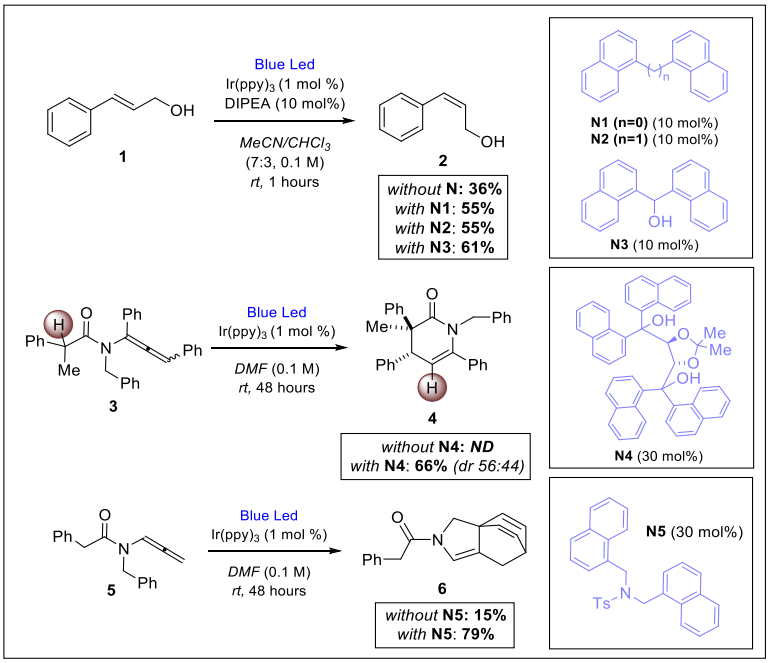

Figure 1: Examples of Visible-Light Promoted reactions by bi-naphtyl derivatives.

The main feature of proteins is to encode specific information by folding, allowing these biopolymers to carry out sophisticated functions. The understanding of peptides folding rules has permitted to design and synthesize linear chains programmed to adopt a defined 3D structure[1]. Conversely, synthetic polysaccharides capable of autonomously folding into a defined 3D structure have not been explored so far, due to their complexity and lack of folding rules.
A glycan hairpin, namely two *strands* chains attached to a *turn unit*, has recently been synthesized[2] adopting: an α-L-Rha-(1,3)-[β-D-Glc-(1-4)]-D-Glc trisaccharide (similar to Lewis X conformation[3]) as a *turn unit* and two linear β-1,4-Glc repeating units (cellulose) as the two *strands* (Figure **1**).

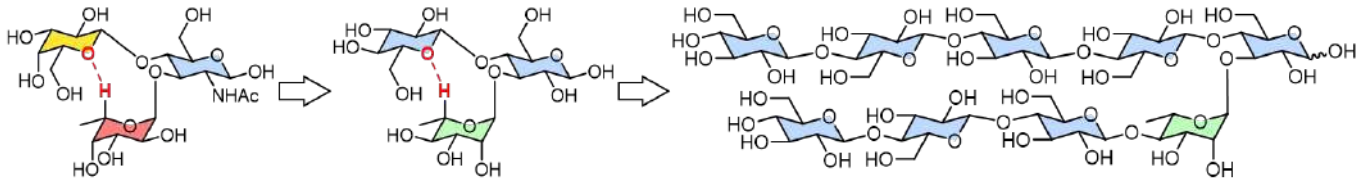

Figure1: evolutionary study of glycan hairpins. From left to right: Lewis X trimer, 3mer-l turn unit, 9-mer glycan hairpin. *Legend: D-Gal, L-Fuc, D-Glc, L-Rha*, CH—O non-conventional hydrogen bond.

Exploiting the design principles developed so far and with the aid of molecular dynamics simulations, we intend to synthesized more complex structures with rigid conformations, mimicking proteins' β-sheets (Figure **2**). Recent progress towards the synthesis of these structures by Automated Glycan Assembly (AGA) on solid phase will be described.[4]

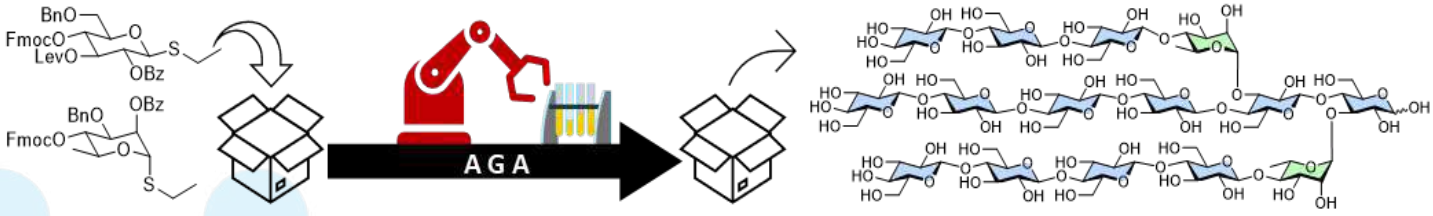

Figure2: one of the most promising to rigid conformation (by molecular dynamics simulation) target molecule

claudia.sciacca@unict.it

Laccases, multicopper oxidases, exhibit significant catalytic activity in oxidizing a wide range of substrates, such as polyphenols, diamine, and some inorganic compounds, in the presence of molecular oxygen. Despite their high activity, selectivity, and specificity, laccases have disadvantages such as low chemical and thermal stability, difficulty in recovery and reuse, and high cost. To overcome these limitations, enzyme immobilization is considered a promising technology for implementing catalytic efficiency and controlling enzymatic reactions. The immobilization of enzymes is typically done using different strategies[1]: i) physical adsorption; ii) ionic adsorption; iii) covalent binding between the enzyme's support and amino acid side chain; iv) entrapment through a physical encapsulation. This work aims to immobilize laccase from *Trametes versicolor* (LTV) onto two different systems: a) a blend formulation of PLA/PBAT loaded with walnut shell extract,[2] b) nylon films activated with APTES and natural products.[3] FT-IR, SEM and TGA will characterize the new systems. The immobilized enzyme's activity and its reusability will be spectrophotometrically tested. These newly developed immobilized enzyme systems can be potentially used to synthesize organic compounds, bioremediate wastewater from organic compounds and for biosensor development.

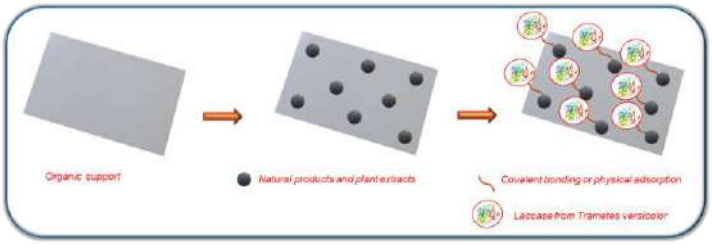

Figure 1. Schematic diagrams of LTV immobilization.

francesca.sechi@unimib.it

The extracellular matrix (ECM) of lung cancer is characterized by interconnected biomacromolecules, including fibrous proteins (i.e. elastin and collagen) and proteo- and glycosaminoglycans (i.e. hyaluronic acid, versican)[1]. The identity and the gradient of ECM components in cancer reflect the cancer grade and localization and it is differential from the ECM fingerprint and structural organization of healthy lung tissue[2]. To produce lung cancer tissue models that mimic the *in vivo* microenvironment, the generation of ECM mimics that can recapitulate the key components involved in cell-ECM crosstalk are needed[2]. Here in this work, biomaterials-based ECM mimics have been produced using chemoselective ligation approaches on different biopolymers[3]. The introduced functional groups have been employed to crosslink polymers of different nature using multiarms linkers in order to control the stiffness and the printability. The produced biomaterials have been characterized by NMR and FT-IR analysis. Morphological features have been also evaluated using SEM analysis in order to compare the porosity and the structural features of decellularized ECM and lung ECM mimics. The formulation with optimal rheological properties were employed in bioprinting protocol to generate 3D in vitro lung advanced models employable for drug screening and cell biology studies.

Hexavalent sulfur fluorides are strategic electrophilic reagents in organic synthesis enabling the linkage of S-O, S-N and S-C bonds[1]. While the preparation and use of sulfonyl fluorides have been widely explored, very little information about the synthesis and reactivity of sulfonyl fluoride aza-isosters, namely sulfonimidoyl fluorides and sulfondiimidoyl fluorides, is currently available[2,3]. Moreover, these compounds can be prepared through lengthy and time-consuming synthetic routes, that often require the generation of more reactive intermediates such as aza-S(VI) chlorides[4], or gaseous reagents[5]. Considering the great potential of such S(VI) derivatives in enabling the straightforward preparation of sulfur pharmacophores, here we present a fast one-pot synthesis of both sulfonimidoyl fluorides and sulfondiimidoyl fluorides starting from sulfinyl amines. The transformations proceed via nucleophilic addition of organometallic reagents to sulfinyl amines and sulfurdiimides[6,7], in turn prepared in situ from sulfinyl amines, followed by subsequent quenching with an electrophilic fluorine source. This process affords the products within a few minutes. Further reactions of such aza-S(VI) fluorides have also been investigated, disclosing their synthetic utility in the preparation of diverse S(VI) compounds.

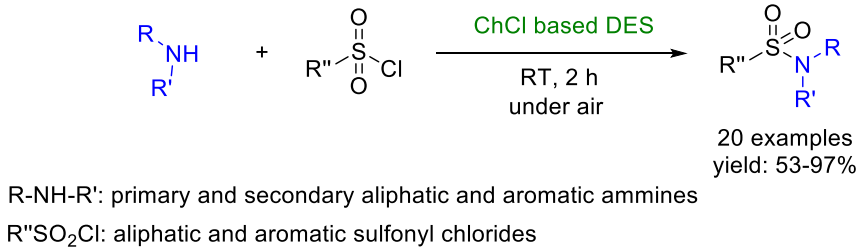
Sulfonamides represent a crucial structural motif in numerous pharmacologically active compounds.[1] Recognizing their diverse applications and significance in the pharmaceutical industry, scientists have been actively seeking sustainable methods for their synthesis since the turn of the century. This pursuit aims to eliminate the use of toxic chemicals and volatile organic compounds (VOCs), such as pyridine and dichloromethane, which are commonly employed.[2] Our research contributes to this endeavor by establishing environmentally benign procedures for the synthesis of sulfonamides under sustainable conditions.

Deep eutectic solvents (DESs) have proven to be highly effective reaction media[3] for facilitating N–S bond-forming processes under remarkably mild conditions, notably at room temperature and under ambient air. This innovative approach enables us to circumvent the need for VOCs, stringent pH control, and the issues associated with poor solubility of starting materials,[4] ultimately leading to improved yields and minimized waste generation, thus enhancing the atom economy of the reaction. Utilizing choline chloride (ChCl)-based DESs, we have successfully synthesized various types of sulfonamides from primary and secondary aliphatic and aromatic amines, as well as sulfonyl chlorides. The reactions typically reach completion within two hours, affording the desired products in yields of up to 97% (**Scheme 1**).



Scheme 1. Synthesis of secondary and tertiary sulfonamides in choline chloride (ChCl)-based DESs.

Optimization of a Nanoparticles Protein Corona Isolation and Identification Platform using Omics

L.Spinelli,[a] P. D'Anna,[a] E. Morretta,[a] C. Cassiano,[a] C. Conte,[a] D. Eletto,[b] A. Zampella[a] and M.C. Monti[a]

[a]*University of Naples Federico II, Via Domenico Montesano 49, Naples*
[b]*University of Salerno, Via Giovanni Paolo II 132, Fisciano*
lucio.spinelli@unina.it

Since the engagement of nanoparticles is becoming more and more relevant in modern medicine, scientific attention has been drawn toward the characterization of the "bio-molecular corona", which is described as a layer of biomolecules assembling on the surface of nanoparticles when they encounter biological fluids.

The dynamic structure of the corona is composed of different biomolecules, such as lipids, sugars, nucleic acids and, first and foremost, proteins accounting for most of the overall mass. Therefore, we mostly refer to this entity as "protein corona".[1]

The "protein corona" provides a new identity to the nanoparticles, hence redefining their pharmacokinetics and fate in the body ranging from their uptake by cells to immunologic responses and resulting in a decrease in their half-life. Therefore, the "protein corona" characterization is essential in the development of nanoparticles with better bioavailability, but it can also help in resolving the nanoparticles path inside the body, opening the way to a targeted delivery of therapeutics.[2]

One of the main challenges in the corona characterization is the optimization of its isolation from the biological environment. In literature, centrifugation is the most frequently described technique since it can be applied to the vast majority of nanoparticle types even though many drawbacks are evident, such as potential disruption of the physiological corona or the creation of artefacts caused by the applied centrifugal force.[3]
Thus, with the aim of an in-depth protein corona characterization, we set to establish the best strategy for corona analysis using polylactic-co-glycolic acid (PLGA) nanoparticles as a model. In particular, preliminary experiments were performed to define the optimal isolation method for the nanoparticle-corona complexes, starting from centrifugation and moving on to less common methodologies, such as microfiltration and size exclusion chromatography, also implementing an array of different variables for the biological fluids.

benedetta.squeo@scitec.cnr.it

A key aspect towards a green and carbon-neutral transition involves enhancing the efficiency of solar cells. However, traditional photovoltaic (PV) devices face inherent limitations due to thermodynamic constraints, such as thermalization losses, which restrict the maximum achievable power conversion efficiency (PCE) to around 29% for an ideal single-junction Si cell[1]. The exploitation of Singlet Fission (SF) is a promising strategy to enhance the PCE[2], relying on the efficient conversion of a singlet exciton into two triplet excitons: in suitably engineered devices this could yield light conversion quantum efficiencies ≈ 100% in the spectral region where the SF material absorbs.

Recently the diketopyrrolopyrrole (DPP)[3,4] core has been proposed as a promising platform for SF, thanks to its excellent photostability, diradical character and the easily modifiable chemical structure, that enables concurrent control over the singlet-triplet energy gap and the molecular packing configuration; the latter, in particular, is known to influence both the efficiency of SF and its successful exploitation in solar cells.

Here we present the synthesis and characterization of a series of DPPs based molecules, with different alkyl chain and different aromatic substituents, which should enhance the diradical character of the molecules and favor the slip-stacked packing in solid thin films.

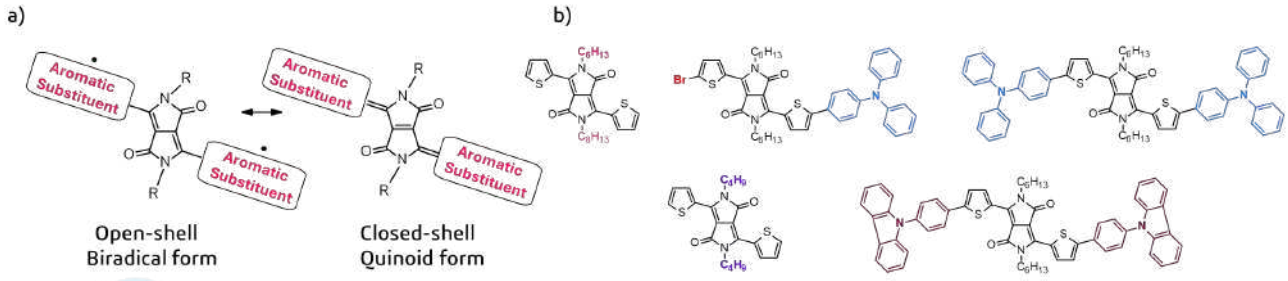

Figure 1: a) the biradical and quinoid form of DPP, b) chemical structures of the synthesized molecules.

lorenzo.taglietti@unimib.it

Herein we present the synthesis of a series of novel 1-deoxy-L-idonojirimycin derivatives exploiting an unexplored synthetic pathway. In recent years this class of piperidines have emerged as promising active-site modulators of the lysosomal glycosidase α-L-iduronidase (IDUA). IDUA deficiency is involved in a neurodegenerative lysosomal disorder known as Mucopolysaccharidosis type I (MPS I). In this context, the proposed synthetic approach led to the successful seven-steps preparation of compound **7** as an analogue of L-iduronic acid (Fig. **1**).[1] Moreover, with the attempt to improve the affinity towards IDUA and investigate conformational features, this synthetic route was expanded for the preparation of compounds **11-14**.[2] A preliminary computational conformational analysis supported the NMR-based evidence that introducing an acyl- or alkyl- moiety at the nitrogen position can switch the $^1C_4$ chair conformation of compounds **4** and **7** into a $^4C_1$ chair in compounds **11-14**. This behaviour suggests that different substitutions at the nitrogen position and the presence of the carboxylic acid at the C6 position can be exploited to modulate the conformation of these small molecules. Furthermore, as a change in conformation of iminosugars has a profound effect on their binding properties towards glycosidases, this strategy could provide preliminary information about the potential biological activity of this class of piperidines.

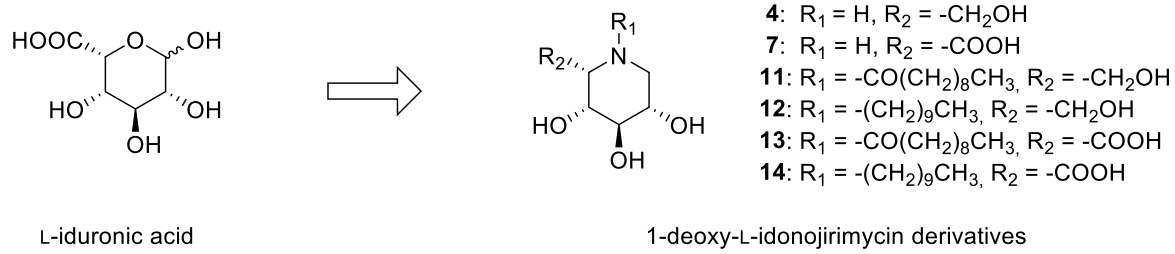

Figure 1: 1-deoxy-L-idonojirimycin derivatives proposed in this work rationally designed as analogues of L-iduronic acid.

Among the living organisms that generate nanostructured components, diatoms are very attractive. Diatoms are a large and prolific class of single cell photosynthetic microalgae, whose mesoporous biomineralized silica shells (frustules) encase the organic protoplasm.[1] Frustules exhibit interesting properties such as high surface area, mechanical resistance, unique optical characteristics and mesoporosity, which make them appealing materials for applications in photonics, sensing, optoelectronics and biomedicine. The availability of numerous chemical and biological approaches to modify the frustules composition represents a powerful resource to produce nanostructured materials with properties tailored for specific applications.[2] Frustules chemically modified with organic dyes have seldom been investigated for their optical properties thus far. We have demonstrated that in vivo incorporation of organic molecular emitters into frustules through diatoms' silica biomineralization represents an efficient biotechnological route to new photonic materials whose properties result from the combination of the frustule hierarchical nanostructure with the luminescence of incorporated emitting molecules.[3] In particular, our study points out that the functionalization of diatoms biosilica with tailored photoactive molecules can represent a powerful tool in order to obtain luminescent micro- and nanostructured biomaterials for applications in biomedicine, optics, photonics and agriculture technologies.

The overuse of antibiotics to treat bacterial infections leads to antimicrobial resistance, one of the most serious threats in our century.[1] The ability to distinguish between bacterial species can provide a useful tool to overcome this dangerous problem with the possible development of a selective, rapid and inexpensive sensor. Knowing that calixarenes are able to selectively bind different types of macromolecules,[2] we studied a series of water-soluble zwitterionic calix[4]arenes, and found that those functionalised at the upper rim with four zwitterionic amino acid moieties, were able to selectively interact with the cell wall of Gram-negative bacteria, among the other families tested. The proline and phenylalanine derivatives (**1** and **2** respectively, Figure 1) have been shown to bind Gram-negative bacteria using on-cell Saturation Transfer Difference NMR techniques.[3] Preliminary results suggest that they are able to interact with the lipopolysaccharide (LPS) portion. LPS-containing lipid interfaces are developed as a mimic of the cell wall of Gram-negative bacteria, and their interaction with the calixarenes is investigated using quartz crystal microbalance with dissipation monitoring.

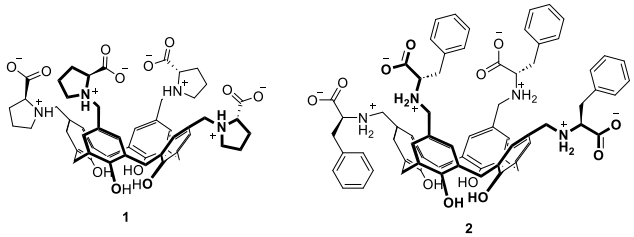

Figure 1: Zwitterionic calix[4]arene based molecular receptors selective for Gram-negative bacteria.

In the last years, graphene oxide nanosheets (GO) has emerged as potential sorbent materials for the removal of contaminants of emerging concern, (i.e. pharmaceuticals and personal care products, Per-and Polyfluoroalkyl substances (PFASs)) from drinking water.[1-5] Oxygenated groups on the surface of GO nanosheets enable specific adsorption selectivity and capacity, mainly driven by specific hydrophobic, van der Waals and electrostatic interactions.[6] Fine tuning of adsorption selectivity can be achieved by tailored chemical modification of GO nanosheets' surface.[1,4] On this line, here we report the design, synthesis and application of GO nanosheets modified with tertiary amines ended functionalities by epoxide ring opening reaction, and then quaternarized by nucleophiclic addition. The adsorption performances in water toward a mixture of PFASs with different alkyl chain length and end groups (carboxylated or sulfonated), will be reported and compared to those of granular activated carbons (GAC), the industrial sorbent benchmark.

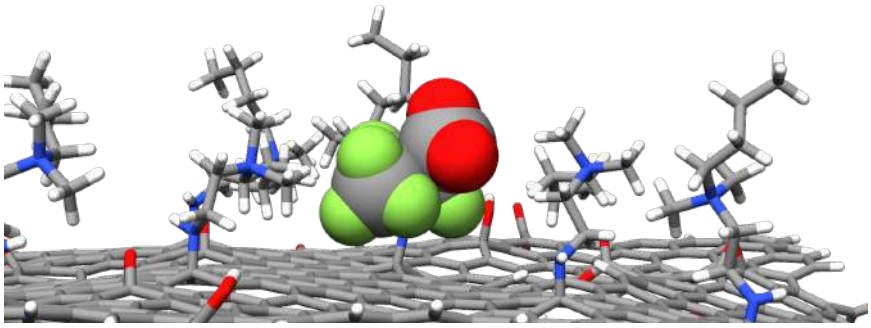

Figure 1: Surface chemical interaction between a modified GO nanosheet and perfluorobutanoic acid (PFBA) obtained by Molcular Dynamic (MD) simulation.

federico.turco@scitec.cnr.it

In the pursuit of more efficient and environmentally friendly energy sources, organic photovoltaics (OPVs) have emerged as a promising alternative to silicon-based solar cells, especially for indoor application. In order to achieve, not only economic viability but also sustainability of OPVs, low cost and large module production need to be coupled with increased greener conjugated polymers production and minimal batch-to-batch variation.

Continuous flow synthesis[1] and microwave assisted synthesis[2] (**Figure 1a**) represent two sustainable and efficient way compared to conventional polymer synthesis: the flow chemistry approach demonstrates a remarkable reduction in reaction times and solvent use, aligning with green chemistry principles, while microwave-assisted synthesis further enhances the sustainability quotient by using small volume of solvent, providing rapid heating and short reaction time, decreasing energy consumptions.

Here we present the case study of PSBTBT (**Figure 1b**) (poly(4,4-dioctyldithieno(3,2-b:2',3'-d)silole)-2,6-diyl-alt-(2,1,3-benzothiadiazole)-4,7-diyl), a wide used low-gap polymer for OPVs[3]. We have synthesized the polymer using Stille cross coupling polymerization with the three different approaches, comparing the molecular weight, the optical characteristics (**Figure 1c**) and the metal residual in the polymers.

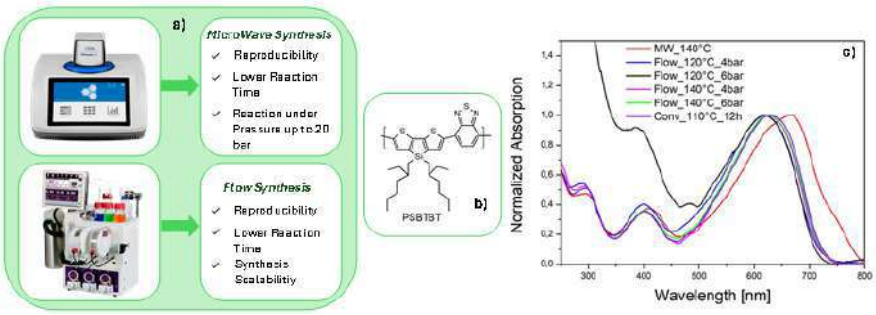

Figure 1: a) the flow and the microwave system for synthesis, **b)**, PSBTBT polymer's structures and **c)** the absorption spectra in chloroform solution.

Synthesis of lanthanide chelates for Time Resolved-Foster Resonance Energy Transfer (TR-FRET)

Filippo Valloni,[a] , Luigi Panza,[a]

[a] *Departement of Pharmaceutical Sciences, Università del Piemonte Orientale, Largo Donegani 2, 28100, Novara, Italy*
E-Mail: filippo.valloni@uniupo.it

Time Resolved-Foster Resonance Energy Transfer (TR-FRET) is an analytical technique that combines Time-Resolved Fluorescence (TRF) and Foster Resonance Energy Transfer (FRET). These two spectrofluorimetry use fluorophores that, when exposed to a light source set at a specific wavelength, emit fluorescence at a higher wavelength with less energy, obtaining a fluorescence spectrum. Classical fluorophores (like fluorescein) have a very short emission time (nanosecond scale) 1. Since proteins also exhibit fluorescence, their emission produces a high background that interferes with the emission of the fluorophore. Unlike classical fluorophores, stable lanthanide chelates (typically europium and terbium) are used, which have large stokeshifts and longer emission times (microseconds to milliseconds). All this makes it possible, after excitation of the fluorophore, to wait for the background fluorescence switched off before making the measurement, thus improving the signal-to-noise ratio. The lanthanide probes, in addition to the chelanting site, has two important sites: the "antennae" site and the bioconjugation site. The antenna is characterised by a system conjugated to the chelating portion of the compound which, depending on its structure, allows light to be emitted at specific wavelength 2. For the bioconjugation component, there are several approaches depending on the type of macromolecule (usually protein) to be bound 3. In TR-FRET there are the fluorophore donor and the fluorophore acceptor 4. The aim of the work is to synthesise lanthanide chelates by modifying the antenna and the bioconjugation part, while keeping the size of the chelating site unchanged.

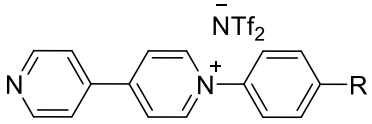
Synthesis and electro/photochemical study of new pyridinium salts

L. Veltri, G. A. Corrente, A. Beneduci, B. Gabriele

Department of Chemistry and Chemical Technologies, University of Calabria,
Via P. Bucci 12/C, 8703, Arcavacata di Rende (CS), Italy
lucia.veltri@unical.it

Bipyridinium chromophores are extensively studied for their interesting photochemical and electrochemical properties.[1] They find application as components for molecular batteries, electrochromic displays, redox-mediators, redox-sensors, and so on. For this reason, there is a great interest in designing new bipyridinium derivatives that behave not only as electroactive moieties but also as fluorophores.

In this contribution, we report on the synthesis and the photophysical/electrochemical characterization of a new series of 1-aryl-(4,4'-bipyridin)-1-ium salts bearing several different alkyl chains on the *para* position of the phenyl ring, as shown in Figure 1.



1 R = $(CH_2)_7CH_3$
2 R = $(CH_2)_9CH_3$
3 R = $(CH_2)_{11}CH_3$
4 R = $(CH_2)_{13}CH_3$

Figure 1

The new compounds **1-4** have been prepared by the ANRORC reaction [2] of 1-(2,4-dinitrophenyl)-(4,4'-bipyridin)-1-ium chloride with the corresponding 4-alkylanilines, followed by counterion exchange with $LiNTf_2$. The redox behavior of **1-4** has been examined by cyclic voltammetry (CV), while the photoluminescence properties were studied by UV/vis spectroscopy.

Selenium, sharing most of its chemical properties with sulfur, can form reversible covalent bonds with other chalcogens. I recently synthetized several selenium (and sulfur) containing compounds (Fig 1, upper) as the first-in-class of covalent inhibitors of the YTHDF m6A binding domain, a class of cancer-related proteins for long been considered undruggable.[1] The covalent interaction with the protein was studied with several orthogonal assays: X-ray, MS, NMR, and biochemical assays.

Arsenic is perhaps one of the most frightening and captivating element in the periodic table. However, less known is that arsenic compounds have a huge historical legacy (Salvarsan/syphilis, arsenic trioxide/leukemia) and undeveloped potential to treat various diseases. Derived from a marine sponge, in 2006 prof. Mancini successfully isolated and characterized the first polyarsenical natural compound.[2] Recently, I expanded the chemical space of this scaffold, with the synthesis and the non-trivial structural elucidation of related organoarsenicals (Fig 1, down), highly potent and selective against glioblastoma stem cell growth.[3]

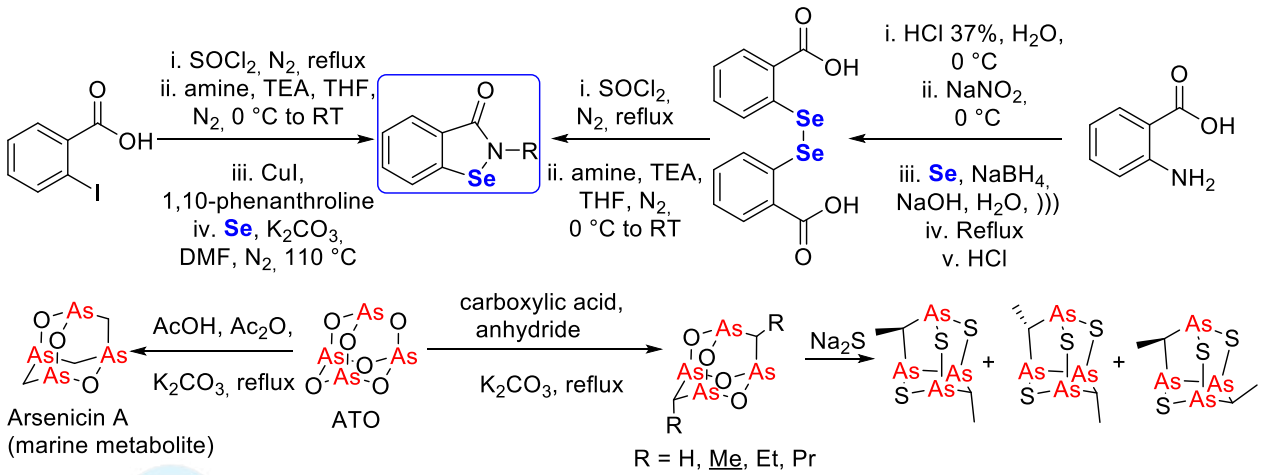

Figure 1: synthesis of organoselenium and organoarsenic anticancer compounds.

The increasing levels of carbon dioxide (CO_2) in the atmosphere and the growing global need for energy impose the development of renewable methods to convert CO_2 into valuable chemicals and fuels, for example by exploiting the coenzyme-dependent activity of formic acid dehydrogenase (FDH) to catalyze the reduction of CO_2 to formate.[1] Nevertheless, the high cost of the coenzymes, as NADH and $MV^{\bullet+}$, have so far limited the application of this technology. In this context, effective coenzymes regeneration methods using low-cost energy sources would provide a suitable pathway for CO_2 reduction with the improvement of artificial photosynthesis systems.[2]

Here we report the application of a semiconducting polymer, poly[2,2""-bis[[(2-butyloctyl)oxy]carbonyl][2,2':5',2":5",2"'-quaterthiophene]-5,5"'-diyl] (PDCBT) for the fabrication of water-processable nanoparticles (WPNPs) through the miniemulsion approach (**Figure 1**). Then, the polymer-based WPNPs were employed as photosensitizer in a visible-light-driven $MV^{\bullet+}$ regeneration system consisting of TEOA as electron donor and MV^{2+} as electron acceptors. Enzyme-catalyzed redox reactions were then used to validate the production of the regenerated cofactor (**Figure 1**).

Our results show a successful example of polymer WPNPs used for the selective coenzyme regeneration in an artificial photosynthesis system, which is easy to build and usable under mild conditions for the easy regeneration of different coenzymes. These results could pave the way for other photoredox reaction systems that enable the selective and sustainable production of chemicals and fuels through the use of solar light.

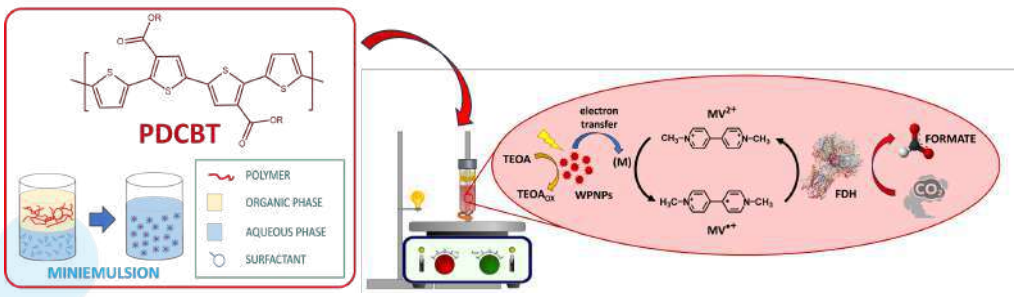

Figure 1: PDCBT-based WPNPs used as photosensitizers for MV^{2+} reduction.

Calixarene - based luminescent mechanophores for mechanoresponsive polymers

L. Visieri,[a] C. Rader,[b] J. A. Berrocal,[b] L. Baldini[a]

[a]*Università di Parma, Parco Area delle Scienze 17/A, 43124, Parma (IT)*

Mechanoresponsive polymers are materials capable of transducing a macroscopic mechanical force into molecular events that, in turn, trigger a response of the macroscopic material. The incorporation of mechanoresponsive dyes, also known as mechanophores, into the polymer matrix results in materials that change their optical properties upon mechanical stress. Various strategies have been explored, from the cleavage of weak covalent bonds, as in the case of spyropyranes[1] or triarylmethanes,[2] to the formation/disruption of pi-pi interactions between fluorescent dyes. Good reversible mechano-responses have been obtained by the use of supramolecular structures such as cyclophanes or rotaxanes, which guarantee a proper preorganization of the dyes.[3] Following this approach, we decided to exploit the peculiar conformational properties of the calix[4]arene scaffold to develop new supramolecular mechanophores. It is well known that calix[4]arenes, when functionalized at the lower rim with alkyl chains, are involved in a rapid interconversion between two equally stable pinched cone conformations.[4] On the contrary, in presence of suitable functional groups at the upper rim, the equilibrium can be strongly shifted towards only one of the two pinched cone conformations, and upon appropriate stimuli, the equilibrium can be reversed.[5]

We synthesized pyrene-functionalized calixarenes, which, in the stress-free state, are pinched in the closed cone conformation allowing intramolecular dimerization of the dyes. We covalently incorporated these calixarenes into polymer chains so that the transduction of an applied mechanical force to the calixarene could trigger the opening of the pinched cone conformation, thus resulting in the monomeric form of pyrene.

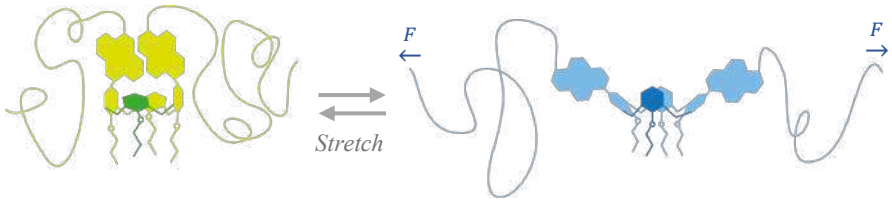

Figure 1: calixarene-based mechanophore behaviour upon application of a mechanical force.

In the field of cancer treatment, Small Molecule-Drug Conjugates (SMDCs) represent an effective strategy to overcome the drawbacks of traditional chemotherapeutic agents by conjugating a cytotoxic compound to a targeting ligand recognizing a specific overexpressed cell surface receptor.[1] To connect the ligand with the payload, a chemical linker is needed, which should be able to release the free payload inside or in proximity of the cancer cell upon external stimuli (i.e. enzymatical proteolysis). Thus, the linker plays a key role in the effectiveness of the final conjugate. Herein, we present the synthesis and the biological evaluation of a novel SMDC **1** bearing a new enzymatic cleavable linker composed by the peptide sequence Gly-Pro-Leu-Gly (GPLG) and by the self-immolative linker *p*-aminobenzyloxycarbamate (PABC).[2] In particular, the GPLG-PABC was here used for the first time to connect the $\alpha_v\beta_3$ integrin cyclic peptidomimetic ligand bearing the recognizing sequence *iso*Asp-Gly-Arg (*iso*DGR)[3] to the potent tubulin inhibitor monomethyl auristatin E (MMAE). The final SMDC **1** was tested for its antiproliferative activity, and the results confirmed a higher potency of the SMDC **1** compared to the corresponding conjugate **2** containing the Val-Ala-PABC cleavable linker recognized by the lysosomal enzyme Cathepsin B, previously reported by our group (Figure 1).[4] A further *in vitro* enzymatical assay assessed the fast release of MMAE from the GPLG-PABC linker through the proteolytic activity of lysosomal enzymes, although a specific protease was not identified. Further studies are currently ongoing in our laboratories to fully characterized this new enzymatical cleavable linker.

In the context of cancer immunotherapy, the inhibition of the interaction between the *programmed cell death receptor 1* (PD-1) and its ligand PD-L1 by monoclonal antibodies (mAbs) has achieved notable success in treating several types of cancers. Nevertheless, the use of mAbs is hampered by drawbacks such as high production costs, lack of oral bioavailability, poor tissue and/or tumor penetrability, and for these reasons small molecule inhibitors of the PD-1/PD-L1 axis could represent a promising alternative.[1]

Our research group has recently reported a small library of triazine-based small molecule PD-L1 inhibitors, among which, compound 10 (**CMP-10**, Figure 1, top) showed high affinity towards PD-L1 (IC_{50} = 115 nM),[2] and a significant anticancer activity in co-cultures of PD-L1-expressing NSCLC cells and peripheral blood mononuclear cells (PBMCs).

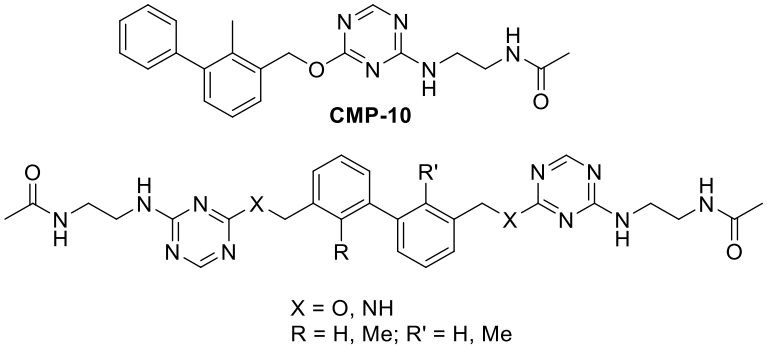

Figure 1: Chemical structure of lead **CMP-10** and general structure of pseudodimeric triazine-based PD-L1 inhibitors.

Here we present the synthesis of a new class of pseudodimeric PD-L1 inhibitors based on lead **CMP-10** (Figure 1, bottom) that, according to literature, should be significantly more active in blocking the PD-1/PD-L1 interaction by stabilizing the PD-L1 homodimer, when compared with their monomeric counterpart.[3]

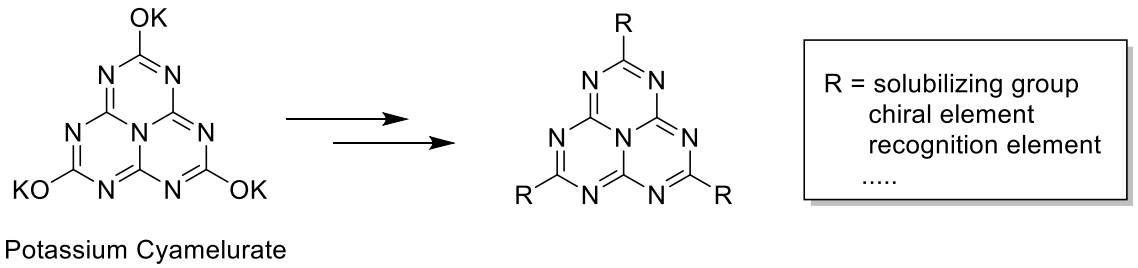

Figure 1: Heptazine derivatives functionalization.

S-Heptazines are a class of molecules within the carbon nitrides family. They are primarily synthesized from s-triazine, and these molecules exhibit remarkable optical and electronic behaviour, largely attributed to their conjugated π-system with a low-lying π* orbital, which arises from the electronegativity of the nitrogen atoms embedded in the skeleton[1].

However, their high stability and poor solubility pose significant challenges for the functionalization of these molecules[2].

The project aims to develop novel chiral and achiral derivatives of s-heptazines (Figure 1) with potential applications as OLED (Organic Light Emitting Diode) emitters.

In this poster we will show the various post-functionalization of these molecules and their optical properties.

IR irradiation-assisted Pd-catalyzed cross-dehydrogenative coupling of polyfluoroarenes with heteroarenes: proving the role of thermal and non-thermal effects

gianluigi.albano@unipi.it

Infrared (IR) irradiation has recently attracted significant attention as non-conventional energy source for organic reactions. IR light sources are able to reduce energy requirement, shorten reaction time, increase product yields and avoid undesired by-products compared to traditional thermal heating with a thermostatic bath.[1] Despite all these advantages, the actual role of IR irradiation as energy source for promoting organic reactions has never been investigated in-depth, and it has been simply considered as a highly efficient form of heating.

Herein we present the use of IR irradiation to assist Pd-catalyzed cross-dehydrogenative coupling reactions.[2] The protocol, performed under solvent-free conditions, is applied to the coupling of polyfluoroarenes with five-membered heteroarenes, affording products with excellent yields in only 30 minutes.

For the first time, the ability of IR irradiation to directly affect the mechanism of a chemical reaction, rather than to simply act as an efficient heating source, is demonstrated by spectroscopic and kinetic studies: while the rate-determining step (RDS) under conventional thermal heating involves Pd(II)-mediated C−H bond activation on the heteroarene ring, the use of IR light shifts the RDS to the oxidation of Pd(0) by Ag(I) oxidant.

The unexpected role of IR irradiation in the reaction mechanism has been evaluated through a series of control experiments and theoretical calculations, concluding that it results from a combination of thermal and non-thermal effects. This finding is highly significant: IR irradiation can be considered as a new powerful enabling technology for synthetic organic chemistry.

Nowadays, molecular scaffold manipulation of natural phenols represents a largely pursued, effective approach to boost or modulate their antioxidant properties and bioactivity. For example, the insertion of S/Se/Te containing substituents on phenols/polyphenols scaffold may increase/decrease their H-donor/acceptor ability by electronic and stereoelectronic effects related to the site of substitution and geometrical constrains, which thus make them ideal prototypes of novel multifunctional compounds combining diverse scavenging and inhibitory activities against oxidative stress.[1-3]

In this frame, we herein report recent studies focused on the development of straightforward procedures for the preparation of selenoderivatives of tyrosol, a natural phenolic compound endowed with many beneficial properties for human health, such as antioxidant, anticancer, antinflammatory, and cardioprotective activities.

In particular, a mild selenylation procedure based on the use of selenium tetrachloride, followed by purification, allowed the isolation of two main products identified as the 3,3'-selenobistyrosol and the 3,3'-diselenobistyrosol based on MS and NMR analysis (Figure 1).

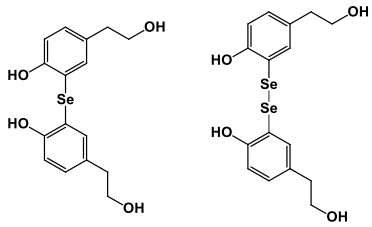

Figure 1: Selenoderivatives of tyrosol.

The selenoderivatives so obtained showed antioxidant activities up to 30-fold higher than that of tyrosol as evaluated by commonly used chemical assays. The results of the investigation of the peroxyl radical scavenging properties of the selenoderivatives using an integrated kinetic, EPR, and computational approach will also be presented. The efficacy of the diselenobistyrosol as potential glutathione peroxidase mimics to destroy H_2O_2 generated in the inflammatory processes will be illustrated.

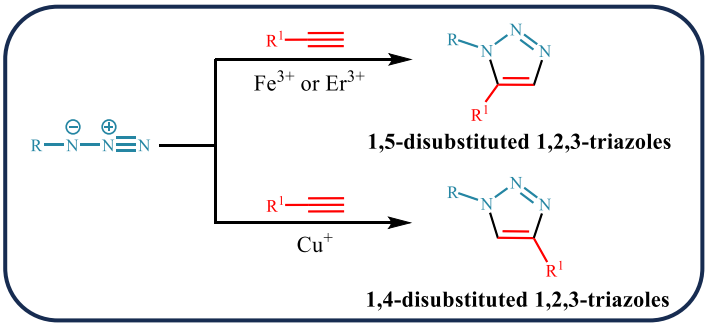
vincenzo.algieri@unical.it

1,2,3-triazoles are five-member heterocyclic compounds bearing three nitrogen atoms in the ring. They are important nucleus for development of drugs because they are resistant to oxidation, reduction, and hydrolysis in both acidic and basic conditions for their aromatic nature. Thanks to active participation in hydrogen bond formation, dipole–dipole and π-stacking interactions they can mimic peptide bonds, enhancing their binding ability with different biological targets. Therefore, triazoles have important biological properties, such as antibacterial, anticancer, antivirus, antimalarial, anti-inflammatory and antituberculosis. In particular, 1,2,3-triazoles found a broad spectrum of biological applications such as β-lactum antibiotic tazobactum, cefatrizine, and anticancer compound carboxyamidotriazole, which are some drugs available on the market.[1]



Scheme 1: 1,3-dipolar cycloaddition reaction for regioselective synthesis of disubstituted 1,2,3-triazoles

In this work, our research group has designed and synthesized a new class of disubstituted 1,2,3-triazoles (**Scheme 1**) through 1,3-dipolar cycloaddition reaction using organic azides as 1,3-dipoles and several dipolarophiles. The reaction was catalyzed with metal Lewis acid and the products were obtained with high yields and excellent regioselectivity because only a single regioisomer was obtained in all proposed cases. In addition, some synthesized triazoles were tested on porcine aortic endothelial cells (pAECs) to evaluate their biological activity and demonstrated a very strong cardioprotective action in *in-vitro* and *ex-vivo* models of cardiovascular pathologies (i.e., hypoxia-reoxygenation and hypertension).[2]

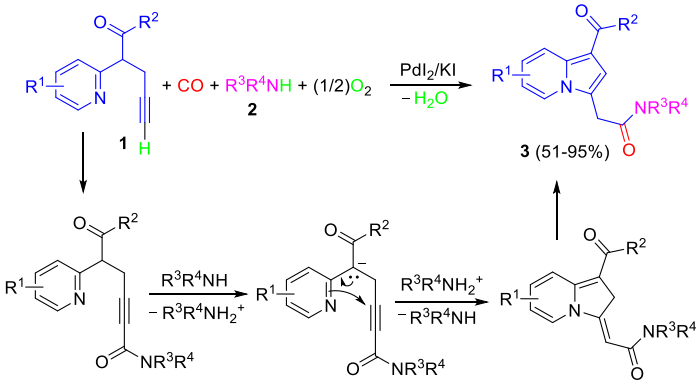
The indolizine core is present in many molecules that display a wide range of pharmacological properties.[1] Moreover, some interesting organic fluorophores possess the indolizine core as the key structural unit.[2] Here we present a multicomponent approach to novel *N*,*N*-disubstituted 2-(indolizin-3-yl)acetamide derivatives with fluorescent properties starting from simple and readily available building blocks [2-(pyridin-2-yl)pent-4-yn-1-carbonyl compounds, CO, amines, and oxygen] through a sequential PdI_2/KI-catalyzed oxidative aminocarbonylation[3] – cyclization – aromatization process (Scheme 1).



Scheme 1

As shown in Figure 1, the tested indolizine absorb (λ_{abs}) in the UV region (374.5–386.0 nm), and emit (λ_{em}) in the visible or blue region (442–448.6 nm).

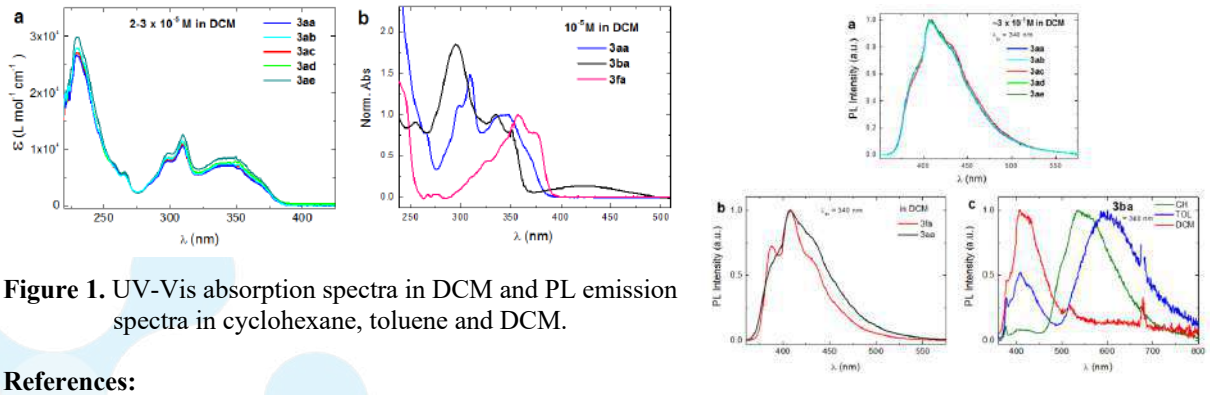


Figure 1. UV-Vis absorption spectra in DCM and PL emission spectra in cyclohexane, toluene and DCM.

vbattaglia@unisa.it

The enantioselective synthesis of epoxides is of considerable interest, as these compounds are used as highly versatile intermediates to obtain bioactive compounds useful in medicinal chemistry.[1] Recently, a new class of molecules, 1-phenylsulfonyl-1-cyano epoxides, has been disclosed and employed for the synthesis of enantioenriched dihydroquinazolinones, via a one-pot Knoevenagel/epoxidation/*DROC* (*Domino Ring Opening Cyclization*) reaction sequence, using a quinine-based organocatalyst and commercially available reagents.[2] In this contribution, an additional application of this one-pot sequence is reported, employing 2-aminobenzylamine in the *DROC* step to obtain the corresponding 7-membered cyclic products, 1,4-benzodiazepinones, privileged scaffolds in medicinal chemistry (Figure 1).
Further iteration of this one-pot strategy afforded α-aryl glycines,[3] through the epoxides opening according to a *DROE* (*Domino Ring Opening Esterification*) mechanism, employing two different nucleophiles such as aromatic amines and methanol. Similarly, enantioenriched mandelic acids, which represent important building blocks to obtain drugs such as *S*-Clopidogrel and Cyclandelate, have been prepared using water as a nucleophile in the final *DROH* (*Domino Ring Opening Hydrolysis*) step (Figure 1).

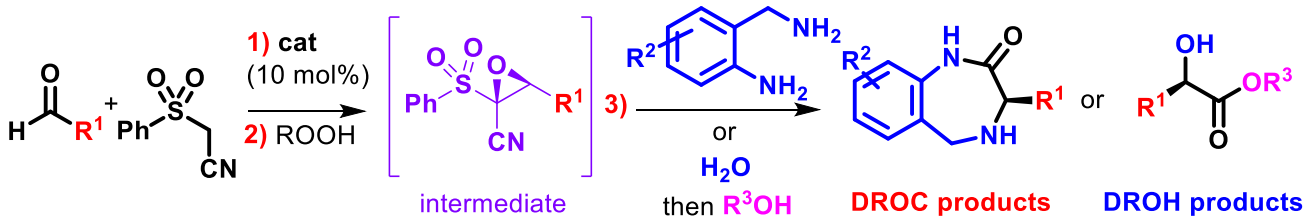

Figure 1: One-pot catalytic approach for the enantioselective synthesis of 1,4 benzodiazepinones and mandelic acids esters.

Mechanochemical N-alkylation of amines with alcohols: A green and sustainable approach

S. Behera,[a] A. Porcheddu [a]

[a] *Università degli Studi di Cagliari, Dipartimento di Scienze Chimiche e Geologiche, Cittadella Universitaria, 09042 Cagliari*

e-mail: porcheddu@unica.it

N-alkylation of amines is a crucial transformation for pharmaceutical and fine chemical industries.[1] The general synthetic procedures for N-alkylation of amines involve harsh reaction conditions such as high temperature and inert atmosphere, harmful reagents like alkyl halides, and prolonged reaction times. These processes also use large quantities of solvents for the reactions. Borrowing hydrogenation (BH) strategies to obtain N-alkylated amines using alcohols has gained significant attention due to its intrinsic atom economy and selectivity. Although it is a significant step to avoid alkyl halides, borrowing hydrogenation strategies often comes with the same drawbacks of harsh reaction conditions, longer reaction times, and use of solvents.[2]

Mechanochemistry, a field that offers tools to perform reactions without the involvement of solvents and sometimes uses a very low amount of liquid for enhancing the milling procedures, has been instrumental in our innovative approach.[3] Thus, in this project, we describe an efficient methodology for borrowing hydrogenation for N-alkylation of amines using mechanochemistry at solvent-free, room temperature, under normal atmosphere, and low catalyst loading conditions. Our procedure offers significant reduction in time and energy along with propounding a greener and more sustainable pathway for the accessibility to N-alkylamines.

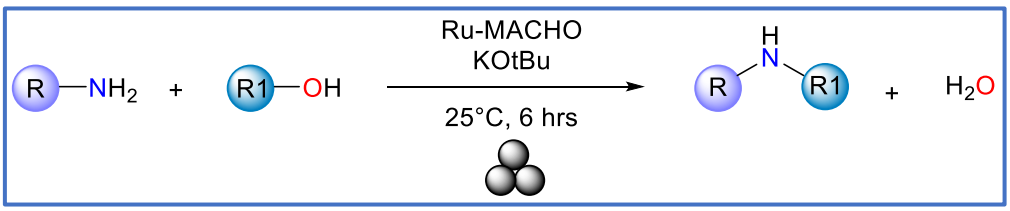

Figure 1: Condition for mechanochemical N-alkylation of amines using alcohols.

Novel Strategies for CO_2 Fixation in Organic Scaffolds: Electro-, Nickel- and Carbo-catalyzed Processes.

G. Bertuzzi,[a,b] M. Bandini[a,b]

[a]Dipartimento di Chimica "Giacomo Ciamician", Alma Mater Studiorum – Università di Bologna, Via P. Gobetti 85, 40129, Bologna Italy, [b]Center for Chemical Catalysis -C³-, Alma Mater Studiorum – Università di Bologna, Via P. Gobetti 85, 40129, Bologna Italy.
e-mail: giulio.bertuzzi2@unibo.it

An overview of the latest strategies developed by our group for the valorization of CO_2 through fixation into organic scaffolds is presented, employing three different approaches. Initially, we have devised Ni-catalyzed methodologies to effect carbonylation reactions using CO_2 as a CO surrogate, facilitated by the presence of $AlCl_3$ as an oxygen scavenger, thereby addressing the formation of cyclic ketones[1a] and amides.[1b] Subsequently, leveraging electrochemistry as a tool for generating reactive nucleophilic species capable of capture CO_2, we are presently advancing carboxylation processes of olefins, including Morita-Baylis-Hillman acetates[2a] and electron-deficient allenes,[2b] in a metal- and additive-free fashion. Lastly, we are investigating the use of Graphene-Oxide (GO) functionalized with natural amino acids, such as arginine, for the realization of "smart" materials capable of executing CO_2-Capture and Utilization (CCU) strategies.[3]

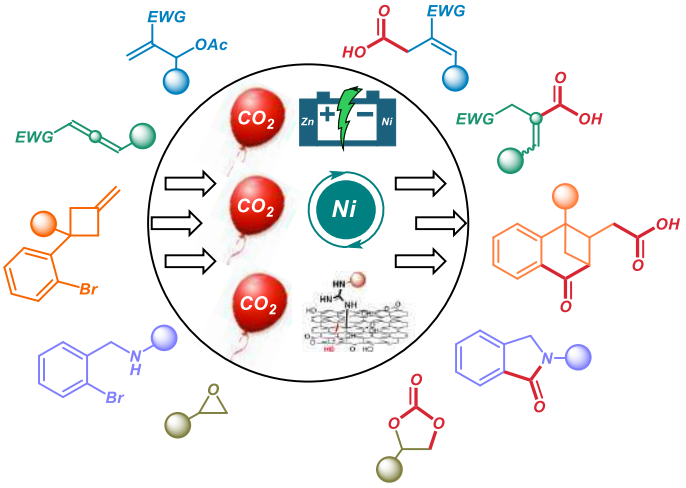

Figure 1. Multiple approaches for the valorization of CO_2.

davide.blasi@uniba.it

Molecules with open-shell electronic configurations are crucial in modern molecular material science. Singlet diradicaloids (SDs) belong to this category. They are molecular compounds with two unpaired electrons that are coupled antiferromagnetically, resulting in a singlet spin state. Their significance in organic chemistry stems from their unique electronic properties, which can lead to intriguing magnetic, optical, and conducting behaviors. One prominent group of SDs is represented by para-quinodimethanes (pQDMs). By utilizing polychlorination as a synthetic tool, we successfully stabilized the Thiele hydrocarbon.[1] This new species, named TTH (Figure 1), exhibited intense photoluminescence (with a quantum yield of 0.84 in toluene), a red-shifted emission (Stokes' shift of 193 nm in cyclohexane), and solvatochromic properties. Through transient spectroscopic techniques and supported by multireference quantum-chemical calculations, we demonstrated that this emission arises from a zwitterionic doubly excited state, typically found at low excitation energies in SDs. This state gains dipole moment and intensity through state mixing *via* twisting around the strongly elongated exocyclic CC bonds of the excited pQDM core, akin to sudden polarization in olefins. While previous studies focused on the influence of para-halogens on the electro-optical properties of Thiele fluorocarbons,[2] our current work delves into the effects induced by structural variations. We synthesized new polyhalogenated Thiele hydrocarbons with different halogenation patterns to showcase the relevance of molecular geometry on the photophysical properties of these derivatives, thereby providing fresh insights into the molecular design of SDs.

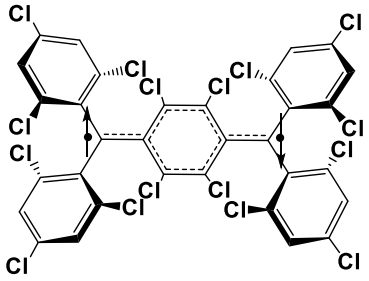

Figure 1: molecular structure of TTH

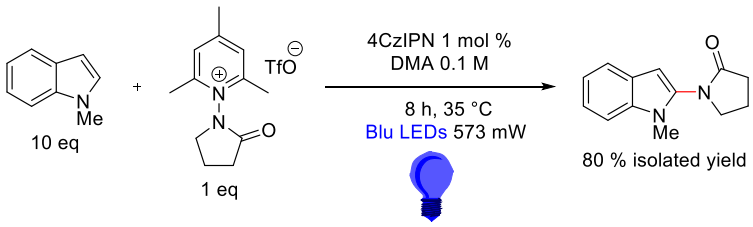
N-lactam radicals in light-promoted reactions

M. F. Boselli,[a] M.Benaglia,[a] A. Puglisi[a]

[a]*Dipartimento di Chimica, Università degli Studi di Milano, Via Golgi 19, Milano, Italy*
e-mail: monicafiorenza.boselli@unimi.it

Nitrogen-containing structures are ubiquitous in natural and in synthetic organic compounds, such as pharmaceutical and agrochemicals products. The development of new synthetic methodologies to build C-N bonds in a mild, sustainable, and possibly stereoselective manner is a topic of great interest for synthetic organic chemists. In the last two decades, photoredox catalysis emerged as a powerful tool for the generation of radical species under such conditions. Among the different radical species, we focused on amidyl radicals, which are electrophilic nitrogen radical species where the single electron is in a p orbital. [1]

Our research group has studied the formation of amidyl radicals through the homolytic cleavage promoted by light of N-O[2] and N-N bonds and the reactivity of these radicals with nucleophiles like enamines and heteroarenes. We also managed to successfully form and react the γ, δ and ε-*N*-lactam radicals, which are not known in literature. For these transformations, we have done an extensive reaction conditions screening by changing the light source, the photocatalyst, the stoichiometry and the solvents; in Scheme 1 the best conditions are summarized. [3]



Scheme 1: General reaction scheme for the reaction under study.

With the best conditions in hand, we have studied the addition of these *N* lactam radicals to different arenes and heteroarenes, collecting 19 different substrates with isolated yields up to 95 %. Gladly, we were also able to directly functionalize *N*-Boc-OMe-L-tryptophan obtaining the addition product in 50 % yield. Then, we performed a wide mechanistic investigation comprehensive of Cyclovoltammetry, X ray analysis, Stern-Volmer and Life-Time studies, Quantum Yield measurements, kinetic analysis and DFT calculations. In the end, we succeeded to run the photocatalytic radical addition of γ-*N* lactam radical in water in 44 % yield, opening the pathway to possible biological applications.

Photoactive organic-based molecular materials hold a great deal of potentials in many technological and biomedical fields. Porphycenes (H_2Po), tetrapyrrole 18π electron conjugated chromophore macrocycles constitutional isomers of porphyrins,[1] are an intriguing class of molecular materials which can serve as multipurpose scaffolds. They have two H atoms in the inner cavity which are subject to fast tautomerism while, as tetradentate ligands, they can also host almost all the metal ions. Being chemically and thermally stable, their periphery (*meso* and *β* positions) can be functionalized for specific scopes and applications. The different pattern of connection of the four pyrrole rings with respect to porphyrins, reflects in H_2Po different molecular symmetry and inner core size which favours optical behaviour suitable for ultrafast responsive material.

We previously reported the first study on vacuum deposited H_2Po continuous and compact 2D/3D thin films[2,3] *via* a combination of UV-Vis-NIR optical spectroscopies (absorption, emission, surface differential reflectivity-SDR and reflectance anisotropy spectroscopy-RAS) and surface microscopies (i.e. AFM). We demonstrate a spectacular chromatic change when the film is exposed to acid and we verified the fast reversibility of the process. We now further investigate this behaviour in porphycenes functionalised with alkyl and aryls substituents in both the β pyrrole and *meso* positions as those reported in Figure 1.

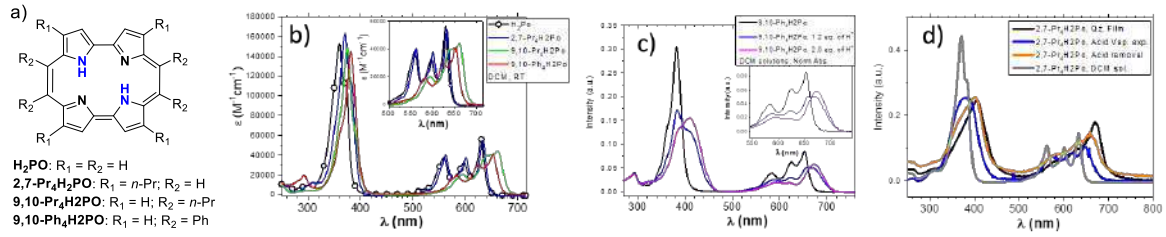

Figure 1: a) Chemical structures of the studied porphycenes; b) comparisons of the optical absorptivities of the studied porphycenes in DCM solutions; c) changes in optical absorptions of 9,10-Ph_4H_2Po upon addition of 1 and 2 equivalent of H^+ (in the form of TFA); d) absorption changes of a 20nm thin film of 2,7-Pr_4H_2Po when exposed to HCl vapours.

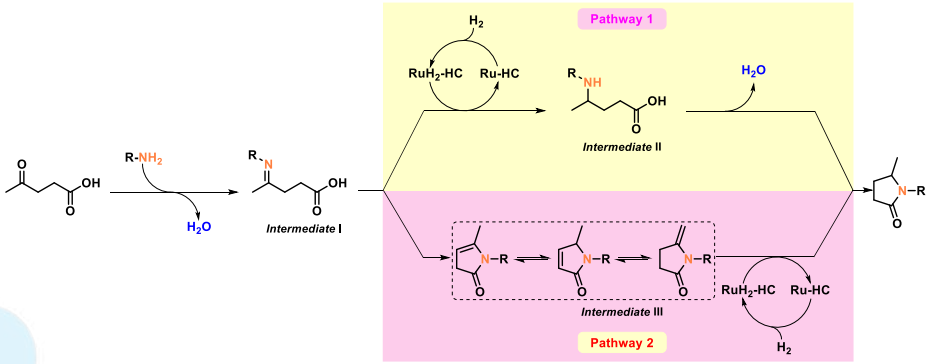
The utilization of biomass waste for a catalytic approach and the subsequent synthesis of valuable products through catalytic reactions are pivotal endeavours addressing pressing energy and environmental concerns. In line with sustainability objectives, this study explores the application of hydrochar derived from hydrothermal treatment of brewing industry waste as a support for a Ru-based catalyst (Ru-HC) in the improvement of reductive amination processes. Employing an efficient continuous flow method, alongside a hydrogen source, has yielded remarkable results, achieving up to 99% conversion in the hydrogenation of biomass-derived molecules such as levulinic acid (LA) and n-butylamine into pyrrolidones compounds. The catalytic ability of Ru-HC extends to a wide array of substrates, including various carbonyl-containing compounds and amines, encompassing green molecules such as furfural, 5-hydroxymethylfurfural, and furfurylamine, leading to the production of valuable N-containing products. Mechanistic insights are elucidated through intermediate formation and recyclability studies, demonstrating the stability and reusability of Ru-HC. The selection of solvents and optimization of key parameters, such as flow rate, temperature, and pressure, significantly influence selectivity.



Adopting a continuous process not only reduces reaction times but also eliminates the requirement for hazardous gaseous hydrogen, ensuring enhanced selectivity while minimizing environmental impact. This research underscores an eco-friendly approach to the production of high-value compounds from biomass, contributing to sustainable amine synthesis through the utilization of biomass-based catalysts.

New Electrochemical Manipulations of Tropones: Selective Alkylation Strategies

A. Brunetti,[a,b] G. Bertuzzi,[a,b] M. Bandini[a,b]

[a]Dipartimento di Chimica "Giacomo Ciamician", Alma Mater Studiotum – Università di Bologna, Via P. Gobetti 85, 40129, Bologna Italy, [b]Center for Chemical Catalysis -C³-, Alma Mater Studiotum – Università di Bologna, Via P. Gobetti 85, 40129, Bologna Italy.
e-mail: andrea.brunetti10@unibo.it

Tropones are seven-membered-ring ketones belonging to the class of non-benzenoid aromatic molecules, that can be encountered in a variety of naturally occurring compounds and constitute a unique platform in the total synthesis of complex scaffolds.[1] Despite this undoubted interest, direct and site-selective protocols for the tropone skeleton decoration are still rare and scattered in scope.

Herein, as part of our ongoing interest on electrochemical organic transformations,[2] we present two different innovative electrochemical strategies for the direct functionalization of tropones. Firstly, we have developed a ***general α-alkylation of tropones*** via a "radical approach", utilizing a metal-free C(sp^2)-C(sp^3) cross coupling manifold. This process relies on an activated form of tropolone undergoing the addition of nucleophilic radicals, generated by the electrochemical reduction of *N*-hydroxyphthalimide esters.[3a] Secondly, we are currently pursuing an ***α-benzylation of tropones*** through a Ni-catalyzed electrochemical cross-electrophile coupling between aldehydes and substituted tropones.[3b]

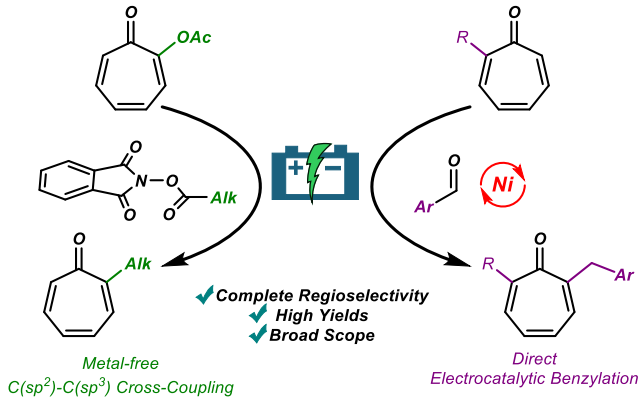

Figure 1. New Electrochemical Functionalizations of Tropones.

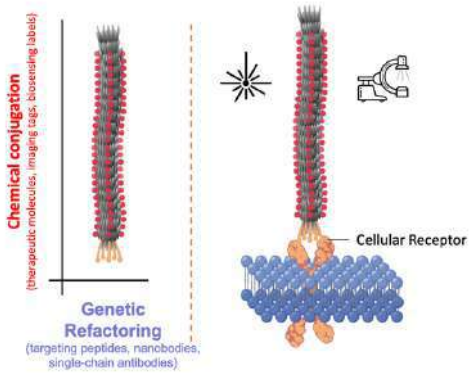
matteo.calvaresi3@unibo.it

Viral capsid can be considered as a chemically addressable structure, providing a synthetic way to decorate the external surface of a virus with molecules of interest. Phages are ubiquitous viruses that infect bacteria but are inactive against eukaryotic cells.

We developed an orthogonal nanoarchitectonics approach (genetic/chemical) to engineer the M13 phages as innovative theranostic platforms.[1] M13 phages were genetically refactored to display on their tip a peptide, a nanobody or a single chain antibody, retargeting them to any type of cell. Using an orthogonal approach to the genetic display, the refactored phages were then chemically modified, conjugating hundreds of imaging tags/therapeutic molecules/biosensing labels on the capsid surface.[1-4] Natural amines present on the surface of the protein capsid allow the direct functionalization of the virus[1-4] or the introduction of abiotic chemical functionalities for "click chemistry" or "supramolecular chemistry". The M13 phage platform can be conjugated with hundreds of molecules without impinging upon the targeting moiety.[1-3] Thereby, many more molecules can be delivered to the cellular target per binding event as compared to one/few molecules for antibodies. In principle, any kind of molecules can be attached to the surface of the phage.



Using this strategy, we developed phototheranostic platforms able to simultaneously detect, image and kill selectively cancer cells at picomolar concentration of the phage vector.[1-3] These platforms are active in photodynamic(PDT) and sonodynamic (SDT) therapy of cancer[1-3] and in antimicrobial PDT/SDT.[4] We also demonstrated the ability to use these bioconjugated viral platforms as receptor-targeted delivery system or for the analytical sensing of pathogens, replacing antibodies with an improvement in the therapeutic/imaging/sensing efficacy of two-order of magnitude.

Sulfonated pine needles derived biochar as efficient heterogeneous catalyst for alkyl levulinates synthesis

F. Campana[a], F. Valentini[a], A. Marrocchi[a], L. Vaccaroa[a]*

Laboratory of Green S.O.C. – Dipartimento di Chimica, Biologia e Biotecnologie, Università degli Studi di Perugia, Via Elce di Sotto 8, 06123, Perugia, Italy

e-mail: filippo.campana@unipg.it

The exploitation of lignocellulosic urban waste represents nowadays an alternative and innovative way toward the constitution of a circular and residues-free economy. In particular, in certain Mediterranean areas such as the Italian coastal zone, Pine needles pose a serious issue being among the major responsible for forest fires contributing to greenhouse gases in the atmosphere. This lignocellulosic material, in addition to its use as a source of value-added products (cellulose, bioethanol, bio-oils, etc), can be also converted into biochar, whose further functionalization can provide a series of heterogeneous catalysts.

In the present work, we aim to highlight the most significant results obtained in the esterification reaction of levulinic acid with a plethora of alcohols, exploiting a homemade sulfonated pine needle-derived biochar as an acidic heterogeneous catalyst, named Pine-SO3H.

Our study wants to demonstrate that green chemistry and modern technologies can give access, exploiting biobased derived starting materials, to a series of valuable and atoxic products such as alkyl levulinates, useful as fuel additives, solvents, and fragrances.

This work has been funded by the European Union – NextGenerationEU under the Italian Ministry of University and Research (MUR) National Innovation Ecosystem grant ECS00000041 – VITALITY. We acknowledge Università degli Studi di Perugia and MUR for support within the project Vitality. The University of Perugia is acknowledged for financial support to the university project “Fondo Ricerca di Ateneo, edizione 2022”

Biocatalysis became a powerful tool for the synthesis of relevant high-added value molecules with excellent chemo-, stereo- enantioselectivities but also allow to perform greener chemical transformations. However, the low solubility of many organic substrates or products in aqueous solutions, commonly used in enzymatic reactions, often hampered the application of enzymes in synthesis, mainly because of substrate concentration restrictions. In this context, non-conventional solvents are acquiring increasingly relevance and, in recent publications, they were demonstrated to improve the yield and selectivity of enzymatic reactions in an economical, health-safe, and environmentally-friendly manner.[1] In this field, Deep Eutectic Solvents (DESs) have rapidly emerged as a promising class of green reaction media as a promising class of green reaction media due to their unique properties.[2] In these work we report a successful example of non-conventional solvents used for the synthesis of cyclic chiral amines by bio-reduction of the starting cyclic imines.[3] The transformation was realized by means of a novel class of NADPH-dependant enzymes, namely Imine Reductases (IREDs). We performed the reduction of cyclic imines in a mixture of phosphate buffer/glycerol (50% v/v). Pyrrolidines, piperidines, and azepines were produced in good yields and excellent S-enantioselectivities (up to >99% *ee*). Also, the use of non-conventional solvents allows to increase the concentration of the starting material up to 100 mM. It is worth mentioning that applying a fed-batch strategy, we were able to work at mmol scale with 80% yield and excellent *ee*, which formally corresponds to a seven-fold use of the same enzyme. Our findings in terms of enantioselectivity, substrate scope and scalability will be presented.

francesca.cardano@unito.it

Peptide nucleic acids (PNA) are key candidates in chemical biology. They are synthetic oligonucleotide mimetics which are capable of interacting with DNA and RNA due to common nucleobase alphabet, although presenting a pseudopeptide backbone.[1,2] They have been already studied in antisense and antigene therapies, gene editing, nucleic acid sensing and imaging.[2] The substitution of natural occurring nucleobases with fluorescent isomorphic analogues into PNA is a unique strategy to impart intrinsic luminescence while maintaining efficient paring, aiming to overcome structural limitations of fluorophores' tagging.[3] Isomorphic fluorescent bases have shown significant emissive read-outs upon variation of pH and polarity and in the imaging of biological relevant events like duplex formation.[3,4] In this work we have prepared and investigated thieno[3,4-d]pyrimidine nucleobases and their incorporation into PNA (Figure 1).

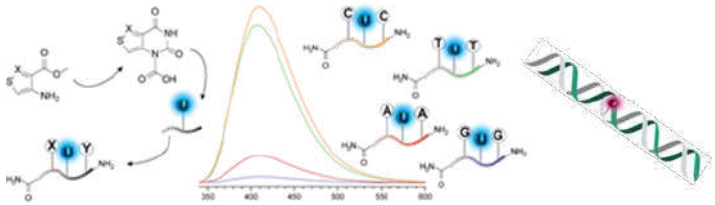

Figure 1: Emissive nucleobases incorporated into PNA.

Our studies confirm how the synthesized bases are compatible for insertion along PNA sequences of different length to deeply understand the emissive traits and to evaluate the ability to form stable heteroduplex with complementary DNAs. These preliminary results highlight that these fluorescent analogues can be easily used for PNA synthesis while conferring significant modular luminescence.

New natural-based hybrids as tyrosinase inhibitors

N. Cardullo, C. Sciacca, A. E. Maccarronello V. Muccilli

University of Catania, Viale A. Doria 6, Edificio 1, 95125 Catania
ncardullo@unict.it

In mammals, tyrosinase is responsible for melanin biosynthesis, which can protect the skin cells against the harmful effects of ultraviolet (UV) irradiation, oxidative stress, and DNA damage. However, melanin overproduction can cause several aesthetic problems and even severe diseases related to hyperpigmentation and malignant melanoma onset. Consequently, tyrosinase inhibitors can effectively inhibit excessive melanin formation and be employed as whitening agents in cosmetics, which have a broad space for market prospects, as well as for hyperpigmentation diseases and malignant melanoma, which is a promising therapeutic strategy.

In the design of new tyrosinase inhibitors, many research groups have employed bioactive natural products as scaffolds to achieve more effective inhibitors.[1] In doing that, molecular hybridization can be an efficient way to include two pharmacophore moieties into a new molecular species with specific and selective activity, and/or less toxicity, and/or improved bioavailability.

The synthesis of new hybrid molecules based on natural tyrosinase inhibitors such as resveratrol, azelaic acid, and others is reported herein (Figure 1), keeping the *m*-hydroxyphenol moiety unchanged, as SAR studies revealed this portion to have significant influence on the inhibitory activity of tyrosinase.[2]The new hybrids will be in-vitro evaluated as tyrosinase inhibitors.

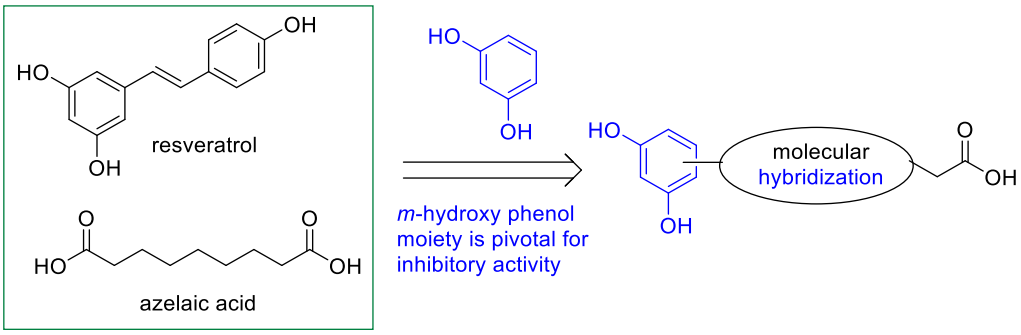

Figure 1: Scope of the work: synthesis of natural-based hybrids as tyrosinase inhibitors.

Lewis acid-catalyzed synthesis of *B,B',B"*-substituted borazines under microwave irradiation

E. Cela,[a] A. Nazari Khodadadi,[a] F. Huang,[a] D. Marchionni,[a] L. Vaccaro*[a]

[a]*Laboratory of Green S.O.C. – Dipartimento di Chimica, Biologia e Biotecnologie, Università degli Studi di Perugia, Via Elce di Sotto 8, 06123 – Perugia – Italy, web: greensoc.chm.unipg.it, ejdi.cela@dottorandi.unipg.it*

Borazine, valence isomer of inorganic benzene, is nowadays a well-known precursor for ceramic materials. Since its first synthesis in 1926 by Stock and Pohland[1] much progress has been made both in the synthesis and application field[2] of this substrate owning to its features that differ from those of benzene. While borazine is isoelectronic with benzene, it is less aromatic and has a higher HOMO-LUMO bang gap (6.2 eV vs 6.0 eV for benzene). Despite the progress made to date, borazine synthesis remains a challenge for scientists. Regarding *B*-aryl substituted borazines, only few synthetic protocols are available. In 2005 Nöth and Troll[3] afforded to synthesize 2,4,6-Triphenylborazine in 98% yield after a 10-day reaction between $PhBCl_2$ and HMDS at 55°C. Successively, Engels and Helten[4] attempted the synthesis of *B,B',B"*-trimesityl-*N,N',N"*-trimethyl borazine but they could obtain the product only in traces after 14 days.

Keeping in mind these challenges, we developed a new synthetic protocol to access *B,B',B"*-substituted borazines. In this context greener, easier to handle and more accessible boronic esters are used instead of harmful boron halides. Moreover, by combining the Lewis acid-catalysed protocol with the known advantages of Microwave Assisted Organic Synthesis, we could synthesize a variety of *B*-substituted borazines in higher yields in 1h while reducing the quantity of waste generated.

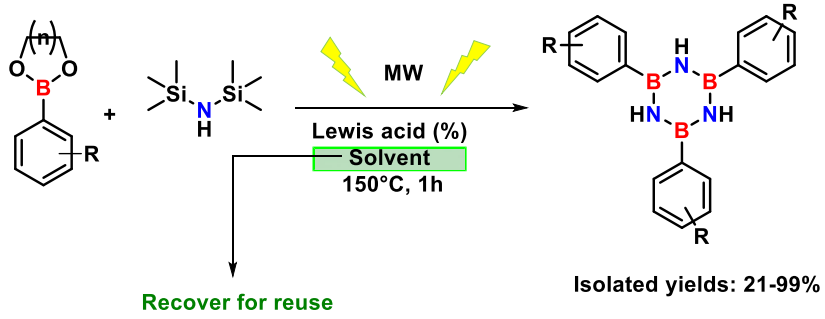

Figure 1: Microwave assisted synthesis of *B*-substituted borazines.

Carbon nanomaterials are promising adsorbents for the removal of organic pollutants from wastewater due to their nanometer size, high surface-to-volume ratio as well as possible chemical modification of the surface.[1] The introduction of selected functional groups through surface functionalization can in principle allow the dispersion in water and establish specific interactions with the pollutant, thus enhancing the adsorption rate and enabling a regeneration strategy. Here we report on a derivative of multi-walled carbon nanotubes (MWCNT) bearing benzenesulfonate groups (MWCNT-S) for the adsorption of methylene blue dye (MB).[2]

MWCNT-S was synthesized through diazotization reaction and characterized with IR, TGA, TEM, XPS and DLS measurements. The obtained material demonstrated to have more than double adsorption capacity and significantly higher adsorption rate than that of the pristine insoluble MWCNT. Surface functionalization ensured the dispersibility of the derivative in water, providing more available surface area, and the possibility of electrostatic interactions between the cationic MB and the anionic sulfonate groups (Figure 1).

Additionally, the reversibility of ionic interactions disclosed the possibility to release the adsorbed cationic pollutant through competition with salts, not only regenerating the adsorbent, but also recovering the dye.

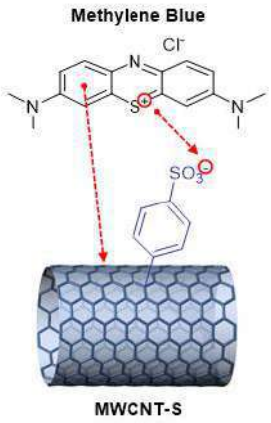

Figure 1: Schematic representation of interactions between MWCNT-S and MB during adsorption.

ALLENAMIDES: A POWERFUL SUBSTRATE FOR THE VISIBLE- LIGHT DEAROMATIZATION OF SIMPLE AROMATICS

M. Chiminelli[a], G. Scarica[a], G. Maestri[a]

[a] *Department of Chemistry, Life Sciences and Environmental Sustainability, University of Parma, Parco Area delle Scienze 17/A, 43124 - Parma, Italy*
maurizio.chiminelli@unipr.it

The extreme development of reactions between sp2 carbons has generated a bias in modern chemistry: the dependence of flatness[1]. In this scenario, dearomatization reactions are extremely useful[2].

We found out that allenamides can be sensitized in presence of visible light[3]. When **R** is a **benzyl** or **naphthyl**, we achieved a dearomative 1,4 para-cycloaddition obtaining a [2.2.2] bicyclooctene(diene)[4]. By tuning the **R** group, we developed two intermolecular dearomatizations[5]. If the amide is substituted with an **alkyl** moiety, a para-cycloaddition on naphthalene occurs. On the contrary, when **R** is an **allyl** group, we got a very complex product with the formation of four new C-C bonds in one step.

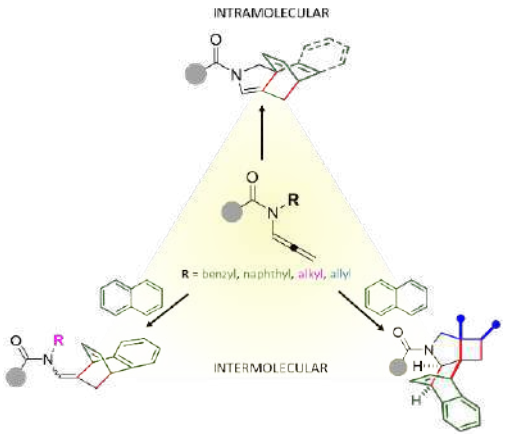

Figure 1: dearomatizations unlocked with allenamides.

Allenamides have therefore proven to be an excellent substrate to allow challenging synthetic transformations, with extremely mild conditions, cheap setups and complete atom economy.

SUSTAINABLE SYNTHESIS OF TACRINE AND ANALOGUES FOR ALZHEIMER'S DISEASE IN DEEP EUTECTIC SOLVENTS: A GREEN APPROACH

L. Cicco, F. M. Perna, V. Capriati, P. Vitale

Dipartimento di Farmacia-Scienze del Farmaco, Università di Bari Aldo Moro, Consorzio C.I.N.M.P.I.S, Via E. Orabona 4, I-70125 Bari, Italy
luciana.cicco@uniba.it

N-heterocyclic compounds exhibit diverse pharmacological properties and serve as constituents of many biologically important molecules, including vitamins, nucleic acids, pharmaceuticals, antibiotics, and agrochemicals.[1] Traditionally, the preparation of *N*-heterocyclic compounds relies on energy-intensive conditions with long reaction times (16–48 h), toxic volatile organic compounds (e.g., $POCl_3$, toluene), and laborious work-up procedures based on volatile organic compounds (VOCs) (e.g., $CHCl_3$, Et_2O, MeOH).[2] Unfortunately, these solvents significantly contribute to the environmental impact of chemical industries and laboratories, resulting in substantial waste generation.[3] A promising solution to address these sustainability concerns lies in the adoption of Deep Eutectic Solvents (DESs), a new class of environmentally friendly solvents.[4] Over the last decade, we have explored valuable sustainable methodologies for the synthesis of heterocycles with anti-inflammatory or antiproliferative properties, such as functionalized triazoles,[5] pyrimidines, imidazoles,[6] and tetrahydropyran derivatives.[7]

In this communication, we introduce a green synthetic protocol for the synthesis of tacrine and analogues, which are utilized in the treatment of neurological disorders, achieving yields of 90–95%. We employ Type I and IV Lewis Acid Lewis Acid DESs (LADESs) as solvent and catalyst (**Figure 1**). Quantitative metrics confirm the eco-friendliness of these novel approaches.[8]

marco.colella@uniba.it

Approximately 37% of marketed drugs contain at least one hydroxyl group in their structure. The introduction of a single hydroxyl group can dramatically influence the drug−receptor binding affinity through the creation of an extensive hydrogen bond network.[1] Moreover, the -OH group can serve as a handle for further derivatizations. In the polar domain, hydroxyalkylations can be accomplished via different reaction pathways. However, retrosynthetically, the possibility to obtain γ-hydroxy substituted derivatives is precluded from polar mechanisms due to a polarity mismatch. α-hydroxyalkyl radicals have emerged as suitable intermediates to promote radical hydroxyalkylations.[2] Despite extensive research into the chemistry of ketyl radicals, we hypothesised that a more direct approach to accessing these intermediates was feasible using readily available feedstocks. In this context, the prospect of utilizing α-hydroxy acids (AHAs) as readily available linchpins for radical hydroxyalkylations seemed particularly promising. In this communication, we demonstrate AHAs can serve as a platform to deliver ketyl radicals via visible light-mediated oxidative CO_2-extrusion. In particular, we developed a photoredox-based γ-hydroxyalkylation via the coupling of α-hydroxy radicals with unsaturated acceptors. Furthermore, flow technology facilitates the scaling of this photochemical methodology.[3,4]

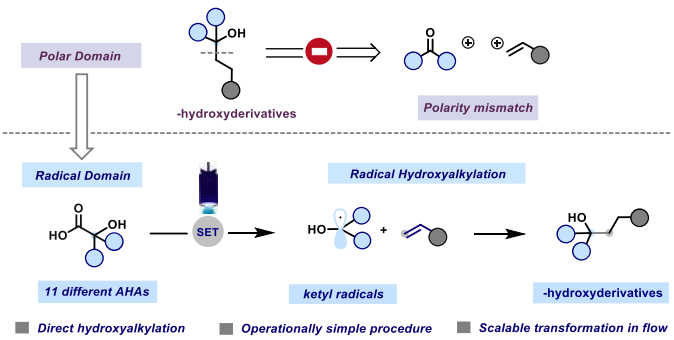

Figure 1: Photoredox hydroxyalkylation leveraging ketyl radicals generated from AHAs.

Recently, dye-sensitized solar cells (DSSCs) have emerged as the technology of choice for indoor applications and Internet of Things (IoT) devices.[1,2] In this context, extensive research has been carried out to design novel organic dyes whose absorption properties match a variety of artificial light emissions at different intensities.[3,4] Nevertheless, this process is often costly and time-consuming. To address this issue, we have combined Machine Learning (ML) and Density Functional Theory (DFT) methods to accelerate the discovery of potentially novel organic dyes with D-π-A architecture for indoor DSSCs. In particular, a two-stage screening approach has been developed by predicting the power conversion efficiency (PCE) of the dye candidates under different light sources and intensities. Additionally, the evaluation of the synthetic accessibility (SAscore) of the dye candidates has been assessed. Our findings demonstrate that the integration of ML and DFT methods offers an effective way to accelerate the discovery of organic dyes for indoor DSSCs, helping to address the growing demand for sustainable power sources for IoT devices.

In 2022, the FDA and EMA have approved 37 and 41 New Chemical Entities (NCE), respectively. Among them, small molecules are still apical representing more than 50% of the recently approved entities.[1] Typically, small molecule drugs are constructed around aromatic core architectures even if it is well established how the three-dimensional topology provided by aliphatic motifs is strongly associated with improved pharmacological properties.[2] In this scenario, heterocycles are one of the most widespread moieties within pharmaceutical small molecule structures and the interest in the functionalization with C(sp^3)−C(sp^3) bond is even more prominent.[3] In the last decades, few new methodologies have been introduced for the α-alkyl functionalization of heterocycles, which are often characterized by the use of particular conditions and/or reagents.[4] For this reason, we developed a simple and strong methodology using easily accessible alkyl-M reagents for the α-functionalization of bulky heterocycles. Starting from a common motif based on a cyclic α-amino acid structure through an oxidation step an aminoacetal intermediate is obtained and converted to the corresponding α-alkyl heterocycle.

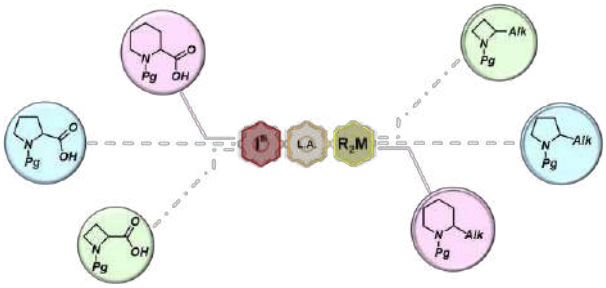

Figure 1: Schematic representation of the α-alkyl heterocyclic functionalization.

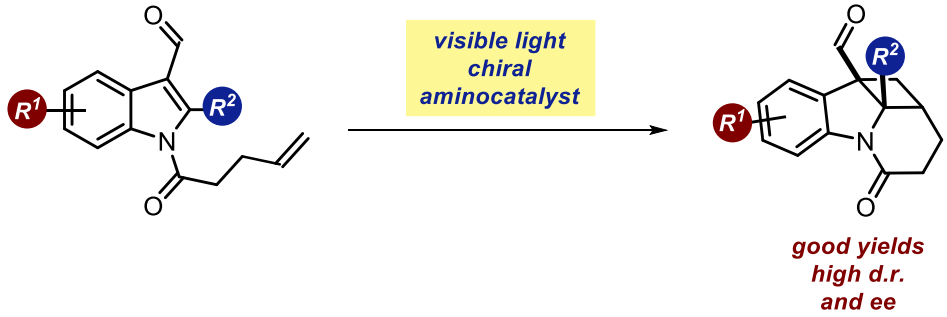
Aminocatalytic enantioselective [2 + 2] dearomative photocycloaddition for the synthesis of indoline polycyclic scaffolds

V. Corti,[a] G. Simionato,[a] L. Dell'Amico,[a]

[a] *Department of Chemical Sciences, University of Padova, Via Francesco Marzolo 1, 35122, Padova, Italy.*

The direct transformation of readily available aromatic feedstocks into structurally diverse three-dimensional molecules makes catalytic asymmetric dearomatization (CADA) reactions of broad interest.[1] Indeed, they provide a sustainable and straightforward route to medicinally relevant archetypes. However, the inherent difficulty of the disruption of aromaticity demands a large energy input during the dearomatization process, which could be incompatible with the typical conditions required by asymmetric catalysis. One promising approach to overcome this issue is the investigation of the excited-state reactivity of (hetero)arenes, which may display different reactivity patterns compared to the original ground-state ones.



Scheme 1: Aminocatalytic enantioselective [2 + 2] dearomative photocycloaddition of indole derivatives.

In this contribution, the successful combination of asymmetric aminocatalysis[2] with the direct activation of visible light (or the use of a photocatalyst)[3] to develop an interesting catalytic asymmetric [2 + 2] dearomative photocycloaddition of the indole core[4] is presented. This methodology relies on the excited state reactivity of transiently generated organocatalytic intermediates, thus enabling the construction of optically active polycyclic products in high levels of yield and stereoselectivity.

The Organic Fraction of Municipal Solid Wastes (OFMSW) can play a key role in the frame of Circular Economy, having great potential as a renewable energy source of biofuel. OFMSW is mainly composed of carbohydrates (50%) and lipids (13%) that are both valuable for the production of bioethanol and biodiesel, respectively.[1] Biofuels have recently gained attention as a sustainable alternative to fossil fuels, allowing to overcome the current environmental issue related to the depletion of raw materials.[2] Moreover, biofuels have higher biodegradation rates, low toxicity and no sulphur content with respect to fossil fuels.[3] Their production from OFMSW can also overcome the problem related to soil and water consumption due to the cultivation of vegetable biofuel sources. Moreover, it can contribute to reduce municipal waste disposal, favouring recycling processes.[4] Indeed, the largest part of OFMSW is disposed at landfills causing environmental and human issues.[5] Here we report an innovative method of biofuel production from OFMSW, based on the use of supercritical carbon dioxide (sc-CO_2) as a green solvent for lipid oils extraction and subsequent conversion into fatty acid methyl esters (FAMEs), suitable as biodiesel. A systematic study, via Central Composite Design (CCD) of Response Surface Methodology (RSM), was performed to identify the optimal operating conditions leading to maximum extraction yields. In particular, the effects of extraction temperature, pressure and supercritical CO_2 flow rate were investigated in the ranges 40-70°C, 150-450 bar and 5-10 l/min, respectively. The obtained FAME mixtures are mainly composed of saturated and unsaturated C10-C18 alkyl chains, being promising for applications as biodiesel.

Double green strategy for the oxidative functionalization of privileged natural scaffolds

E. De Marchi[a], L. Botta[a], C. Zippilli[a], B. M. Bizzarri[a], R. Saladino[a]

[a]*Department of Biological and Ecological Sciences, University of Tuscia, 01100 Viterbo, Italy*
elisa.demarchi@unitus.it

There is an increasing need for ecologically friendly procedures in the chemical and pharmaceutical industries. In this context, photocatalytic generated singlet oxygen ($^1O_2$) has attracted a great interest. Singlet oxygen is a potent and green oxidant for the functionalization of natural organic compounds in order to obtain potentially active derivatives. Here we report a double green strategy for the oxidative functionalization of estrogens[1], stilbenes and coumarins[2] in a two-liquid-phase system composed by buffer and eco-certified 2-methyltetrahydrofuran (2-MeTHF) in the presence of meso-tetraphenyl porphyrin (meso-TPP) as photosensitizer. Depending on the experimental conditions, $^1O_2$ can directly functionalize the selected substrate by [2+2] and [4+2] cycloaddition with high efficiency and rate constants, or in alternative, it can contribute to the activation of horseradish peroxidase (HRP) by selective formation of the hydroperoxide of 2-MeTHF. In this latter case, the selective insertion of $^1O_2$ in the 2-MeTHF tertiary C-H bond was operative, avoiding enzyme inactivation due to excess of H_2O_2, as well as the formation of undesirable and low selective radical species[2,3]. These procedures were effective for the chemical space analysis and scaffold morphing of estrogens, stilbenes and coumarins, yielding bioactive compounds such as natural bicoumarins identified from pharmacologically active extracts of *Erycibe obtusifolia Benth* (Convolvulaceae)[4].

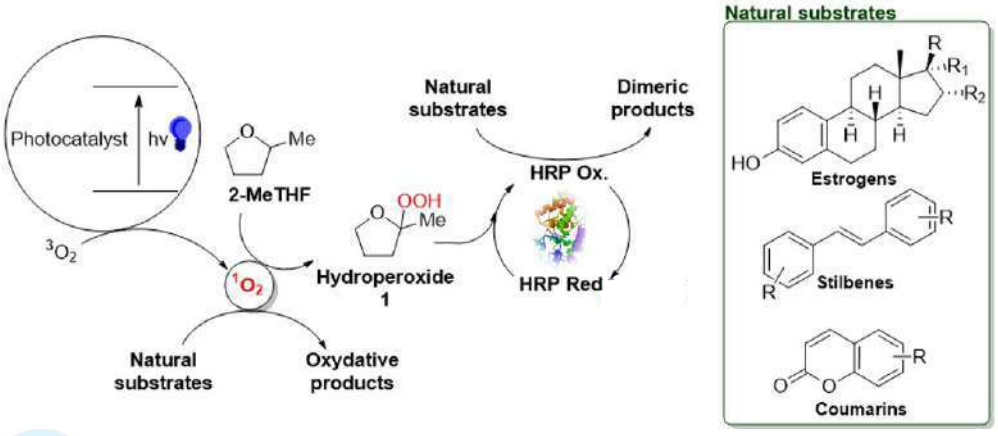

Figure 1: general scheme of the double green strategy for the oxidative functionalization of privileged natural scaffolds.

Exploring the potential of NADPH-dependent Imine Reductases in non-conventional solvents for enantioselective biocatalysis

Federica De Nardi,[a] Francesca Paradisi,[b] Cristina Prandi[a]

[a]Dipartimento di Chimica, Università di Torino, via P. Giuria 7, 10125 Torino, Italy, [b] Department of Chemistry, Biochemistry and Pharmaceutical Sciences, University of Bern, Freiestrasse 3, CH3012, Bern, Switzerland
federica.denardi@unito.it

Biocatalysis has seen a growing adoption in both academic and industrial domains in recent years. Enzymes offer the possibility to obtain high ratios of chemo-, stereo- and enantioselectivities in chemical transformations using mild reaction conditions and without the use of polluting reagents and solvents.[1] Moreover, they can be easily produced by means of a microbial host, also in large quantities. Chiral amines are key intermediates in the synthesis of several biological active compounds and biocatalysis has emerged as an efficient method for their preparation. In this report, we propose the use of NADPH-dependent Imine Reductases (IREDs)[2] from different organisms to perform the enantioselective reduction of cyclic imines and the reductive amination of simple ketones and amines. These enzymes were selected and produced in the form of lyophilized cell extracts, avoiding expensive enzyme purifications. We are also interested on the use of non-conventional solvents applied to chemical transformation and biocatalysis.[3] Indeed, we envisaged the possibility of using the produced IREDs in non-conventional systems consisting of glycerol and Deep Eutectic Solvents (DES) as additives. Our findings in terms of enantioselectivity, substrate scope and applicability will be presented.

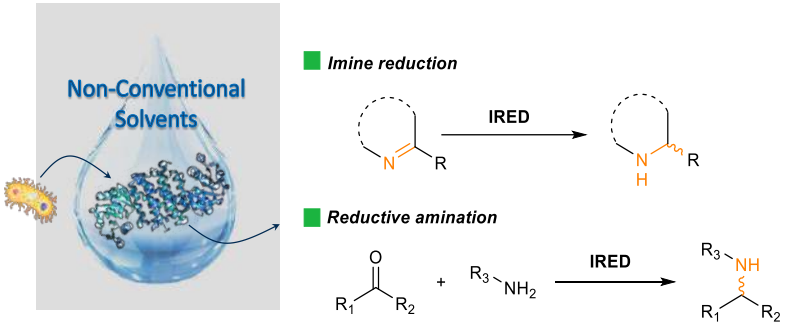

Figure 1: Chiral amines synthesis by means of Imine Reductases in non-conventional solvents.

The introduction of fluorine atoms into organic molecules often induces significant changes in their chemical and biological properties. Consequently, organofluorine compounds have gained widespread methods for their synthesis and new applications in pharmaceuticals, agrochemicals, and advanced materials.[1] Compared to direct C–F bond formation or nucleophilic introduction of a fluoroalkyl unit,[2,3] the selective activation and/or functionalization of the chemically robust C–F bond have emerged as intriguing methods for manipulating fluorine-containing compounds.[4] Recently, we have identified that a pre-installed bromodifluoromethyl group can function as a C1 and F1 synthon through selective multiple cleavages and atom recombination under basic conditions and in the presence of amines, facilitating the synthesis of a diverse range of valuable N-containing compounds such as α-fluoroamides and acylfluorides. This discovery introduces an innovative and promising platform for the transformation of halodifluoromethyl compounds.

Modular and Regioselective C–H Functionalization of Electron-rich Azole Nuclei

A. Del Vecchio,[a] E. Rosadoni,[a] C. Campinoti,[a] M. Lessi,[a] F. Bellina,[a]

[a] *Department of Chemistry and Industrial Chemistry, University of Pisa, Via Moruzzi 13, 56124 Pisa, Italy*
antonio.delvecchio@unipi.it

Heterocyclic compounds are key structural frameworks whose variety covers applications in disparate fields of modern organic, medicinal, crop and material chemistry.[1] In recent years, many efforts were oriented on the late-Stage Functionalization (LSF) of five-membered electron-rich azoles, aiming for the introduction of a desired moiety in a selective fashion, possibly *via* single step, at the end of a synthetic process.[2] In this context, radical chemistry and transition-metal catalyzed C–H activation played a pivotal role in the rising arena of LSF.[3] Within the framework of our research program on the C–H functionalization of electron-rich nuclei,[4] we report on a series of transition-metal catalyzed, mediated and radical transformations for the selective alkylation and arylation of pharmaceutically relevant imidazole-based scaffolds.[5-7] The methodologies include newly established radical pathways (Minisci-type reaction)[4] as well as transition-metal catalyzed C–H activation and transition-metal mediated direct and selective arylation of electron-rich azole nuclei for the modular LSF of key structures with applications in medicinal[6] and material chemistry (Organic Room Temperature Phosphorescent structures)[7] (Figure 1).

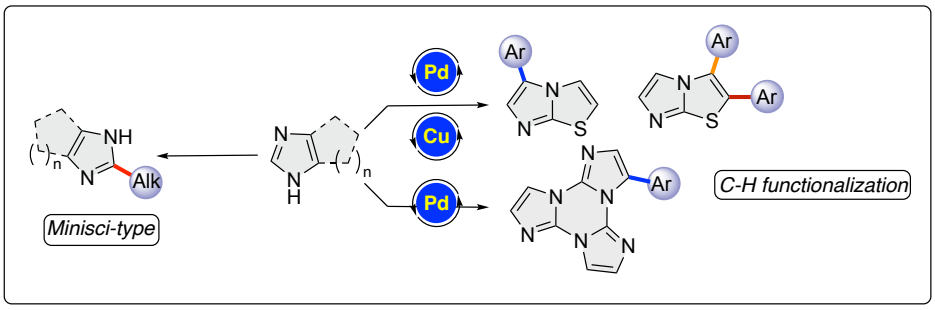

Figure 1: LSF of electron-rich azole nuclei: radical *vs* transition-metal catalyzed and mediated reactions.

Hydrodeoxygenation of phenols *via* hydrazone chemistry: a valuable solution to arene derivatives

B. Di Erasmo,[a,b] L. Vaccaro,[a] C.-J. Li [b]

benedetta.dierasmo@studenti.unipg.it

Throughout the years, phenols have been considered a byproduct of biomass processing due to the difficulty of oxygen removal. Crude biomass-oil, mainly composed of lignin components, contains a large amount of oxygenated compounds, which make it non compatible with the actual oil industry.[1] Efforts exploiting molecular hydrogen have been made to remove hydroxyl group in lignin-derived phenolic compounds to make them appealing for the chemical industry.[2] However, these processes rely on high pressures, elevated temperatures, and expensive catalysts, presenting challenges in terms of safety, hydrogen storage, and cost-effectiveness. This highlights the urgent demand for sustainable alternatives with safer and more accessible reaction conditions.

Our long-time interest in Green Chemistry played a key role in driving us to the formulation of a more sustainable protocol for the hydrodeoxygenation of phenols to arene derivatives that does not involve molecular hydrogen. To pursue this objective, we initiated our research from the work on the conversion of phenols to primary anilines *via* hydrazone chemistry.[3] Instead of promoting the reductive cleavage of the N–N bond of the hydrazone to form the C(Ar)–NH_2 bond, we focused on promoting a C–N bond cleavage to form the C(Ar)–H bond. To do this, we employed an acid additive (trifluoroacetic acid), hydrazine and heterogeneous Pd/C. This innovative method aims to convert phenols into valuable aromatic products while bypassing the challenges associated with hydrogen gas, such as safety risks and storage issues.

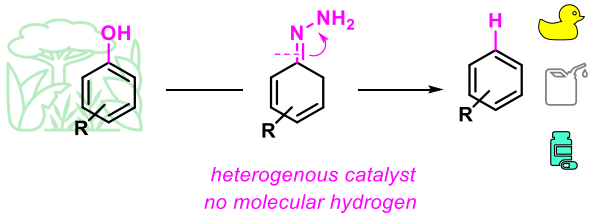

Figure 1: Hydrodeoxygenation of phenols to arene derivatives without molecular hydrogen.

Recoverable and recyclable heterogeneous $Y(OTf)_3$ for Michael and Diels-Alder additions

E. Donato,[a] V. Chiroli,[a] A. Puglisi,[a] M. Benaglia[a]

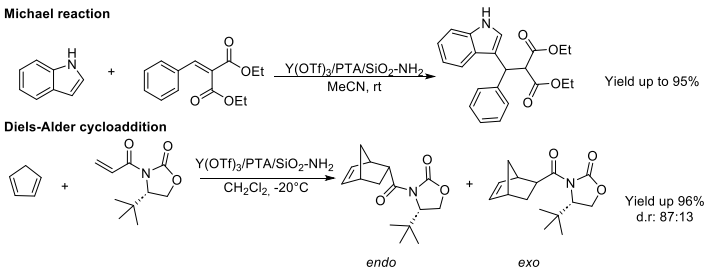
[a]*Università degli Studi di Milano, Via C. Golgi 19, Milan*
Emanuela.donato@unimi.it

Heterogeneous catalysts have many advantages over homogeneous ones, such as easier catalyst separation, recovery, regeneration, and reuse, even though the latter have higher selectivity and active sites accessibility.

In the present study the attention was focused on $Y(OTf)_3$. Yttrium is a Rare Earth Element (REE), and its triflate functions as a Lewis acid in promoting a variety of reactions including Michael addition[1,2] and Diels-Alder cycloaddition[1,2]. In this work we decided to immobilize $Y(OTf)_3$ through a noncovalent interaction between $Y(OTf)_3$ and phosphotungstic acid (PTA) that is anchored onto amine functionalized silica nanoparticles. The PTA was found to be crucial for the preparation and the activity of the catalysts[3].

Figure 1: Design and general procedure for silica-supported yttrium catalyst.

We developed an example of supported Yttrium catalyst, which demonstrated excellent activity in the Michael addition between different benzylidene malonates and indoles[1] but also in the Diels-Alder cycloaddition between cyclopentadiene and (4*S*)-3-acryloyl-4-tert-butiloxazolidin-2-one[1,2]. The catalyst was tested in batch and in flow conditions.



Scheme 1: Michael addition and Diels-Alder cycloaddition.

Moreover, Y_2O_3 recovered from E-waste, such as fluorescent lamps, was supported, converted in triflate salt and successfully used as catalyst in the Michael and Diels-Alder cycloaddition.

The Black-Box: Investigating the Key Pathways for the Reduction of Pd^{II} to Pd^{0}

T. Fantoni,[a] C. Palladino,[a] R. Grigolato,[a] L. Ferrazzano,[a] A. Tolomelli,[a] W. Cabri[a]

[a]*Department of Chemistry "Giacomo Ciamician", Via Gobetti 85, 40129 Bologna, Italy*
tommaso.fantoni3@unibo.it

Palladium cross-coupling reactions represent among the most versatile and useful tools in organic synthesis for the carbon-carbon (C-C) bond formation.[1] Although the general mechanism of palladium cross-coupling reactions is well known, the first step, the formation of Pd^{0} active catalyst from Pd^{II} pre-catalyst, is still a matter of investigation for several research groups.[2]

A rapid and complete pre-catalyst reduction is critical for an efficient process. Understanding exactly the mechanisms allows the possibility to lower the amount of catalyst and avoid an excess of phosphine to be used. In addition, it enhances the overall efficiency of the process, leading to higher yields of the desired product and reducing the formation of unwanted by-products.[3,4]

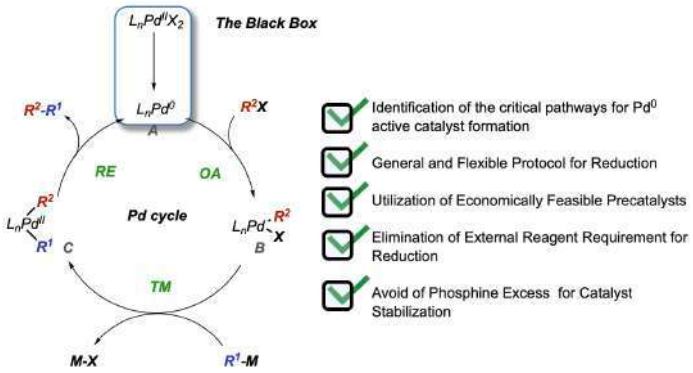

Figure 1: The Palladium Reduction Black Box

To clarify the reduction mechanism, stoichiometric and catalytic reactions were carried out and monitored by $^{31}P/^{1}H$ NMR spectroscopy. We have studied the reduction starting from the most common and cost-effective pre-catalysts such as $PdCl_2$ and $Pd(OAc)_2$, employing various types of ligands. Our focus has been on identifying the most efficient reduction mechanisms utilizing bases, phosphines, and solvents, enabling us to create a versatile library of pre-catalysts and phosphines for tailored reactions. This approach not only ensures superior performance but also avoids the use of expensive Pd^{0} or palladacycles, thereby enhancing the flexibility and cost-effectiveness of the processes.

Development of Reusable Electrolytes for the Waste-Minimized Synthesis of 2-arylbenzoxazoles

F. Ferlin,[a*] F. Valentini,[a] F. Campana,[a] L. Vaccaro [a*]

[a]*Laboratory of Green S.O.C. – Dipartimento di Chimica, Biologia e Biotecnologie, Università degli Studi di Perugia, Via Elce di Sotto 8, 06123 – Perugia – Italy francesco.ferlin@unipg.it*

Using a current of electrons to replace redox reagents presents a promising route for sustainable organic synthesis.[1] However, many sustainability challenges persist in this sector, and the effectiveness of electrosynthesis depends on the quantities of electrolytes used, influencing, for example, electron transfer and current density.[2] Equimolar amounts of supporting electrolytes are needed, leading to a significant generation of waste. These electrolytes, typically non-recoverable, require separation from the final reaction mixture, further increasing waste production.[3]

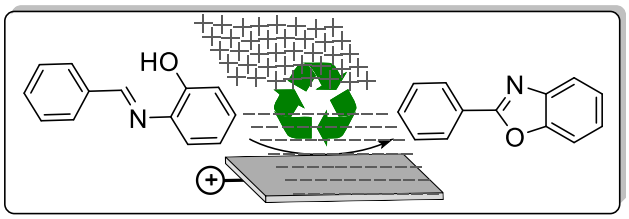

Figure 1: Reusable electrolytes in the synthesis of 2-arylbenzoxazoles.

To find a solution to this critical sustainability challenge for electrosynthesis, we report here our commitment to developing an easily recoverable supporting electrolyte. We representatively applied our study to the synthesis of 2-arylbenzoxazoles under batch and flow conditions. Importantly, the electrochemical flow cell also allowed us to improve current efficiency and overall performance. With a comprehensive analysis of green parameters, one can also quantify how our strategy is very promising and a valuable approach to minimize the quantity and quality of waste produced in organic electrosynthesis.

annarita.flemma@uniba.it

In the last century, intensive human activities changed the equilibria of our planet, mainly by the increase of CO_2 concentration and by the introduction of persistent pollutants in natural environments. Among all the available remediation technologies, bioremediation seems to be the most attractive, thanks to its eco-compatibility and efficacy. Several organisms (or parts of them, such as enzymes) could be involved in bioremediation activities. In this context, diatoms, a class of eukaryotic microalgae, are gaining increasing interest, thanks to their presence in quite all aqueous habitat and their adaptability to extreme conditions. Their main feature is the ability to produce a nanostructured biosilica shell, named frustule. Frustules, together with the exopolysaccharides (EPS) external matrix, represent physical and chemical structures for the interaction and sequestration of pollutants in natural environments[1]. Our research group has recently investigated the ability of living diatoms to bioremediate contaminated seawater from heavy metals[2] and persistent organic pollutants[3]. We tested both the intrinsic bioremediation property of the microalgae towards pollutants and the possibility of enhancing this ability via the direct synthesis of a biocompatible coating of polydopamine (PDA) around living cells. Our studies, focused on the diatom model organism *Phaeodactylum tricornutum*, showed bioremediation activities in seawater model solutions against As, Cr, Pb, Cu, Zn and Sn, and a remediation activity against several biphenyls up to 47% for bare *P. tricornutum* and up to 97% for PDA-coated microalgae.

Efficient Synthesis of 1,4,7-Triazamacrocycle Derivatives for Functionalized Polymers

D. Gentili, F. Catalini, C. Cimarelli, S. Gabrielli, G. Lupidi, G. Pastore, F. Stella, E. Marcantoni

ChIP – Chemistry Interdisciplinary Project, Unicam Research Centre, University of Camerino, Via Madonna delle Carceri SNC, 62032, Camerino (MC) - Italy
dario.gentili@unicam.it

Synthetic chemists, inspired by polyazamacrocycles present in nature (such as porphyrin and corrine), have worked on the development of numerous organic molecules able to chelate a wide variety of metal ions as natural analogues make.[1] The presence of nitrogen atoms in the structure of these compounds makes them very incline to associate with metal cations, forming very high stable complexes due to thermodynamic and kinetic effects.[2.]

In particular, 1,4,7-triazacyclononane (TACN) and its derivatives, that are isoelectronic to cyclopentadiene, compose an essential class of aza-macrocycles since they can stabilize high oxidation states of different metal cores.[3] Our research group, starting from the results obtained on the synthesis of 1,4,7-trimethyl-1,4,7-triazacyclonane, used as hardener of alkyd emulsion for painting, has focused their effort to synthesize a 1,4,7-triazacyclononane functionalized with a long aliphatic chain with a terminal diol. These vital structure features will lead to the possible development of a new class of functionalized polymer[4] that could be able to chelate metal present in wastewaters and/or develop a new class of heterogeneous catalyst.

sabrina.giordano@unina.it

Ultrashort aromatic peptide-based multicomponent hydrogels (HGs) have been used as biocompatible matrix for tissue engineering, drug delivery, and biosensor production. One of the most explored hydrogelators is the low molecular-weight Fmoc-FF (N^{α}-fluorenylmethoxycarbonyl-diphenylalanine) homodimer because of its ability to gel under physiological conditions such as of pH and ionic strength.[1] Additional molecules, such as proteins, chemical compounds, or different peptide sequences, can be included into the Fmoc-FF hydrogel to create unique hydrogels with enhanced mechanical and functional characteristics. From this standpoint, a collection of unique multicomponent hydrogels based on Fmoc-FF that were doped with a range of concentrations of the tripeptide Fmoc-FFX, where X can be Cys, Ser, or Thr have been examined.[2] Among these tripeptides, Fmoc-FFC was chosen as it generates hydrogels functionalized with thiol groups, which can be post-derived chemically with desirable bioactive compounds, such as biosensing, therapeutic or diagnostic agents. One of the most valuable nucleic acid mimetics is Peptide Nucleic Acid (PNA).[3] Hybrid hydrogels are non-toxic and can serve as scaffolds for various applications in biotechnology, such as for controlled drug release in the presence of a reducing environment, such as the tumour microenvironment.[4] In this regard, the functionalization of mixed (Cys)HG at different molar ratios compared to Fmoc-FF (1/5, 1/10 and 1/20, respectively) with (Cys)PNA molecules *via* specific and non-specific interactions is shown here, followed by the supramolecular characterization through several techniques, such as HPLC, MS, CD, FT-IR, NMR and microscopy.

demetra.giuri2@unibo.it

Low-Molecular-Weight Gelators (LMWGs) are a versatile class of compounds able to self-assemble into supramolecular materials thanks to non-covalent interactions. Peptide derivatives, especially those containing aromatic amino acids, such as Phenylalanine and Tyrosine, are ideal candidates as LMWGs because they are biocompatible, biodegradable, and promote the assembly in a variety of conditions.[1]

In our group, we focused our attention on L-Dopa (3,4-dihydroxyphenylalanine), which can be functionalized also on the catechol moiety. We reported a robust gelator, Boc-L-Dopa(Bn)$_2$-OH, able to form strong gels under several conditions and to trap different materials, such as crystals, fragrances and antioxidants. We have recently designed a small library of amphiphilic Dopa-based gelators, substituting the Boc group with long chain fatty acids (lauric, palmitic and azelaic acid) to introduce additional Van der Waals interactions, contributing to the self-assembly process.[2] The structure of the new gelators resembles that of surfactants and allows self-assembly also in basic aqueous solutions, a property which highly affects the outcome and features of the final gel, obtained by lowering the pH. The relationship between the gelator structure, the self-assembly and the gel properties was deeply investigated by means of EDC, FT-IR, XRD, SEM and rheology, demonstrating that the propensity of these compounds to form β-sheets is correlated to the final properties of the gels.

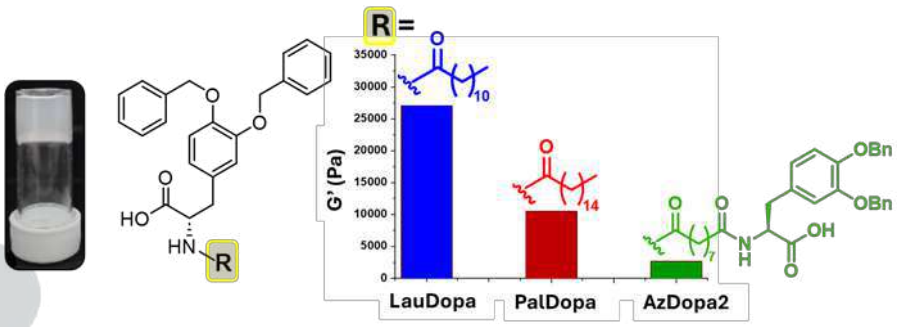

Figure 1: Schematic representation of the work, with the structures and stiffness of the gelators studied.

Engineering Photocatalytic Protocells for Artificial Photosynthesis

T. Gobbato,[a] G. Errichiello,[a] F. Rigodanza,[a] D. Rosa-Gastaldo,[a] M. Bonchio[a]

[a]*Department of Chemical Sciences, University of Padova, Via Marzolo 1, Padova, Italy*
thomas.gobbato@unipd.it

Wireless artificial photosynthetic systems, a technology at the edge of the academic research in solar fuels, envision a machinery that mimic Nature to exploit sunlight energy to convert abundant resources, such as water and carbon dioxide, into high-added value products like H_2 or carbon derivatives (formic acid, methane) and O_2 without any external bias or circuitry.[1,2] In particular, in the design of a bio-inspired molecular-based photocatalytic artificial system, four fundamental components need to be considered: a photosensitiser (PS), a catalyst, an electron relay (ER) and a vesicle forming the reactor.[3]

PLANKT-ON project, part of the initiatives of the program of the European Innovation Council as Pathfinder Open 2022, inserts in this framework proposing coacervate vesicles as micro-compartmentalised protocells for artificial photosynthesis.[4]

Herein, we present the synthesis and characterization of protocells functionalized by the encapsulation of the artificial analogue of the natural Photosystem II (PSII), namely the artificial quantasome (QS).[5-7] Artificial quantasomes are an emerging class of supramolecular systems designed for photocatalytic water oxidation reaction. QS are based on the self-assembly of bis-cationic perylene bisimide derivatives, acting as antenna, and tetra-ruthenium deca-anionic polyoxometalate, being the water oxidation catalyst.[5-9] These two components readily self-assemble in water, exploiting the complementary electrostatic interactions, forming a hierarchical supramolecular system.[5-7] In this work, we focused on the functionalization of innovative photocatalytic reactors to design a photoactive protocell specifically engineered to achieve the light-induced water oxidation reaction.

Towards a Circular Future: Sustainable Strategies for Agri-Food Waste Valorization

G. Grillo,[a] G. Capaldi, [a] E. Calcio Gaudino,[a] G. Cravotto[a]

[a] *Department of Drug Science and Technology, University of Turin, Via P. Giuria 9, 10235 Turin*
giorgio.grillo@unito.it

Minimization of waste stands as a cardinal principle within the Circular Economy framework, striving to repurpose end-of-life products into valuable resources, thus fostering closed-loop systems within industrial systems. The proliferation of sustainability consciousness underscores an escalating focus on waste reduction and pollution mitigation. In particular, processing operations within the agri-food sector often yield by-products still rich in bioactive compounds, boasting significant nutritional benefits for human health and commercial value. Those enormous volumes of residues can serve as a source of high added-value molecules that can find applications in several fields, including functional foods, nutraceuticals, and cosmetics.[1] Innovative green methodologies typically entail reduced timeframes, energy expenditure, and solvent volumes compared to traditional processes. In recent years, attention has gravitated towards those pioneering extraction methodologies geared as an answer to the sustainability issues. Microwave-Assisted Extraction (MAE) stands out among such innovations, presenting process advantages together with enhanced extraction efficiencies and yields.[2]

The presented study investigates MAE in water to recover metabolites from Pomegranate Peels (PP), refining extraction parameters and energy consumption.[3] The total phenolics, anthocyanins, flavonoids, and tannin contents of the extract have been determined, alongside their antioxidant activity (356.35 mgGAE/gextr., 303.97 µgCy3G/gextr., 37.28 mgQE/gextr., 56.48 mgGAE/gextr., and 1.43 µmolTE/gextr., respectively). The research explores water recycling through nanofiltration (approx. 75% of water reuse), simultaneously achieving product concentration and significant energy savings. The overall sustainability of the protocol is assessed evaluating energy consumption (20.92 W/mgGAE) and main Green Metrics. Finally, the antimicrobial features of the PP extracts have been evaluated against Gram-positive and Gram-negative bacteria, as well as their antiproliferative activity towards human cancer cells (HeLa).

The collected information supports the proposed valorisation protocol as a green and sustainable approach to upcycle PP, achieving a final product with interesting biological features.

Although hydrogen is widely recognized for its promising improvements in clean energy applications, its still predominant supply from fossil fuels presents environmental challenges, also associated with H_2 storage and distribution issues. In light of this, there is a pressing need for efficient and sustainable hydrogen production, storage and use alternatives. Liquid organic hydrogen carriers (LOHCs) are emerging as promising candidates. Among them, formic acid stands out as a green hydrogen source derived from renewable feedstocks. In addition to serving as an energy carrier, biomass-derived formic acid has potential as a "on-demand" hydrogen source in chemical hydrogen transfer reactions (figure 1).[1,2] Additionally, hydrogenation processes in biomass upgrading, leading to high-value added products, have gained increased importance. Biomass, being natural, abundant, renewable, and carbon-neutral, offers a promising approach to replace fossil feedstock in producing chemicals, fuels, materials, and energy.[3,4] The design of high-performance durable and reusable catalysts is one of the key challenges in hydrogenation and dehydrogenation of FA. Here, we present a tailor-made water-tolerant heterogeneous catalytic system for advancing green hydrogen production and hydrogen transfer processes in aqueous medium.

Visible-light generation of aryl radicals from C-halogen bond in cross-coupling reactions

N. Intini, G. Quattrocchi, Prof. S. Rossi, Prof.ssa A. Puglisi, Prof. M. Benaglia

Dipartimento di Chimica, Università degli Studi di Milano, Via Camillo Golgi 19, 20133 Milano,
niccolo.intini@unimi.it

The generation of aryl radicals has been widely investigated during the last century for their synthetic utility. The typical generation methods involve the combination of aryl halides and an excess of radical initiator, such as AIBN or Bu_3SnH, or diazonium salts with strong metal-based reductants. These strategies have several problems related to low efficiency and vast by-product formation, and, for this reason, aryl radicals found low applicability in organic synthesis[1].

In the last decade, the development of photoredox catalysis led to a renaissance of aryl radicals, since using an efficient catalytic system it is possible to generate aryl radicals under mild conditions. Seminal papers reported the use of diazonium and iodonium salts as aryl radical precursors[1]. Aryl radicals find synthetic applications in two main classes of reactions: atom transfer (XAT) and radical addition[2].

In this work, we propose an innovative, more general and efficient photochemical method to perform cross-coupling reactions with an electronrich aromatic compound.

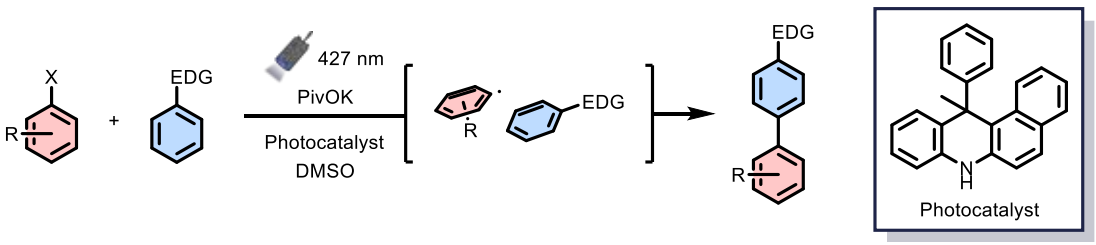

Figure 1: General scheme of the reaction.

Cross-coupling reactions are one of the most common classes of chemical transformations. The general approach to perform this reaction is well described in the literature and, generally, it requires the use of metals such as Copper, Nickel, or, more commonly, Palladium[3].

The reaction consists of the generation of an aryl radical by the reduction of a C-X bond by an organic photocatalyst in its excited state. This radical can then react with an electronrich species to form a new C-C bond.

alessandro.kovtun@isof.cnr.it

The "on-demand" capture and utilization of CO_2 is effectively realized with a readily accessible dual function organic composite. The covalent and controlled derivatization of graphene oxide (GO) surface with naturally occurring arginine led to a "smart" material capable of capturing (chemisorption) CO_2 from high-purity flue-gas as well as low-concentration streams (i. e. direct air capture) and concomitant chemical activation toward the incorporation into cyclic carbonates. The overall integrated CO_2 capture and conversion (ICCC) strategy has been fully elucidated mechanistically via dedicated computational, spectroscopic and thermal analyses.

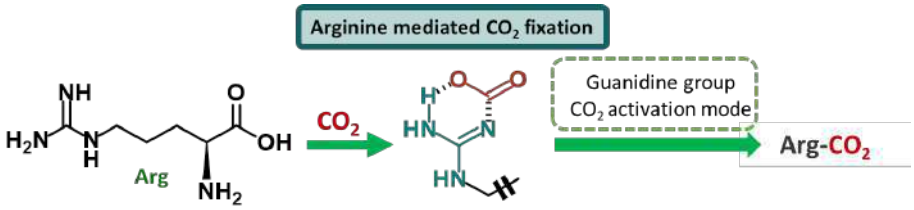

Figure 1: caption.

The in situ investigation of CO_2 chemisorption or physisorption on functionalized graphene oxide – or on a heterogeneous catalyst - usually requires the low temperature Solid State Nuclear Magnetic Resonance (ssNMR)[1], while in present work we were able to observe the chemical environment of chemisorbed CO_2 by using the Hi-Resolution X-Ray Photoelectron Spectroscopy via analysis of C 1s, N 1s and O 1s signals. The presence of guanidine group was fundamental for further development of Quantum Mechanics/Molecular Mechanics calculation on the reaction mechanism[2]. The role of XPS in heterogeneous catalysis on GO and functionalized GO is not limited to study the in situ chemistry of the reaction, but may also support the understanding of limits and issues present in carbocatalysis as a complementary technique to ssNMR[3].

Synthesis of Tetra-*ortho*-Methoxylated Azobenzene Photoswitches via Sequential Catalytic C−H Activation and Methoxylation

L. Lamelza,[a] A. Ruiz-Soriano,[b] E. Pizzamiglio,[b] X. Just-Baringo[b]

[a]*Sapienza University, Piazzale Aldo Moro 5, Rome*
[b]*Universitat de Barcelona, Gran Via de les Corts Catalanes 585, Barcelona*
lara.lamelza@uniroma1.it

In recent years, particular attention has been paid to the development of new strategies to counteract antibiotic resistance. One of these consists in limiting the release of active antibiotics into the environment: visible light can be used as a tool to modulate the activity of drugs.[1] Recently, Just Baringo et al. have demonstrated how the introduction of a photoswitch, the amino acid tetra-*ortho*-chloro-diethylene-azobenzene (CEBA), can allow control over the activity of tyrocidine A analogues using visible light. In particular, upon isomerization under red light, the *cis* form would become the major isomer and re-establish the biologically active secondary structure of the natural product whereas, upon exposure to other visible light wavelengths, the activity quickly turn-off.[2] Nevertheless, due to the electrophilic nature of the C-Cl bond, CEBA needs to be introduced at the end of the growing peptide in order to avoid the use of strongly nucleophilic bases used during solid-phase peptide synthesis (SPPS). For this reason, methoxy-azobenzenes represent a much more appealing alternative for SPPS as they can be isomerized at 650 nm (red light), like chlorine derivatives, but are not sensitive to SNAr. However, the synthesis is highly limited. The methods reported in the literature had extremely low yields and limitations in functionalization.[3,4] To overcome these restrictions, the aim of this research is to develop a new strategy for the methoxylation of azobenzenes that allows a wide range of functionalization and good yields. This objective was achieved through a two-step procedure: 1) synthesis of tetra-ortho-bromo-azobenzenes by C-H activation 2) cross-coupling of the brominated derivatives with methanol (Figure 1).

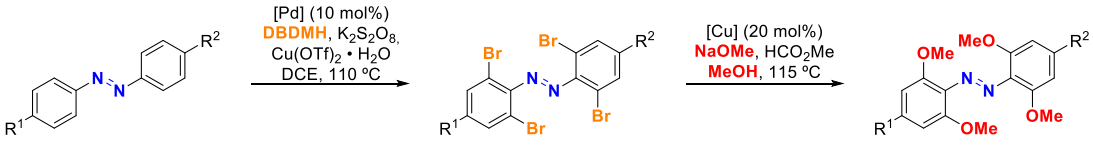

Figure 1: Synthesis of tetra-*ortho*-methoxyazobenzenes.

Theoretical study of the reaction mechanism and solvent effect in the reaction between $LiCH_2SiMe$ and N-benzoylpirrolydine

C. Meazzo,[a] F. De Nardi,[a] F. Lauria,[a] S. Ghinato, A. Maranzana,[a] C. Prandi,[a] M. Blangetti[a]

[a] *Dipartimento di Chimica, Università degli Studi di Torino, Via Pietro Giuria, 7, I-10125, Torino*
federica.lauria@unito.it

A theoretical investigation was conducted in conjunction with the department's organic chemistry laboratory to explore the conversion of non-activated amides to α,β-unsaturated ketones using $LiCH_2SiMe_3$.[1] This study employed two different solvents, THF and CPME, resulting in the formation of distinct products exhibiting high stereoselectivity (Figure 1). The primary objective of this study is to elucidate the reaction mechanism occurring in these solvents using Density Functional Theory calculations (M06-2X/def2-TZVP//M06-2X/def2-SVP). Given the propensity of lithium to form aggregates in solution[2], various model scenarios have been explored to represent the reagent, ranging from monomeric to dimeric structures, to capture the solvation effect on the complex. Dimeric structures were investigated using the two-layer ONIOM method. In addition to examining the reaction in THF and CPME, studies were carried out in water, as the reaction was experimentally quenched with water. This study underscores the significance of explicitly incorporating the solvent into calculations: substantial alterations in the topology of the potential energy and energetics were detected in the dimeric system (Figure 2) and when explicit solvent only (PCM) was used.

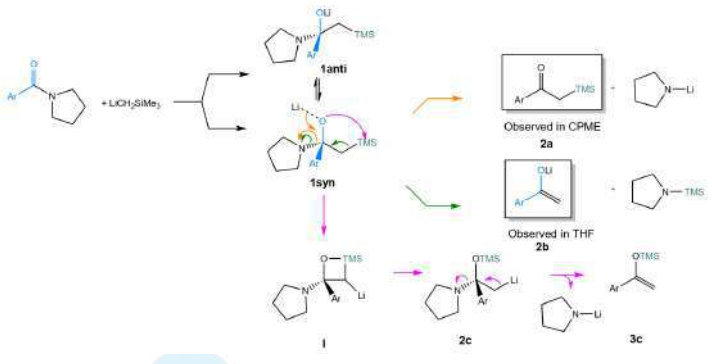

Figure 1: Reaction pathways for acyl nucleophilic substitution initiated by $LiCH_2SiMe_3$.

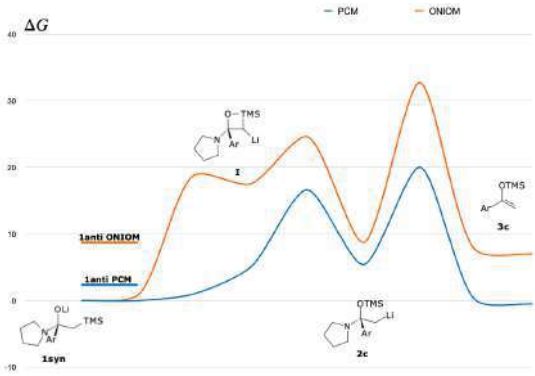

Figure 2: Differences in Gibbs free energy profiles for the same reaction pathway with two types of solvent simulations, expressed in kcal mol^{-1}.

Electrochemical approach for cyclization/bromination of unactivated alkenes

C. Loro, G. Broggini, S. Colombo

Università degli Studi dell'Insubria, Dipartimento di Scienza ed Alta Tecnologia, 22100, Como, Italy
camilla.loro@uninsubria.it

Various combinations of functional groups have been installed on alkenes through either intra/intra- or intra/intermolecular processes, resulting in differently functionalized heterocyclic systems. In organic synthesis, the electrosynthesis has emerged as a powerful and green tool to construct complex molecules without the use of stoichiometric amounts of hazardous oxidants or reductants.[1] Indeed, *in-situ* electro-generation of highly reactive species allows the use of safe reactants and provides a simplified approach. The development of sustainable electrochemical cascade reactions as efficient method to synthesize added-value molecules, possibly involving the formation of heterocyclic rings, is extremely intriguing. Our research group has been involved in the vicinal difunctionalization of multiple C-C bonds[2] and recently we undertook the study of electrochemical cascade cyclization/bromination reactions, focusing on the synthesis of directly functionalized heterocyclic systems by intra/intermolecular processes.

Pursuing the search for a new class of homonucleoside derivatives, an electrochemical palladium-catalyzed alkoxybromination was developed to access 2-bromomethyl morpholines (Figure 1, path A). Some examples of electrochemical alkoxybromination reactions are reported in the literature,[3] but analogous aminobromination procedures have been much less developed. In this context, due to the broad possibilities in brominated heterocycles functionalization, we planned palladium-catalyzed amination/bromination procedures in the presence of TBAB as electrolyte and bromine source (Figure 1, path B).

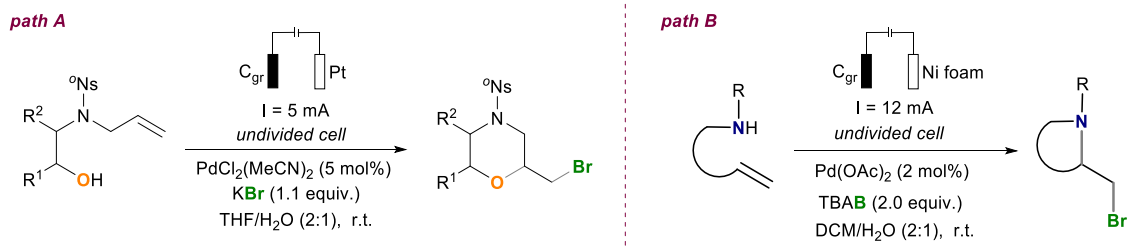

Figure 1: Electrosynthesis of bromomethyl-substituted heterocycles.

Optimization, scope, and mechanistic aspects will be discussed in the communication.

alice.maiocchi@unimi.it

Targeted Protein Degradation (TPD) is a revolutionary therapeutic concept that exploits cellular protein regulation systems to control protein degradation. In this context, PROteolysis TArgeting Chimeras (PROTACs) are heterobifunctional molecules able to interact with an over-expressed or misfolded Protein of Interest (POI) and an E3 ligase. Such constructs bind to both their targets and form a ternary POI-PROTAC-E3 ligase complex, where the POI is polyubiquitinated, freed from the ternary complex and driven to the proteasome for degradation.[1]

Our idea is to develop PROTACs targeting tubulin, an essential dimeric protein with a key role in cancer development and neurodegeneration.[2] The known tubulin binder maytansinol was selected as a POI ligand to build PROTAC-type molecules, as it is located on an exposed pocket of β-tubulin offering wider design possibilities. It has been rationally functionalized and coupled via click chemistry to chosen linkers bearing cereblon (CRBN)- or VHL- ligand as E3 ligase recruiters (Figure 1).

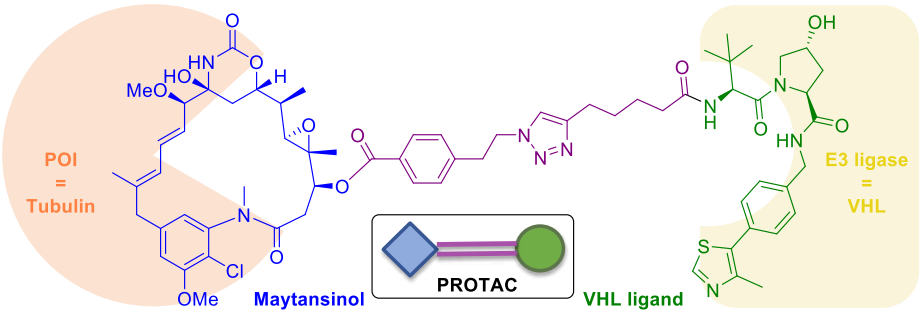

Figure 1. Chemical structure of maytansinol-based PROTAC targeting tubulin and VHL ligase.

The biophysical and structural characterization of four synthesized compounds was carried out, proving that such PROTACs can bind and recruit tubulin with high-resolution crystal structures. Additionally, it was confirmed that the compounds can bind to VHL and CRBN, respectively, with a crystal structure obtained in the case of VHL. The most significant achievement was the discovery of the capability of the four PROTACs to form the desired ternary complexes tubulin-PROTAC-E3 ligase, which is a groundbreaking discovery in chemically driving the conjugation of tubulin with a ligase.

Over the past ten years, the conjugation of bioactive substances to biocompatible carriers has proven to be a successful approach for the targeted delivery and controlled release of drugs. This strategy encompasses the covalent linkage of drugs to biological macromolecules thereby enhancing their solubility, stability, and pharmacokinetics while lowering toxicity and side effects.[1] Several biologically active molecules, including lipids, carbohydrates, aptamers, and antibodies, have been used as effective carriers to create novel molecular constructs for the treatment of various diseases. The drug of interest, also termed payload, can be directly linked to the carrier or it can be spaced by a properly designed linker. In both cases, once the bioconjugate has selectively engaged with its target, specific chemical or enzymatic stimuli induce the release of the payload, which is free to exert its pharmacological activity. In this context, we investigated the possibility for cholic acid (CA) and folic acid (FA) to function as carriers for different cytotoxic agents, thus obtaining small molecule-drug conjugate as selective anticancer agents. CA is a primary bile acid whose trafficking in the liver is finely regulated by intracellular lipid-binding proteins (ILBPs).[2] This acid has been directly linked to Mirin, an inhibitor of the DNA damage response processes, endowed with anticancer activity along with chemo- and radio-sensitising properties.[3] This new conjugate has been evaluated for its ability to bind ILBPs, and potentially to accumulate in the liver where, upon release of Mirin, it exerts its antitumor activity. Similarly, FA has been used for the creation of a novel prodrug involving an inhibitor of histone deacetylases (HDAC) as the payload. Folate receptors are frequently overexpressed in different forms of solid tumours,[4] hence FA could selectively shuttle the payload on tumour cells, limiting the off-target toxicity on healthy ones. The HDAC inhibitor has been loaded on FA via a specifically designed self-immolative spacer. This latter is based on a 5-nitropyrrole scaffold that allows the release of the payload via an electron push−pull mechanism activated by the reduction of the nitro group to the corresponding electron-donating amine. For the synthesis of the FA-prodrug, both in-solution and solid-phase synthetic techniques have been exploited.

Landfills represent the most common routes to solid wastes disposal, and provide two main kinds of products related to wastes degradation, *i. e.* leachates and biogas.[1] Landfill leachates derive from water percolation through waste deposits: they are toxic and have a negative impact on environment. They are composed of highly concentrated organic and inorganic contaminants that require severe treatment protocols for degradation to comply with environmental legislation[2]. The parameter used to evaluate the level of contamination in landfill leachate is the Chemical Oxygen Demand (COD), *i.e.* the amount (mg) of oxygen required to oxidize organic and inorganic chemicals present in 1 liter of aqueous sample[3]. The protocol used for COD determination is provided by the EPA Method 410.4 (Revision 2.0: "Determination of chemical oxygen demand by semiautomated colorimetry"), and it is based on the use of $K_2Cr_2O_7$ and H_2O_2 as the oxidants and potassium hydrogen phthalate as the standard. Here we provide a method of COD reduction that includes a preliminary reverse osmosis step of the landfill leachate and further acid-oxidative steps that lead to a COD value closely matching the limit required by legislation for disposal.

Resolving the structural complexity of antibody-epitope interaction in *Neisseria gonorrhoeae* strains: Insights into antibody recognition

A. A. Masi,[a] M. Tiemblo,[a] A. Molinaro,[a] A. Silipo [a]

[a]*University of Naples Federico II, Via Cintia, Naples*
alessandroantonio.masi@unina.it

Neisseria gonorrhoeae infection remains a prevalent sexually transmitted disease, with 82.4 million new cases reported globally in 2020. Its consequences, including pelvic inflammatory disease (PID), infertility, and adverse pregnancy outcomes, underscore the urgent need for effective treatments. In the context of increasing antibiotic resistance, the World Health Organisation (WHO) aims to reduce the impact of gonorrhoea by 90% by 2030. Therefore, alternative therapies are being explored. Monoclonal antibodies represent an alternative strategy as they offer targeted action against bacterial pathogens, minimising side effects and hospitalisation. Understanding the complex relationship between antibodies and bacterial epitopes is essential for developing effective treatments[1]. In this context, this study focuses on the chemical and structural characterization of the lipooligosaccharide (LOS) of *N. Gonorrhoeae* strain associated with disseminated infections[2]. The Core oligosaccharide (OS) was purified from cells in stationary phase and the exact mass was determined by Matrix-Assisted Laser Desorption/Ionization Time-of-Flight mass spectrometry (MALDI-TOF). We used NMR approaches to identify the conformation of the oligosaccharide in the free-state and compared it with the bioactive conformation obtained in the bound-state using a specific monoclonal antibody (mAb 2C7) directed against the lipooligosaccharide using STD-NMR and tr-NOESY techniques[3]. The experimental results were confirmed by computational techniques such as Docking and Molecular Dynamics simulations.

Synthesis of chiral amines by a chemoenzymatic one-pot tandem protocol

A. Carolina Meazzo,[a] B. Marco Blengetti,[a] C. Cristina Prandi,[a]

[a] *Department of Chemistry, University of Turin, Via Pietro Giuria 7, I-10125, Turin*
carolina.meazzo@unito.it

Multistep one-pot synthetic protocols are an emerging and attractive field in organic chemistry, since the development of these synthetic strategies allows to produce chemicals in compliance with criteria of more sustainable and green processes.[1] One-pot and/or tandem reactions are a strategic tool when it is not possible to isolate highly reactive or transient species. In this context, the combination of chemical and biocatalytic transformations represents a valuable alternative to traditional approaches. In this context, our preliminary investigations revealed the possibility to synthesize chiral amines by means of a chemoenzymatic tandem protocol which combines the reactivity of organolithium reagents with the enzymatic asymmetric reduction of cyclic imines, generated in situ in the first step of the reaction (Figure 1). Compared to the previously reported operating conditions,[2] promising results have been obtained performing the addition of PhLi to 5-bromovaleronitrile under sustainable conditions, using a greener solvent such as cyclopentyl methyl ether (CPME), at room temperature and under air, within a short reaction time. The bioenzymatic transformation is then realized by means of a novel class of NADPH-dependant enzymes, namely Imine Reductases (IREDs), which have been recently employed for the asymmetric reduction of chiral imines under sustainable conditions.[3] Preliminary results will be discussed.

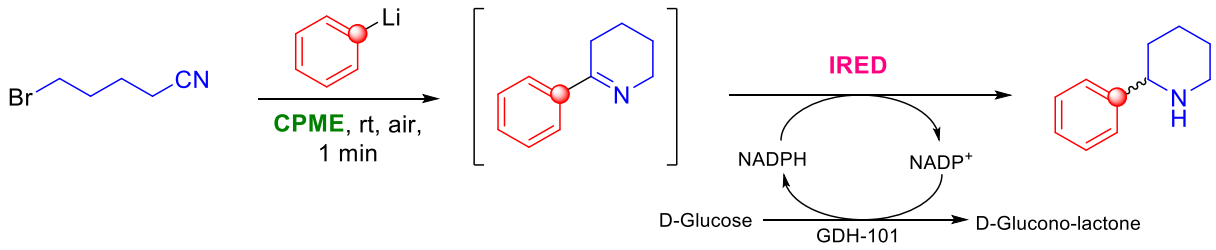

Figure 1: Chemoenzymatic tandem protocol to synthesize chiral amines.

Solid state excimer emitting polychlorinated trityl radicals

D. Mesto,[a] D. Blasi,[a] A. Punzi,[a] C.N. Dibenedetto[a], M. Striccoli[a], G.M. Farinola[a]

[a]*Dipartimento di Chimica, Università degli Studi di Bari "Aldo Moro", Via Edoardo Orabona, Bari*
davide.mesto@uniba.it

Polychlorinated trityl radicals are considered inert carbon-centered free-radicals thanks to their high chemical and thermal stability both in solution and in solid state.[1] Organic nanoparticles (ONPs) and polymeric films of tris(2,4,6-trichlorophenyl)methyl radical (**1** in **Figure 1**) form excimers from stable and persistent supramolecular radical-pairs.[1] It is reported that these ONPs present a two-photon excitation and emission in the biological transparency window and can be used to monitor temperature changes with an excellent thermal absolute sensitivity of 0.6-3.7% K^{-1} in the temperature range of 278-328 K.[2,3] Here, we report the synthesis and the characterization of two new polychlorinated trityl radicals (**2** and **3** in **Figure 1**) that can form excimers at the solid state. In $CHCl_3$ solution, monoradical **3**[4] shows a Fluorescence Quantum Yield (QY) of 9.5 %, a value markedly higher than that measured for **2** and for other trityl radicals reported in literature (QY < 1%).[5] Similarly, radical **3** shows an increased QY compared to **2** at the solid state (94% *vs* 83% for films containing a 2% of radical in the matrix).

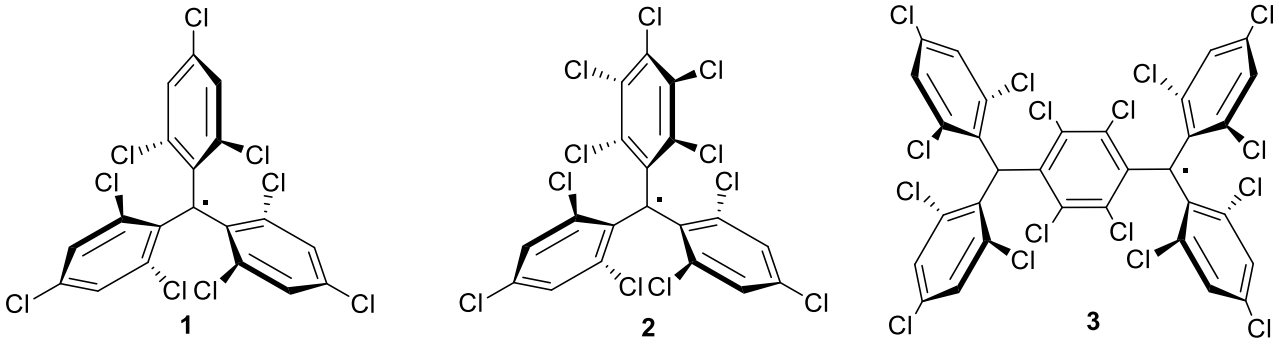

Figure 1: Molecular structure of radicals **1**, **2** and **3**.

FimH is a mannose-specific adhesin that mediates the adhesion of uropathogenic *Escherichia coli* (UPEC) to urothelial cells and can be targeted thanks to the glycoside cluster effect given by carbohydrate-lectin interactions.[1]

Among the different synthetic scaffolds used to build multivalent glycoconjugates,[2] calixarenes show peculiar properties dependent on the different valences of the scaffold and on the stereochemical disposition of the saccharide units. Thus, we inserted two trivalent mannosylated dendrons onto the upper rim of a calix[4]arene scaffold, obtaining hexavalent glycocalixarenes (Figure 1). The antiadhesive properties of compounds **5a-b** was then assessed by an assay based on yeast cell agglutination to UPEC, a highly conserved FimH-dependent binding property among isolated *E. coli* strains. On-cell STD NMR experiments, acquired in the presence of UPEC living cells, confirmed the specific binding of calixarenes functionalized with Man units (**5a-b**) to FimH proteins at the cell surface.[3] Mannosylated calixarenes **5a-b** are thus promising hit compounds for the development of novel antiadhesive therapies aimed at fighting urinary tract infections caused by UPEC.

Chemoselective S_N2' Homologation of Allylic Platforms with Zinc Carbenoids

A. Nardi, V. Pace

[a] *University of Turin – Department of Chemistry*
Via Giuria 7 – 10125 Turin (Italy)

alberto.nardi@unito.it

Homologation chemsitry has been subject of considerable attention in the last decade, leading to a lot of studies and publications investigation the possible combination of homologating agent and substrates.[1] Most of the known procedures foresee the employment of a nucleophilic species as the medium of the chain enlargement; among the several nucleophiles, lithium and magnesium carbenoids have been largely exploited for the exploration of this kind of chemistry.[2] A exception relies in zinc carbenoids, mostly known for their electrophilic behavior which made possible the Simmons-Smith cyclopropanation reaction of alkenes by iodomethylzinc iodide[3] and ethyl(iodomethyl)zinc.[4] Still, zinc carbenoid chemistry is not as explored as other metals one. Herein we present the homologation of allylic halides (X: Br, Cl) to homoallylic iodides derived from a iodomethylene unit S_N2' type transfer mediated by iodomethylzinc iodide. More than 30 examples were synthesized achieving remarkable scope and chemoselectivity thanks to the neutral nature of zinc carbenoids toward electrophilic site sas amides, esters, ketones and aldehydes.

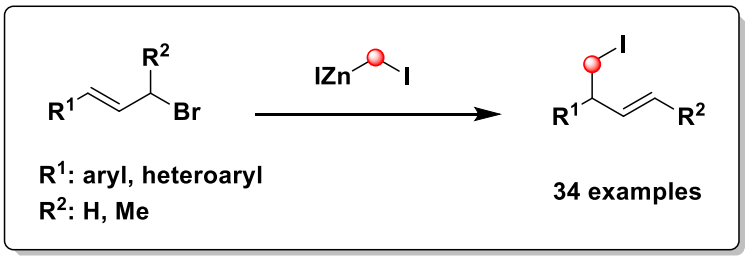

Figure 1: Zinc carbenoid homologation of allylic halides.

LED lighting plays a fundamental role in the energy transition, due to its superior energy efficiency, compared to traditional light sources. For this reason, LEDs have now become the standard for indoor and outdoor applications, but their production and disposal still poses concerns in terms of sustainability, due to the need of employing rare-earth based colour down-converting filters. In the search for alternative solutions, fluorescent proteins (FPs), in which an organic fluorophore is embedded into a peptide scaffold, have been proposed as bio-based emitters for sustainable downshifter materials.[1] An ideal FP emitter should display high fluorescence quantum yield values and good photo- and thermal stability, to ensure long lifetime, compatible with the required applications. To achieve such features, we studied several classes of fluorescent organic compounds, in order to cover the whole range of the visible light spectrum, by tailoring the absorption and emission properties. In this regard, we selected a well-known fluorescent core based on a photostable thiadiazole molecule as a flexible molecular platform, whose emission wavelength can be extensively modulated from green-yellow to orange-red, with relatively low synthetic effort, through conjugation with different (hetero)aryl moieties.[2] Through synthetic modification of the fluorophore scaffold, we investigated the possibility to adapt it for efficient interaction with a properly designed protein scaffold. Finally, we revised the whole synthetic route to improve the overall sustainability of the process.

luca.nicchio01@universitadipavia.it

The 1,2,4-triazole core is present in several bioactive molecules and therapeutically significant drugs including alprazolam and fluconazole. The growing interest for this scaffold and the drawbacks of traditional approaches have raised the demand for mild and sustainable synthetic routes.[1] Photochemical approaches utilizing visible light to achieve this target remain underexplored. In the view of this, we exploited arylazo sulfones as photoactive substrates for the synthesis of the 1,2,4-triazole ring. The dyed auxiliary group (N_2SO_2R) in arylazo sulfones is responsible for visible light absorption and photoreactivity, allowing the formation of radical species.[2] Indeed they have been recently employed as photoactive reagents in the visible-light-mediated metal and (photo)catalyst-free preparation of α-sulfonyl arylhydrazones.[3]

We present herein a one-pot, 100% atom economy, mild and transition-metal-free photochemical route to *N*-aryl-1,2,4-triazoles, by irradiation of variously substituted arylazo sulfones **1** in the presence of different *N*-alkenyl amides **2** (Figure 1). The desired products **3** have been isolated in moderate to satisfactory yields via cyclization of the key intermediate **I** and the developed protocol showed an excellent group tolerance. Post-transformations on compounds **3** and their preparation under flow conditions have been also performed.

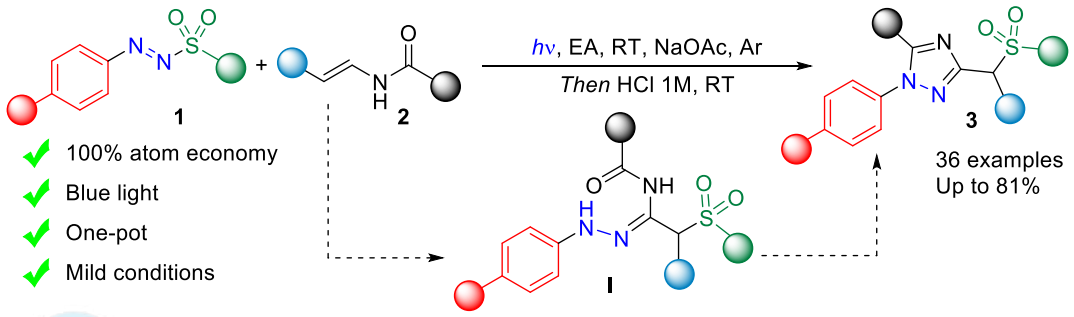

Figure 1: General scheme of the proposed photochemical approach to 1-aryl-1,2,4-triazoles.

This study delves into Porous Silicon Nanoparticles (PSiNPs), with a specific focus on their potential surface passivation with bioorganic molecules for therapeutic applications1. Porous Silicon (PSi) is a nanostructured material renowned for its optical properties and sponge-like morphology, characterized by a substantial surface area that renders it highly suitable for biomolecule decoration. The optical properties of PSi stem from voids within its network, which can be controlled by adjusting various process parameters (crystalline silicon doping, attack time, electrolyte concentration, etc.), yielding diverse photonic structures (Fabry-Perot Bragg mirror, optical microcavity, aperiodic multilayer sequence, etc).2 3 4

The primary challenge associated with employing PSi lies in its chemical instability when exposed to air or aqueous environments. In such conditions, the native Si-H bonds undergo replacement with Si-O-Si bonds, resulting in the formation of a surface oxide layer. This chemical transformation is thermodynamically driven and compromises the stability of PSi. To overcome this hurdle and ensure the stability of PSiNPs, a crucial passivation process for their surface is imperative.4 In this study, PSiNPs have been effectively passivated using carbohydrates to enhance their suitability for drug delivery applications.

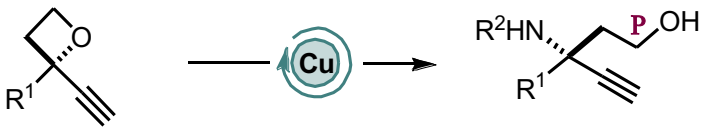
The synthesis of compounds featuring quaternary stereocenters represents one of the most demanding tasks in organic synthesis due to the large steric repulsion present in congested carbon centers.[1] Although ɣ -amino alcohol fragments are present in a multitude of pharmaceutical and intermediates for natural product synthesis (e.g. benzo[1,4]oxazepines and benzo[1,4]diazepines), enantioselective approaches for the preparation of such targets comprising quaternary stereocenters has remained largely unexplored.[2,3]



- high atom-economy
- functionalized g-amino-alcohols
- versatile enantio-enriched BBs

Here, we present a simple, scalable, and attractive method for the enantioselective synthesis of ɣ -amino alcohols having quaternary stereocenters. Enantioselective Cu-catalyzed ring-opening amination of oxetanes is demonstrated to provide access to these compounds in high yields. These functional propargylic compounds are illustrated to be suitable and versatile synthons for the preparation of a series of biological importance intermediates such as ß -unnatural amino acids.

f.palmeri@uniroma1.it

In recent years, driven by the increasing environmental awareness, the development of alternative and greener strategies for the synthesis of organic molecules has experienced a growing interest in the scientific scene. In this sense, step economy stands as an important concept in the synthetic design and strategic implementation of chemical reactions from an environmental, economical and practical point of view[1]. In this contribution, a new one-pot procedure for the synthesis of substituted metallophthalocyanines is reported, assessing its environmental sustainability through green chemistry metrics.

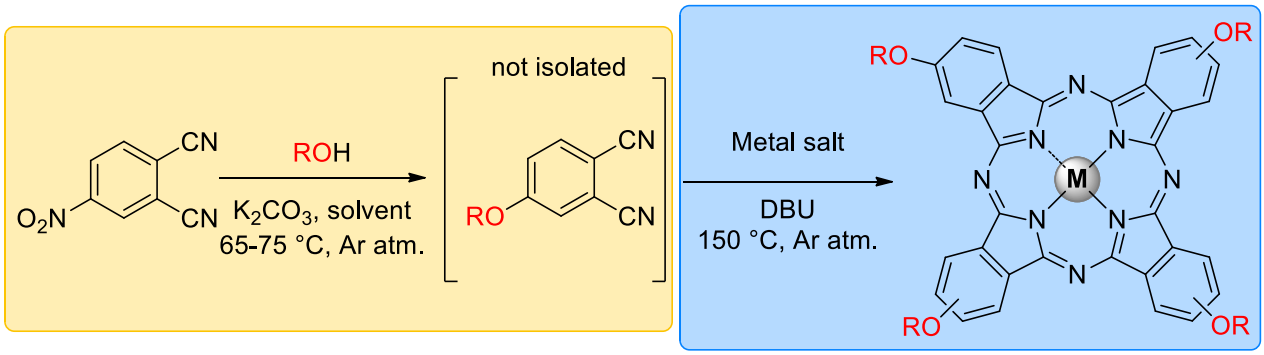

Figure 1: Scheme of the one-pot procedure for the synthesis of substituted metallophthalocyanines.

Furthermore, the noteworthy photophysical properties of such prepared sustainable-by-design metallophthalocyanines can be used for sensing application. Through a multidisciplinary approach the electrospray deposition technique (ESD), used in previous works of my group to immobilize enzymes[2] onto suitable supports to fabricate biosensors, has been now explored to immobilize metallophthalocyanines.

Gel permeation chromatography (GPC/SEC) is the most widely used technique for determining the molecular weight distribution of polymers. It is employed not only for their characterization but also for the separation of the polymer matrix from oligomers, additives, degradation products, and residual monomer. The chemical structure of both synthetic and natural polymers (polysaccharides, proteins) can be investigated by GPC/SEC using organic or aqueous solvents.[1] Furthermore, multi-detector options (multiple detection with viscometry, concentration and static light scattering detectors) allow accurate molecular weight values and to study structural properties, such as the number of branches on the polymer backbone. We employed this technique to control the polymerization reaction of polyester and polyurethane.[2] We performed, in particular, an optimization of reaction conditions taking into account the molecular weight and the percentage of monomer conversion. The formation of linear polymer with a very low percentage of ramification was observed.[3] The molecular structure of natural and synthetic polymers was also studied to verify the goodness of recycling process and functionalization.

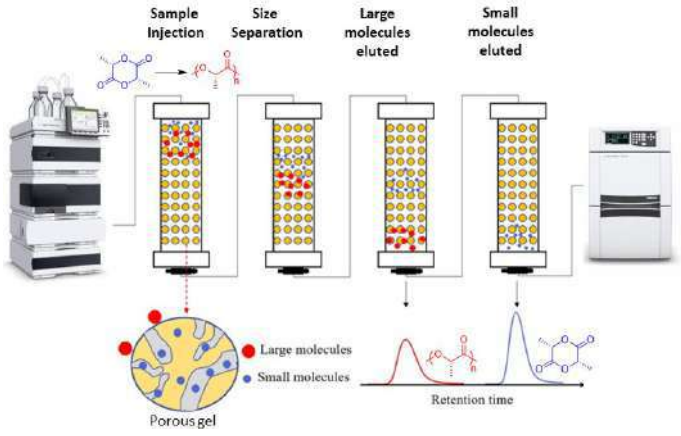

Figure 1: Principle of separating molecules by GPC/SEC.

The mechanistic investigation of homogeneous electrocatalytic CO_2 reduction is crucial for the development of new and increasingly high-performance catalysts.[1] Tris(2-pyridylmethyl)amine **TPMA** cobalt complexes have been reported as promising species able to catalyzes the CO_2 reduction.[2] Despite several mechanism have been proposed, an overall understanding is still missing and the selectivity of CO_2RR vs HER still remains an opened issue.

Here we report a novel strategy to investigate the reaction mechanism based on the evolution of CO2RR vs HER selectivity during the controlled-potential electrolysis experiments.

A decrease in the production of CO vs H_2 was found during the CPE experiments suggesting the intermediate formed during the electrolysis shift the selectivity towards H_2 production. Through a deep computational study, it was found that the stable Co(I)-CO intermediate formed during the electrolysis is the key intermediate responsible for this experimental trend. Moreover, the presence of the intermediate was experimentally confirmed though in-situ IR-SEC experiments.

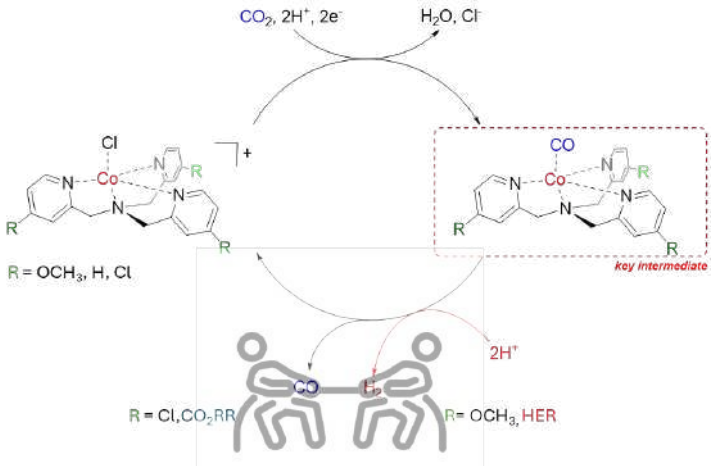

Figure 1: Simplified mechanism for CO_2RR and HER catalysed by Co**TPMA** complexes.

serena.pilato@unich.it

The growing use of Graphene Oxide (GO) as biomaterial brings to light many important questions regarding its possible toxicity to organs, tissues and cells. One of the most interesting fields of study would be the characterization of the GO exposure effect on reproductive functions. In a recent study,[1] it has been demonstrated that GO at low concentrations can promote an increase of membrane fluidity of the apical membrane of mammalian spermatozoa and a reduction of cholesterol/phospholipidic ratio in a dose/dependent manner. As a result, it was found that GO improved the spermatozoa fertilizing ability in an *in vitro* fertilization model (IVF) by extracting cholesterol from membranes, without affecting sperm membrane integrity.

Starting from this evidence, the aim of this work was to investigate whether the ability of GO to promote membrane remodelling was reproducible even in the presence of an artificial phospholipid membrane. The effect of GO was studied on liposomes consisting of cholesterol and 1,2-dioleoyl-*sn*-glycero-3-phosphocoline (DOPC), by using two different fluorescent probes, such as 5(6)-carboxyfluorescein and Filipin III. The former dye was embedded into the aqueous core of liposomes and its rate of leakage was monitored to evaluate the kinetic stability of the membranes in presence and absence of GO. Filipin III marker is known to form complexes with cholesterol and the analysis of its excitation spectra has been used to suggest either cholesterol extraction or membrane remodelling induced by GO. Liposomes treated with GO were also characterized in terms of dimension, morphology and phase transition temperature by DLS, AFM and DSC analyses. In addition, Raman spectroscopy analysis of the liposomes was performed in order to evaluate the phospholipid chain packing, and therefore the variation of fluidity of liposomes membrane treated with GO. The obtained data may offer a better insight into GO interaction with lipidic membranes and open the way to new potential engineering of sperm membrane for improving assisted reproduction technologies outcomes.

Hollow fiber membranes play a pivotal role in advanced filtration technologies, finding applications in various fields such as biomedical treatments and water purification. The inherent chemical inertness of the polymers constituting these membranes poses a significant challenge for functionalization.[1] Thus, this study addresses the challenge of enhancing selective filtration in polymeric membranes by introducing graphene oxide (GO), a two-dimensional material that serves as an ideal platform for post-functionalization due to the presence of oxygenated groups on its surface.[2, 3] The incorporation of GO was achieved through a systematic approach, involving the coating of polyethersulfone (PES) fibers.[4] This procedure featured a novel post-functionalization strategy designed to obtain a chemically modified GO-polymeric membrane. Lysine (Lys) was selected as a case study, and successful GO covalent modification was confirmed through SEM, XPS, and contact angle measurements. Adsorption experiments conducted with both pristine PES-GO and modified PES-GO-Lys fibers revealed improved removal of carbamazepine pollutants after Lysine-modification. Several examples of chemical modification and applications of resulting composite membranes for water treatment will also be discussed.

Figure 1: Post-functionalization of GO-modified hollow fiber membranes.

Thanks to its ability to chelate metal ions, hydroxamic acid is one of the most interesting functional groups in medicinal chemistry, especially in the context of metalloenzyme inhibition. Vorinostat, also known as suberoylaniline hydroxamic acid (SAHA), is a pan HDAC inhibitor approved by the FDA in 2006 for the treatment of relapsed/refractory cutaneous T cell NHL, inhibiting cell proliferation and selectively inducing apoptosis in hematologic and solid tumor malignancies.[1] Its large-scale preparation has been widely studied and essentially consists of the cyclic suberic anhydride opening by aniline, followed by acid activation with highly reactive chloroformates and condensation with hydroxylamine. Herein, we report the design of a new chemoenzymatic pathway for the synthesis of vorinostat. The preparation of the suberoylaniline acid was performed in water, in presence of *Mycobacterium smegmatis* acyl transferase (MsAcT),[2] and further functionalized with an *O*-protected hydroxylamine, *via* lipase-catalyzed condensation. Final deprotection in presence of acidic cationic resins afforded pure vorinostat in 60% total yield. In order to improve the productivity of the process, all the steps were performed testing several solvent mixtures, based on the most recent guidelines about solvent sustainability. In the best case, pure vorinostat was obtained in a 3-step-5-hour synthesis of in 79% overall yield. Finally, the entire procedure was further optimized and transferred to a continuous flow system, where the final product was obtained in a time-saving automated way, large scale, high yield and high purity, paving the way for a more sustainable preparation of pharmacologically active hydroxamic acid derivatives.

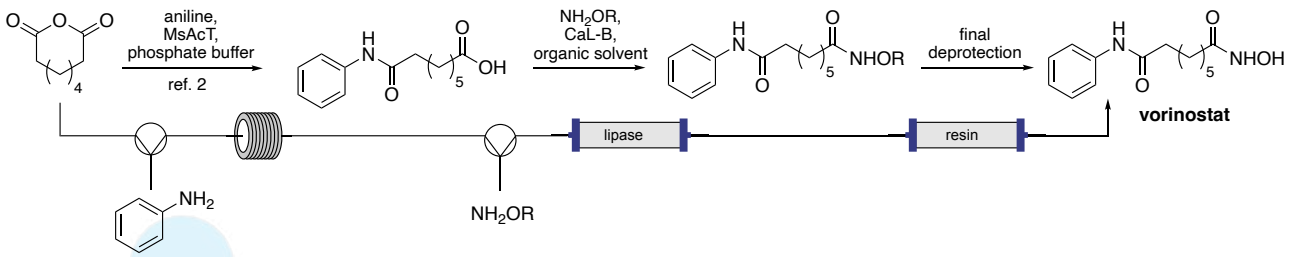

Figure 1: Schematic chemoenzymatic preparation of vorinostat

Anthropogenic activities cause the release of harmful compounds in air and water (e.g. VOCs and PAHs), posing a serious risk to overall ecosystem. Thus, the development of reliable technologies capable to detect pollutants at low concentration high efficiency, portability and low cost, is highly desiderable.[1]

In this context, the use of luminescent probes anchored to natural and eco-compatible nanomaterials is emerging as promising strategy to obtain sensing and remediation platforms.[2-3] Clay minerals (CM) are gaining growing interest as smart nanomaterials for several applications, due to their eco-compatibility, tuneable surface chemistry and low cost.[4] In this context, new naphthylimide-based fluorescent probes were synthesised and functionalised to be anchored to clay minerals, obtaining naphthylimide-CM nanomaterials. The physical-chemical characterization of the obtained materials was carried out by several techniques, and optical properties were investigated as well. The sensing performance towards the selected pollutants was evaluated both in solution and solid phase, observing an easy detectable signal after the recognition.

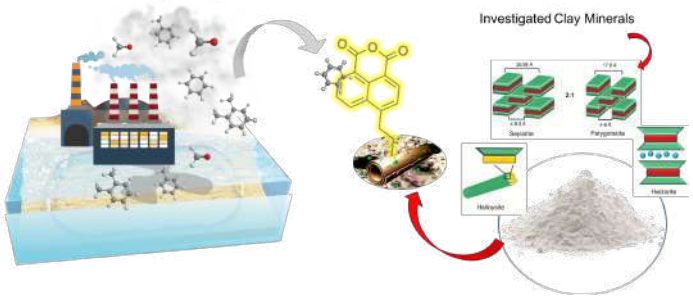

Figure 1: Example of some clay minerals that can be used for environmental remediation.

Green and more sustainable synthetic approaches are urgently needed in modern Organic Chemistry. Since the pioneering works by Lipshutz,[1a-b] the micellar catalysis emerged as an attractive opportunity to reduce/eliminate organic solvents. By now, many reactions were successfully performed but just few papers were devoted to the micellar Claisen-Schmidt aldol reaction,[2,3] and a general approach to widen its scope is lacking. Here we report the successful micellar-based Claisen-Schmidt synthesis of chalcones, considering their high-interest for medicine and organic electronics,[4,5] by considerably widening the scope. Reactions in CTAB or Tween 80 solutions and with NaOH at rt for 24h gave good to excellent yields.

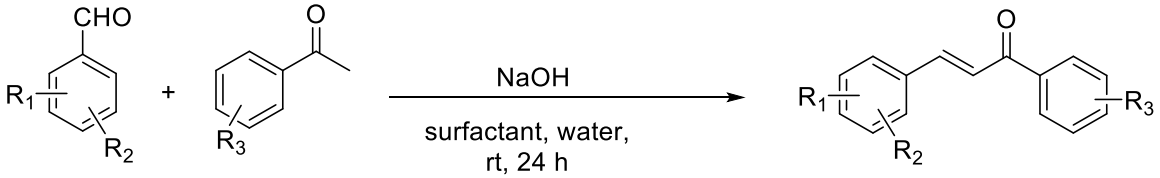

Figure 1. General scheme for the Claisen-Schmidt reaction in micellar solution.

Reactions in CTAB solution promoted also tandem/domino reactions, such as the further Michael addition, which, conversely, was suppressed by the non-ionic surfactants. Some substrates, e.g. those with free phenolic groups, reacted with higher difficulty, giving lower yields. In specific cases, protocol modifications to improve unsatisfactory yields were needed, e.g. by working at 45°C. Heterocyclic substrates reacted better in Tween 80, while the CTAB often lead to more by-products by promoting cascade reactions. Some chalcones of interest for application in medicine and organic electronics were successfully synthesized by the here presented method and the substrate-micellar binding and localization were studied to elucidate the reactions' outcome.

roberta.ragni@uniba.it

Reaction Centres (RCs) of photosynthetic bacteria are enzymes employing solar energy to generate charge separated states with almost unitary conversion efficiency. This efficiency, optimized by Nature in billions of years of evolution, is very attractive in view of designing biohybrid systems for light-responsive bioelectronics.[1] Our studies have demonstrated that the covalent functionalization of the bacterial *Rhodobacter sphaeroides* RC with tailored organic light harvesting antenna molecules is an efficient route to hybrid systems that outperform the native photoenzyme in photocurrent generation.[2,3] Moreover, smart supramolecular architectures can be assembled by multiple covalent bioconjugation of both bacterial RC and Cytochrome c proteins by means of tailored organic photoactive linkers. Such systems feature an almost doubled photoactivity versus the pristine RC upon illumination at 660 nm, and ~ 10 times higher photocurrent versus an equimolar mixture of the unbound proteins, this being a promising outcome for the development of eco-sustainable systems for biophotovoltaics.[3]

The design, synthesis and photophysical properties of RC-based bioconjugated constructs, as well as their suitability as solar energy bio-photoconverters, will be herein discussed.

Bile acids (BAs) are cholesterol metabolites serving several functions in our bodies. Other than their role into digestion, BAs act as hormones regulating several metabolic processes. Many transmembrane and nuclear receptors, especially expressed along the gastrointestinal apparatus, were identified as endogenous counterparts of BAs. Over the years, the wide druggability of these receptors has been explored to address several unmet clinical conditions such as cholestatic liver diseases, metabolic syndrome, GI cancer, and inflammatory bowel disease (IBD).[1,2]

The high variability of the steroidal scaffold yielded abundant biologically active small molecules with promising pharmacological results. In such a fascinating context, our interest focused on both deepening the biological role of a vast pool of bile acids and harnessing the steroidal backbone to selectively target pathologically relevant receptors. Indeed, some BAs were identified as first endogenous antagonists of the leukemia inhibitory factor receptor (LIFR).

LIFR is a heterodimeric membrane receptor formed by LIFRβ subunit and glycoprotein (gp-130) and binds LIF protein, an IL-6 cytokine, fostering epithelial mesenchymal transition and stimulates cell growth. LIFR inhibition prompts the advancement of BA-based treatments in LIF-mediated oncogenesis.[3]

Moreover, we designed a novel class of bile acid derivatives acting as GPBAR1 agonists and RORγt inverse agonists. Both receptors are indeed attractive drug targets to develop clinically relevant small modulators as potent hybrid medicines for autoimmune diseases. We were able to identify several compounds endowed with great efficacy and potency values and excellent pharmacokinetic profiles.[4]

Electrochemical stereoselective synthesis of biaryl scaffolds

Simonetta Resta,[a] Stefano Andolina,[a] Sergio Rossi,[a] Alessandra Puglisi,[a] Maurizio Benaglia[a]

[a] *Dipartimento di Chimica, Università degli Studi di Milano, Via Golgi 19, Milano*
Simonetta.resta@unimi.it

Biaryl scaffolds are widely spread in biologically important natural products, in numerous therapeutic agents, but they are also considered a privileged class of ligands and (organo)catalysts; therefore, the development of efficient alternative methodologies to prepare such compounds is always attracting much attention.[1] Traditional methods to achieve these structures are based on transition metal-catalysed coupling reactions, such as palladium or rhodium, and nucleophilic organometallic species, which show a notable environmentally impact. However, more recently few protocols based on an electrochemical approach have been reported.[2] In particular, in 2018, Waldvogel et al. investigated on the direct anodic cross-coupling between aryl amines and different-substituted phenols and naphthols, affording the desired products in up to 48% of yield.[3] Considering these results, we envisioned the possibility of developing an enantioselective synthesis of biaryl scaffolds (such as BINAM) using naphthylamines derivatives bearing a chiral auxiliary directly connected to the heteroatom in order to exert a stereochemical control over electrochemical-driven coupling (**Figure 1**).
Initially, an exploration of various electrochemical parameters (conductivity, electrodes, F/mol) were undertaken to optimize yield, employing a model substrate based on naphthylamine scaffold. Subsequently, different chiral auxiliaries were investigated in order to reach good level of diasteroselectivities. According to this approach, the desired biaryl products were obtained in moderate to good yields and up to 85:15 diastereomeric ratio. The two diastereoisomers were subsequently separated by chromatographic purification before the removal of the chiral auxiliary.

Pd-catalyzed carbonylation reaction: process optimization and industrial scale up

Jacopo Roletto[1], Paolo Paissoni[1], Alessandro Barozza[1], Monica Donnola[1], Veronica Reali[1],

[1]*Procos S.p.A. (Cameri - NO).*

e-mail: roletto@procos.it

The use of palladium-catalyzed carbonylation reactions of aryl halides is increasing in the pharmaceutical chemistry due to their very high atom-efficiency, improved milder conditions and large availability of aryl halides intermediates[1].

A case study of process optimization of a reductive Pd-carbonylation of an aryl halide intermediate using silanes as hydride donor to achieve the desired aldehydic intermediate is discussed. Studies of reaction parameters like i.e. catalyst loading, temperature, CO pressure, oxygen content and concentration, including also kinetic data, helped understanding side reactions and impurities formation.

The scale up of the above carbonylation reaction was based on the gas-liquid mass transfer coefficient kLa performing down-scale optimization experiments using similar kLa value of the industrial autoclave.

All above studies allowed to achieve at industrial scale very high conversion, purity and yield

Similarly to its natural counterpart, artificial photosynthesis harnesses sunlight to promote the transformation of water and carbon dioxide into energy-rich products.[1] The synthetic architectures designed for artificial photosynthesis rely on three key elements: light-harvesting chromophores, a water oxidation catalyst, and a semiconductor.[2] The "quantasome" (QS) architecture designed in our group relies on a self-assembled supramolecular aggregate generated by the hierarchical organization of perylenebisimide dyes (PBIs), the artificial antennas, on a ruthenium-based polyoxometalate (RuPOM), the reaction center for photo-assisted water oxidation.[2,3] The complex exhibits quantitative faradic efficiency and excellent performances on electrode.

A modular click chemistry approach allowed the decoration of the PBIs with different moieties to tune the properties of the aggregate. Introducing chiral carbohydrates had the double aim of generating QSs with improved water affinity and introducing optical activity into the system. The intriguing chiral assembly of the new QS allowed us to explore the effect of this property on the efficiency of the system and on the possibility of chiral-induced spin selectivity (CISS) effect in QS-mediated water oxidation.

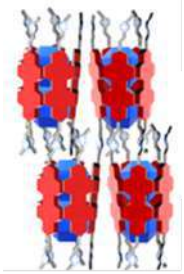

Figure 1: schematic representation of the “quantasome” architecture.

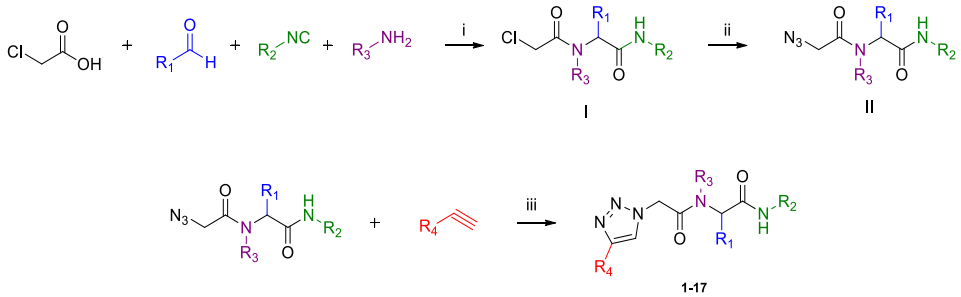
Cancer cells strategically exploit the protein quality control system to deal with the stress caused by rapid proliferation and adverse environmental conditions. The BAG3 (Bcl-2-associated athanogene 3) co-chaperone plays a crucial role in this process by interacting with HSP70 (Heat Shock Protein 70) forming an important functional module involved in cancer cell survival, apoptosis inhibition, and autophagic clearance of damaged proteins. [1] Therefore, the BAG3/HSP70 axis emerges as a focal point in various cancers, making it a promising target for drug development. However, due to the complex BAG3 biology, only a few modulators that disrupt its interaction with HSP70 are known. [2] In light of this, we decided to leverage the modular nature of multicomponent reactions to develop new chemical platforms that can interfere with the BAG3 protein. We successfully synthesized a novel class of 1,2,3-triazole-α-acylaminocarboxamides by combining the Ugi reaction with the alkyne-azide Huisgen procedure in a sequential tandem approach. [3] Our compounds underwent biophysical and biological evaluation, leading us to identify interesting molecules able to inhibit both BAG3 and HSP70 protein. These compounds, emerging as new drug prototypes, offer a therapeutic approach with enhanced efficacy against cancer. Our findings represent a significant advancement in developing effective treatments targeting the BAG3/HSP70 axis in cancer cells.



Reagents and conditions: (**i**) CH_2Cl_2, rt, 48-72 h, (60-98%); (**ii**) NaN_3, K_2CO_3, DMA, rt, 4 h, (>99%); (**iii**) $CuSO_4.5H_2O$, sod. ascorbate, DMSO/t-BuOH/H_2O, rt, 12 h, (70-98%).

The development of human tissue mimetics is crucial in advancing theragnostic solutions for healthcare management through the generation of in vitro organs for drug screening and cell biology studies [1]. With the advent of automated manufacturing systems like 3D printing and collaborative robot, it is now possible to control the synthesis and formulation of biomaterials, limiting the combinatorial and artisanal chemical approach that is typically used to obtain 3D in vitro tissue models with tuneable advanced biomolecular and physical properties [2,3]. In this communication, the synthesis of functional biomaterials for the generation of colorectal cancer (CRC) tissue models will be presented. Furthermore, the integration of Artificial Intelligence (AI) and Machine Learning (ML) algorithms in biomaterials synthesis and formulation, to reduce synthetic effort and predict the most efficient synthetic conditions to generate hybrid multifunctional biopolymers with selected properties and features will be included.

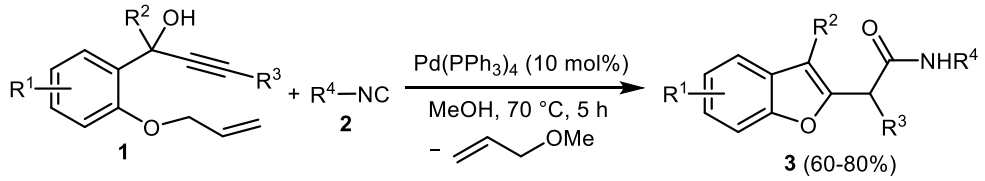
Synthesis of 2-(Benzofuran-2-yl)acetamides via Palladium-Catalyzed Coupling of 1-(2-(Allyloxy)phenyl)-2-yn-1-ols and Isonitriles

P. Russo,[a] R. Mancuso,[a] B. Gabriele[a]

[a]*Laboratory of Industrial and Synthetic Organic Chemistry (LISOC) Department of Chemistry and Chemical Technologies, University of Calabria, Via P. Bucci, 12/C, 87036, Arcavacata di Rende (CS), Italy*
patrizio.russo@unical.it

(2-(Benzofuran-2-yl)acetamides represent a class of organic compounds of particular interest, due to their significant pharmacological activities, including antifungal[1] and anticonvulsant[2,3] activities, in particular. Their structural versatility makes them promising candidates for drug discovery and development, motivating research efforts aimed at developing new methods for their synthesis as well as at understanding their biological functions and therapeutic potential.

In this contribution, a novel catalytic method is presented, which allows the synthesis of 2-(benzofuran-2-yl)acetamides **3** starting from readily available 1-(2-(allyloxy)phenyl)-2-yn-1-ols **1** and isonitriles **2** and with $Pd(PPh_3)_4$ as simple catalyst (Scheme 1). Reactions are carried out in MeOH at 70 °C for 5 h.



Scheme 1

Formation of **3** derives from a mechanistic pathway involving an ordered sequence of steps, beginning with the oxidative addition of the phenoxyallyl moiety of **1** to Pd(0) followed by the insertion of **2** to give an (allyl)(imidoyl)palladium complex. The isonitrile group, being isoelectronic with CO, in a similar manner as carbon monoxide[4] is, in fact, able to insert into the palladium-carbon bond arising from the oxidative addition of a suitable substrate to Pd(0). Water attack to the (allyl)(imidoyl)palladium complex followed by β-H elimination from the H-O-C-Pd(allyl) moiety leads to formation of an allylpalladium hydride species (allyl)PdH and a 2-(3-hydroxybenzofuran-2(3*H*)-ylidene)acetamide intermediate. Reduction of the latter by (allyl)PdH and MeOH finally affords the desired (2-(benzofuran-2-yl)acetamides.

Puzzling Synthesis of Novel Fluorinated Bioactive Compounds

F. Sabuzi,[a] F. Valentini,[a] A. Iannini,[a] V. Conte,[a] P. Galloni [a]

[a] *University of Rome Tor Vergata, Via della Ricerca Scientifica, 00133 Roma*
federica.sabuzi@uniroma2.it

The beneficial effects of fluorine atoms inclusion in the chemical structure of therapeutic or diagnostic drugs candidates are well established[1]: enhanced activity and selectivity, as well as improved membrane permeability, stability and pharmacokinetic properties are just few of the advantages related to the presence of one fluorine atom or a fluorinated functional group, as -CF_3. Not by chance, the list of F-containing drugs approved by the U.S. Food and Drug Administration is continuously updated[2].

As the demand for safer non-steroidal anti-inflammatory drugs (NSAIDs) has rapidly grown, a series of dual inhibitors of cyclooxygenase-2/lipoxygenase-5, enzymes involved in inflammatory processes, appeared in the literature, in the attempt to limit adverse effects typically associated with individual inhibitors[3]. Next to synthetic drugs, naturally occurring quinones, terpenoids and phenols, as eugenol or thymol, exhibited relevant bioactivity. However, targeted functionalization of natural phenols is known to further extend and enhance their effectiveness, in a wide range of biological application[4].

In this communication, an overview of our recent efforts on the synthesis of fluorinated thymol and anilines derivatives, eventually bearing -CF_3 functionalities, will be presented, together with a focus on their application as dual inhibitors of cyclooxygenase-2/lipoxygenase-5 enzymes.

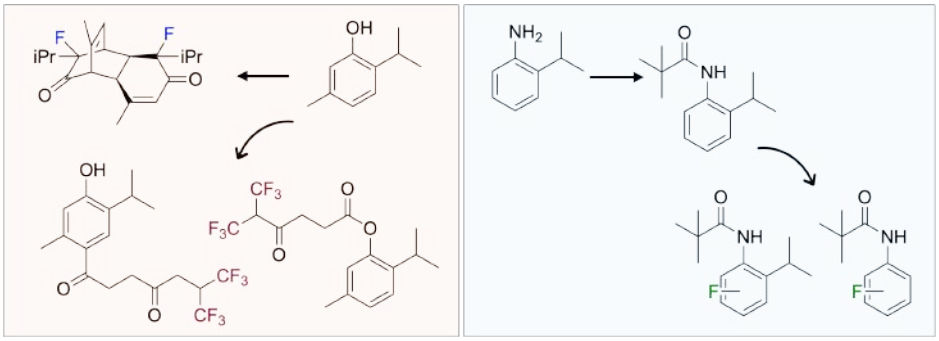

Figure 1: Structures of thymol and 2-isopropylaniline derivatives.

To replicate the exceptional performance of natural processes at a reasonable cost, scientists have often looked to nature for inspiration when creating high-performing, low-cost bio-based materials. Regarding those above, we decided to focus our recent research on alginic acid (Figure 1), a polymer extensively found in brown algae's cell walls.[1] To achieve our aim, we chose the functionalization of alginic acid with Kojic acid, a chelating agent produced by different species of fungi.[2] Due to Kojic acid's ability to chelate, the material has exhibited siderophore action and antibacterial activity against Gram-positive and Gram-negative bacteria without any cytotoxic effect. In addition, alginic acid was also functionalized with an ionic liquid.[3] The latter already had recognized antibacterial properties that were enhanced by the functionalization. This new material was further modified with another interesting chelator, tris(3-hydroxypyridin-4-one) (THP).[4] Antibacterial tests performed on this material have also shown excellent antibacterial activity.

The development of biosensors for the quantitative detection of stress biomarkers such as dopamine, noradrenaline, epinephrine and cortisol in biological fluids such as blood, urine, saliva and sweat has a significant impact on the field of medical diagnostics.[1] Our goal is to develop a portable sensor device to detect stress biomarkers in harsh and adverse environments, such as space missions.[2] We chose to use array technology for the realisation of the sensor device because of its particular characteristics: ease of use, extreme selectivity, sensitivity and ease of implementation.[3] The array was designed with an optical/colorimetric output. In particular, we have selected and synthesised some organic fluorophores (probes) taking into account two important characteristics: *1)* the spectral properties of the transducer, in particular the absorption/emission range of the probe; *2)* the interaction with the analyte through non-covalent interactions. The interaction between each probe and the stress biomarker was previously tested in solution at different analyte concentrations, from 1 nm to 1 pM, and then the response of the array was analysed on a solid state using an optical fibre as a detector. In particular, we detected Dopamine, Cortisol and Adrenaline in real saliva samples.[4]

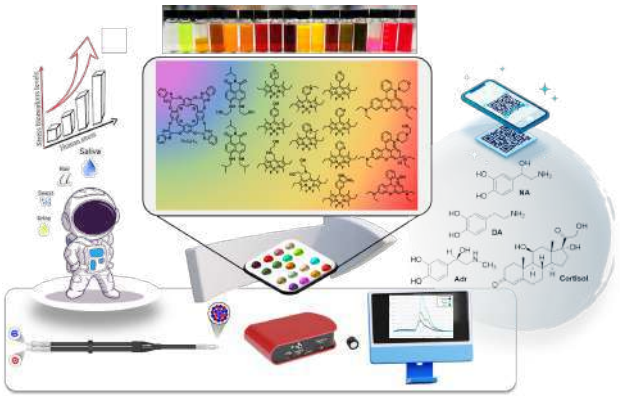

Figure 1: Real sample of the sensoristic device.

andrea.sartori@unipr.it

Idiopathic Pulmonary Fibrosis (IPF) is a fibrotic lung disease in which the deposition of collagen within the pulmonary interstitium causes stiffness in the lungs and compromises the respiratory function. The decline is progressive and irreversible. Nintedanib, a tyrosine kinase inhibitor able to block the signaling of several growth factors receptors (GFRs), is one of two drugs nowadays approved as pharmacological treatment of IPF, that only slows down the progress of the fibrotic process. The $\alpha_V\beta_6$ integrin is overexpressed in fibrotic tissue and is the major activator of transforming growth factor-β (TGFβ), the principal pro-fibrotic mediator, that stimulates proliferation of fibroblasts, their transition into myofibroblasts and the deposition of collagen. For this reason, $\alpha_V\beta_6$ integrin has been recently recognized as a possible IPF marker and therapeutic target[1]. Our group recently synthesized six dual conjugates[2] in which the $\alpha_V\beta_6$ integrin-recognizing moiety *c*(AmpLRGDL) and a nintedanib portion were connected through different types of uncleavable linkers, with the aim of delivering nintedanib to the fibrotic tissue and inhibiting TGFβ activation. In particular, compound **1** (Figure 1) gave promising results in preliminary biological assays, thanks to the contribution of both active units (nintedanib and integrin ligand).

This communication will report on recent advances in the biological evaluation of dual covalent conjugate **1** both *in-vitro* on human fibroblasts from IPF patients and *in-vivo* on IPF-like mouse model.

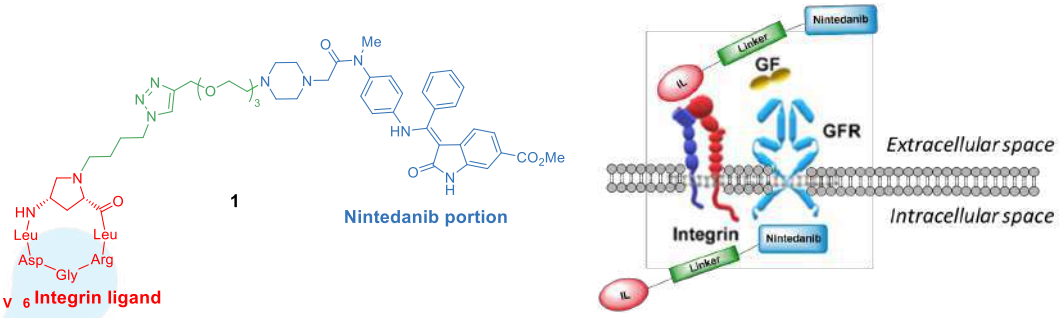

Figure 1: Dual conjugate **1** and its schematic interactions with $\alpha_V\beta_6$ integrin and GFRs.

Low-Impact Synthetic Strategies for Constructing Stereodefined Coumarin-Based Molecular Architectures

Francesco Secci

Università degli Studi di Cagliari, Dipartimento di Scienze Chimiche e Geologiche, Cittadella Universitaria di Monserrato, Blocco D, 09042, Monserrato, Cagliari
fsecci@unica.it

Coumarins represent one of the most important tools in medicinal chemistry (MedChem) for designing and developing new bioactive molecules and drugs. Various coumarin-based compounds have been proposed for treating diverse human pathologies, as pesticides in integrated pest management, and as luminophores for developing fluorescent probes in bioimaging and theranostics. In recent years, our research group has conducted several studies aimed at developing different synthetic strategies for constructing novel coumarin scaffolds and achieving their chemo- and stereoselective transformations. This endeavor has enabled access to new chemical architectures with significant biological activity and notable photophysical properties. These results were attained through diverse synthetic approaches, spanning from photochemistry to organocatalysis, and the exploration of new reaction pathways. Herein we report our recent results in the development of novel stereo- and enantioselective synthetic processes aimed at obtaining a series of different coumarin-based compounds and their potential as antiviral drugs.

caterina.testa@phd.unict.it

Supramolecular chemistry-based sensing offers distinct advantages, such as the possibility of selective and specific design based on the complementarity of size, shape, and function between the receptor and the analyte, and the ability of re-use the systems thanks to the non-covalent approach. Calix[5]arene macrocycles have been extensively tested against bioactive ammonium-containing substrates and the complexation processes have been observed by NMR spectroscopy.[1] However, it is known that the efficiency of the recognition process is strongly dependent on the ion pair interaction between the ammonium cation heads and their counterions. To this end we proposed a novel fluorophore-ureido-calix[5]arene luminescent receptor for the detection of bioactive species that contains linear alkylammonium motif. The design of this receptor implies that, in addition to the known complexing capabilities of calix[5]arenes for linear alkylammonium guests, the complexation will be improved by the synergistic action of the ureido group,[2,3] trapping the anionic counterion, and the presence of a fluorescent label will allow to follow the host-guest complexation by fluorescence spectroscopy.

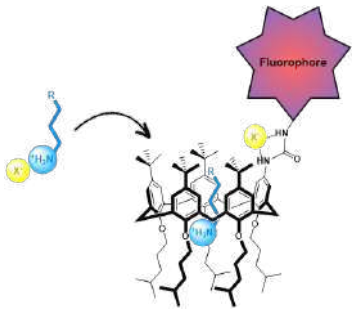

Figure 1: proposed recognition mechanism of fluorophore-ureido-calix[5]arene luminescent receptor.

elisabetta.tomarchio@phd.unict.it

A new heterogeneous and recyclable bio-based cryogel containing palladium was synthesized as a heterogeneous catalyst for organic reactions.[1] The synthesis of the macroporous material started from the appropriately functionalized amino acid L-phenylalanine complexed with palladium and subjected to free radical polymerization in water at subzero temperature.[2,3] The pore size, surface morphology, composition, and thermal stability of the obtained cryogel were studied using SEM/EDX, FTIR, and TGA techniques. The hybrid cryogel was successfully used as a catalyst for Suzuki-Miyaura coupling reactions using water as solvent. The material demonstrated robust mechanical strength while reusable across multiple catalytic cycles without any discernible loss in activity. Moreover, palladium remains complexed within the cryogel and is not lost in solution once the catalytic cycle is complete. The catalyst can be easily recovered by removing the cryogel from the reaction and washing it with a mixture of ethanol/water, preserving its integrity with minimal weight loss or alteration in appearance. This innovative cryogel catalyst boasts several appealing features, including its utilization of eco-friendly and non-toxic solvents for catalysis and effortless recovery and reusability.

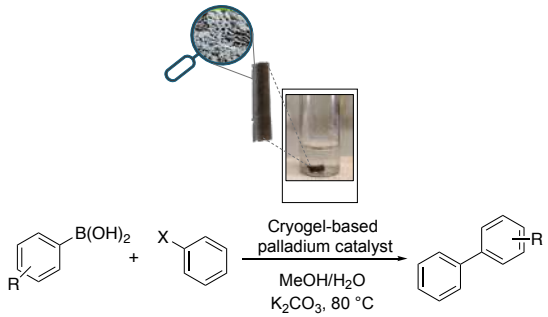

Figure 1: Schematic representation of the Suzuki reaction. The SEM image depicts the macroporous structure of the synthesized material.

Nowadays, the chemical industry is intensively working to achieve net-zero carbon dioxide emissions.[1] Electrochemical manufacturing, which uses electricity as the major source of energy, is becoming a promising alternative to reduce the environmental impact of chemical production.[2] Although the current research is focused on the optimization of key electrochemical parameters such as energy efficiency, product selectivity, productivity per time unit and so on, there is little attention on the use of electrodes made from waste.[3] For example, aluminium is a highly recyclable metal, and it can be recycled at a very low energy cost compared to its primary production.[4]

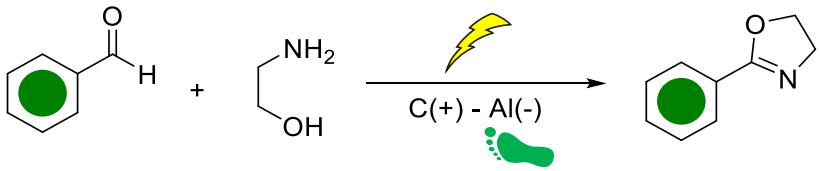

Figure 1: Recycling of aluminium cans in the electrochemical synthesis of 2-oxazolines.

We are currently developing electrosynthetic methods using electrodes deriving from inexpensive and recyclable materials, specifically spent aluminium cans. In this contribution, we report our study on the electrochemical synthesis of differently substituted 2-oxazolines. An extensive green metric assessment has been carried out to quantify the overall sustainability of our protocol compared to those reported in the literature.

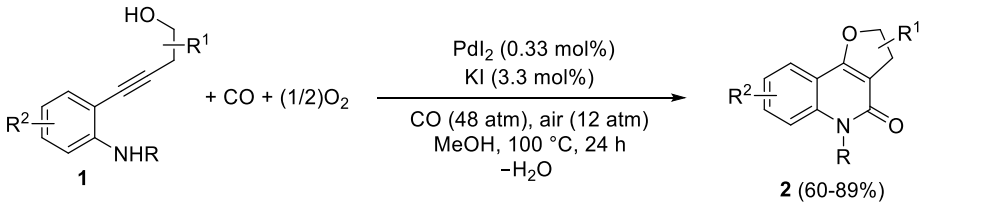
sofia.tropiano@studenti.unipg.it

Quinolinone derivatives play a very important role in medicinal chemistry, as numerous molecules containing this scaffold have shown interesting antitumor[1] and antibacterial[2] activities. In this communication, a carbonylative double cyclization[3] approach to 2,3-dihydrofuro[3,2-*c*]quinolin-4(2*H*)-ones derivatives **2** from readily available 4-(2-aminophenyl)-3-yn-1-ols **1** is presented, based on the use of PdI_2/KI as the catalytic system[4] under oxidative conditions. Products have been obtained in fair to high yields (60-89%) in one step and in a multicomponent fashion, working under relatively mild conditions (100 °C in MeOH for 24 h, under 60 atm of a 4:1 mixture of CO-air).



(R = Me, Bn; R^1 = H, alkyl, aryl; R^2 = H, Me, Cl)

Scheme 1

The reaction represents a single-step method for synthesizing a particularly important class of fused heterocycles, using easily and accessible materials [4-(2-aminophenyl)-3-yn-1-ols, carbon monoxide and oxygen (from air)], with selective and sequential formation of three new bonds and two cycles. The working mechanism has also been investigated by DFT calculations following a protocol designed for Pd-containing systems,[4] and this approach helped to shed light on the molecular source of the catalytic activity, providing atomistic details on the intermediates and transition states of the chemical event.

giuseppe.trusso@unict.it

The monitoring of cortisol levels should be extremely important to control the human health, thus funding important medical application.[1] The standard analytical methods for cortisol identification and quantification cannot be self-performed, due to the bulky size of the instruments and the necessity of specialized persons.[2] Molecular probes solve these problems due to their fast and easy use.[3] In this contribution, the synthesis of new fluorescent rhodamine probes, able to interact with cortisol by non-covalent interactions, the recognition properties in solution as well as in solid state by optical array, using a smartphone as detector, is reported. DFT calculations and FT-IR measurements suggest the formation of hydrogen bonds between probes and cortisol. The ability to detect cortisol in artificial saliva, in a linear range from 1 mM to 1 pM has been demonstrated, thus leading to the realization of practical smart device for the detection of cortisol in real life.

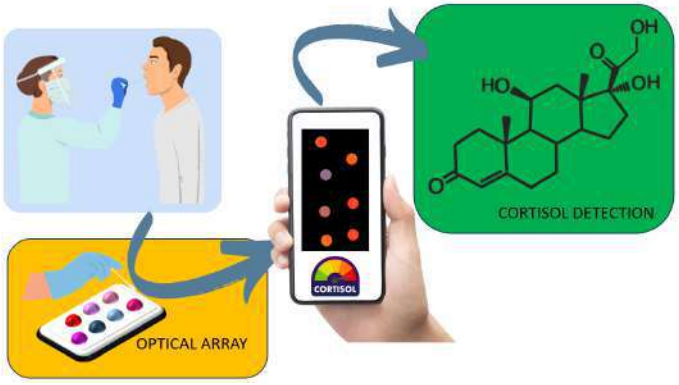

Figure 1: cortisol detection by optical array.

Multifunctional hybrid materials from biowaste valorization

V. Venezia

Department of Chemical, Materials and Production Engineering, University of Naples Federico II, Naples, Italy
virginia.venezia@unina.it

According to a Circular Bioeconomy approach, humic acids (HA) are biowastes that can be viewed as a promising and cost-effective source for high-value products and novel materials, because of their chemical and biological richness. Indeed, HA are rich in phenolic and carboxylic groups, which enhance plant growth, flame retardancy and antiviral properties. The amphiphilic nature of HA allows them to self-assemble in water, act as metal chelating agents, and interact with organic contaminants. Quinone and phenol moieties in HA provide antioxidant and pro-oxidant properties by scavenging or generating reactive oxygen species (ROS). However, their technological use is limited by their instability in water, leading to their classification as waste nowadays, while their presence in water environment raises big issues to decontamination processes. The present PhD work defined different synthetic approaches to turn HA environmental issues into technological opportunities through the design and the development of multifunctional hybrid materials based on HA biomolecules. The PhD thesis has been focused on two main parts: I) Design of hybrid nanostructured HA-based materials; II) Design of HA-based polymeric materials. In the former, the molecular combination of these heterogeneous moieties with an inorganic matrix (e.g., SiO_2, TiO_2, ZnO) through a ceramic templated approach proved to be an effective method for limiting HA aqueous degradation phenomena, thus improving physicochemical stability, mechanical properties, and even enhancing intrinsic organic moieties features in the final hybrid nanostructured HA based materials [1]. This approach was also combined with the electrospinning technology to produce bioactive and sustainable nanocomposite films for active packaging applications made of electrospun biodegradable and bioderived polymers and hybrid nanoparticles [2]. In the latter, HA were explored as functional additives for polymer materials. Indeed, proper synthesis strategies were designed to use these biomolecules as functional biowaste flame retardant for epoxy-based systems or as an additive for gelatine hydrogels to obtain hybrid HA-3D network with tunable rheological features and significant biological activity, including antimicrobial and antioxidant efficacy, for a broader range of biotechnological applications [3]. From a scientific point of view, this thesis has contributed to clarify the chemistry of HA with a special focus on their interaction with either organic or inorganic components as well as on the physico-chemical features of HA-based hybrid nanomaterials. From a technological point of view, it has provided viable routes for HA valorization by developing different materials of interest in diverse areas, especially environmental ones.

Biomimetic Design of Novel Structural Biomaterials through Halogen Bonding

P. Metrangolo

Laboratory of Supramolecular and Bio-Nanomaterials (SBNLab), Department of Chemistry, Materials, and Chemical Engineering "Giulio Natta", Politecnico di Milano, 20131 Milan, Italy
pierangelo.metrangolo@polimi.it

A halogen bond occurs between an electrophilic region associated with a halogen atom in a molecule and a nucleophilic region in another molecule.[1] Although many modifications of peptide sequences have been utilized to tune their self-assembly behaviour, halogenation has rarely been pursued. The advantage of the introduction of halogen atoms on peptide motifs lies in the fact that halogenation is a minimal structural modification, which, on the other hand, induces a large difference in the peptide supramolecular behaviour as a consequence of the rich variety of noncovalent interactions given by halogen atoms.[2]

In this seminar, I will show how the halogen bond can be used to promote the molecular self-assembly of peptides. We have applied this new supramolecular concept to the augmented fibrillation of amyloidogenic peptides[3] and the control of their nanostructures (Figure 1).[4] The obtainment of a novel unnatural amino acid functioning as strong halogen-bond donor has allowed to engineer the hydrophobic cavity of an amyloid fibril. Our results prove that selective halogenation of an amino acid enhances the supramolecular organization of otherwise unstructured biologically-relevant sequences. This method may develop as a general strategy for stabilizing highly polymorphic peptide regions.

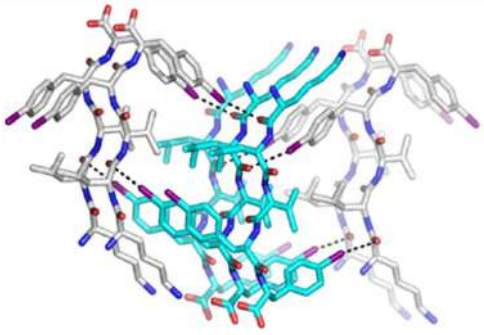

Figure 1: Steric zipper motif formed by KLVF(I)F(I) showing halogen bonds with the carbonyl oxygens.

TEC-OR-002

Adsorption of Cisplatin and Its Derivatives on Graphene.

Maria Cracchiolo[1], Andrea Melchior[1]
[1]*Polytechnic Department of Engineering and Architecture, Laboratory of Chemical Technology, University of Udine, via del Cotonificio 108, 33100, Udine, Italy*
cracchiolo.maria@uniud.it

Cisplatin, is a key anticancer metallodrug, which is nowadays is a key-tool in the treatment of solid tumors. The mechanism of action consists in the diffusion into the cell, followed by activation via chloride group hydrolysis. This generates a highly reactive species which forms adducts, that trigger a cascade of events and cause cell death[1]. However, a significant % of administered cisplatin is excreted intact or as one of its reactive hydrolysis products. This uncontrolled release posed serious concerns for the potential threat to environment and human health, also due to its poor biodegradability[2]. To decontaminate aqueous solutions containing such persistent drug pollutants a simple and economic approach is to remove them by adsorption onto materials possessing high affinity towards these drugs. Carbon-based materials have been considered as promising adsorbents for the removal of pharmaceutical pollutants from water[3], especially when combined with advanced oxidation processes (AOP)[4]. In this his study we report the results of molecular dynamics (MD) simulations performed to investigate the adsorption of cisplatin and its mono- and di-aquo derivatives on a graphene model surface to provide insights into adsorption mechanisms and thermodynamics. MD simulations were conducted for cpt, wcpt, and w2cpt within a tetragonal box (x,y =5.1 nm, y= 11.0 nm). The graphene surface (5x5nm) was generated using the GOPY application, and its topology was established as previously described[5,6]. An in-house flexible force field was employed for the Pt-complexes[7]. The box was filled with SPC/E water molecules to replicate water density, and the particle-mesh Ewald method was used for long-range electrostatic interactions[8], with a 1.2 nm cut-off for short-range interactions. Following energy minimization, the system was equilibrated for 5 ns in both the NVT and NPT ensembles at 1 bar and 300 K. Production simulations were run for 50 ns. Potential of mean force profiles were obtained via umbrella sampling. Furthermore, ΔH and ΔS were computed from the van't Hoff relation using free energies calculated at multiple temperatures. All simulations were performed using GROMACS 2021.3. Platinum complexes spontaneously adhered to graphene surfaces in a parallel orientation, with derivatives showing stronger affinity than cisplatin. This was confirmed by lower adsorption free energies (ΔG_{ads}) for cisplatin compared to its derivatives, possibly due to increased mechanical strain upon adsorption. Van't Hoff plots suggested an enthalpy-driven process for all complexes, facilitated by water molecule liberation from graphene to the bulk phase, enhancing adsorption.

Starting from a series of chloro-2-oxo-1,2-dihydroquinoline-3-hydrazone derivatives bearing different aroyl moieties, we synthesized the corresponding copper (II) complexes to study their biological activity against selected cancer cells lines.

Hydrazones have shown a great potential as modulable ligands in medicinal chemistry for the preparation of cytotoxic agents.[1,2] Thanks to the huge variety of available building blocks to make the hydrazone X-CH=N-NH-C(=O)-Y structure, it is possible to create species with tuned chemical and coordination properties.

The new complexes have been characterized in terms of X-ray structure and solution behaviour with the support of DFT calculations.[3] They showed very promising cytotoxic activity against human colon (HCT-15), lung (H1573), pancreatic (BxPC3 and PSN-1), ovarian (A2780), and colorectal (LoVo) cancer cell lines and their resistant sublines.

federica.gulino01@unipa.it

The wound healing process results in chronic wounds if the complex interplay between cytokines, growth factors, blood components and the extracellular matrix is disrupted by aging or underlying health conditions like diabetes.[1] In chronic wounds, an excessive inflammatory response prevents the proliferation of the healthy tissue, causing a serious infection which can even be life-threatening, if not treated properly.[2]
Egg white proteins, such as ovoalbumin, ovotransferrin and lysozyme, are attracting interest because of their demonstrated antioxidant and antibacterial activities.[3] By incorporating these bioactive proteins, advanced wound dressing films gain the ability to manage oxidative stress in the wound. This promotes faster healing and potentially reduces the risk of bacterial infection.
Wound dressing films can be easily produced crosslinking polymers, such as polyvinyl alcohol (PVA) or polyvinyl pyrrolidone (PVP), by high-energy radiation.[4] This technique does not require expensive initiators and catalysts and it can guarantee simultaneous product sterilization, depending on the irradiation doses. When PVA is mixed with selected polysaccharides, the hydrogel wound dressings have shown faster healing rates and scarless healing, probably due to antioxidant properties of polysaccharide fragments produced upon irradiation.[4] The aim of this work is to develop novel hydrogel formulations incorporating egg white proteins and/or their peptides. The hydrogel systems demonstrated rheological and adhesion properties that make it suitable for a wound dressing. Fluid retention ability, morphology, protein release and the antibacterial and antioxidant properties were also assessed to investigate the applicability of the hydrogel formulation as an advanced wound dressing.

Janus-type dendrimers (JDs) are dendritic macromolecules bearing two domains of different polarity. A tailored balance between the two portions allows to control their physico-chemical properties, and therefore their function.[1] The use of fluorinated chains is a powerful tool to increase JDs colloidal stability and influence their self-assembling properties.[2] Moreover, the use of branched fluorinated moieties can be exploited for non-invasive *in vivo* monitoring by ^{19}F-MRI to develop new theragnostic systems.[3]
Here, we show how the balance between a perfluoro-*tert*-butyl moiety and polyester dendrons of generations 1-3 can strongly affect self-assembling behavior of a family of Fluorinated JDs (FJDs),[4] see Figure 1, and how the final physico-chemical properties can be exploited to synthesize an ionizable fluorinated JD for gene delivery applications.[5]

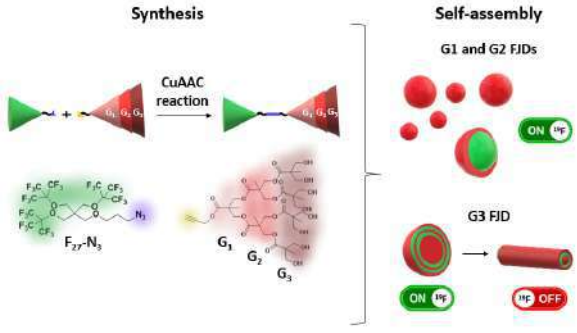

Figure 1: The three fluorinated JDs (Gen. 1 to 3) showed different magnetic properties at ^{19}F-NMR depending on their self-assembly in aqueous media.

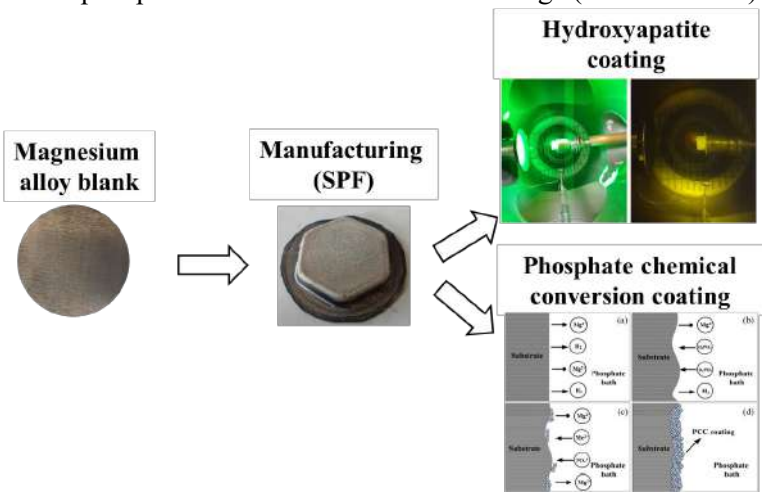
Magnesium alloys are considered as promising candidates for biodegradable orthopaedic implants, due to their mechanical properties and biocompatibility. Challenges related to the production of Mg-based prostheses are (a) the choice and the design of flexible manufacturing processes to produce complex-shaped parts (e.g. reproducing geometries of the human bones) and (b) the control of magnesium degradation rate in body fluids *via* specific surface coating techniques. Among flexible sheet metal forming processes, superplastic forming (SPF) allows to produce customized and complex-shaped implants characterized by a satisfying shape accuracy and surface quality. SPF can affect the microstructure and, thus, the corrosion resistance of the alloy, whose value is crucial in influencing the biodegradation rate. In the present contribution, a pulsed laser deposition of hydroxyapatite (HA)[1] coating and a phosphate chemical conversion coating[2] (see Scheme 1) were applied to AZ31 Mg alloy components, formed by SPF process, to decrease their degradation rate. Chemical-physical characterizations, electrochemical corrosion tests and electrochemical impedance spectroscopy were performed to assess the most promising deposition route and the possible beneficial effect of the applied coating on the corrosion behaviour of the superplastic formed AZ31 Mg components.



Scheme 1: Surface coating approaches applied to AZ31 Mg alloy.

Early detection and effective treatment significantly impact survival rates in disease management. In prenatal diagnostics, micromanipulation is a dependable method for manually isolating rare fetal cells from maternal fluids for molecular or cytogenetic analysis. While effective, this approach is costly and time-consuming due to the need for skilled personnel and specialized equipment[1].

This study aims to enhance the efficiency and affordability of prenatal diagnosis in hospital settings by developing a device for semi-automated selection of rare cells from biological samples. The device utilizes polymeric mats functionalized with antibodies to selectively capture target cells based on surface antigens.

The polymeric mats were electrospun with materials that provide the fuctional groups for further coupling. Bioconjugation methods employing EDC/NHS chemistry were developed to impart cell-capture capabilities to the mats, exploiting the streptavidin or avidin with biotin lock and key bound. Fluorescently labelled antibodies enabled assessment of conjugation success via fluorimetry and spectrofluorimetry.

Cell capture tests were conducted using fetal cells (CF) and mesenchymal stem cells (MSC) on antibody-decorated mats, with observations made using optical and confocal microscopy to evaluate capture efficacy. Release after capture mechanism of the streptavidin or avidin with biotin lock and key bound was also tested using fluorescent biotinylated probes.

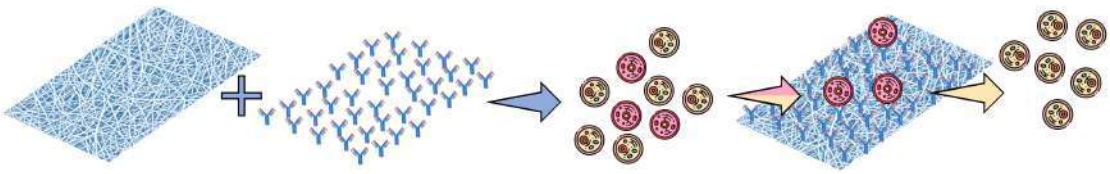

Figure 1: Schematic representation of mat antibody decoration and specific cells selection.

arianna.rossetti@polimi.it

Spinal cord injury (SCI) is a frequent disabling injury of the spine that leads to cell degeneration, involving neurons, astrocytes and oligodendrocytes[1]. Secondary processes (e.g. inflammation, apoptosis and oxidative stress) cause additional loss of neurons and glial cells (secondary injury). After an acute damage, the reactive pro-inflammatory response of the astrocytes, with the subsequent formation of scar tissue and the inhibition of axonal regrowth, is pivotal. Astrocytes with A1 phenotype exert indeed neurotoxic effects, upregulating genes associated with the synapse and neuronal degeneration, suggesting that A1 has harmful pro-inflammatory action[2]. Various approaches have been employed to counteract this detrimental progression of the secondary injury[3]. For this purpose, a large number of nanoparticles-based systems have been tested, but none are selective for pro-inflammatory astrocytes[4]. Therefore, the challenge is to formulate a targeted, effective therapy with neuronal protective effects, reducing the side effects. In this study we have developed a novel delivery tool, a nanogel-based nanovector able to be selectively internalized in activated astrocytes. When loaded with Rolipram, an anti-inflammatory drug, this nanovector allows a selective and controlled release in the spinal cord, reversing the toxic effect of A1 astrocytes on motor neurons in vitro. When tested acutely in a SCI mouse model it improves motor performances, reducing the astrocytosis and preserving neuronal cells[5]. Interesting results are being obtained for the regulation of other neuronal cells, e.g. the glial component, involved in the inflammation process.

Insights into factors influencing the performance of immobilized enzymes and biocatalytic membrane reactors

L. Giorno, G. Vitola, E. Piacentini, R. Mazzei

National Research Council - Institute on Membrane Technology (CNR-ITM), Rende, Italy

l.giorno@itm.cnr.it

It is known that heterogenization of enzymes by attaching/loading to a carrier such as nanoparticles, nanoemulsions and nanostructured membranes increases their stability, although this may lead to a decrease in their catalytic activity and selectivity. However, this inverse relationship is not a general rule. The lecture will illustrate that high catalytic activity and selectivity (including enantioselectivity) and high stability can be achieved simultaneously. This was confirmed by case studies with different enzymes (including lipase, beta-glucosidase and phosphotriesterase) immobilized on supports of different materials (organic, inorganic, mixed matrix) and shapes (nanoparticles, droplets, porous membranes) using different methods (entrapment, covalent binding).

Studies on the performance of enzyme-loaded membranes in continuous biocatalytic membrane reactors show that, in addition to the immobilization conditions and the physicochemical properties of the microenvironment in which the catalytic biomacromolecule is located, the topography of the support and the transport phenomena through the biocatalytic matrix also play a role in the resulting biocatalytic performance of heterogenized enzymes. A better understanding of the factors that influence a biomacromolecule such as an enzyme when it is compartmentalized in an artificial, durable membrane opens up strategies to enable green, intensified, sustainable biocatalytic membrane reactors for numerous applications[1-4].

Adducts of sp^2 Carbon Allotropes Functionalized with Pyrrole Compounds and with Transition Metal atoms: Towards Single Atom Catalysis

V. Barbera, F.Magaletti, D.Gentile and M. Galimberti

Department of Chemistry, Materials and Chemical Engineering "G. Natta", Politecnico di Milano, Via Mancinelli 7, 20131 Milano, Italy

vincenzina.barbera@polimi.it

The confinement of organic synthesis within nanospaces is being considered with increasing attention to improve its yield and reduce environmental impact. Along with this, active site heterogeneity, achievable through anchoring metals onto solid supports, offers a promising means to combine the advantages of homogeneous and heterogeneous systems.

With a view to further optimizing the two processes, a synergy between the two systems would be desirable.

In this work, facile metal decoration of sp2-hybridized carbon allotropes is achieved, and their compatibilization into compostable matrices through 3D printing was used to obtain the zeolike's concept.

First, functionalization of the graphene layers was performed with 2-(2,5-dimethyl-1*H*-pyrrol-1-yl)-1,3-propanediol (serinol pyrrole, SP).[1]

SP is a serinol derivative obtained from the pure reaction of 2-amino-1,3-propanediol with 2,5-hexanedione, with an atom economy of approximately 85%, almost quantitative yield, and therefore high atom efficiency. The only co-product is water, in the absence of solvent and catalyst.

The decoration of the allotrope was carried out with metals such as ruthenium, copper, and silver, and the catalytic activity was tested in C-H activation reactions (hydrogen isotope exchange), reductions, and cross-coupling reactions.[2,3]

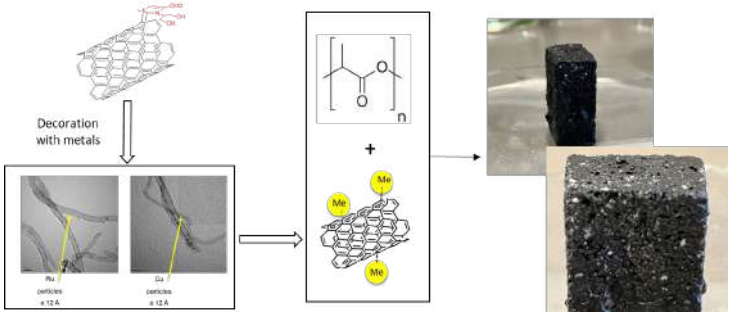

Figure 1: process for the preparation of zeolike's.

Europium-doped yttrium orthophosphate (Eu^{3+}:YPO_4) is attracting increasing interest as luminescent material due to its applications in bioimaging and as advanced light sources and optical markers. [1, 2] In this work, a rapid microwave-assisted hydrothermal method under mild aqueous conditions was investigated for the preparation of such phosphors with tunable morphology and narrow size distribution in the nanometre range. Well-crystallised Eu^{3+}:YPO_4 (5% mol Eu) nanopowders with tetragonal single phase structure and low degree of hydration were obtained in very short times (5 min) of MW heating at 200°C compared to conventional methods and without the need for additional calcination treatment. In addition, varying the reaction time (up to 30 min) and temperature (up to 240°C) resulted in different nanocrystal morphologies and sizes, which can be tuned by controlling the reaction parameters, thus potentially tuning the optical properties of the nanoparticles. The resulting nanopowders exhibit intense red emission using 396 nm as the excitation wavelength, showing the characteristic emission bands of the Eu^{3+}in the crystal matrix. Moreover, their optical properties, studied by measuring both excitation and emission spectra, luminescence lifetimes and quantum yields, are comparable to those of analogous materials prepared by conventional hydrothermal method. [3, 4] These results suggest that the MW-assisted hydrothermal process optimized in this work is a faster and energy-saving strategy to efficiently produce single-phase Eu^{3+}:YPO_4 (5 mol% Eu) luminescent nanopowders with monodisperse tuned morphology and narrow particle size distribution together with suitable optical properties which could have potential applications in both biological and security fields.

micaela.pozzati@polito.it

2D materials have gathered significant attention due to their interesting and tunable properties and their wide range of applications. They can be produced in several ways, but one important and easy methodology is the "liquid phase exfoliation" (LPE)[1]. It consists in using specific solvents to exfoliate the material, however N-methyl-2-pyrrolidone (NMP), dimethyl sulfoxide (DMSO) and N,N-dimethyl formamide (DMF) are expensive, high boiling point solvents and toxic[2], therefore limiting their use and applications. Ideal solvents are instead low boiling point solvents and above all: water, but it has a low exfoliation yield and quality.

Therefore, it is possible to add stabilizers, for example surfactants, to improve the process[3]. However, the surfactant concentration can influence the final concentration and quality of the material and high concentrations can also be detrimental for different applications. In this work, we investigate the role of the surfactant concentration on the exfoliation process of two bi-dimensional materials, MoS_2 and WS_2 using sodium dodecyl sulfate (SDS), sodium dodecylbenzene sulfonate (SDBS) and sodium hexadecyl sulfonate (SHS) as surfactants.

Moreover, it is necessary to confirm the outcome of exfoliation using different characterization techniques such as TEM, UV/Visible and Raman spectroscopies, which provides informations on the structural integrity and size of the nanosheets. We find that all the surfactants work efficiently to exfoliate the materials, particularly SHS.

Development of Doped Li_4SiO_4-based Pellets for CO_2 Capture at High Temperature

D. Rossi [a], U. Desideri [b], M. Seggiani [a]

[a] DICI, University of Pisa, Largo Lucio Lazzarino, 56122 Pisa (Italy). [b] DESTEC, University of Pisa, Via Carlo Francesco Gabba 22, 56122 Pisa (Italy). e-mail of submitter damiano.rossi@unipi.it

This study focuses on the development of K_2CO_3-doped lithium orthosilicate (Li_4SiO_4) sorbents for CO_2 capture from high-temperature flue gas generated by gas turbines [1] using a versatile process aimed at the easy production of sorbent pellets. The methodology involves the synthesis of Li_4SiO_4 powders from quartz silica (SiO_2) and Li_2CO_3 followed by the addition of different amounts of K_2CO_3 as an activity promoter and viscous linear polyalphaolefins. The latter acts as both a compatibiliser and a pore-forming agent. The resultant mixture was extruded in form of cylindrical pellets and sintered at moderate temperatures (550 °C) to obtain porous and mechanically resistant sorbents [2]. The performance of the resultant pellets was assessed by thermogravimetric analysis at 580 °C, during sorption under low CO_2 partial pressure conditions, and 620 °C, during desorption with N_2. The results indicate that an optimal K_2CO_3 content of 20 wt.% facilitates the formation of a homogeneous molten K_2CO_3-Li_2CO_3 mixture during CO_2 chemisorption, thereby preventing phase segregation across multiple cycles. The inclusion of 30 wt.% olefin yields durable, porous pellets (Fig. B-D) capable of maintaining a consistent and regenerable CO_2 sorption capacity of 130 mg CO_2/g (with a Li_4SiO_4 conversion of 45 %) over 25 cycles, each spanning 30 minutes (Fig. A). The sorption kinetics of these sorbents were characterised and analysed using the double exponential model to elucidate the influence of cycling and K_2CO_3 concentration on the overall sorption performance.

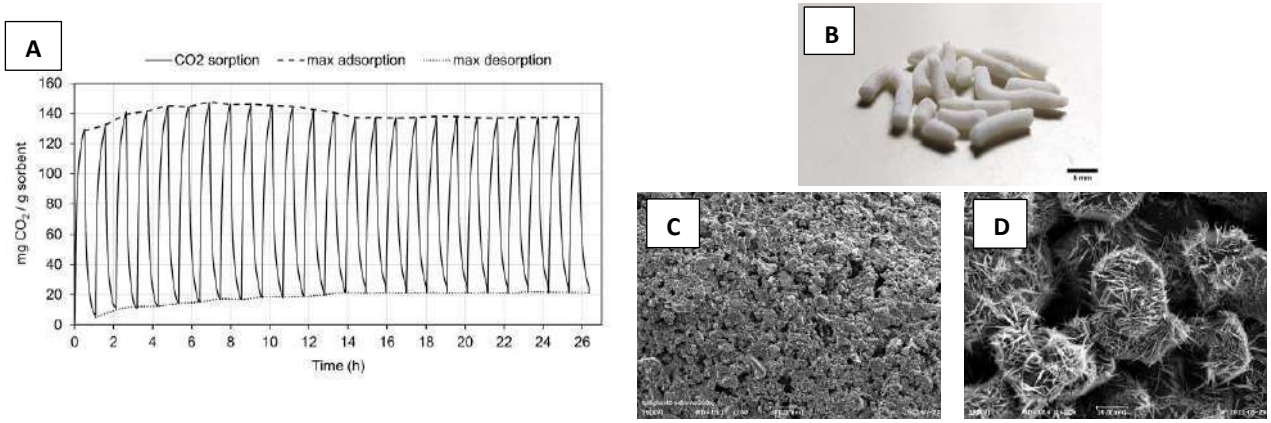

Figure: (**A**) Pellet sorbent capacity during 25 CO_2 sorption/desorption cycles. (**B-D**) Porous pellets.

This research introduces a simplified pelletizing technique for developing innovative, solid, and robust pellets with enhanced CO_2 capture and cycling capabilities making their use feasible in industrial fixed-bed adsorption systems.

Carbon capture technology is an essential option for mitigate climate change by reducing greenhouse gas emissions (GHG).[1,2] Governments worldwide are urged to adopt net-zero transition strategies.[3] This study proposes a promising class of sustainable CO_2-effective absorbents: Ionic liquids based on amino acid (AAILs). Ionic liquids (ILs) are organic molten salts with melting temperature below 100 °C and high thermal stability.[4] These innovative materials hold promise for application in energy and industrial sectors to foster in climate change mitigation. With their tuneable properties driven by cation and anion selections,[5] AAILs exhibit potent reactivity with CO_2. Despite their efficacy, their viscosity at room temperature has hindered widespread use. However, by employing various CO_2 separation methods, including solvent mixing to reduce viscosity, AAILs can be effectively utilized. Through a comprehensive analysis involving CO_2 absorption tests, ATR Spectroscopy, TGA, and DSC, this study explores the synthesis and characterization of AAILs and their solutions. Newly developed solutions such as [Cho][AA] (Choline-based AAILs) and [MMPyrr][AA] (Dimethylpyrrolidinium-based AAILs) exhibit remarkable CO_2 absorption capability, low energy consumption, and low release temperature, offering a sustainable strategy for post-combustion capture technologies.

The growing and urgent demand for water and wastewater decontamination from a wide range of pollutants asks for the development of more effective and safe technologies. In this context, the design of manufactured nanomaterials (MNM) for an efficient water treatment is attracting more and more interest due to their promising adsorption performances. At the same time, MNM also raise concerns due to their potential (eco)toxicity and the uncertainty related to their final fate. For this reason, a safer-by design strategy is recommended in developing new MNM, which should combine a high decontamination efficiency with verified eco-safety.[1] The goal of this work is to show an overview of our recent findings on how nanocellulose, simply derived from biomass as renewable source, can represent a sustainable and eco-safe solution for developing new MNM with high sorption performances for water treatment. 2,2,6,6-Tetramethypiperidinyloxyl (TEMPO)-oxidized cellulose nanofibers (TOCNF), bearing carboxylic groups on the C6 position of some glucopyranose units, have been produced from different sources and their eco-safety has been verified by an *in vivo* acute study with marine mussels *Mytilus galloprovincialis*.[2] Cellulose nanofibers have been successfully used as suitable supports for silver nanoparticles, providing nano-composites with enhanced sorption performances towards heavy metals[3] and as building blocks for the design of nanostructured cellulose-based materials, obtained by thermal cross-linking with branched polyethylenimine. These cellulose-based nanosponges (CNS) were proven to be suitable for removing heavy metal ions from fresh- and seawater, also confirming their efficiency after several cycles of reuse. To support a non-impacting *in-situ* application, their eco-safety was demonstrated performing *in vivo* tests on marine species, toward which no genotoxic effects were observed.[4] Further studies were conducted on freshwater species, proving that CNS can be considered suitable safe candidates for metal sequestering, without altering cellular physiological activity in the considered organisms.[5] A more recent study of eco-safety assessment of CNS on sea urchins demonstrated that appropriate conditioning of these materials can lead to their safe use in water remediation applications.[6] All the topics described are investigated within Spoke VS4 of the PNRR RETURN project.

b.russo@itm.cnr.it

In the last decades, the production and consumption of plastic items have seen exponential growth, causing both aquatic and terrestrial pollution. In particular, micro- and nanoplastics (MNPs), due to their small size and a non-biodegradable nature, enter the food chain posing a potential health risk to all living organisms.[1,2] Currently, municipal water treatment plants are not suitable for the removal of MNPs, thus reducing the quality of water released into the environment. In this context, membrane technology[2] represents a concrete and promising solution for the removal of small plastic particles from municipal water. For this purpose, water leaving a municipal plant was treated using an integrated membrane system (Figure 1), combining ultrafiltration (UF) and nanofiltration (NF) processes, to evaluate its performance in terms of permeate flux, fouling index (FI%), cleaning efficiency (CE%) and MNPs rejection. The integrated system houses tubular ceramic membranes, selected to improve transmembrane flow and reduce membrane fouling. Results showed that proposed integrated system allowed the complete recovery of MNPs from municipal water and the complete recovery of the initial performance of the membranes used with a CE of 98% and a FI of 30%. In addition, a degradation step for retentate streams was studied by means of a photocatalytic process using TiO_2 and UV light, to completely degrade the MNPs coming from municipal plants.

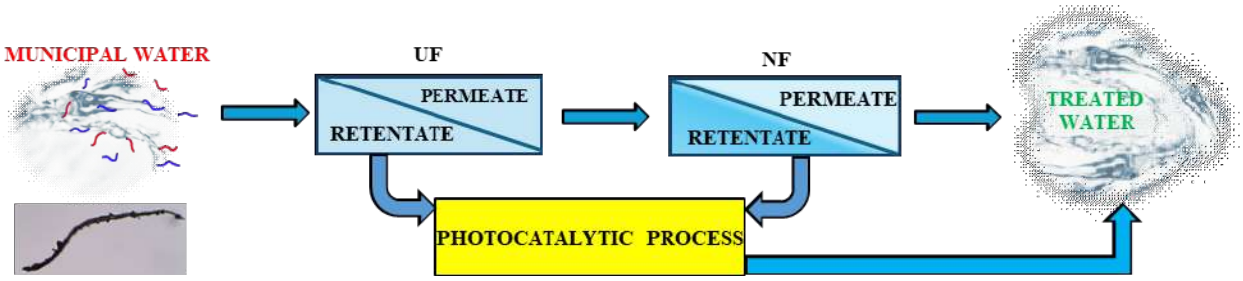

Figure 1: Scheme of UF/NF lab-scale plant.

In wastewater treatment plants (WWTP), sewage undergoes comprehensive purification processes to remove contaminants. The residual solids from this treatment, known as sludge, can be incinerated, transforming into ash, a practice that necessitates careful management due to potential environmental and health considerations[1]. Harnessing the latent potential of fluidized bed mono-combusted ash from sewage water treatment, this study unveils a versatile approach to water remediation within the framework of a circular economy. Through activation, the ash demonstrates heightened sorption efficiency, actively participating in the adsorption of dyes and metals from contaminated water, showcasing competitive Qmax values across various isotherm fits and dynamic kinetic studies, tailored to address different types of contaminants present. Additionally, characterization studies such as SEM, BET, and XRD analyses provide valuable insights into the structural and surface properties, enhancing our understanding of its adsorption mechanisms and performance. The incorporation of both direct ash and activated ash into immobilized polymeric-ash beads, collectively forming effective adsorption matrices, demonstrates their effectiveness in adsorption and their improved ability to be regenerated for different types of contaminants. Polymer immobilization involves confining polymers in a fixed matrix, which enhances their performance and usefulness. The successful regeneration of ashes, with an 80% reuse rate and sorption efficiency, is contingent upon the types and levels of contaminants present. Ash in landfilling entails health hazards and environmental concerns, yet its advantageous role in adsorption processes makes it a valuable tool for efficiently removing contaminants[2]. This study not only facilitates the simultaneous removal of diverse contaminants but also contributes to a waste-to-waste treatment paradigm, advancing eco-friendly methodologies in wastewater treatment.

Phenolic compounds, such as tannins, are widely recognized for their antioxidant and antimicrobial properties that can help inhibit the growth of bacteria and prevent oxidation in packaged foods. These compounds can be extracted from various natural sources as well as from agri-food industry by-products, leaving exhausted ligneous residues rich in lignin. The latter is widely used as a green additive, capable of imparting functional properties to polymeric composites used for food packaging, drug delivery, and environmental applications. Undoubtedly, the effectiveness of the extraction process and consequently the chemical composition of extracts and residues of the extraction process are principally determined by the extraction parameters, such as temperature, time, solvent, etc.

In a previous study by Moccia et al. [1] it was demonstrated that the choice of solvents and extraction protocols for chestnut wood fiber (CWF), derived from exhausted chestnut wood, significantly influences the composition of the extracted compounds. In the literature, there are also studies where entirely biobased composites are produced by dispersing lignin of different origins into a bioderived polymer [2]. It was evident that the nature of the lignin additive affected the thermal and mechanical properties of these biocomposites.

Here we present a work where the extracts and extraction residues of CWF, as well as the CWF themselves, are used as functional fillers in biopolymer-based composites. The effects of the addition of these fillers on the composite's structural and functional properties are evaluated. The final purpose is to assess whether the extraction process effectively leads to an enhancement of filler antioxidant efficiency compared to untreated CWF, together with their effect on composite mechanical properties.

Aknowledgments: This study was conducted within the Agritech National Research Center (Task 8.1.1. Valorisation of the waste by green chemistry to obtain high value molecules or new products, and Task 8.1.3. Valorization of the waste to obtain biomaterials) and received funding from the European Union via Next-Generation EU (PIANO NAZIONALE DI RIPRESA E RESILIENZA (PNRR)—MISSIONE 4 COMPONENTE 2, INVESTIMENTO 1.4—D.D. 1032 17/06/2022022, CN00000022).

Unlocking the potential: green strategies for rapeseed meal

D. Allevi[a], F. Cairone[b], G. Fabrizi[b], A. Goggiamani[b], A. Iazzetti[a]

Figure 1. A green way from waste to useful product.

Rapeseed meal (RSM) is a byproduct of rapeseed extraction for oil manufacturing. It is reported to be high in proteins [1], phenolics, and flavonoids [2], substances with antioxidant and anti-inflammatory qualities that make it suitable for use in functional foods, nutraceuticals, and cosmetics. Various valorization procedures have been developed for fully exploiting RSM, including numerous extraction strategies [3] aimed at bioactive extraction.

In this study, we compared a traditional ethanol Soxhlet extraction to a supercritical CO_2-based technique with ethanol as a modifier. This approach, which uses supercritical carbon dioxide as a solvent to extract target molecules from a feedstock, is widely regarded as environmentally friendly and efficient. It has various advantages over standard extraction procedures, including minimal toxicity, good selectivity, and high purity of extracted chemicals. [4]

The current study seeks to valorize the RSM by developing "green" extraction techniques for bioactive substances using alcoholic solvents and/or supercritical CO_2.

Enhancing the recovery of polyphenolic components was prioritized, and the results were assessed using NMR and HPLC-DAD studies. Additionally, using specific methods, the antioxidant qualities of the extraction residues were investigated. Based on our findings, a quantitative recovery hypothesis has been put forth for bioactive-rich extracts that are repurposed in nutraceuticals and cosmetics. [5]

Metal-organic cages (MOCs) represent a great option for molecular recognition, sensing and guest inclusion.[1] This is possible via host-guest chemistry because of the presence of internal binding sites that can interact with specific moieties of the guest, anchoring it to the host structures. One special kind of these assemblies, still little investigated, is the $M_{12}L_8$ poly-[*n*]-catenane[2] (**1**) formed from the mechanochemical bonding of interlocked icosahedral $M_{12}L_8$ MOCs using a tridentate pyridine-based ligand and ZnI_2. This material showed dynamic behaviour and presents interesting binding sites for the trapping of aromatic compounds.[3,4] In this work[5] we present the uptake of different aromatic guests by molecular recognition via several single-crystal-to-single-crystal (SCSC) experiments and the mechanics behind the dynamic behaviour enabling their capture. By means of single crystal X-ray diffraction (SC-XRD) we could determine the complete structure of a single crystal under multiple gas-solid SCSC guests exchange and identify preferential guest uptake. DFT calculations were fundamental to confirm the experimental results. The combination of SC-XRD, DFT and solid-state ^{13}C NMR allowed the full characterization of **1**, proposing a mechanism in which the pyridines of the ligand act as nanorotors, making possible the guest diffusion inside and outside the cages.

This study shows the responsiveness of **1** to external stimuli, making $M_{12}L_8$ MOCs candidates in the application fields of sensing, potentially able to trap pollutants and toxic compounds from the air.

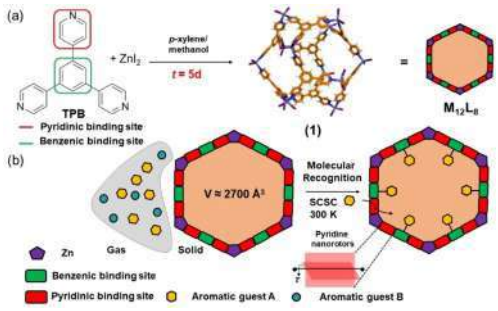

Figure 1: Molecular recognition of aromatic guests by $M_{12}L_8$ in **1** in a gas-solid reaction.

valentina.dichiarante@polimi.it

Non-natural amino acids, in particular fluorinated ones (F-AA), are attracting considerable interest in materials and biomedical sciences, thanks to their ability to self-assemble into peculiar supramolecular structures. The conformational changes induced by the presence of fluorine atoms obviously affect their functions, as well as their aggregation behaviour, resulting for instance in an improved tendency to form fibrils, and gels therefrom.

We recently investigated a crystal engineering-based approach for obtaining multicomponent F-AA hydrogels with tuneable strength and properties, by mixing them with suitable partner molecules. Our studies proved the matching between the driving noncovalent interactions in crystals and hydrogels, as shown by the exemplary case of *N*-Fmoc-pentafluoro-phenylalanine (**1**, Fig. 1).[1]

The ability of fluorination to influence physical, chemical, and structural properties of these substrates offers the possibility to engineer bioinspired materials with specific and tuneable functions.

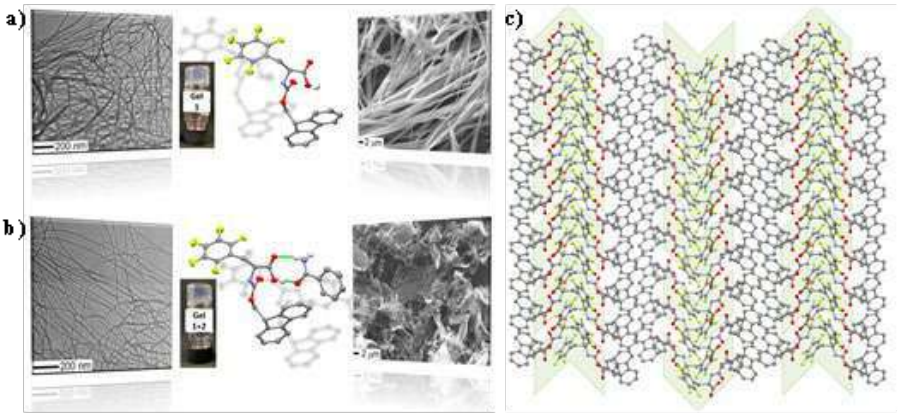

Figure 1: Supramolecular hydrogels of fluorinated amino acids: a) TEM and SEM images of **1** hydrogel; b) TEM and SEM images of bicomponent hydrogel of **1** with benzamide (**2**); c) crystal packing of **1**·**2** supramolecular complex.

susanna.romano@uniroma3.it

Plastic has become ubiquitous in modern life due to its practicality, convenience, and safety benefits. However, its widespread use has led to significant environmental issues, particularly in the field of food packaging, significant contributor to world's plastic waste[1]. Once used, most of this packaging is either incinerated or landfilled, contributing to ecosystems contamination. Plastic pollution could be reduced by replacing conventional plastics with biodegradable ones. However, to ensure the sustainability of these alternatives, it is crucial to keep them in the economy and out of the environment for as long as possible. Hence the need to study their recycling, particularly in closed-loop system for food packaging applications. Today, only PET bottles are decontaminated and thermally reshaped in the recycling process[2], and there is a huge lack of knowledge on the end of life (EoL) loops of biodegradable plastics. This is partly due to misconceptions about the technical and economic challenges of their recycling, such as insufficient volumes, contamination risks, and greater degradation under thermal recycling conditions. ECO2R project in which this work is included seeks to challenge the misconception that biodegradable plastics are only suitable for composting. It aims to design the end-of-life route for biodegradable plastic packaging by identifying the properties that influence recyclability in a closed-loop system, such as decontamination efficiency and structural stability (figure 1). In particular, the work presented here is focusing on the ability of certain biodegradable polyesters such as PLA, PBS and PBAT to be contaminated by the surrogate's panel identified for PET and referenced in FDA and EFSA regulations. The relationship between the polymer structures and their capacity for contamination was studied. In the future, a wider range of contaminants will be investigated.

The expansion of industries like textile, food, cosmetics, and pharmaceuticals has led to the release of hazardous and persistent pollutants, including heavy metals[1], microorganisms (such as bacteria, fungi, and viruses)[2], and nano/microplastics[3], which are associated to serious risks for nature and humans. Similarly, monitoring the intricacies of cellular signalling pathways and networks is decisive to understand cellular regulation, homeostasis and progression of complex disease states related to many serious pathologies[4]. In this context, a growing request of rapid, highly sensitive, and precise sensing technologies able to detect and monitor chemical and/or biological analytes is attracting a great scientific interest to safeguard human health and environmental integrity. Colloidal quantum dots (QDs) present a promising alternative to conventional, expensive, and time-consuming methods[5]. Among them, carbon quantum dots (CQDs) offer distinct advantages due to their non-toxic nature, sustainability, biocompatibility, and versatile properties in terms of redox activity and photoluminescence[6].

Here, a waste-to-wealth approach was adopted to synthesize colloidal CQDs with enhanced photoactivity, photoluminescent and pro/anti-oxidant functionalities through a green hydrothermal route by using molecular precursors derived from different biowaste sources, such as humic substance (HS), lignin (LG), and coffee grounds (CG), and bi-distilled water serving as the solvent. The functional abilities of such CQDs were finely tailored based to the surface, structural, and optical characteristics directly influenced by the chemical composition of the biowaste feedstocks. Through a comprehensive physicochemical analysis based on cryo-TEM, dynamic light scattering (DLS), X-ray photoelectron (XPS), Fourier-transform infrared (FT-IR), UV-visible and photoluminescence (PL) spectroscopies, the formation of ultra-small QDs with an average diameter ranging from 2 to 4 nm was assessed, showing distinct atomic doping and surface defects that significantly influenced their redox behaviour and emission yield. Notably, CQDs derived from coffee grounds exhibited remarkable radical-scavenging properties and excellent colloidal stability. Also, fluorescence analysis was useful to monitor the optical ability of CQDs to detect metals in aqueous media. Finally, bioassays lead to evaluate the biocompatibility, cytoprotecting behaviour as well as cells internalization as function of chemical and physicochemical assets of CQDs, thus proposing them as multifunctional fluorescent nanodevices for probing different biological or chemical processes.

Innovative clay based hybrid materials for thermochemical energy storage applications

E. Previti,[a] L. Calabrese,[a] J. M. Coronado,[b] E. Mastronardo,[a] C. Milone[a]

The capacity to decrease and reuse energy is pivotal for preserving the environment. Thermal energy storage (TES) systems are commonly employed for these purposes. Although sensible and latent heat storage technologies represent convenient alternatives, thermochemical materials (TCM) are the most interesting candidates for their high energy storage density. TCM usually exploit a reversible solid-vapour reaction in which the direct endothermic process represents the charge step, while with the subsequent reverse stage the heat stored is released.[1] Recently, hydrated organic salts such as Calcium Lactate pentahydrate (CL) have been suggested to overcome deliquescence issues in low temperature applications.[2] CL presents a large storage capacity (1127 J/g) and it is an environmentally safe material, however it exhibits a slow hydration kinetic.[3] The possibility of distributing CL onto the surface of a natural clay could promote not only hydration kinetics but also avoiding salt agglomeration during multiple dehydration/hydration cycles. In this work CL was impregnated with sepiolite at different load of salt respect clay (30-90 %wt.). The obtainment of a hybrid TCM/sepiolite material represents a novelty in the present literature. Complementary characterization techniques were used for studying the composite materials. The salt presence and its transition phase from dehydrated to hydrate in composite was investigated by X-Ray Diffraction. Infrared spectroscopy analyses show only the spectra of the constituent material. On a morphological point of view, micrographs obtained by scanning electron microscope show the formation of agglomerates where CL is uniformly distributed among sepiolite particles. Thermal analyses were carried out to investigate the water losses suffered by hybrid materials and the corresponding storage capacities. On the other hand, the water uptake was tested in both static and dynamic vapour conditions resulting in a clear enhancement of hydration kinetics and vapour sorption at higher mineral content. Considering the low cost of CL and the large natural reserve of sepiolite, in view of the preliminary studies carried out, the mineral results a valid support for hydrated salt loadings, promoting, therefore, the combination of both as a promising technology for TES applications.

Recent statistics have demonstrated that the direct reuse of polymeric wastes can be considered one of the most sustainable and advantageous approaches. However, many applications require the use of products with specific shape and geometry: in this context, thermosetting wastes may be very difficult to readapt for new uses. To overcome this challenging issue, the scientific literature has witnessed the potential of shape memory epoxy thermosets. The shape recovery can be triggered by various stimuli, including pH, heat, and electricity, though the most studied is the thermally-induced shape recovery. Shape memory epoxies are employed as components in the transportation industry, where the demand for transparent and fire-resistant coatings is enormously increasing. Mostly, the flame retardancy of such coatings is improved by the chemical modification of the polymer matrix, together with the use of specific flame retardants. Unfortunately, these approaches often lead to the loss of transparency and a detrimental effect on the overall mechanical performance of the final product.

In our work, we report the design and development of new multifunctional epoxy nanocomposites that exhibit photoluminescence, high hydrophobicity, fire resistance, and heat/flame-triggered shape recovery features [1]. It is worth noting that these all-in-one peculiarities can be achieved using very simple formulations, without using halogen- or phosphorus-based flame retardants, avoiding any specific modification of the polymer network, and employing carbon dots at very low loadings (namely, 0.1 and 0.3 wt.%). These latter are synthesized starting from vegetable wastes by a sustainable hydrothermal route, hence also fulfilling the circular economy concept [1].

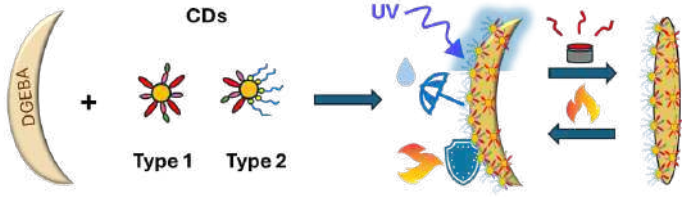

Figure 1: Synthesis strategy and functionalities of the multifunctional epoxy nanocomposites.

Sustainable valorisation of industrial black mass through circular solvometallurgy

Alberto Mannu,[a] Maria Enrica Di Pietro,[a] Viviana Bosello,[a] Andrea Mele[a]

[a]*Department of Chemistry, Materials and Chemical Engineering "G. Natta" – Politecnico di Milano*
Piazza L. da Vinci 32 – 20133 Milano
alberto.mannu@polimi.it

The extraction of Critical Raw Materials (CRMs) from exhausted Li-ion batteries (LIBs) represents a pivotal target for industry and academics. Once the electrodes are discarded and mechanically treated, a black powder called Black Mass (BM) is obtained. It is rich of valuable elements which can be extracted through different procedures, as hydro-, solvo-, and pyro-metallurgy which, however, suffer from low degree of sustainability and circularity.
In this context, a high sustainable solvometallurgy approach to treat different types of BM arising from lithium-cobalt oxides cathode (LCO) and nickel-cobalt-manganese oxides anode (NCM) was designed and tested. With the target of maximizing the extraction of CRMs while simultaneously minimizing environmental impact, three types of extractants were explored: water-, glycerol-, and eutectic-based systems.
Lithium recovery rate was assessed by a customized quantitative ^{7}Li NMR methodology, while the extraction of Co, Ni, Mn, and Al were determined by ICP analysis. Characterization of starting and treated BMs was conducted by powder x-ray spectroscopy and through SEM/EDS microscopy.
Excellent extraction rates were reached in different conditions and graphite recovery was also achieved by employing water or glycerol/water mixtures. Hydrophobic eutectic combinations of Free Fatty Acids (FFAs, hydrogen bond donors) and menthol (hydrogen bond acceptor) showed good selectivity toward some elements such as Al. The glycerol and the FFAs employed were derived rom the recycling of Used Vegetable Oils (UVOs) and subsequent hydrolysis, crosslinking two main value chains: exhausted LIBs and UVOs and thus increasing the overall sustainability of the processes.
Finally, green metrics (mass yield, mass productivity, E-factor, process mass intensity) and EcoScale were calculated for the best performing procedures.

$CaMnO_3$: a promising material for low temperature hydrogen storage

G. Calabrese,[a] E. Mastronardo,[a] E. Proverbio,[a] C. Milone[b]

[a]*Department of Engineering, University of Messina, Contrada di Dio 98166, Messina, Me, Italy*
giulia.calabrese1@studenti.unime.it

To our days, the hydrogen storage, especially in the solid state, is a very interesting and challenging research topic. Hydrogen, in fact, is one of the most favourite candidates to replace fossil fuels, that are not sustainable and renewable energy sources.[1] This gas has a high energy density (of 120 MJ/kg = 33.33 kWh), and its only reaction product is H_2O. However, due to the extremely low density of hydrogen (0.089 kg/m^3) solid-state storage systems are one of the most viable solutions. Particularly, we are studying ABO_3 perovskite oxides, that have a high thermal stability, they are relatively active and they allow the exploitation of a great variety of elements in the composition while maintaining the basic structure unchanged.[2] We are focused on $CaMnO_3$ that is a promising material for hydrogen storage at low temperature. This perovskite oxide, whose constituent elements are earth-abundant and non-toxic, was synthesized by a modified Pechini method and characterized by X- ray diffraction (XRD), thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), and scanning electron microscopy with energy dispersive X-ray spectroscopy (SEM-EDX) microscopy analyses. Then the hydrogen storage capacity was tested as a function of pressure with a High Pressure Gas Sorption Analyzer volumetric system (i-Sorb, Anton Paar). Specifically, we are considering the storage capacity of this material up to 40 bar of H_2 at 100 °C. In these conditions $CaMnO_3$ shows a storage capacity of 0.02 wt% (0.89 kg/m^3). In order to improve the hydrogen sorption for this material, Pd^0 was added (1 wt%.), since it can help the hydrogen molecule dissociation into atoms and therefore promote its absorption. $CaMnO_3$/Pd 1%, in fact, in the same condition of pressure and temperature, has a hydrogen storage capacity equal to 0.86 wt% (38.70 kg/m^3). The sorption kinetics of this material was investigated considering different equilibration times (5, 60, 120 minutes, and until equilibrium condition is reached) for each adsorption step (from 0 up to 40 bar). The maximum adsorption recorded at 120 min of time limit is comparable with the longest equilibration time, indicating that 2h is an optimum compromise for the equilibration time for this hydrogen storage material. With respect to other materials, such as metal hydrides, despite a relatively lower gravimetric storage capacity but a comparable volumetric capacity, perovskite oxides enable the hydrogen storage at significantly lower temperature, namely 100 °C vs 300 °C required for hydrides. [3] Moreover $CaMnO_3$/Pd 1% can retain hydrogen even by decreasing pressure and release it when required at low temperatures. The evaluation of the storage kinetics model is ongoing.

Molecular Tweezer based on Zn(salen)-type complexes: role of spacer flexibility on aggregation and sensing properties towards biogenic amines

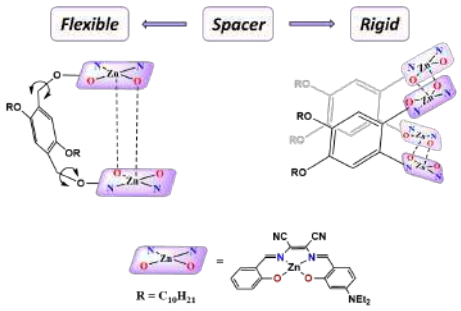
I. P. Oliveri, A. Attinà, G. Consiglio, S. Failla, S. Di Bella

Dipartimento di Scienze Chimiche, Università di Catania, I-95125 Catania, Italy

Email: ivan.oliveri@unict.it

Biogenic amines (BA) are nitrogen Lewis bases formed by the decarboxylation of amino acids that represent a health hazard when they are formed in foods in inadequate hygienic and storage conditions.[1] For the latter reason, the development of chemosensors for the rapid and sensitive detection of BA plays a crucial role in the field of food safety.

Recently it was demonstrated that the dinuclear Zn(salen)-type complex **1**, having a flexible spacer, is a chromogenic and fluorogenic chemosensor for biogenic amines.[2] Considering that spacer flexibility could limit selectivity of the chemosensor,[3] here we present the synthesis and characterization of a new dinuclear Zn(salen)-type complex **2**, having a rigid spacer, in order to study the role of spacer flexibility on aggregation and sensing properties towards biogenic amines.



Through a combinate approach of ^{1}H NMR, ^{1}H DOSY NMR, UV-vis and fluorescence spectroscopy, we have demonstrated that complex **2**, forms dimeric aggregates via intermolecular Zn···O interactions in non-coordinating solvents unlike to complex **1** which, under the same conditions, is stable as intramolecular aggregate.[4] This different aggregation mode, which could be attributed to rigidity of the spacer, has a significant impact on sensing properties of complex **2**.

This work was supported by the University of Catania, PIACERI 2020/2022, Linee di Intervento 2 e 3, and partially funded by European Union (NextGeneration EU), through the MUR-PNRR project SAMOTHRACE (ECS00000022).

In recent years, water quality conservation has emerged as a critical global concern due to the growing threat posed by heavy metal contamination, which impacts both agricultural ecosystems and public health. Among these pollutants, arsenic is a potent and dangerous toxic element that is widely present in natural watersheds, especially in regions that rely on groundwater sources for consumption.[1] Traditional monitoring methods are often insufficient in terms of sensitivity, selectivity and environmental sustainability. This study employs an innovative approach using electrochemical sensors with bacterial polysaccharides.[2,3] These modifications are designed to optimise the sensors' ability to selectively bind to heavy metal ions, thereby amplifying their sensitivity. The ecological nature of polysaccharides aligns with the overall goal of sustainable and environmentally friendly sensing technologies. Preliminary electrochemical results, performed at pH 7.4 using As^{3+} concentrations in the nanomolar range, are promising and indicate improved detection limits and selectivity compared to conventional sensor configurations. The incorporation of natural polysaccharides not only improves the analytical capabilities of sensors, but also contributes to reducing the environmental footprint associated with sensing technologies.

Recovery of strategic metals from NCM-lithium battery black mass through a microwave hybrid heating process

A. Cornelio,[a] A. Zanoletti,[a] M. Scaglia,[a] A. Bonometti,[a] E. Bontempi[a]

[a]*INSTM and Chemistry for Technologies Laboratory, Department of Mechanical and Industrial Engineering, University of Brescia, via Branze 38, 25123, Brescia, Italy*

antonella.cornelio@unibs.it

The energetic transition to electric power, needed to reduce CO_2 emissions, has driven a rapid expansion of the new global electric vehicle (EV) industry in recent years. It is estimated that by the year 2030, the worldwide EV population will reach 140 million, leading, in the next future, to the disposal of approximately 11 million tons of depleted batteries[1]. NCM-lithium batteries are the most used in the automotive industry. They are mainly composed by nickel, cobalt, manganese and lithium, inserted in the list of critical raw materials (CRMs). The recovery of these strategic materials becomes imperative pursuing solutions with low environmental impact. This work proposes a hybrid heating process based on microwaves[2] that, in few minutes, allows to reach temperature higher than 650 °C in a patented equipment. The thermal treatment promotes the formation of Li_2O, soluble in water, and increases the solubility of Co, Mn, Ni that can be recovered by a weak acid leaching.

Advanced oxidation processes are potentially effective solutions for water remediation and wastewater treatment by means of reactive oxygen species (ROS). ROS can be produced at metal oxide surfaces either through photocatalysis (light irradiation), upon energy-intensive pre-treatments, or in the presence of a radical source. Recently, this research group discovered that hybrid materials based on TiO_2 or ZrO_2 with specific organic ligands can spontaneously generate and preserve superoxide radicals ($O_2^{\bullet-}$) on their surface owing to the ligand-to-metal charge transfer complexes.[1] The consequent oxidative ability of these materials enables the degradation of various organic pollutants in water without any illumination.[1,2] Moreover, the visible light absorption of TiO_2-β-diketone hybrids allows increasing the reaction rate under sunlight.[2]

In the search for a suitable biowaste organic ligand, we found that rosin, a derivative of pine resin mainly composed of abietic acid, can be directly used in the sol-gel synthesis of redox-active hybrid TiO_2 (T-Abi, see Figure 1). This was assessed by XPS, FTIR and EPR spectroscopy.[3] Due to the growing concern for the spread of microplastics in the environment, this material was tested to treat LLDPE samples in aqueous suspension under indirect daylight at room temperature. Chemical alterations of the polymer were observed, as confirmed by the detection of degradation products by GC-MS.[3] These results open to the potential application of T-Abi in the chemical recycling of plastic waste, in addition to other ROS-related processes.

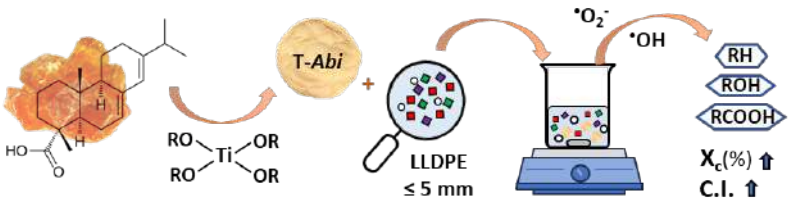

Figure 1: Scheme of the synthesis of TiO_2-rosin (T-Abi) and its use in LLDPE degradation tests.

chiara.loporto@poliba.it

Titanium dioxide stands out as a highly interesting photocatalysts due to its low cost and toxicity; however, a notable obstacle must be overcome for its practical applications. Commercial TiO_2 nanoparticles (e.g. P25) have a band gap energy of 3.2 eV resulting predominantly UV-photoactive. This limitation hinders the full harnessing of solar power. To circumvent this problem, it is possible to functionalize this inorganic material with an organic charge transfer sensitizer. In this framework, catechol is a small and simple molecule that can easily and stably bind the surface of TiO_2, reducing the band gap.[1,2] In this study, we adopted this strategy to functionalize the surface of TiO_2 nanorods (NR), a peculiar nanostructured titania that, due to its pronounced dimensional anisotropy, exhibits a better delocalization of the photoinduced charge carriers with respect to their sphere-like counterpart.[3,4] Therefore, oleic acid capped TiO_2 anatase nanorods (NR) were synthesized[4] and a partial ligand substitution was conducted to bind catechol on their surface to act as sensitizer (NR-Cat). The success of the functionalization procedure was testified by diffuse reflectance spectroscopy (DRS, fig.1) as well as thermogravimetric analysis, X-ray photoelectron spectroscopy and ^{1}H-NMR spectroscopy. While the as-synthesised NRs show an optical band gap of 2.75 eV, the binding of catechol on the surface of the rods caused a further remarkable red-shift of the absorbance and a band gap of 1.72 eV. This study reports novel findings on the catechol functionalization of TiO_2 nanorods specifically designed for photocatalytic processes that would greatly benefit from activity in the visible range, from contaminants degradation to hydrogen evolution processes. This work is part of the NEST-Network 4 Energy Sustainable Transition project (PE0000021–Next Generation EU).

The development of sustainable and efficient processes for biomass exploitation represents a primary target both in industrial and academic research. In particular, hydroxy methylfurfural (HMF) has gained increasing attention as it is a valuable synthon for many chemicals.[1-3] New and sustainable chemical routes can be achieved by using alternative reaction systems as selected mixtures of Hydrogen Bond Donors and Acceptors (HBDs, HBAs). In this context, HMF interaction with selected type V Deep Eutectic Solvents (DESs) has been assessed by multinuclear NMR, FTIR and Raman spectroscopy. Based on previous HMF-DES systems scouting, HMF reactivity in the most promising DESs has been studied (**Figure 1**).

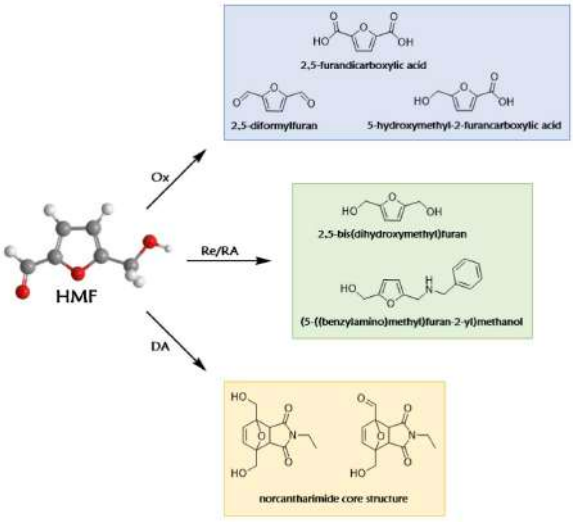

Figure 1: Proposed HMF transformation in DES.

Finally, green metrics such as atom economy, solvent recycling, environmental factor and EcoScale have been calculated for the most relevant scenarios.

biagia.musio@poliba.it

Xylella fastidiosa (*Xf*) has been extensively documented as a quarantine pathogen threatening important crops and natural species in the Americas. The outbreak discovered in 2013 in Salento has raised major concerns, being the bacterium associated with a deadly and rapidly spreading disease: the quick decline olive syndrome (OQDS). Considering the complexity of this phytosystem and the heavy economic impact, it is a matter of urgency to understand the host-pathogen interaction in a way to *i*. identify a containment solution; *ii*. understand the base of the immunity-resistance-susceptibility behavior of different species to *Xf* infection.

Plant metabolomics represents a useful approach to acquiring information on the composition of a metabolite pool in plants. Metabolomic regulation in plants is often affected by biotic and abiotic stresses. Thus, unveiling variations in the metabolite composition can help to understand plant adaptation, acclimation, and defense responses to environmental stresses. Thus, metabolomics can help both in detecting plant desease at an early stage and in understanding the determinants of host-specificity, namely the reason at the base of the incompatibility between a plant species with a given bacterial strain (i.e. immunity), or, conversely, which are the interactions that, for the same plant species, result in a successful host colonization (susceptibility) by a different Xf strain. Resistance consists of the intermediate scenario between immunity and susceptibility. The crop species characterized by this phenotype are of particular interest, since their study can help in discovering new strategy of management of Xf diseases.

In the present communication, an overview of the projects currently in progress in our lab will be described focusing on the hetero-spectral non-targeted approach for the early detection of the Xf infection and on the combination of NMR-based metabolomics and in vitro study to unravel biological features of Xf subspecies pauca ST53 in immune, resistant and susceptible crop species. Both the research pipelines are aimed at intercepting the infections before the bacterium gets established and colonizes a new environment.

e-mail: mariamichela.dellanna@poliba.it

Nitroarenes are a class of environmental pollutants generated by various industrial processes such as dye and pharmaceutical production. This harmful waste can be possibly valorised by reducing the nitro group to amine to obtain substituted anilines, which are highly valuable chemical intermediates[1,2].
This presentation deals with the reduction reaction of nitroarenes employing hydrazine monohydrate as reducing agent and modified steel slags as a novel heterogenous catalyst prepared by treating steel slags with iron (II and/or III) salts.
Steel slag is a waste product from steelmaking industry, which represents an interesting support for the catalytically active iron species. Indeed, because of their basicity, ensured by the presence of calcium hydroxide and calcium carbonate, it was possible to deposit iron oxides/hydroxides on the surface of the support by easy precipitation.
A systematic study was carried out comparing the catalytic activity of steel slags modified with the following salts (or mixtures): $FeCl_3$, $FeSO_4$, $FeCl_3$ + $FeSO_4$ in various proportions, $FeCl_2$.
The modified steel slags were characterized by X-ray Diffraction (XRD), Scanning Electron Microscopy (SEM), Energy Dispersive X-ray Spectroscopy (EDX) and X-ray Photoelectron Spectroscopy (XPS).
All iron-charged steel slags revealed active in the hydrogenation of nitrobenzene at 80 °C with the best results, in terms of activity, selectivity and recyclability achieved with the precatalyst loaded with Fe(III), for which the scope of the reaction was also explored.

Due to the continuous emissions of greenhouse gases (GHG) in the atmosphere because of anthropogenic activities, it is very important to reduce their concentration using several approaches. One of the best ways is to use the dry reforming of methane (DRM) reaction that consumes GHG to obtain syngas, a mixture of H_2 and CO. DRM is promoted using catalysts, often based on Pt or other critical raw materials (CRMs) for EU[1]. To face CRM issue, we fabricated Pt/CeO_2 catalysts with 2%wt of Pt by direct impregnation of the CeO_2 support with the leachate HCl based solution of Spent Automotive Diesel Oxidation Catalysts submitted to a mild hydrometallurgical recycling process, without purification of the leachate solution[2], which contains H_2PtCl_6 complexes as Pt precursors. A synthetic leachate Pt/CeO_2 solution was also prepared for comparison. CeO_2 has been chosen because of its widely accepted positive influence on the conversion of the products[3]. The results obtained from the catalytic tests were very encouraging, as shown in Fig.1, where the conversions of CO_2 and CH_4 are reported for the Pt/CeO_2 catalysts obtained from commercial Pt precursors. The ratio of H_2/CO was 0,9 at T=850 °C. Lower conversion efficiency was found in case of the real leachate solution. Catalysts were characterised by TPR, TGA, XRF, XRD, SEM and Raman Spectroscopy.

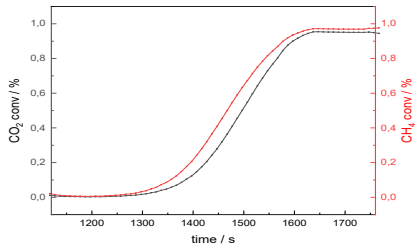

Figure 1: conversions of CO_2 and CH_4.

giulia.lodigiani@polimi.it

Liposomes, phospholipid-based nanocarriers, have become integral components of nanomedicine, offering a versatile platform for targeted drug delivery and imaging applications. These nanoparticles can be considered an ideal candidate to obtain a robust versatile and biocompatible nanoplatform that can be exploited for a variety of applications and targets, thanks to their biocompatibility and functionalization strategies[1].

With this in mind, we've been developing different liposome-decorated systems in which a biomarker-specific macromolecule is properly attached to the lipidic nanoparticle. This is feasible through a variety of functionalization techniques, resulting in a nanoplatform that may be customized with macromolecules of interest, being antibodies, peptides etc.

Our research has mostly focused on the use of target-specific peptides, that show fewer side effects than other biomolecules. These can selectively bind to the target, allowing the liposome to exploit its purpose, which is either to release a drug at its site of action if used as a drug delivery system or to detect the presence of its target in a sample if used as a diagnostic tool. Specifically, we have been working on the design and engineering of liposomes functionalized with epitopes specific for CD38 receptor involved in multiple myeloma[2].

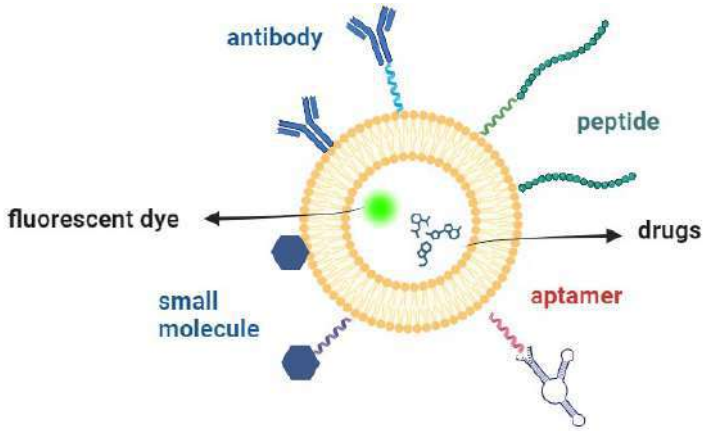

Figure 1: possible strategies for the engineering of liposomes.

e-mail: shakir.ul.azam@polsl.pl

Carbon nanotubes (CNTs) have gained substantial importance in catalysis due to their unprecedented properties[1]. Functionalization of CNTs is another advantageous approach for modifying the interaction between the support, catalyst, and guest molecules[2]. In this study, carboxylated MWCNTs were functionalized with copper(II) ions (MWCNT-COO-Cu) and then coated with dissolved *N*-hydroxyphthalimide (NHPI) in an ionic liquid (IL) ([emim][$OcOSO_3$]). The resultant catalytic system represented both the SCILL (solid catalyst with an ionic liquid layer) and SILP (supported ionic liquid phase) systems; therefore, it was identified as a novel SCILL-SILP hybrid catalytic system (Figure 1). The catalysts were evaluated for solvent-free oxidation of ethylbenzene using molecular oxygen as a greener oxidant. The recyclability and reusability of the MWCNT-COO-Cu and the SCILL-SILP hybrid catalytic system were thoroughly investigated[3]. In the subsequent study, novel SILP and SCILL-SILP hybrid catalytic systems were synthesized by coating NHPI dissolved in various ILs onto MWCNTs and MWCNT-COO-Cu, respectively. The effect of lipophilicity of ILs on the catalytic activities of the SILP systems was investigated. Furthermore, the recyclability and reusability of the catalytic systems were thoroughly investigated.

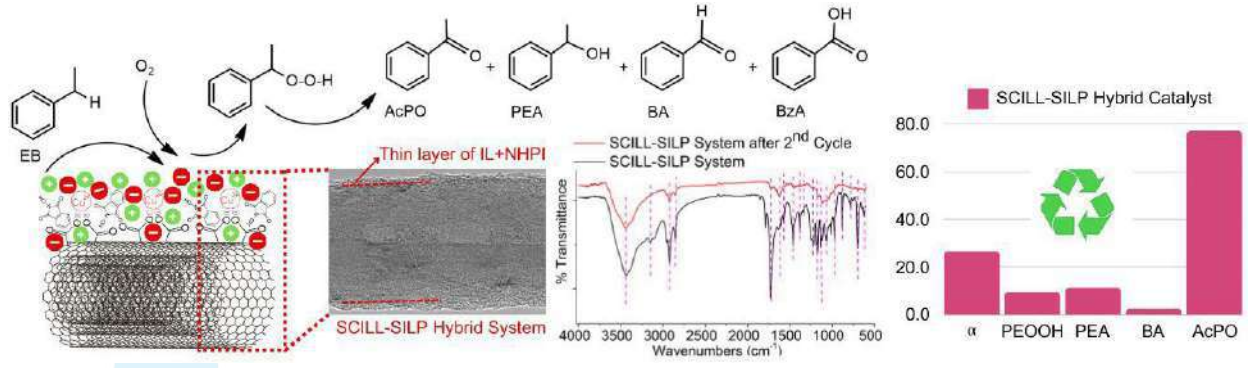

Figure 1: SCILL-SILP hybrid catalytic system for the aerobic oxidation of ethylbenzene.

Light, especially near-infrared (NIR) radiation, offers a non-invasive method with high spatiotemporal resolution for triggering drug delivery, facing challenges such as carcinogenic risks and limited tissue penetration of UV light. Lanthanide-doped upconverting nanoparticles (UCNPs) provide a solution by converting NIR to UV light. Despite promising, their low upconversion quantum yield necessitates high laser powers and prolonged irradiation, posing overheating risks to tissues. To overcome this, strategies like core surface passivation and coating UCNPs with photolabile drug carriers (either mesoporous silica (UCNP-MS) or polymeric coatings) have been adopted. UCNP-MS, emerging as a robust carrier, still faces challenges like high power and long exposure times for drug release. Unlike unchanged UCNP-MS systems during drug release, polymer-coated UCNPs with UV-breakable bonds disintegrate structurally, enabling drug release for only hydrophilic molecules. This study introduces UCNPs encapsulated with a thin, UV-breakable MS shell, merging MS's scalability with an efficient drug release mechanism of a thin breakable coating.

More in detail, we present the one-step synthesis of a nanocomposite consisting of $LiYbF_4:Tm^{3+}@LiYF_4$ UCNP coated with an UV-sensitive mesoporous organosilica shell. We demonstrate that a thin shell can be easily broken under NIR light exposure at 1 W/cm^2, significantly lower than traditional systems. Loading the mesopores with the hydrophobic vitamin D3 precursor, 7-dehydrocholesterol (7-DH), results in the release of contents upon shell breakage. Vitality tests on HeLa cells confirm the nanoparticles' safety. Their internalization is assessed by conventional confocal and non-linear optical microscopy via up-conversion luminescent emission, in which the sequential absorption of two or more low-energy photons in the infrared promotes the absorption into a high-energy state, enabling a correct drug delivery. The system's tunability, enabled by its simple synthesis and low-power operation, opens new avenues for NIR-triggered drug release via UCNP, making it a scalable, flexible, and translational option.

Access to clean and safe drinking water is essential for human health and well-being, but it is increasingly threatened by the presence of various contaminants, such as iodine. Iodine is a common disinfectant used in water treatment, but it can also cause adverse health effects, such as thyroid dysfunction, at high concentrations[1]. Therefore, the development of sensitive and selective sensors for the detection of iodine in water is of great importance for ensuring the safety and quality of drinking water.

Hexamethonium salts have emerged as promising porous materials for iodine capture due to their unique properties, such as high surface area, structural flexibility and chemical selectivity (Figure 1)[2,3].

The work has been organized in several key steps, including the synthesis and characterization of hexamethonium-based sensing layers, the development and optimization of the sensor design and fabrication process, and finally the testing and validation of the sensors with real water samples. Overall, the successful optimization of these sensors could have significant implications for water quality monitoring and public health, and could lead to new technologies for water treatment and purification.

beatricelucia.bona@polimi.it

In 2019, global poultry meat production reached 130 million tons, with Europe contributing 13.4 million tons annually, resulting in 3.1 million tons of feather waste.[1] Despite this abundance, the current recovery of valuable raw materials, particularly keratin, from feathers remains minimal. Existing technologies repurpose only a fraction of feathers, mainly as low-nutrient animal feed or organic fertilizers, while the majority is incinerated or landfilled. This not only represents a loss of a renewable resource but also poses environmental and health risks.[2]

Implementing eco-friendly approaches to managing feather waste could mitigate biological hazards and enable the valorization of keratin-based materials. These materials have shown potential in various high-end applications, including biomedical ones, offering a sustainable alternative to conventional resources.[3,4] As part of the KARATE project, we developed new technologies for converting waste feather fractions into high-value materials aligning with a circular economy approach. Our primary objective is to reduce the environmental impact of the poultry supply chain, while driving innovation. Specifically, we isolated a novel microbial strain capable to efficiently degrade feather wastes to extract keratin enzymatically. The resulting peptide and protein samples were fully characterized, with a particular emphasis on their self-assembly properties. These samples were subsequently engineered to create innovative keratin-based materials with substantial added value.

Figure 1: Illustration of keratin enzymatic extraction from feather waste and keratin-based materials production.

RNA based therapies have gained strong interest for the treatment of various diseases, but their in vivo applications require delivery systems to prevent the degradation of the nucleic acid (NA), facilitate cellular uptake and enable NAs release. Lipid nanoparticles (LNPs) have already been used in the clinic to deliver NAs as vaccines against SARS-CoV-2 and treatment for polyneuropathy.[1] Aiming to enhance LNPs efficiency as NA carriers, we developed fluorinated ionizable lipids, which will be used for the preparation of LNPs to promote encapsulation of NAs, improve interaction with cellular membranes and encourage intracellular NA release.[2] Furthermore, the inclusion of a fluorinated tag makes the obtained LNPs active in ^{19}F-MRI, hence potentially traceable in vivo.[3] Here we will describe the synthesis and characterization of two distinct ionizable lipids with different polar heads, focusing on their behavior in physiological conditions with regard to self-assembly and their impact on LNPs structure.

Sustainability is becoming more and more the compass to drive the design of materials and processes. From this perspective, cellulose can be considered a sustainable natural source for the development of innovative materials due to its renewability, biodegradability, and interesting mechanical properties. Moreover, the possibility to cleave its hierarchical structure opens the way to the production of nanocellulose. Cellulose nanocrystals (CNC) find applications in different fields, such as packaging, cosmetics, energy storage and nanocomposites production.[1] However, synthetic procedures could be impactful in terms of energy demand.

Herein, CNC were obtained through two processes, the first one based on the standard and widely used H_2SO_4-treatment[1], the second following a claimed "greener" process which foresees the use of the oxalic acid/choline chloride deep eutectic solvent (DES)[2]. For each process, CNC were produced and characterized.

The sustainability of both lab-scale processes was assessed using the "ESCAPE"[3] tool. The sustainability was evaluated in terms of embodied energy (EE) and carbon footprint (CF), keeping track of the local energy mix and comparing it to foreign energy mixes. The DES-based production was found to be more sustainable, primarily due to its lower purification time and higher mass recovery. These results allowed for the identification of the most impactful steps in the synthesis process, particularly the purification step and water usage. Consequently, targeted improvements in these steps allowed to reduce the overall environmental impact without affecting the morphology of final products.

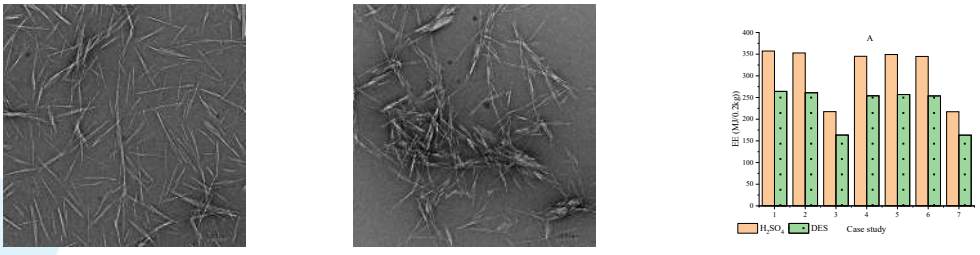

Figure 1: TEM of CNC-H_2SO_4 (left), CNC-DES (centre), total EE of CNC production (right)

Barrier properties of cellulose nanofibers-based coating agents in paper industry

Arianna De Santis,[a] Gloria Nicastro,[a] Laura Riva,[a] Davide Ghirardello,[b] Alessandro Sacchetti,[a] Carlo Punta[a]

arianna.desanantis@polimi.it

Nowadays, packaging materials are mostly based on fossil-derived products which, differently from paper, are characterized by high barrier properties against water, water vapour, oxygen and oil. However, the non-biodegradability of petroleum-based materials has given rise to environmental concerns, promoting the development of cellulose-based materials. Cellulose is the most abundant biopolymer on Earth, which has a wide range of applications thanks to its renewability, non-toxicity and biodegradability.[1] Moreover, the hierarchical structure of this polymer allows the extraction of nanoscale constituents combining an enzymatic or chemical pre-treatment with a mechanical treatment, such as homogenization or ultrasonication.[2,3] In the last decade, nanocellulose has become one of the emerging sustainable materials that can be employed in packaging industry. Indeed, the ability to form a dense network of hydrogen bonds allows nanocellulose to be a potential coating agent able to enhance barrier properties of paper. Furthermore, due to the presence of a large number of hydroxyl groups, nanocellulose can be functionalized, giving the possibility to tune its hydrophilic nature.[1] 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO)-mediated oxidation is the most commonly applied chemical treatment which leads to the regioselective conversion of C6 primary hydroxyls to carboxylic groups.[3] On the other hand, enzymatic hydrolysis of cellulose, conducted with endoglucanase, is used to obtain nanofibers bearing hydroxyl groups on C6.[2]

The aim of this work is to compare barrier properties of different nanocellulose-based coating agents. The formulation of coating dispersions varies in different factors: pre-treatment, concentration, pH, degree of oxidation of TOCNF and number of cycles of homogenization. The effect of cross-linking agents and functionalization with lipophilic moieties were also investigated. The application mode used was the spray coating. Barrier properties against oils and water were examined *via* KIT test and $COBB_{60}$ test, respectively and the results obtained, notably in oil resistance properties, are promising.

In recent years, gene therapy has emerged as a promising approach for the treatment of motorneuron diseases, such as amyotrophic lateral sclerosis (ALS), a fatal neurodegenerative disease characterized by motor neuron loss associated with muscle atrophy[1].

microRNAs (miRNAs) are small non-coding RNAs that modulate gene expression and they are key molecules in the onset of muscle atrophy[2]. Yet, the delivery of Nucleic Acids (NAs) inside the cell is a challenging task. Cationic lipids and polymers, particularly cationic dendrimers, have shown to be promising as gene delivery vectors due to their ability to complex NAs and protect them from degradation. In this context, some of us have recently developed FJD_2N, a novel gene delivery vector based on a fluorinated Janus-type dendrimer[3] bearing four terminal ammonium groups. This molecule is able to self-assemble in aqueous solution forming positively charged micelles that are able to interact with the negatively charged phosphate groups of NAs forming dendriplexes[4]. This carrier was tested on cells derived from G93A-SOD1 mice, a purported model of ALS. Immunofluorescence and molecular analysis displayed a good carrier cellular internalization, no cytotoxic effects on proliferation, as showed by caspase expression levels and a significant modulation of the selected miRNA on the target genes implicated in cell regeneration.

Based on these results, this new vector appears to be a promising carrier for gene delivery applications but further *in vitro* tests on a larger scale are needed to ultimately understand its complete functioning.

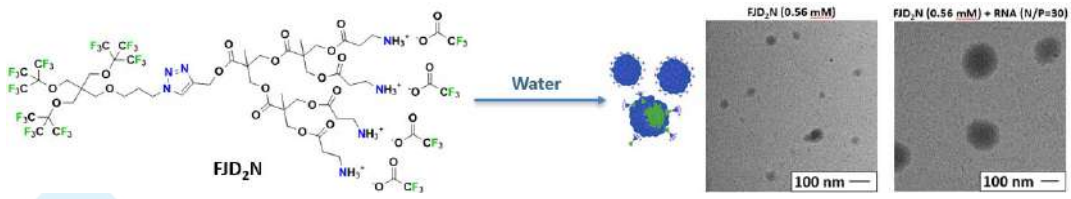

Figure 1: Chemical structure of FJD_2N and self-assembly behaviour in water. Images collected via cryoTEM analysis[4].

In recent years, perovskites have found use in numerous fields beginning with photovoltaics and expanding to light-emitting applications and other optoelectronic devices[1]. Despite the competing costs and efficiencies, the presence of defects, both at the surface or in the bulk, is critical for the long-term stability and considerably limits perovskite efficiency. Several strategies have been developed to overcome these limits. Among them, perfluoroalkyl-methyl imidazolium ionic liquids have been applied as passivating agents due to their ability to self-assemble on perovskite surface, resulting in the formation of ordered structures and higher film quality with fewer def ects[2,3]. Furthermore, the presence of highly fluorinated saturated molecular fragments in the resulting Low Dimensional Halide Perovskites (LDHPs) can bestow additional water-repellent properties and superior stability compared to fully hydrocarbon-based cations[2].

In this work, imidazolium cations functionalized with linear perfluoroalkyl chains were applied for the synthesis of new LDHPs. A combination of structural and thermal characterization allowed to study effects of perfluoroalkyl chains on the properties of perovskites. Indeed, fluorous-fluorous interactions and segregation of fluorinated moieties have been demonstrated to induce the formation of ordered structures in perovskite containing fluorinated imidazolium cations, resulting in a thermotropic liquid crystalline behavior. In addition, instead of Pb, a non-toxic metal such as Sn, has been utilized for the same reactions and the obtained LDHPs also showed a liquid crystalline behaviour. Collectively, these results may pave the way for a new class of halide perovskite-based soft materials.

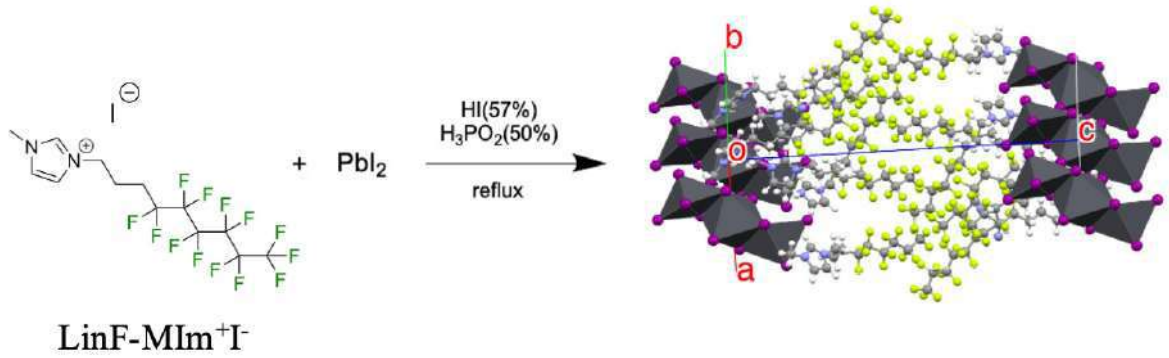

Figure 1: Crystal structure of the $(Pb_3I_{12})^{6-}(LinF\text{-}MIm)^{+}_6$ Low-Dimentional Perovskite (LinF-MIm=Linear Perfluoroalkyl-Methyl Imidazolium). Colour code: gray=C, white=H, blue=N, yellowish green=F, purple=I.

elisa.marelli@polimi.it

Resilin, an elastomeric protein found in arthropods, possesses remarkable mechanical properties such as high resilience and elasticity, making it an attractive candidate for bioinspired materials. However, translating these unique properties in synthetic materials has remained a challenge, primarily due to the protein's intricate structure and extensive amino acid sequence.[1] In our recent work, we focused on the modification of resilin consensus sequence SDSYGAP through bromination of the tyrosine residue.[2] This minimal alteration induced peptide self-assembly due to the increased supramolecular stability conferred by bromine atoms,[3] resulting in a robust three-dimensional network of fibrils within a hydrogel matrix which exhibited elastic properties absent in the wild-type sequence. Building upon these findings, this study explores the combination of this modified peptide with other biomaterials, such as gelatin, and the fabrication of nanofibrous mats through electrospinning. This technique offers precise control over scaffold morphology and architecture, enabling tunable mechanical properties and excellent biocompatibility. We successfully produced electrospun nanofibers with uniform morphology, showing good stability in water and a strain-hardening behaviour characteristic of biological tissues, highlighting the potential of the fabricated scaffolds for various biomedical applications. Furthermore, the brominated heptapeptide scaffolds demonstrated antioxidant activity, attributed to the inherent properties of the peptide sequence. This study presents a promising avenue for the development of biomimetic materials with tunable mechanical properties and added functionalities,[4] inspired by nature's design principles.

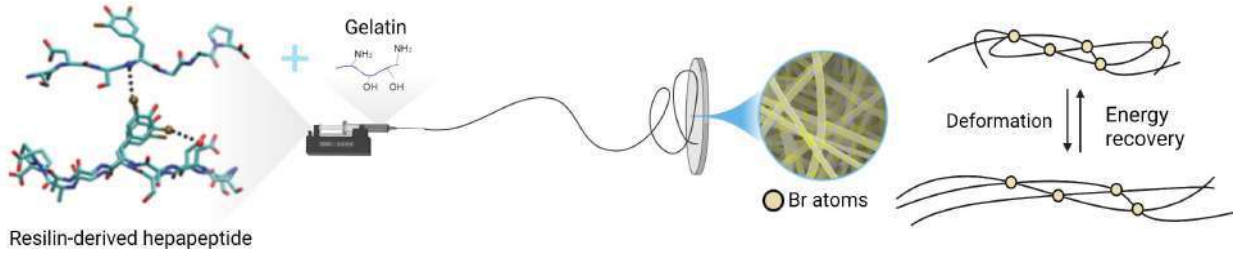

Figure 1: Design principles of the electrospun scaffolds based on the resilin-derived brominated heptapeptide combined with gelatin.

anaronne@unina.it

The development of nanostructured nonlinear optical (NLO) materials play an increasingly key role in photonics, due to their advanced functionalities. NLO processes in solid-state materials are widely used for generating quantum light, including single photons, entangled-photon pairs, and quadrature-squeezed states. The ability to generate NLO processes in nanostructures should allow improving the efficiencies pointing toward the realization of photonic sources operating at the nanoscale. The design and the development of nonlinear nanostructured materials with large nonlinearities should satisfy some technological and economical requirements, among them the compatibility with contemporary optical fiber telecommunications and with chip-scale semiconductor technology. Glassy and/or crystalline nanostructured materials whit significant NLO properties obtained by sol-gel represent a remarkable alternative to traditional NLO materials due to the intrinsic versatility of the synthetic technique that allows to finely tune the NLO properties of the final material by means the process parameters and is easily integrable with other technologies, such as those used to obtain quantum photonic devices. In this work sol-gel nanomaterials belonging to Nb_2O_5-SiO_2 and ZrO_2-SiO_2 binary oxide systems, with variable contents of high polarizable element, will be synthesized using cost-effective sol-gel routes inspired to sustainability and circularity criteria of Green Chemistry, such as the use of green solvents, safe, cheap and available materials, and energy-efficient protocols. The final goal will be the synthesis of NLO nanostructured materials in form of powders or transparent thin film containing the active component, in amorphous or crystalline form, embedded in a silica matrix. These materials will be subjected to proper drying and heat treatment programs to give film/gel-derived materials with amorphous and/or crystalline nanostructuring.

The nitroxyl radical 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) has been widely investigated due to its ability to participate in redox reactions.[1] In this work, aiming for the synthesis of novel versatile materials, different TEMPO-derivatives were synthesised and subsequently grafted to polyethyleneimine (PEI). The obtained PEI-TEMPO polymer was used as is or in the production of new materials to take advantage of the radical's properties both for biomedical and chemical applications. In particular, PEI is recognised as the golden standard for non-viral gene delivery. In this case PEI-TEMPO is used to obtain polymeric nanoparticles and polyplexes with nucleic acids able to mitigate the intrinsic cytotoxicity of PEI thanks to the protective antioxidant activity of TEMPO radical. In the field of material science, TEMPO is already employed for the oxidation of alcohols to aldehydes and carboxylic acids, and thus extensively used in the pre-treatment of cellulose to facilitate the production of nanofibers (TOCNFs)[2]. In this context, TEMPO-PEI structures are explored for the preparation of heterogeneous catalysts with the aim of innovating the process of cellulose oxidation. All the synthesised structures were completely characterised by NMR, EPR, and FT-IR techniques, successfully obtaining performing materials.

The formation of ice on exposed surfaces causes serious problems to the safety and operation of instruments and facilities. Active methods of ice removal can be costly and energy consuming. Thus, research focused on passive methods, such as superhydrophobic and liquid-infused porous surfaces (know with the acronyms SLIPS or LIS), which however can lose hydrophobicity in humid conditions or due to degradation.[1] Moreover, superhydrophobic coatings are usually made of fluorinated materials, intrinsically hydrophobic, but also potentially hazard for the environment and human health.[2] Surfaces infused with a hydrophilic lubricating layer may be an alternative strategy for functional icephobic coatings, allowing the formation of a liquid water layer on the surface which enables ice sliding.[1] In this context, polysaccharides, that are soft hydrophilic absorbent materials, non-toxic and biodegradable, may be of particular interest.[3] Hence, an electrolyte hydrogel of chitosan, an abundant polysaccharide, was physically crosslinked and infused with different amounts of salted water (Fig. 1). A 10-fold reduction of ice adhesion with respect that on aluminum and glass in the same conditions was obtained, due to the exploitation of the colligative properties of water preventing ice nucleation at the ice-hydrogel interface. This is a bio-based and cost-efficient strategy to reach easy ice detachment in humid marine environments, with potential application in offshore platforms and ships.[4]

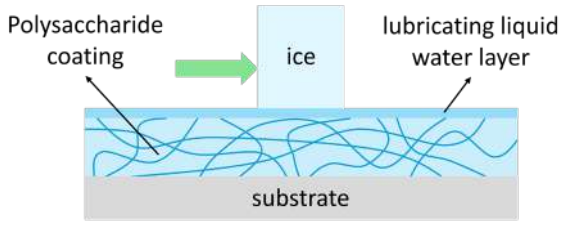

Figure 1: Scheme showing the substrate, the polysaccharide coating, an ice block, a pushing force, and the lubricating liquid water layer at the interface between ice and coating that facilitates ice detachment in freezing conditions.

E-mail: silvialaura.molteni@polimi.it

Fluoropolymers and fluorinated materials (*e.g.*, PVDF, PFPE, fluoro and perfluoroelastomers, perfluorosulfonic resins, etc.) are characterized by the presence of carbon-fluorine bonds which lends outstanding characteristics of fluorinated materials, such as thermal and chemical resistance and stability, dielectric, surface and rheological properties, barrier and permeation attributes. For these reasons, fluorinated materials are crucial chemicals in industry and everyday life and play an important and unique role in key applications such as Batteries, e-mobility, renewable energy, hydrogen economy, water purification membranes, connectivity and life solutions to address sustainability goals

A swift transition to a full circular economy is a topic of primary importance for the sustainability of fluorinated materials.

Different recycling technologies can be applied to meet this target exploiting complementary approaches such as mechanical recycling, physical, and chemical recycling (*e.g.*, depolymerization, pyrolysis, mineralization). Selected technical approaches are investigated and described as sustainable solutions to address circularity of fluoropolymers and materials.

Hydroxylated hexagonal boron nitride as filler for polymeric composites

F.Magaletti,[a] U.Giese,[b] M.Galimberti,[a] V.Barbera[a]

[a] *Politecnico di Milano, Department of Chemistry, Materials and Chemical Engineering, Via Mancinelli 7, 20131 Milano, Italy*

federica.magaletti@polimi.it

Introduction

Two-dimensional hexagonal boron nitride (hBN) has attracted tremendous attention over the last few years, thanks to its stable structure and its outstanding properties, such as mechanical strength, thermal conductivity, electrical insulation, and lubricant behavior. As carbon materias, boron nitride has many allotropic forms, of which the most stable is the hexagonal multilayered structure.

hBN has many similarities with its carbon counterpart, graphene. Indeed, the material has many appealing properties, such as thermal and chemical stability, thermal conductivity, and biocompatibility.

Results

In this work, innovative strategies for the chemical modification of hBN are reported.

Starting from a deep study of the material, three approaches were designed for the sustainable insertion of -OH functional groups, mainly on the edges of hBN. The modification of its solubility parameter was also achieved.

The possibility to tune its solubility parameter was exploited in order to introduce this reinforcing filler in two divergent matrices an elastomer matrix (Styrene-butadiene rubber, S-SBR and 1,4 *cis* isoprene, NR) and a biopolymer (chitosan, CS).

Alongside with the chemical modification a reduction of the staked layers has been induced through the application of mechanical energy by dry and wet methods.

S-SBR based rubber composites were characterized through static and dynamic mechanical tests. This work demonstrates that hBN can also improve the rheological and mechanical properties of elastomer composites when used to partially replace silica.[1]

Chitosan-based suspensions, papers and aerogels were also prepared: composites were characterized by means of infrared spectroscopy, thermogravimetric analysis, and X-Ray diffraction.

The pressing need to decrease global CO_2 emissions is driving research and advancement in creating new materials and technologies that have a minimal carbon footprint, while still providing beneficial properties and long term durability[1]. Alkali-activated materials have shown great potential not only because of their performance, but also because various types of waste and by-products can be used in their production, resulting in both environmental friendliness and cost effectiveness. Sustainability can be further enhanced by minimizing the use of additives and/or their concentration, i.e. alkaline activators with low molarity.

Glass waste was alkaline activated with 2.50 M KOH or NaOH solutions. Fourier transform infrared spectroscopy was used to study the covalent bonds in the hardened materials. Leaching tests (EN12457) were also carried out to assess the possible presence of metals from the starting materials. In addition, antimicrobial activity was evaluated using the Kirby-Baur method[2,3]. Four microbial strains were used for this purpose, namely *Escherichia coli, Pseudomonas aeruginosa, Staphylococcus aureus* and *Enterococcus faecalis*. The result was a well-formed material with interesting antimicrobial activity.

This study focuses on the solvent-free mechanochemical synthesis of two fluorinated perovskites, $KCuF_3$ and $KNiF_3$, that can be seen as a practical green alternative to the classical solvothermal synthesis.[3]The process has been optimized to find the refined milling time at constant rotational speed.[4] The main outputs of the process are $KCuF_3$ and $KNiF_3$ in the desired crystalline phase[2], which are present after 6 hours of milling. Other crystalline phases have been found at greater milling durations for Cu- and Ni-based perovskites, known as K_2CuF_4 and K_2NiF_4, respectively. The fluorinated perovskites were characterized by using X–Ray Diffraction Spectroscopy (XRD), X–Ray Photoelectron Spectroscopy (XPS) and Scanning Electron Microscopy (SEM), confirming the selective formation of the fluorinated perovskites. The mechanochemical route was also compared to a new mild solvothermal method. The promising results coming from this innovative method opened the research to the use of solvent–free mechanochemical syntheses as suitable approach also in the field of crystal engineering.

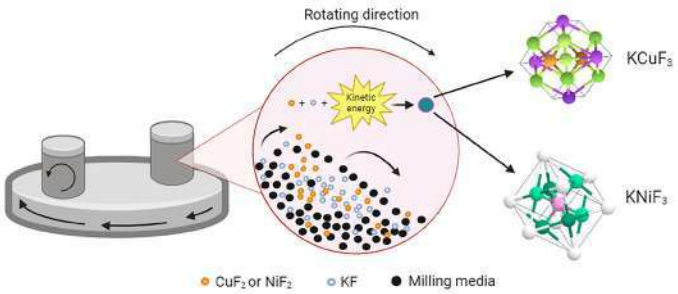

Figure 1: A graphical illustration of the synthetic approaches for the two fluorinated perovskites, KCuF3 and KNiF3.

Alkali activation is a room temperature process for consolidating aluminosilicate powders of various types. The resulting 3D aluminosilicate network is a good fixative for heavy metal ions and provides high mechanical strength to the final ceramic-like solid. In such treatments, physical encapsulation, ion exchange, and the formation of the gel structure were found to form compounds to stabilise heavy metals[1]. In addition, a unique three-dimensional zeolite-like cage structure can often occur at cryptocrystalline stage and has been shown to trap anions and organic macromolecules together with heavy metal cations[2].

This work investigated the addition of chelating agents (hydroxyapatite, tartaric acid, etc) to improve to the stabilisation of heavy metals in metakaolin-based geopolymer. The first individuated wastes are galvanic sludges and tannery wastewaters. The metakaolin powder was mixed with NaOH 8 M and sodium silicate solution, then the chelating agent and wastes were added at different percentages. The final consolidated material was tested for the geopolymerisation process by FT-IR and for the encapsulation efficiency by toxic leaching tests. The combination of geopolymer gel formation and the presence of the chelating agent resulted in the stabilisation and inertisation of not only heavy metal cations but also anions at room temperature.

Towards Sustainable Mobility: Innovation in Polymer Binders for High-Performance EV Lithium Battery Technology

R. Pieri[a], P. Cojocaru,[a] A.V. Oriani,[a] M. Avataneo[a]

[a]*Battery Materials Growth Platform, SYENSQO, Viale Lombardia 20, Bollate (Milan) - Italy*

Lithium-ion batteries (LIBs) have become indispensable energy-storage devices for various applications, ranging from portable electronics to electric vehicles and renewable energy systems. The performance and reliability of LIBs depend on several key components, among which the role of the binder for the electrodes, often overshadowed by the active materials used, is also crucial for long-term durability.

Binders provide no electrochemical benefits to the electrodes, but function to interconnect the active materials and carbon additive and adhere the electrode slurry to the metal current collector foil, preserving the electrode integrity.

Polyvinylidene fluoride (PVDF) binder is the polymer of choice because of its chemical and electrochemical stability, coupled with high mechanical strength, high strain and heat resistances, and good processability. Despite several advantages, PVDF usually has low cohesive force with the current collector because of the non reactive functional groups tethered onto the PVDF backbone, resulting in low adhesion to the metal foil.

Syensqo, former part of Solvay group, has taken advantage of its expertise in fluorine chemistry and polymerization technologies for designing a new generation of PVDF polymers, designed for use as binder and is especially tailored for high-demanding xEV battery applications, where it is necessary to guarantee best performance during battery operation. The combined effect of several polymer parameters has been studied showing how the reinforced intermolecular interactions between polymer, active materials and current collector result in increased performance in terms of adhesion and chemical resistance in the electrolyte and can influence the binder crystallinity. This can ultimately influence the final properties of lithium-ion batteries.

Issue of nanomaterial migration in food packaging.

Mohammed Dilsad Ansari[a], Principato Laura[b], Luigi De Nardo[a], Carlo Punta[a],

mohammeddilsad.ansari@polimi.it

The target of food packaging experts is to leverage the merits of nanomaterials (NMs) to obtain sustainable and efficient solutions. However, along with the functional properties of NMs, safety concerns exist in their application in food contact materials (FCM). The toxicological studies have shown the negative impacts on human health due to nanoparticle (NP) exposure through inhalation, skin contact, or ingestion[1]. Based on accumulated migration data, regulatory bodies of the US and EU have laid down specific protocols for migration measurement, but these accumulated data refer to only chemical compounds. The application of theoretical and experimental models developed for ions and molecules requires a significant revision when dealing with nanoscale products. A model based on Stokes-Newton equation to predict specific migration has been proposed by Simoneau C[2]. However, it ignores the chemistry of the surrounding environment and the possibility of dissolution. It only considers the theoretical diffusion phenomenon based on the polymer's dynamic viscosity, the diffused particles' size, and the exposed area. Utilizing ICP-MS analysis methods for monitoring elemental concentrations can aid in evaluation. However, details about the migrant's form (dissolved species or single particles) are not retained when the sample undergoes the inductively coupled plasma. SP-ICP-MS can solve this issue since it can distinguish the migrant form, but the issue with this technique is that it requires a uniform liquid base, indicating that either the sample needs to be digested or the NMs need to be extracted. Similar to traditional ICP-MS, SP-ICP-MS is probably not as effective for organic NMs because the polymer matrix might have a very similar carbon-based composition. AgNPs have been detected in a migration solution by TEM/EDS. Still, distinguishing between diffusion or in situ synthesis of AgNPs is not clear. Enzyme-linked immunosorbent assay (ELISA) was used to quantify nano gelatin in fruit juices[3]. This approach requires developing antibodies specific to only the target NMs. Since different NMs have different enzyme-linked antibodies, the problem arises with no scope for comparison. In summary, most studies on nanomaterial migration have high variance and are mostly based on metallic nanoparticles and their oxides; the data available on NMs, such as nanocellulose, nanochitin, nanoclays, etc., which have a high potential in the food packaging application, are very scarce. The objective of this poster presentation aims to highlight these issues. Solutions that are currently available and ones that could be conceivable suitable for FCM will be analysed highlighting the opportunities and criticalities related to their use. Furthermore, the initial findings on nanocellulose migration from barrier coated paper-based substrates will be outlined.

eliana.quartarone@unipv.it

In 2022, a global LIBs manufactured capacity of 1.5 TWh was estimated. This is expected to increase to 4 TWh by 2025 and reach 6.8 TWh by 2030, with China producing 76% of global capacity and leading the market, whose total value is projected to increase from 46.2 billion dollars in 2023 to 189.4 billion dollars in 2032[1,2]. These figures do not take into account supply shortages which, nowadays, are increasingly more likely and have implications not only on the economic level (causing the increase of LIBs cost of production), but also on the geopolitical one since the majority of materials sources usually lies under politically unstable countries. Therefore, the Li-ion batteries (LIBs) penetration in the automotive market makes more urgent the boosting of zero-waste battery recycling. This can play a crucial role in developing a circular economy through the recovery of Critical Raw Materials, as well as non-metallic components back to use. LIBs are complex devices and do not only contain metals and graphite, but also valuable fluorinated materials. For example, fluorinated lithium salts organic solutions (e.g.: 1.0M LiPF6 in EC/DMC) are used as electrolytes; poly(vinylidene fluoride) (PVDF) is the benchmark binder for the state-of-the-art cathodes, due to its outstanding properties, such as safety, chemical stability, good adhesion to the current collectors and excellent free-standing performances[3-7]. In recent years, the recycling technologies for LIBs entered in a new stage focused on the development of i) advanced pre-treatment processes to separate all the valuable battery components, and ii) more sustainable metallurgical approaches, with the aim to reduce the energy consumption in the subsequent metallurgic processes.

The recovered materials can be used to prepare and assemble a new cell using the recovered separator and characterized to evaluate the effective feasibility of the whole recycling process. The work here presented is now progressing in the frame of RENOVATE EU funded project, with several valuable Partners, especially including Polytechnic of Milan.

SUPREME – Sustainable nanoparticles enabled antimicrobial surface coatings

E. Merli,[a] D. Spinelli,[a] I. Canesi,[a] N. Cei[a]

[a]*Next Technology Tecnotessile, via del Gelso 13, 59100 Prato (Italy)*
e-mail of submitter

As observed during the last catastrophic pandemic, the spread of harmful pathogens can be fast and facilitated by high traffic surfaces and crowded places, highlighting the importance of an economically and environmentally sustainable solution for antimicrobial surfaces as a potential strategy to mitigate the spread of disease outbreaks.[1] Nanoparticles (NP_s) filled coatings, with recognised effectiveness against bacteria, viruses, and fungi, are valuable candidates for developing antimicrobial surfaces and minimising the surface adhesion of pathogens.[2, 3] However, due to the many technical challenges, including difficulty to develop nano-coatings with a long-term antimicrobial capability, durability under real conditions and safety assurance, their application at industrial level is still limited.

The SUPREME project aims to develop a platform of efficient and multifunctional antimicrobial nano-coatings, building upon bespoke TiO_2 NP_s, that have demonstrated an exceptional antimicrobial ability at lab scale (TRL3).[2, 3, 4] Two sustainable routes: 1) customised core/shell and advanced functional NP_s and 2) hybrid fibre-NP_s (using sustainable bio-based cellulose materials and NP_s) will be pursued.[5, 6, 7] The production of the SUPREME coating will follow a sustainable-by-design approach, that considers both toxicity and environmental impact. The scaling-up of the nano-coating production and their validation according to the industrial requirements from different market segments (e.g., textile) will enable to reach the TRL6 by the end of the project. The SUPREME consortium consists in 18 partners from 8 EU countries (UK, IT, ES, GR, BE, MT, NL and NO), including research centres, universities, a National Institute, small and medium-sized enterprises (SME_s) and large companies.

Next Technology Tecnotessile (NTT) is involved in technical activities regarding the evaluation of different coating application technologies on textile-based substrates (WP6), including plasma treatments for increasing the adhesion of the coatings on the surface (WP2). The WP6 also aims to implement the design principles and the proof-of-concept nano-coating systems produced by WP2 and verified by WP3-4 in industrial applications.

The concept of flexible electronics, evolving over decades, saw significant strides with the introduction of conductive polymers, organic semiconductors, and amorphous silicon. These materials enable devices to bend, roll, fold, and stretch, distinguishing them from conventional electronics. The pursuit of novel materials and manufacturing techniques for high-performance, scalable electronic devices on flexible substrates is ongoing.[1,2]

Addressing escalating environmental concerns, recyclable elastomeric materials, particularly Dynamic Covalent Polymer Networks (DCPNs), show promise. [3,6]

However, the lack of reversibility in current covalent coupling reactions in rubber compounds hinders recycling efforts. This research project aims to advance recyclable elastomeric materials for flexible electronics by preparing composites with reversibly cross-linked elastomers and bio-fillers. Modified liquid rubbers for reversible curing and functionalized bio-fillers such as lignin for compatibility will be synthesized. The Diels-Alder reaction is used as the reversible system.

Recycling of Permanent Magnets with Phosphonium Based Ionic Liquids

Anđela KOVAČEVIĆ, Martina SANADAR, Andrea MELCHIOR and Marilena TOLAZZI

Dipartimento Politecnico di Ingegneria e Architettura, Laboratorio di Tecnologie Chimiche, Università di Udine, Via Cotonificio 108, 33100, Udine, Italy.
marilena.tolazzi@uniud.it

Due to the limited availability of primary ore deposits and supply risk, research attention is being drawn towards the recovery of Rare Earth Elements (REEs) from secondary sources[1,2]. Raw materials play a fundamental role in the current and future technologies necessary for achieving sustainable development goals as outlined in the UN 2030 Agenda. Notably NdFeB and SmCo magnets, as secondary solid wastes, are significantly rich in REEs such as Nd, Sm, and Dy[3]. Current hydrometallurgical processes for the recovery of the REEs from aqueous solutions have some interesting advantages but require the use of significant amounts of toxic volatile organic compounds[4]. Ionic liquids (ILs) have many potential applications since they present many advantages such as negligible vapor pressure, reusability, and high thermal stability[5].

In this work, we assess the performance of phosphonium based ILs ($[P_{66614}][Dec]$ and $[P_{66614}][Cl]$) for separation of REEs from transition metals from magnets after HCl leaching. It was found that bivalent ions are extracted from highly acidic media, while REEs prefers neutral pH in both ILs. After extraction, stripping of metals from ILs was performed with various media. The water phase was measured by ICP-OES to quantitatively determine metal concentrations after extraction and stripping and magnet composition after leaching.

In their R&D phase, perovskite/silicon tandem solar cells have continued to demonstrate excellent power conversion efficiencies (PCEs) while promising low-cost manufacturing[1]. With prospects for further enhancements, this technology has been pushed closer to market entrance. Nevertheless, for a photovoltaic technology to reach commercialization, factors such as high efficiency, scalability, long-term stability, cost competitiveness, and environmental friendliness need to be considered. Bifacial perovskite/silicon tandem solar modules offer a promising pathway toward greater stability and energy yield compared to the monofacial perovskite/silicon tandems. The bifacial configuration exploits the extra photons that originate from reflected and scattered light from the ground (albedo), resulting in a current larger than that producible by the monofacial configuration, enabling a higher performance[2]. There has been a growing interest in the development and deployment of bifacial solar cells; however, estimates show that they are expected to reach a meaningful market share within the next ten years[3]. It is therefore crucial to evaluate the environmental impacts and anticipate the mitigation of potential critical issues of bifacial perovskite/silicon tandem solar cells alongside technological advancements to guide their development in an eco-design perspective.

In this study we use the prospective life cycle assessment (PLCA) approach[4] allowing the use of multiple upscaling scenarios to assess emerging technologies at the laboratory scale with a future-oriented perspective (large-scale or industrial scale). Using the UpFunMatLCA scheme[5] to generate scenarios, we perform a systematic and comprehensive analysis taking into account the scalability of material and the processing steps of the tandem solar cell. Results highlight the possible implications of future perovskite/silicon tandem design choices and processes from an environmental perspective. Early awareness of the environmental hotspots will be essential to support the technological development before commercialization.

A Multivariate Statistical Approach to Monitor the Synthesis of Polyurethanes

A. Scarpiello, [a] A. Ciampa, [b] R. Ragone, [a] A. Rizzuti, [a] B. Musio, [a] M. Latronico, [a] V. Gallo, [a] P. Mastrorilli [a]

[a] *alessia.scarpiello@poliba.it*

Diisocyanates, due to the presence of two functional groups –N=C=O, are commonly used for the synthesis of polyurethanes (PUs), in combination with an appropriate polyol. Physical, chemical and mechanical properties of PUs can be modulated by varying the nature of the diisocyanate compounds. In this study, two kinds of acrylate polyurethanes (PUAs) were synthesized: one using isophorone diisocyanate (IPDI), with an aliphatic R group, the other using 2,4-toluene diisocyanate (TDI), with an aromatic R group. As shown in Figure 1, in the first step, the diisocyanate compound reacts with a polyol to obtain an urethane prepolymer with two terminal –N=C=O groups; in the second step, the as-obtained urethane prepolymer is functionalized with an hydroxy methacrylate derivative.

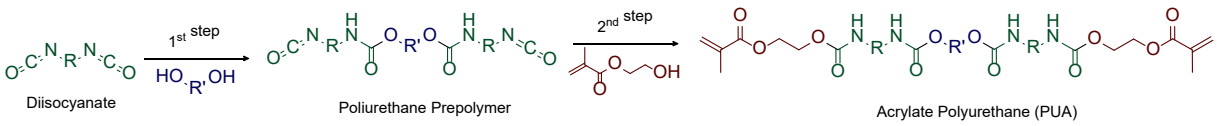

Figure 1: Synthetic pathway of the preparation of PUs with methacrylate as end groups (PUA).

The aim of this study was the application of a methodology, faster than the conventional titration method[1], for the quantification of the free isocyanates in the first step of the prepolymer synthesis. IR spectra were recorded, in the wavenumber range between 1800 and 2100 cm^{-1}, on calibration solutions and on aliquots collected from the reaction batch at different times. Then, a multivariate statistical approach was applied to build a calibration model, able to monitor the rate of decrease of the diisocyanate reagent. Results were in line with those obtained through the conventional method.

Recycled PET, chosen as the polyester for mechanical recycling, underwent regradation utilizing a dianhydride derived from a biobased C6 building block. The biobased derived component was sourced from a 2-pyrone, extracted from lignocellulosic materials to produce mellophanic dianhydride (MEDA)[1], as illustrated in Figure 1. MEDA represents an alternative to the conventional oil-based pyromellitic dianhydride[2]. In the context of mechanical recycling of rPET, MEDA functioned as a chain extender. Chemical and rheological characterization of the recycled materials was performed.

This study, conducted as part of the European ECOTRON[3] project, specifically addressed the end-of-life considerations of polymers employed as substrates for flexible printed electronics, emphasizing circular, biobased, and biodegradable solutions. The key principles applied to the substrate in this research were:

- Recycle the used materials for integration into new products.
- Incorporate renewable, biobased, or plant-derived chemicals to reduce the use of fossil-based chemicals.

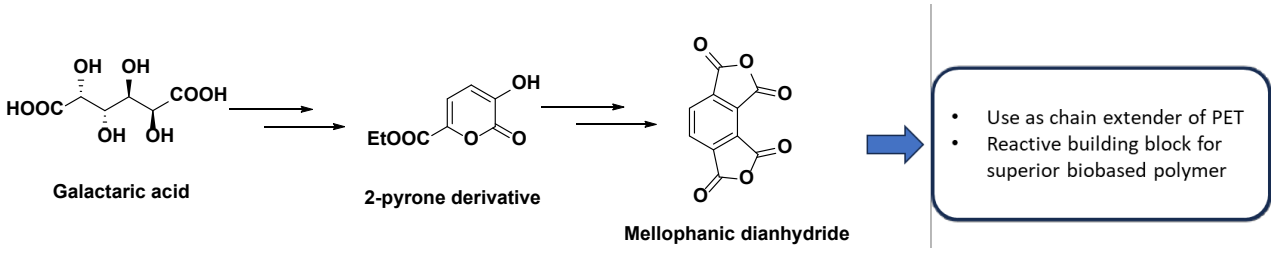

Figure 1: Chemical structure and synthetic path of MEDA; specific objectives are also reported.

The authors would like to thank ECOTRON project for the support provided for this work.

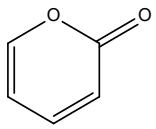
Since the 1990s, the escalation of environmental apprehensions has propelled the development of green chemistry, with the primary aim of reducing the use of hazardous substances.

Galactaric acid, from fruit peels, is crucial in organic chemistry and polymer synthesis. 2-Pyrones, or α-pyrones, are unsaturated heterocyclic compounds with a C-6 atom containing an oxygen atom and a carbonyl group at the α position. (Figure 1).[1]



2*H*-pyran-2-one

Figure 1: Chemical structure of 2H-pyran-2-one.

They represent a versatile class of structural compounds found in numerous biologically active metabolites. Their chemical versatility is explained by the resonance of 2-pyrone, which exhibits partial aromaticity. 2-pyrones react as dienes and can undergo typical reactions such as the Diels-Alder cycloaddition.

A huge amount of research has been focused on graphene due to its high surface area, exceptional mechanical strength and high charge carrier mobility[2]. Graphene is being developed mainly in the electronic field, whereas few layers graphene (FLG) are finding applications in the material field.

In this work, FLG were prepared by exploiting the edge functionalization with 2-pyrones, promoted by the mechanical energy of a high shear mixer (HSM). One pot functionalization and exfoliation were obtained, in water as the dispersion medium. Adducts of FLG were prepared by mixing a high surface area graphite (HSAG) and 2-pyrone in deionized water, in the HSM. The grafted 2-pyrone was supposed to promote the exfoliation.

The adducts were characterized by means of X-ray diffraction, UV, IR and Raman spectroscopy, investigating the degree of exfoliation.

Starting from the Organic Fraction of Municipal Solid Waste (OFMSW) as a feeding substrate for the insect Black Soldier Fly (BSF), this research aims to derive functional materials from its proteins, hence contributing to close a circular economy model for the full valorization of OFMSW. Specifically, a BSF protein-based bio-nanocomposite material enriched with a functionalized Conductive Carbon Black (CCB) for flexible electronics applications is here presented.

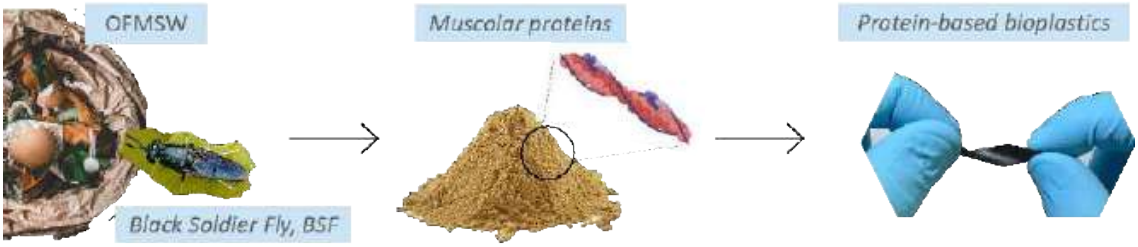

Figure 1: Circular electro-conductive nanocomposite bioplastic from BSF reared on the OFMSW.

The BSF insect proteome was deeply characterized through SDS-PAGE and LC-MS/MS, disclosing a prevalence of muscular proteins. TGA, WA-XRD analyses, and Hansen solubility tests were utilized for the characterization of the filler. Kraus plots and electrical conductivity measurements, together with associated mathematical models, served as practical tools to evidence stronger filler-polymer interactions after functionalization of CCB with the pyrrole methodology [1]. Obtained composites are flexible and mechanically robust, with conductivity values up to 0.9 S/m. Taken together, these findings not only support the development of green flexible electronics, but also contribute to the valorization of the OFMSW, aligning with European policies of circular economy [2].

Politecnico di Milano, Department of Chemistry, Materials and Chemical Engineering, Via Mancinelli 7, 20131 Milano, Italy
daniele.brighenti@polimi.it

Pyrroles are essential compounds in biological systems and are utilized in drug synthesis and material chemistry. They are typically formed through the Paal-Knorr reaction, in which 1,4-dicarbonylic compounds react with amines. Here we present a sustainable approach to the synthesis of *N*-substituted pyrrole derivatives *via* the reaction of primary amines with 3-hydroxy-2-pyrones.[1] These latter compounds are easily prepared from renewable sources and can effectively mask 1,4-dicarbonylic functionalities, enabling the efficient synthesis of substituted pyrrolic rings (**Figure 1**).[2]

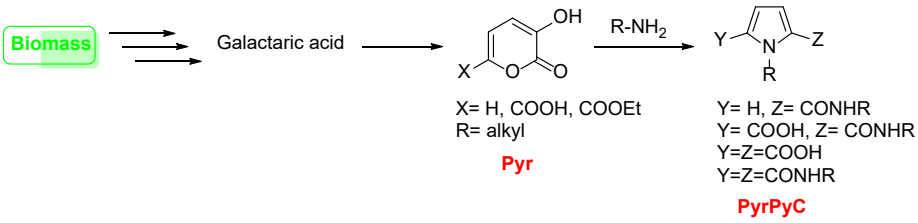

Figure 1: synthesis of green pyrrole derivatives (PyrPyC).

Based on the research conducted by the research group,[3] these pyrroles have been employed to decorate graphene layers with the aim of obtaining catalysts for sustainable water remediation (**Figure 2**), through the catalytic ozonation of recalcitrant pollutants.[4]

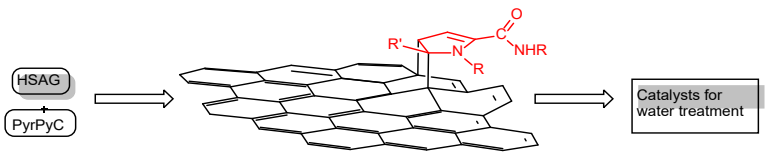

Figure 2: Preparation of catalysts for water remediation.

Protein-based compostable films: from chemical modification to application in flexible electronics

D. Gentile, V. Barbera, A. Ravicini and M. Galimberti

Department of Chemistry, Materials and Chemical Engineering "G. Natta", Politecnico di Milano, Via Mancinelli 7, 20131 Milano, Italy

davide.gentile@polimi.it

Bio-based materials, such as proteins, are considered the most promising candidates for next-generation flexible electronics due to their high sustainability and variety of chemical structures, which can be depolymerized and recycled into monomers, offering the possibility of reducing and minimizing the future environmental impact of electronics.[1,2]

In this work, zein was selected as the starting protein, and flexible films were developed. Therefore, some physical and chemical modifications were designed and performed based on the native structure of the protein. Two routes were explored: (i) thermoreversible Diels-Alder reactions and (ii) thermosets from bio-based acrylics. Computational studies have been carried out for the design of cross-linkers of different lengths for the Diels-Alder (DA) reaction between zein (diene) and a cross-linker molecule (dienophile). The reversibility was checked through the retro-diels alder reaction.[3] Bio-nanocomposites based on proteins and chemically functionalized carbon allotropes (such as carbon nanotubes, graphene, and conductive carbon black) have been developed and studied.

The samples were characterized by DSC, FT-IR, SDS-PAGE, and NMR analysis. In addition to the mechanical properties, molecular dynamics studies were performed, which allowed us to understand the reorganization of the protein as a function of chemical modifications.

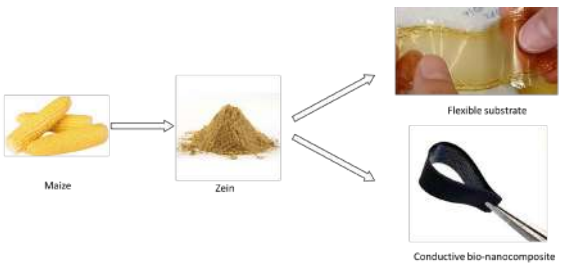

Figure 1: Schematic representation of film production: from maize to a flexible substrate and conductive bio-nanocomposite.

TECNOLOGIE PER LA GENERAZIONE E L'UTILIZZO DI IDROGENO VERDE ED I MATERIALI INNOVATIVI NECESSARI ALLA LORO REALIZZAZIONE

D. Facchi,[a] M. Mirko,[a] L. Damen,[a] L. Mazzapioda,[a]

a SYENSQO - Solvay Specialty Polymers Italy S.p.A.,

Viale Lombardia 20, 20021, Bollate, MI, Italy

daniele.facchi@syensqo.com

Secondo il ben noto rapporto Brundtland [1], pubblicato nel 1987 dalla Commissione mondiale sull'ambiente e lo sviluppo (WCED), lo sviluppo sostenibile è definito come quello sviluppo che: "*soddisfa i bisogni del presente senza compromettere la capacità delle generazioni future di soddisfare i propri bisogni*". In questo quadro, la scienza gioca un ruolo fondamentale nel continuo progresso di nuove tecnologie sempre più performanti e a basso impatto ambientale e richiede lo sviluppo di nuovi materiali che ne garantiscano l'implementazione.
L'idrogeno è considerato un vettore molto efficiente e versatile per la conversione e lo stoccaggio di energia, soprattutto da fonti rinnovabili, e quindi è stato recentemente rilanciato come elemento indispensabile per la transizione energetica.

In questo intervento verranno presentati i materiali innovativi fondamentali per la conversione e lo stoccaggio dell'energia attraverso la gestione dell'idrogeno, in cui Syensqo sta puntando e investendo per contribuire allo sviluppo sostenibile. Verranno presentate due diverse tecnologie per la conversione dell'energia legate all'idrogeno che impiegano tali materiali innovativi: la cella a combustibile o *fuel cell* (PEM FC) e l'elettrolisi dell'acqua (PEM WE e ALK WE). Verranno presentati e discussi i principi di funzionamento di tali tecnologie e i polimeri sviluppati in Syensqo che trovano utilizzo nei componenti di queste apparecchiature elettrochimiche, con speciali attenzione agli ionomeri per la fabbricazione delle membrane a scambio protonico (PEM) [2].

nadia.pastori@polimi.it

Atrazine is a synthetic herbicide, one of the most studied compounds in the scientific literature[1] to validate the adsorption efficiency of sorbent materials. Furthermore, its chemical structure allows synthetic modifications with the introduction of functional groups able to change its chemical-physical properties.

In this work, we considered atrazine as potential model compound to predict the behaviour of a wider family of pesticides and their interaction with sorbent materials. In a first step, we conducted a cluster analysis which allowed to group pesticides onto consideration of three chemical-physical parameters. This analysis confirmed that Atrazine could be considered an ideal model compound for a high number of pesticides. Moreover, we also carried out a meta-analysis on the adopted operating conditions for pesticide (ad)sorption lab tests, aimed to understand if Atrazine could also predict the (ad)sorption behaviour of other similar compounds. Results confirmed that Atrazine could be considered a reliable model compound for describing (ad)sorption on the same class of sorbents, emphasizing the importance of solute-sorbent interactions.

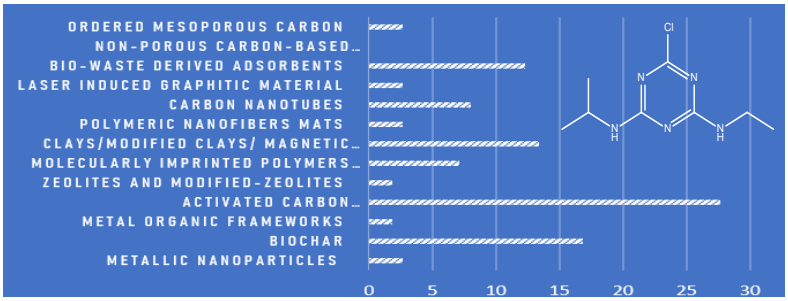

Figure 1. Percentage of Materials used in atrazine isotherm studies.

Based on these outputs, we used Atrazine to better investigate the (ad)sorbing properties and its chemical-physical interaction with new classes of cellulose-based nanostructured materials[2] and a cellulose-based commercial product. To do that, Atrazine was also chemically modified by introducing lipophilic and hydrophilic functional groups on its triazine core.

This comprehensive study allowed us to better understand the mechanisms of interaction between Atrazine and the designed cellulose-based materials, also suggesting a way to improve the sorbent for a more efficient removal of pesticides well represented by the model herbicide.

Metabolomics is a powerful tool for studying various aspects of plant physiology and biology, which regulate plant growth, development, and stress response. To protect themselves from pathogens, plants produce a wide range of secondary metabolites through a network of different biosynthetic pathways. The analysis of metabolomic data allows the identification of groups of metabolites, whose concentration significantly changes already at the first stages of disease. Metabolomics can be utilized as a tool to detect host-pathogen interaction and also to differentiate the type of compounds produced in resistant and susceptible phenotypes.[1]

Recently, our lab has been involved in a number of projects based on the application of spectroscopy-based metabolomics for the study of plant diseases, including *Erwinia amylovora* infections in pear[2] and *Xylella fastidiosa* infections in olive crops.[3,4] Furthermore, some important clues on the resistance phenomenon against *Xylella fastidiosa* were obtained by investigating the composition of the xylem sap of plant species characterized by a different phenotype towards Xf subspecies pauca.[5]

This study focuses on *Citrus Tristeza Virus* (CTV) infections in citrus trees. CTV is the causal agent of "tristeza", one of the most destructive viral diseases of citrus. The CTV is phloem-limited and its transmission into new geographic areas occurs by the introduction of infected plants or budwood, with subsequent local dispersal in a semi-persistent mode by several aphid species.[6] In this study, a combined approach by nuclear magnetic resonance (NMR) and hyperspectral reflectance (HSR) spectroscopies is used. NMR is the most robust and non-destructive technique for the elucidation of unknown compounds: as it is not selective, it allows for an unbiased view of the chemical composition of the sample. HSR provides a rapid detection tool, requires limited sample preparation, and is a non-invasive technique for plant disease detection.

Among the objectives of the present study is the identification of possible biomarkers of CTV infection by NMR and subsequent correlation with specific HSR wavelengths. The latter can be advantageously exploited for the development of sensors for the early detection of CTV infections.

Box 541, FI-33014 Tampere University, Finland. e-mail: daniele.conelli@poliba.it

In recent years, cesium lead halide perovskites have made a significant breakthrough in photocatalysis due to the straightforward modulation of their chemical composition, structure, energy levels, and bandgap.[1] In this study, we propose a room-temperature supersaturated ligand-free recrystallization approach for the obtainment of $CsPbBr_3$ photocatalysts by using three different antisolvents: ethyl acetate (EA), isopropanol (IPA), and acetone (ACE).[2] The corresponding synthesized materials (namely EA-$CsPbBr_3$, IPA-$CsPbBr_3$, and ACE-$CsPbBr_3$) have morphologically, structurally, and optically been characterized and tested in the methylene blue (MB) photodegradation under visible-light irradiation ($\lambda > 420$ nm). The evaluation of the pseudo-first-order rate constants for the selected degradation revealed the best performances of the series for the EA-$CsPbBr_3$ material, highlighting the impact of synthetic conditions on the specific surface area of the photocatalyst and the efficient generation of active species (superoxide and hydroxyl radicals) in the degradation. The EA-$CsPbBr_3$ material was systematically employed in the photodegradation of differently structured organic dyes, resulting extremely efficient in degradation of model hazardous xanthene-based structures (EoB and RhB, see Figure 1). Furthermore, we observed that the EoB degradation kinetics remained unaltered for at least five times using the recovered photocatalyst after each cycle. The investigations on the photocatalytic mechanism of EoB degradation evidenced the key role of the superoxide radical along with the important contributions of injected electrons and hydroxyl radicals. In perspective, beyond the reported catalytic study, this work not only establishes the potential of $CsPbBr_3$ materials in dye degradation but also provides new insight into the impact of the synthetic methods on their photocatalytic activity.

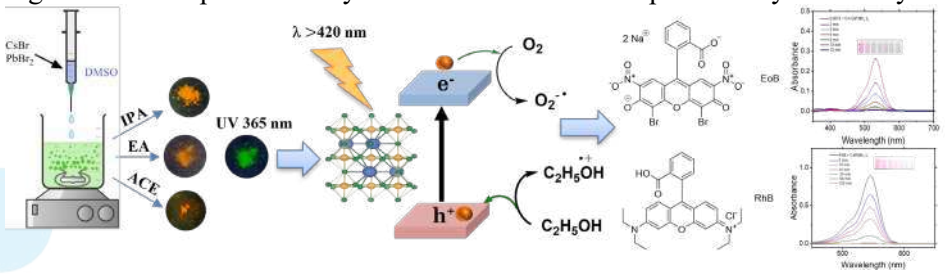

Figure 1: Schematic diagram of the synthesis process and photocatalytic mechanism of $CsPbBr_3$.

Cancer remains a significant global health challenge, accounting for nearly 10 million of deaths in 2020, whose incidence and mortality cases are steadily increasing[1]. Conventional chemotherapy is the most common approach in the treatment of the disease, but it is often hindered by issues such as the lack of selectivity towards cancerous cells and the premature drug degradation. This results in the need of administering higher doses of chemotherapeutic compounds and leads to drug resistance, which commonly determines the failure of the treatment[2]. Nanoparticles respond to this issue, and the creation of drug delivery systems that can selectively target the affected cells, protect the administered drug, and increase its efficacy, is an innovation in the field of precision medicine[3]. Aqueous solutions of poly(N-vinylpyrrolidone) and acrylic acid (AA) underwent high-energy radiation-induced cross-linking to obtain nanogels. This work focused on the creation of non-immunogenic, blood-compatible, sterile, and colloidally stable systems to be eliminated through the final excretory system. Nanogels were loaded with a model chemotherapeutic drug through a redox-sensitive linker, decorated with a model targeting agent, and evaluated in 2D and 3D cellular models, to assess their applicability as modular nanosystems for precise and efficient delivery of therapeutic payloads to cancer cells.

Mitochondria-encapsulation nanotechnologies to enhance mitochondrial transplantation

M. D'Amato,[a,b] V. Tiranti,[a] P. Metrangolo[b]

marco.damato@polimi.it

Mitochondria are dynamic cytoplasmic double-membrane organelles that generate most of the chemical energy needed to power the cell's biochemical reactions and play crucial roles in maintaining cellular signalling. Mitochondria dysfunction has been showed to be a key factor in the pathogenesis and in the progression of many diseases from cardiovascular to neurodegenerative diseases and cancer, as well as physiological conditions such as ageing[1]. Recent evidence of active transfer of mitochondria occurring between cells suggests that it is possible to deliver mitochondria to correct cellular dysfunction *in vitro* and *in vivo*[2]. Mitochondrial transplantation (also known as mitochondria replacement therapy or MRT) is therefore emerging as a promising therapy for the treatment of many pathological conditions where conventional pharmacological approaches fail, and gene therapy is not feasible[3]. Several *in vitro* techniques have been developed to improve the transfer of mitochondria and evaluate its validity[4]. With current methods, however, it is not possible to maintain the stability of the mitochondria in the long-term and/or to trace the fate of mitochondria after they have been introduced into the recipient cells and tissues. These challenges represent a stumbling block for the successful translation of this revolutionising approach to the clinical practice. Recently, chemical engineering techniques have been focused on finding a way to encapsulate mitochondria in order to improve their stability, integrity and to pilot their delivery[5-7]. Despite positive data, these methods have limitations in terms of efficiency and heterogeneity. Development of mitochondrial encapsulation technologies has the potential to advance translational application of mitochondrial transplantation and provide new ground-breaking strategies for the treatment of mitochondrial dysfunctions. In summary, limitations and future perspectives will be highlighted to address long-term stability of mitochondria while improving tissue-specific mitochondrial distribution and minimising the related immune response.

The coordination chemistry of transition metal ions in ionic liquids (ILs) attracted much attention in the last two decades, due the numerous applications, such as selective separations for hydrometallurgical processes[1], electrodepositions, energy storage and catalysis.[2] Ionic liquids (IL) are salts existing in the liquid state at temperatures < 100°C which have been considered for many applications as alternatives to classical organic solvents owing to their numerous interesting features[3]. Among the hydrophobic ILs, those based on the alkylimidazolium (C_nCmim^+) cation and bis(trifluoromethylsulfonyl)imide (Tf_2N) anion have been studied both for metal extractions, energy storage and as solvents for electrodepositions in recent years.[4] The knowledge of the metals speciation in ILs, especially in presence of common inorganic ligands (e.g. Cl^-, NO_3^-), is essential to understand their properties and behavior. In the present communication, we report our recent results on the complex formation between Cu(II) and Co(II) ions and Cl^- and NO_3^- anions in the 1-butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([C_4mim][Tf_2N]) ionic liquid. Spectrophotometric titrations (Figure 1) and ITC were employed to obtain the thermodynamic parameters related to complex formation. Theoretical and spectroscopic studies were employed to obtain structural information.

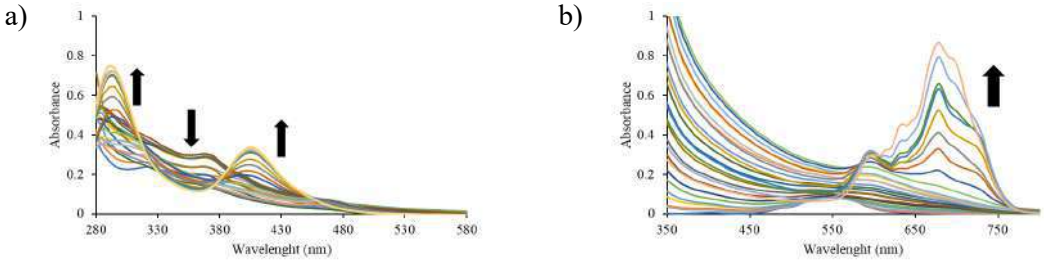

Figure 1. Spectrophotometric titration of a) Cu^{2+} and b) Co^{2+} with Cl^- in dry [C_4mim][Tf_2N]

Food waste, marine and environmental pollution are global problems that have been of particular interest to the scientific community in recent years. The increase in world population and the consequent consumption of non-reusable materials are amplifying these problems.

In this communication we present a series of bioplastics, which are completely biodegradable and environmentally friendly, with the goal of replacing fossil fuel-based packaging and slowing the degradation of food.

In fact, thin films based on Polybutylene Succinate (PBS) have been prepared and different weight percentages (1.2 and 3%$_{wt}$) of extra virgin olive oil (OO) and extra virgin coconut oil (CO), were added to improve the chemical and physical properties of the polymer and slow down the aging of fruit and vegetables. Attenuated total reflectance Fourier transform infrared (ATR/FTIR) spectroscopy was used to evaluate the interactions between the polymer and oil. Furthermore, the mechanical properties and thermal behaviour of the coating films were evaluated as a function of the oil content. SEM images showed the surface morphology of the materials. Finally, food-contact tests were carried out to assess the performance of the oil-enriched films.

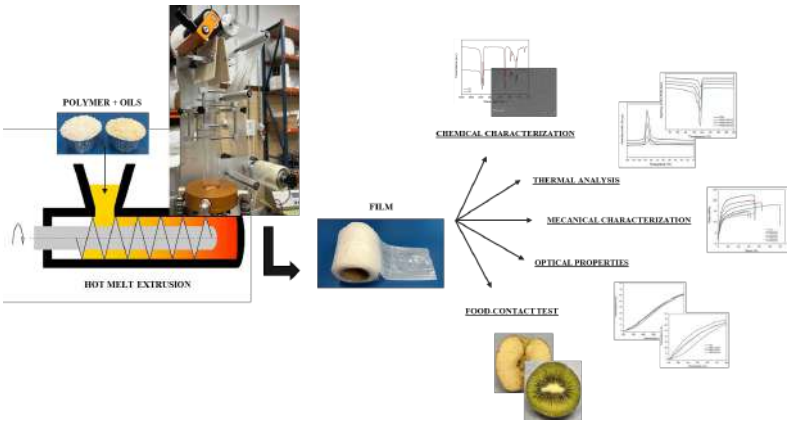

Figure 1: Flowchart of preparation of functionalized films

Recyclable bio-based epoxy/acrylate blends for Liquid Crystal Display 3D printing: design, preparation and characterization

I. Blanco,[a] C. Tosto,[a] L. Saitta,[a]

Department of Civil Engineering and Architecture, University of Catania and UdR-Catania Consorzio INSTM, Via Santa Sofia 64, 95125, Catania, Italy

iblanco@unict.it

Bio-based epoxy resins are widely utilized in various application fields such as adhesives, coatings, composites, and electrical components, offering comparable performance characteristics to conventional epoxy resins, including high strength, durability, and chemical resistance [1-3]. The use of bio-based materials in 3D printing has been receiving increasing attention as a means of reducing the environmental impact of this technology, because most formulations available for stereolithography (SLA) and digital light processing (DLP) are generally non-renewable [4-6]. This study aimed to explore the potential of blending a bio-based epoxy resin with a commercial daylight-curable resin at various weight percentages to enhance the thermomechanical properties of 3D-printed parts while adhering to the working principle of LCD (Liquid Crystal Display) printers. The prepared formulations were initially characterized in terms of their thermo-mechanical properties both before and after post-treatments like photo- and thermal-curing. This procedure facilitated a comparison of the various blends based on their mechanical strength, glass transition temperature, and other pertinent properties. Upon identifying the optimal formulation, 3D-printed samples were produced using LCD printing technology. Calorimetric and morphological tests were then carried out to evaluate the thermal stability and microstructure of the printed parts. Overall, the findings of this study indicate that blending recyclable bio-based epoxy resins with commercial ones can lead to enhanced properties in additive manufactured parts. This approach has the potential to promote sustainability in 3D printing by reducing the consumption of non-renewable resources, while still meeting the standard performance required for numerous applications.

A paper-based vapoluminescent chemosensor based on a Zinc(II) salen-type complex for the selective and sensitive detection of *n*-butylamine vapours

A. Attinà, I.P. Oliveri, S. Di Bella

Università di Catania, Dipartimento di Scienze Chimiche, Viale Andrea Doria, 6 - 95125 Catania.
e-mail of submitter: agostino.attina@phd.unict.it

Aliphatic amines are widely involved in chemical industries and their presence in food products is often related to food spoilage processes. Furthermore, aliphatic amines with short chain length (C2 – C6) possess high volatility and toxicity at low concentrations (ppm). Among them, *n*-butylamine (BA) is used in chemical industries as reactant, or intermediate in many synthetic routes. Because of its high volatility (93 mmHg at 25 °C) the main risk for human health is the inhalation. Prolonged exposure to this amine vapours can cause nausea, vomiting, and, in some cases, damage to the nervous system. For this reason, its quantitative detection is very important for human safety.

To this end, a Lewis acidic Zn(salen)-type complex[1,2] was chosen for the development of a new molecular material with vapoluminescent properties, as potential chemosensor for vapour-phase detection of BA. A paper-based sensor, fabricated by the dip-coating technique using THF solutions of the complex, was used for the quantitative detection of BA vapours. Static exposure experiments, show a linear response between 0 and 50 ppm, with a limit of detection of 2.0 ppm, below the permissible exposure limit (5 ppm) established by OSHA for BA. The effect of exposure time, exposure temperature and relative humidity on the sensor performance was also evaluated. Competitive experiments demonstrate the high selectivity of this sensor towards BA. In summary the developed paper-based sensor of the Zn(II) complex represents a simple, disposable, and cost-effective chemosensor for the selective and sensitive direct in-situ detection of BA vapours.

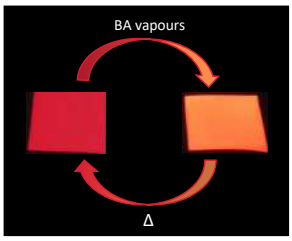

Figure 1: Fluorescence emission changes of paper-based sensor before and after exposure to BA vapours.

This research is funded by European Union (NextGeneration EU), through the MUR-PNRR project SAMOTHRACE (ECS00000022).

Optimization of Carbon-based Electrodes for Energy Storage and Conversion

Khair Un Nisa [a], Williane da Silva Freitas [a], Beatrice Ricciardi [a], Alessandra D'Epifanio [a], Barbara Mecheri [a]

[a] *Department of Chemical Science and Technologies, University of Rome Tor Vergata, Via della Ricerca Scientifica, 00133 Rome Italy*

barbara.mecheri@uniroma.it

Electrochemical energy storage and conversion devices are crucial for providing solutions to clean and green energy sectors, particularly for decarbonizing industry and long-range transport sectors. Among those devices, Metal-Air Batteries (MAB) and Microbial Fuel Cells (MFC) represent unique added values regarding sustainability, for the possibility of using oxygen from air at the cathode side and organic waste as a fuel in the case of MFC [1,2].

The critical challenges for developing MAB and MFC are the intrinsically slow kinetics of oxygen reduction at the cathode side, leading to the need to use efficient electrocatalysts. However, using critical raw materials (CRMs), such as platinum-group metals, at the cathode side jeopardizes sustainability and increases costs. By developing an efficient electrode design for MAB and MFC performance enhancement, CRM-based cathodic catalysts should be replaced with CRM-free materials [3].

This work proposes developing and optimizing iron-based air cathodes to enhance oxygen reduction at the cathode side of Zinc-Air Batteries (ZAB) and MFC. By subjecting iron phthalocyanine and carbon black pearls to controlled thermal treatments, we obtained Fe-N-C electrocatalysts with high surface area (628 m2g-1) and high oxygen reduction in both near-neutral pH and an alkaline environment. The electrocatalysts were integrated on carbon cloth and carbon paper to obtain gas diffusion electrodes, the architecture of which was optimized to maximize MFC and ZAB performance. The optimization was performed by screening different commercial carbon gas diffusion electrodes (carbon cloth and carbon paper), investigating the effect of hot pressing the catalyst layer, and the pore size of the current collector.

When assembled at the cathode side of a ZAB, the Fe-based cathode showed an excellent galvanostatic polarization discharge peak power density (PPD), outperforming the Pt/C benchmark electrocatalyst.

Moreover, the optimized electrode also showed promising features as cathode for energy recovery in an MFC: a good performance was obtained in MFC: for the Fe-based carbon paper (1028 mWm^{-2}, as PPD) as compared to a traditional electrode design based on carbon cloth (619 mWm^{-2}).

Acknowledgments:

alessandra.zanoletti@unibs.it

To achieve the energy transition targets, it is estimated that by 2050 the demand for lithium, cobalt and graphite will increase by 506%, 460% and 417%, respectively. Considering that these elements are included in the list of raw materials at risk of exhaustion it is essential to recycle. This work proposes a new microwave (MW) treatment of spent lithium-ion batteries (LIBs), for strategic metal recovery (Li, Mn, Ni and Co) by carbothermic reduction, involving short treatment times[1]. The dedicated MW device, consisting of a refractory chamber and a susceptor, allows to increase the equipment thermal insulation, to recover the MW energy furnished to a carbothermal reduction reaction. Figure 1 reports the layout of the proposed recycling process based on the black mass (BM) leaching with water and environmentally friendly organic acid (L-malic acid), after the MW treatment, for the simultaneous extraction of Li (mainly in water), Ni, Co, and Mn.

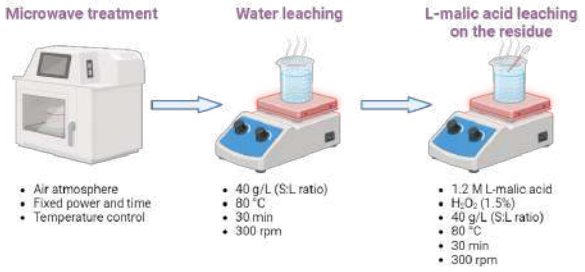

Figure 1: Scheme of the metals recovery procedure. (Figure created with BioRender.com).

The first experiments performed on LCO ($LiCoO_2$) batteries show that the MW treatment at 600 W for 5 min increased Li recovery, reaching 85%. This result encourages the development of MW technology able to reach high temperatures in a short time, compared to pyrometallurgical processes.

This study was carried out within the MICS (Made in Italy – Circular and Sustainable) Extended Partnership and received funding from Next-GenerationEU (Italian PNRR – M4 C2, Invest 1.3 – D.D. 1551.11-10-2022, PE00000004).

New memory-shaped materials based on PBS and PPAz for ophthalmic suture.

A. Palumbo,[a] G. Guidotti,[a] M. Soccio,[a] P. Versura,[b] N. Lotti[a].

[a] *Department of Civil, Chemical, Environmental, and Materials Engineering, University of Bologna, Via Terracini 28, Bologna, Italy.*
[b] *Department of Experimental, Diagnostic and Specialty Medicine, University of Bologna, Via Massarenti 9, Bologna, Italy.*
arianna.palumbo3@unibo.it

Memory-shaped polymeric sutures have recently emerged as a promising innovation in ophthalmic surgery. These sutures are designed to have shape memory, allowing them to revert back to their pre-programmed shape after being stretched or deformed. This unique property allows for improved wound closure and enhanced tissue healing in surgeries, like ophthalmic ones. The ability of memory-shaped polymeric sutures to provide controlled and precise tension during the healing process significantly contributes to better surgical outcomes. Additionally, the use of this kind of sutures eliminates the need for knot tying, reducing the risk of post-operative complications such as suture slippage[1]. Furthermore, the biocompatibility and biodegradability of these sutures make them suitable for use in ophthalmic field, where long-term tissue support is not required.
In detail, a shape memory material requires a rigid phase with a sufficiently high melting point that can maintain the permanent shape, together with a soft phase that can create the temporary shape. In the present study, poly(butylene succinate), PBS, was used as the hard segment, being characterized by high crystallinity, high elastic modulus, high melting temperature and proven biocompatibility[2]. The soft segment was made of poly(propylene azelate), PPAz, a flexible aliphatic polyester with a melting point near body temperature.

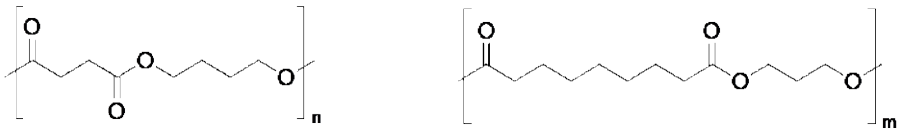

Figure 1*: Chemical structure of PBS (on the left) and PPAz (on the right).*

In this context, the synthesis of the two homopolymers (Figure 1) was carried out by a two-stage melt polycondensation process. A physical blend and a block copolymer were obtained by dissolution in a common solvent and reactive blending (for 13 minutes), respectively, from a 50:50 weight ratio of the two homopolymers. Compression moulding was then used to process the materials into films. Chemical characterisation was carried out by Nuclear Magnetic Resonance (NMR) and Gel Permeation Chromatography (GPC), while the crystallinity was analysed by Wide Angle X-ray Scattering (WAXS). Thermal analyses including Differential Scanning Calorimetry (DSC) and Thermogravimetric Analysis (TGA) were also performed. The mechanical properties of the materials were also investigated and preliminary shape memory analyses were successfully carried out. Hydrolytic degradation and cell viability studies were also performed.

carlo.punta@polimi.it

Nowadays, there is a growing awareness of the impact that climate change is having not only on the quantity of water, but also on its quality. Among the several implications that this phenomenon generates, a critical aspect refers to the provision of safe drinking water to guarantee human health security. In fact, worldwide both surface water and groundwater are the predominant sources for drinking water supply. The continuous increase of background natural organic matter (NOM), chemicals and microbial contaminants due to climate change asks for the development of more efficient and specific treatments for their removal.

For these reasons, disinfection of drinking water before distribution could take on an increasingly important role in the upcoming years for providing a microbially safe water. However, disinfection by-products (DBPs) can be formed, depending the presence on natural organic matter (NOM), which is one of the main DBPs precursors, representing in turn an additional risk for human health.

Among the different approaches suggested to overcome this issue, the development of effective adsorption-based processes to remove NOM before disinfection is a promising route. In the last decade, we have developed a new class of cellulose-based nanoporous materials which resulted particularly effective for the decontamination of wastewater and seawater from a wide range of both heavy metals[1] and organic contaminants.[2] They result from the covalent cross-linking between cellulose nanofibers and polyamine polymers.[3]

Herein we report a purposely designed new family of cellulose nanosponges (CNS) for NOM sorption before undergoing disinfection of water intended for human consumption, as part of the results obtained within the ongoing EU project SafeCREW (Climate-resilient management for safe disinfected and non-disinfected water supply systems), funded by the European Union under grant agreement No 101081980.

The removal efficiency by CNS has been verified on water matrices spiked with custom NOM solutions, resulting even higher than that measured with both micro- and meso-porous powdered activated carbons, selected as referent adsorbing materials.

Plastic pollution has become one of the most global graves environmental issues for their impact on the environment and on human beings[1]. The significant and continuous increase of plastics waste require an implement strategy for the reduction/elimination of plastic pollutants. In this work an innovative system that combines the membrane separation and the photocatalytic process for the treatment of polyester-polluted water is proposed (Figure 1). The complete recovery of fibres from water and the almost complete recovery of the initial performance of the membrane used (CA 2 kDa NF) with a cleaning efficiency of 98% and a low fouling index (16%) was obtained. Preliminary photocatalytic tests on some polyester fibres, recovered by a membrane process, showed a decrease in their length and in the weight, the photocatalytic decomposition was confirmed also by py-GCMS characterization[2], highlighting the potential of the photocatalytic process to degrade micro/nanoplastics. The obtained results suggested that the photocatalytic process can be tuned to allow the decomposition of micro/nanoplastics avoiding the use of dangerous and costly methods such as the thermal process that can produce toxic by-products. Future work will be directed toward the optimization of an integrated separation/photocatalytic process for the treatment of micro/nanoplastics from polluted water.

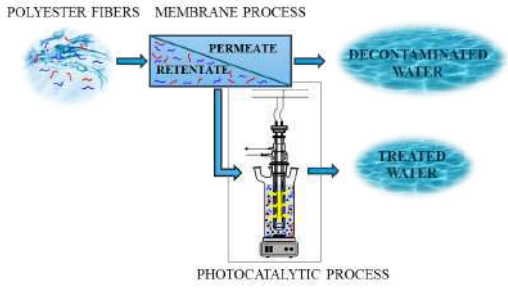

Figure 1: Scheme of the recovery by membrane and photocatalytic decomposition of polyester fibres.

PVDF coated membrane for improved saline water treatment

Mirko Frappa, Francesco Galiano, Francesca Russo, Enrico Drioli, Francesca Macedonio, Alberto Figoli
Institute on Membrane Technology, National Research Council of Italy (CNR-ITM), via P. Bucci 17/C, Rende (CS), 87036, Italy
e-mail of submitter: m.frappa@itm.cnr.it

MEloDIZER is a European project, funded by the European Union under the Horizon Europe programme, with the overall aim of providing the necessary step to transform membrane distillation (MD) into products that benefit industry and society[1].

To do this, the heart of the research will focus on providing high-performance membranes and modules through the use of components (such as polymers, solvents, functionalization materials, etc.) that can be used on a large scale but which at the same time are sustainable (replacing current potentially harmful materials with non-harmful ones and following the principles of green chemistry)[2]. The best design of this technology, when combined with the most appropriate mix of renewable energy resources, will be the key to its effective application in different fields, both in industry and on a domestic or community scale.

To this end, two different paths were followed in the creation of new membranes. The first involves the creation of flat PVDF-based membranes through the use of non-toxic solvents instead of classic solvents (e.g. N-butylpyrrolidone with the trade name Tamisolve). The second path involved the study of the coating of commercial PVDF membranes in order to improve MD performance. Fluorinated oligomer (PFPE) was chosen as the coating, with the trade name Fluorlink®. Fluorolinks were selected for their high chemical resistance, water-oil repellency, tendency to increase hydrophobicity and chemical energy, and low surface tension[3].

The performance of PVDF membranes was evaluated in MD devices where different concentrations of salt were used as feed. Specifically, direct contact and vacuum membrane distillation were used to test coated and uncoated membranes. When the PFPE coating is present on the PVDF membranes, an improvement in hydrophobicity was achieved. For example, in the case of the commercial PVDF membrane, the contact angle increases from 132 to 150°. These results indicate an improvement in the wetting resistance of the membranes during long-term MD tests (membrane tested for 60 hours without wetting). In fact, in the case of 0.6M NaCl solution as feed, the flow obtained with the coated membrane appears more stable than the uncoated membrane (average flow of 8.42 and 8.14 L/m^2*h, respectively). Furthermore, salt rejections range from 99.99 to 100% for the uncoated membrane and 100% for the coated membrane. The results obtained, within the Melodizer project, encourage the implementation of high-performance membranes and modules in strategic membrane distillation applications, thus providing the decisive step for the success of MD.

Microwave assisted synthesis of polypyrrole-polyketone copolymers for electrochemical applications as anion exchange membranes

F. Lanero,[a] K. Vezzù,[a] G. Pace,[a] V. Di Noto,[a] P. Sgarbossa[a]

[a]*Department of Industrial Engineering, University of Padova, via Marzolo 9, Padova 35131, Italy*
francesco.lanero@phd.unipd.it

As the core component of alkaline fuel cells (AFC), anion exchange membranes (AEMs) have to withstand a strongly reactive alkaline environment[1]. Among the proposed polymeric material proposed not only to show good chemical stability but also to provide high ion conductivity, polypyrrole-polyketone copolymers enjoy an easy synthetic procedure and a low-cost starting material, polyketone[2,3]. A drawback in the application of the Paal-Knorr reaction to link the amino (then turned into ammonium) functionality is the need for long reaction times when using conventional heating systems. We studied the possibility to reduce reaction time and energy consumption by applying alternative heating/reaction modes, in particular with the use of a microwave reactor. Here we report the preparation of some derivatives characterized by heterocyclic ammonium groups, prepared by varying the amine/PK molar ratio to influence the degree of functionalization, f (Figure 1). The polymers have been cast to produce anion exchange membranes after quaternization and anion exchange.

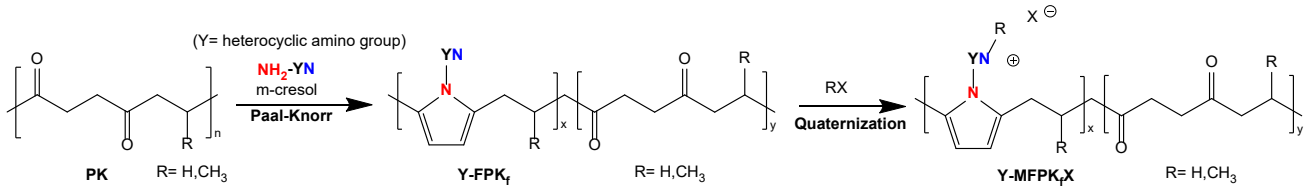

Figure 1: Synthetic scheme for the copolymer preparation (f = degree of functionalization).

The membraned have been characterized to understand their chemical composition, thermal and conduction properties proving the efficacy of the devised synthetic procedure in obtaining AEMs with promising ion conductivity.

l.donato@itm.cnr.it

The technological progress of the modern society as well as the necessity of recovery and recycling precious resources allowed the development of more and more efficient and sustainable separation materials. In this perspective, a relevant contribution comes from the employment of membrane-based separation systems. In particular, the production of imprinted membranes offers the possibility of achieving a high separation level of targeted compounds. Some example of applications are the selective separation of ions and toxic substances from wastewaters and the recovery of bioactive compounds from food matrices or other sources[1,2].

This work deals with the development of imprinted polymeric membranes for the selective recovery of theophylline (THEO) from water samples containing also the structural analogue caffeine (CAFF). Theophylline is a xanthine used in the cure of asthma, chronic obstructive pulmonary disease and chronic bronchospasm[3,4]. Firstly, flats-sheets imprinted membranes were prepared *via* the non-solvent induced phase inversion technique by dispersing different amounts of a pre-synthesized imprinted polymer in a modified poly(ether ether ketone) (PEEK-WC) polymer solution. Molecular recognition investigations carried out in aqueous environment permitted to assess the specific recognition properties of the imprinted membranes with respect to the simple (PEEK-WC)-based membranes and the non-imprinted membranes prepared under the same operating conditions. Starting from these results, the phase inversion technique was also applied for producing novel hybrid hollow-fiber imprinted membranes containing the 5% of THEO-imprinted polymer with respect to the (PEEK-WC). Membranes were prepared at two different compositions of bore fluid and using water as the non-solvent.

Synthesis and characterisation of lignin-based hydrogels for the removal of emerging pollutants from wastewater

S.Ranieri,[a] F. Luzi,[a] P. Astolfi,[a] M. Pisani [a]

[a] *Department of Materials, Environmental Sciences and Urban Planning, Polytechnic University of Marche, via Brecce Bianche 12, Ancona, Italy*

s.ranieri@pm.univpm.it

Lignin is the second most abundant organic polymers on Earth and consists of cross-linked aromatic units called "lignols" [1]. Nowadays, most lignin is pyrolysed as biomass. However, new possibilities for its application have recently opened, including its use as a component of hydrogels for drugs removal from wastewater due to its adsorption and retention properties [2].

In this study, LS_pAAm hydrogel was synthesised from lignin sulfonate and acrylamide by a free radical copolymerisation, using N,N′-Methylenebisacrylamide as the crosslinking agent. In addition, a hydrogel with cationic functionalities (LS_pAAm_DAC) was obtained by free radical grafting with Acryloxyethyltrimethyl Ammonium Chloride (DAC) of the main chains of the copolymer LS_pAAm.

Physical-chemical characterisation of the prepared hydrogels (Infrared Spectroscopy, Scanning Electron Microscopy, Differential Scanning Calorimetry and Thermal Gravimetric Analysis) confirmed the obtainment of a porous material able to incorporate high amounts of water and, in the case of LS_pAAm_DAC, with the cation the DAC quaternary ammonium moiety.

The cationic LS_pAAm_DAC hydrogel, which showed a higher swelling degree than LS_pAAm one, was tested for the removal of the model drug Diclofenac in its anionic form (DCF-Na) and showed a Removal Efficiency of 85% after incubation with a 30 mg/L aqueous solution of DCF-Na.

The kinetic of DCF-Na removal as well as the isotherm adsorption were also studied: the removal follows a pseudo-second order kinetic whereas a linear absorption of the drug by the hydrogel is suggested.

Although technological progress has brought undeniable benefits, it has generated some issues related to the excessive exploitation of planet's resources and to the resulting effects on environment and human health. In reply to this concern, there has been a growing focus on a new concept of industrial advancement which could integrate economic growth with social and environmental responsibility, converting old technologies into new eco-friendly processes. Membrane technologies play a dominant role in offering a valid solution to the aforementioned problems and they are currently proposed as greener alternative productive processes in different field. Membrane nanoprecipitation (MN) is emerging as sustainably manufacturing method to formulate different polymeric particulate materials. The process is based on the precipitation of the polymer as a form of nanoparticles (NPs) due to the solvent- non solvent mixing at the membrane pores level; these products could find application in various sectors. MN is recognized as environmentally friendly method because allows to operate using few steps, minimizing energy consumption and waste output.[1] MN has been extensively studied to produce hydrophobic NPs, while limited literature data have been reported for hydrophilic ones. To fully explore the potentiality of the technology in this field, two case-studies will be presented in this study focus on the use of MN for the development of 1) chitosan NPs for the encapsulation of organic bioactive molecules and 2) hybrid materials in which inorganic components are enveloped within the polymeric shell. Chitosan has been selected as biopolymer material for its relevant role among the hydrogel carriers for drug delivery and because its positive charge allows electrostatic interactions with not only organic, but also inorganic compounds with the purpose of creating hybrid structures. A methodical investigation on chitosan NPs preparation by MN will be discussed examining the results in terms of uniform distribution, particle size and productivity, encapsulating a protein (BSA) as model. The MN will be also studied for the production of hybrid particles using zeolites as anionic models. The effect of the type of reagents and their concentration will be analyzed. The sustainability impactful of the process will be evaluated by calculating the energy consumption, the environmental factor (E-factor) for the two cases studies presented and the results will be compared with conventional methods used in the field.

TEC-PO-054

Development of biofunctionalized membrane-based platforms to enhance recognition selectivity and sensitivity of sensing systems

S. Regina, G. Vitola, R. Mazzei, L. Giorno

National Research Council - Institute on Membrane Technology (CNR-ITM), Rende, Italy

s.regina@itm.cnr.it

To achieve more selective and effective management in the detection of traces of small molecular weight micropollutant (SMWMP) in aqueous phase, the development of biosensors built on biofunctionalized membrane-based platform has attracted considerable attention. The introduction of the membrane with appropriate chemical-physical characteristics into the biosensor architecture contributes, in fact, to support the bioreceptor in a well-defined structure, regulate the analyte transport, promote the bioreceptor-analyte interaction, increase the analyte concentration, act as a microenvironment that aids the transduction of the biochemical interaction into a physical signal.

In this work, phosphotriesterase enzyme (PTE) was used as a model bioreceptor to selectively recognize the pesticide paraoxon (as SMWMP model). PTE was covalently linked on various home-made and commercial membranes (polyvinilidene fluoride - PVDF, polyvinylidene fluoride/alkali lignin - PVDF/AL, regenerated cellulose - RC, and polyamide - PA) using glutaraldehyde as crosslinker[1]. The activity and stability of the biofunctionalized membranes were monitored over time. Adsorption experiments of paraoxon (substrate) and p-nitrophenol (product) on membranes enabled us to design strategies for sensing systems.

RC and PA membranes were selected for the membrane-based sensing systems development as they showed the highest specific enzyme activity after biofunctionalization. Due to the chemical composition differences between the membranes, RC membrane showed no adsorption of either the substrate or the product, while the PA membrane adsorbed only the latter (turning yellow). A colorimetric detection is provided for both the developed platforms using two different detection instruments: a UV-Vis spectrophotometer for RC membrane and a color detector for PA membrane. The lecture will discuss the strategies investigated to enhance sensing selectivity and sensitivity.

mariastella.leone@poliba.it

There are several sustainability issues that the scientific community must tackle by giving high priority to the implementation of the circular economy concept. Wastes can be reused to obtain high-value products and in this context, steel slags, due to their chemical properties, can play a significant role in catalysis by contributing to the reduction of solid wastes.[1] On the other hand, converting waste biomass, such as spent cooking oil, into valuable biofuel perfectly fits green chemistry principles and follows the attempts of the world decarbonization.[2] In this framework, the present work reports on the synthesis and characterization of new materials constituted of iron oxides and nickel nanoparticles deposited onto waste steel slags to be used as catalysts for the partial hydrogenation of FAMEs (Fatty Acid Methyl Esters) coming from waste cooking oil. The partial hydrogenation reaction aims at selectively converting all C18 polyunsaturated esters of the FAMEs mixture into C18:1 monounsaturated product, avoiding the formation of C18:0 methyl stearate (Figure 1), thus upgrading the biodiesel parameters of the whole blend.

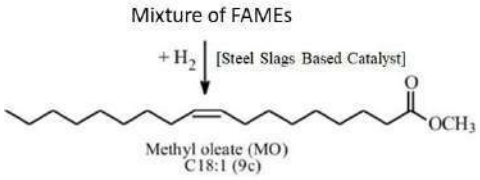

Figure 1: Hydrogenation reaction of FAMEs

The novel catalysts were characterized by Thermogravimetric Analyses (TGA), Scanning Electron Microscopy (SEM), Fourier Transform-Infrared Spectroscopy (FT-IR), X-Ray Diffraction (XRD) and Transmission Electron Microscopy (TEM) analytical techniques.

x.li@itm.cnr.it

Poly(vinylidene fluoride) (PVDF) flat sheet membranes were prepared by using the Dimethyl isosorbide (DMI) as the green solvent via NIPS-VIPS method. DMI is a high boiling green solvent that possess good physical/chemical properties for the casting membrane. The PVDF membranes were prepared at the temperature of 120 ºC to obtain the completely homogeneous solution. After degassing of about 2 h, the casting solutions were casted by the casting knife on the glass, with the air gap of 250 μm at the temperature of 90 ºC in a climate chamber, where the relative humidity is 65% and the temperature is 25 ºC [1]. A series of membranes were prepared by varying the exposure time in the humidity, which is 0, 1, 1.3 and 2.5 mins, respectively. The membranes were characterized in terms of thickness, porosity, contact angle, mechanical strength and SEM morphologies. The membranes were applied in direct contact membrane distillation (DCMD) operations. Feed temperatures were set at around 40, 50 and 60 ºC respectively for pure water membrane distillation tests. Fluxes were increased with feed temperatures. Results achieved until now showed that, the membrane prepared under 1.3 mins in the humidity chamber presented high fluxes at around 13 L/m^{2}h, and rejections above 99.9% in the 0.6 M NaCl solution DCMD test, which is operated at the feed temperature of 40 ºC and permeate side temperature of 15 ºC.

The application of waste materials as catalysts holds significant relevance in the field of sustainable chemistry and green synthesis. Steel slags are a waste-product of the steel manufacturing process, originating from the extraction of molten steel from contaminants in steel production furnaces.[1] This slag material exists in a molten liquid state as a solution of silicates and oxides, which undergoes solidification upon cooling. Its chemical composition typically comprises calcium, silicon, iron, aluminium, magnesium, and their oxides. Given to their extensive composition, alkaline characteristics, and good mechanical properties, herein steel slags were chosen as valuable catalyst support for an important organic reaction, such as the reduction of nitroarenes. Copper was selected as the active component for catalysis among transition metals, due to its high level of activity, abundance, and relatively moderate cost.[2]

A novel Cu/SteelSlags catalyst was obtained by mixing copper sulphate pentahydrate ($CuSO_4 \cdot 5H_2O$) solution and sieved steel slags powder for 2 hours. The precipitation of copper hydroxide onto steel slags occurred without the addition of any further alkaline compound. The transformation of the active component from copper (II) to copper (0) nanoparticles occurred in-situ under reductive reaction conditions, as evidenced by TEM analyses and by the change of the colour of the catalyst from blue-grey to black.

Catalyst revealed active, selective and recyclable in nitroarene reduction to anilines at room temperature in the presence of $NaBH_4$, as the reductant, in deionized H_2O as the solvent in few hours. Cu/SteelSlags material was characterized by FT-IR, XRD, PXRF, TGA, SEM and TEM techniques before and after the catalytic cycles.

p.hamidizadeh@phd.poliba.it

Cisplatin, a widely-used chemotherapy agent, has significant drawbacks, including severe side effects like kidney damage and nerve toxicity. Finding a new platinum drug with better efficacy and fewer side effects remains a key goal in cancer treatment.[1]

The strategic substitution of ligands within cisplatin, incorporating moieties characterized by both biological activity and anticancer potential such as flavones, represents a compelling direction of inquiry. In pursuit of this objective, our research group has synthesized novel complexes aimed at realizing this dual functionality.[2]

3-Hydroxyflavone (3-Hfl) and ethyl gallate (etga) exhibit notable antioxidant, anti-inflammatory, and anticancer properties, making them highly appealing candidates for inclusion as ligands in platinum derivatives. This highlights their potential significance in biomedical research and therapeutic development.[3]

Nowadays, it is vital to find an alternative source of fuel to oil. This presentation deals with the development of an innovative catalytic system for biodiesel synthesis starting from waste biomass (waste cooking oil, WCO) in the presence of waste material (steel slags) as the catalyst.
The importance of this issue is well documented by the presence of many reports on both the use of WCO as a feedstock[1] and a waste as the catalyst[2]. Recently, the use of steel slags as active and selective catalyst for the synthesis of fatty acid methyl esters (FAMEs) by transesterification of soybean oil in methanol under conventional heating (120°C) has been reported to take several hours (12 h) to reach completion[3].
In this study, microwave (MW) irradiation protocols were developed for fast and low energy consuming biodiesel synthesis from WCO in the presence of steel slags. After some preliminary tests, the reaction conditions were investigated and optimized by setting a design of experiment. Time, temperature and catalyst weight were set as factors. The almost quantitative conversion of WCO could be achieved in only 18 min at 134°C. The recyclability of the catalyst and the variations of its structure during cycles were also investigated. Steel slags were characterised by Scanning Electron Microscopy (SEM), Total X-ray Florescence (TXRF), X-Ray Diffraction (XRD) and Thermogravimetric Analysis (TGA).

Do we really understand catalysis?

M. Parrinello,[a]

[a] *Italian Institute of Technology, Genova, Italy*
michele.parrinello@iit.it

The transition to a green economy depends critically on the development of efficient catalysts that could for instance help in sequestrating CO2 or producing H2. To reach this goal a detailed understanding of the catalytic mechanism would be of great value. Unfortunately, most industrial catalysis takes place at temperatures and pressures, so high that both experimental and theoretical investigations are challenging. Current theories cannot explain the extreme durability and stability of industrial catalysts under these conditions. In our view the root of this difficulty lies in a static view of the catalytic process in which the catalyst is only seen as a static platform for reaction. We argue instead that industrial catalysts are dynamical entities that, under reaction conditions evolve forming reactive sites with the reagents. Recent technical development, driven by machine learning methodologies, allow realistic and accurate atomistic simulations to be performed. These simulations are validating such a complex dynamical picture, and we find in our simulations that efficient catalysts are better described as functional materials. We focus our attention on the synthesis and cracking of NH3. The final purpose of these studies is twofold. On the one hand one wants to reduce the remarkably large carbon footprint of ammonia production which account for 4% of the global CO2 emission. On the other, having in mind a hydrogen-based economy indicating ways of dissociating ammonia into its constituents nitrogen and hydrogen so as to allow using ammonia to store and transport hydrogen.

Accurate reduced cost VRC-TST rates for barrierless reaction by means of DFT geometry optimizations, coupled cluster composite methods, and difference-dedicated multireference contributions

L. Crisci,[a]

[a] *Scuola Normale Superiore, Piazza dei Cavalieri 7, 56126 Pisa, Italy*
luigi.crisci@sns.it

Recent theoretical and hardware developments have turned computational investigations into valuable assets for every chemist's toolkit. Advanced versions of Transition State Theory (TST), Variational Transition State Theory (VTST), and Variable Reaction Coordinate Transition State Theory (VRC-TST)[1] are at the forefront of addressing the complexities of chemical kinetics. While both approaches mitigate the non-recrossing approximation, their effectiveness strongly hinges on the quality of the underlying potential energy surface, with this aspect being particularly daunting for VRC-TST, which relies on a Monte Carlo (MC) phase-space sampling. In this regard, existing strategies are based on *geometric* and *electronic* mono-dimensional *on-the-fly* corrections. The first aims to alleviate the implications of adopting asymptotic fragment structures during MC, whereas the latter tries to overcome the inaccuracy of cheap quantum chemical models. However, this protocol hides intricacies. First, acquiring accurate *reference potentials* can be prohibitive, and establishing the most effective *low level* model for the MC sampling is neither a straightforward nor a black-box process. Second, applying *geometric* corrections may not fully account for the coupling of the reaction coordinate with transitional and conserved modes[2]. Here, we propose an efficient yet accurate solution to these problems. After the acquisition of a suitable wave-function for the single-reference high-spin state by employing the Pisa composite scheme (PCS),[3] the *reference potential* is obtained by adding the energy difference between the high- and low-spin states (*spin-splitting* correction)[4] computed by the Iterative Difference Dedicated Configuration Interaction (I-DDCI)[5] or its perturbative version (I-DDCI-PT2) presented here for the first time. This embodies a rapid basis-set convergence, reduced number of doubly excited configurations, and lack of intruder states interferences. Then, the *geometric* issue is tackled by relaxing the conserved modes during the MC, ensuring they closely match the values of a set of reference geometries. On these partially optimized geometries, the sampled energy is derived at a *low level*, which reduces the electronic correction relative to the *reference potential*. A black-box framework simplifies the time-consuming selection of the appropriate exchange and correlation functional[6].

Non-equilibrium dynamical effects on excited states within polarizable environment: perspectives from an open quantum system approach

Ciro A. Guido[a]

[a]*Dip. Scienze ed Innovazione Tecnologica, Università del Piemonte Orientale, v.le T. Michel 11, 15121 Alessandria*
ciro.guido@uniupo.it

The accurate simulation of environment effects in the formation and relaxation of electronic excited states (ES) is still a challenge for theoretical chemistry: from one hand, the time dependent non-equilibrium effects can play a major role for ES properties, from the other, the QM approach used to calculate the excitation can describe in different ways the polarization response of the environment.[1,2] Recently[3] the time dependent problem of a solute described by Quantum Chemistry within an environment represented as a polarizable continuum model (PCM) has been reconsidered in terms of the open quantum systems (OQS) theory.[4] This method can be also extended to polarizable QM/MM approaches, due to the similar formalism with continuum models.[2]

In this talk I will discuss how using a non-Markovian stochastic Schrödinger equation (SSE) formulation,[5] comprehensive picture of the electronic energies and the coupling between solute and environment electronic dynamics is provided, ranging from the limit where the solute electronic dynamics is much faster than the embedding one to the opposite case. [6]

It proves to be a unifying theoretical framework[3] able to describe the delayed solvent response due to the solute charge density reorganization evolving in a time regime. It naturally includes polarization and dispersion interactions, paving the way for development of empirical but effective simpler protocols [7,] that can be used in different applications ranging from biophysics[8] to optoelectronics[9,10].

Real-Time and Strong Coupling between Molecules and a Continuum Environment

Pipolo, Silvio[a]; Corni, Stefano[b]

a Dipartimento di Chimica, Universita di Lille, Francia;
Dipartimento di Chimica, Universita di Padova, Italia
silvio.pipolo@univ-lille.fr

We present here a recently developed real-time approach for accounting for the non-equilibrium interaction between a continuum environment and a molecular system described by the propagation of its wave-function [1] or electronic density [2] respectively at the Real-Time TDCI and TDDFT levels.We reformulated the Boundary Element Method (BEM) for the the description of the molecule-environment interaction using a diagonal representation for the frequency-dependent response matrices. We show that our "diagonal" formulation is equivalent to (i) the Polarizable Continuum Model [3] if the BEM approach is formulated to describe the interaction between a molecule placed in a vacuum cavity within a dielectric medium sourrounding it (ii) an analogous approach developed to describe the response of plasmonic excitations in metallic nanoparticles [4] close to the molecule of interest. In addition, the diagonal approach clearly highlights the connection between BEM-based and multipolar-based description of the interaction potential [1].Moreover our approach provides "equations of motion" in the time domain for the fictitious degrees of freedom (polarization charges) describing the molecule-environment time-dependent interaction that we derived both for a Debye, Drude-Lorentz and general (numeric) continuum response [1,5,7].At last we have exploited the features of the diagonal BEM formulation to quantify the quantum coupling between a plasmon in the medium and an exciton in the molecule [7,8].

Tackling size and complexity of Metal-Organic Frameworks from cheap hybrid DFT methods

Lorenzo Donà[a], Mattia Raimondo[a], Bartolomeo Civalleri[a]

[a] *University of Turin, Via Pietro Giuria 5, Turin*
lorenzo.dona@unito.it

The chemical versatility and modular nature of Metal–Organic Frameworks[1,2] (MOFs) make them unique materials for a wide range of possible applications[3-10]. However, from a computational view point, ab initio modeling of MOFs is a challenging and demanding task, in particular, when the system reaches the size of giant MOFs as MIL-100[11] and MIL-101[12] with several thousand atoms in the unit cell. Here, we show how such complex systems can be successfully tackled by a recently proposed class of composite electronic structure methods revised for solid-state calculations[13]. These methods rely on HF/density functional theory hybrid functionals (i.e., PBEsol0, HSEsol and r2SCAN0) combined with a double-zeta quality basis set. They are augmented with semi-classical corrections to take into account dispersive interactions (D3 scheme[14]) and the basis set superposition error (gCP[15]). The resulting methodologies, dubbed "sol-3c," are cost-effective yet reach the hybrid functional accuracy. Here, sol-3c methods, implemented in the CRYSTAL code[16], are effectively applied to predict the structural, vibrational, electronic, and adsorption properties of some of the most common MOFs. Calculations are feasible even on very large MOFs containing up to 3700 atoms in the unit cell as MIL-100 and MIL-101, with small-scale computing resources (e.g. 80 cores). We propose to use our composite methods for the routine In Silico screening of MOFs targeting properties beyond plain structural features.

From Theory to Practice: DFT Insights into Anharmonicity Effects on Vibrational Spectra in Solid-State Chemistry

D. Mitoli,[a] J. Maul,[b] A. Erba [a]

[a]*Dipartimento di Chimica, Università di Torino, Torino, Italy*
[b]*Materials Science and Engineering Graduate Program, UFPB, Joao Pessoa, Brazil*
davide.mitoli@unito.it

We introduce a computational tool for the quantum-mechanical simulation of anharmonic infrared (IR) and Raman spectra of materials.[1] The approach, implemented in the CRYSTAL software,[2] stems from a Taylor's expansion of the potential energy surface (PES) on the basis of normal modes up to cubic and quartic terms. The PES can be sampled with four different numerical schemes at the level of density functional theory (DFT). Anharmonic states are obtained by solving nuclear Schrödinger's equation with either the vibrational self-consistent field (VSCF) or vibrational configuration interaction (VCI) methods. Nuclear quantum effects (NQEs) are thus fully accounted for.[3] IR intensities are computed numerically through a Barry phase approach or analytically through a coupled-perturbed (CP) approach. Raman intensities are computed analytically via the CP approach.

A variety of anharmonic features of vibrational spectra of materials can be simulated, including band shifts, combination bands, overtones, resonances (first order Fermi, second-order Darling-Dennison), and hot bands. We showcase the effectiveness of the approach on the description of a first-order Fermi resonance (FR) in CO_2 dry ice: a challenging test-case given that the FR occurs in the Raman spectrum, requires NQEs, and involves two- and three-mode couplings.[4] Fundamental mechanistic differences with respect to the well-know FR in molecular CO_2 are addressed. This application represents the first quantum-mechanical, periodic description of FR in dry ice.

A time averaged semiclassical approach to IR spectroscopy

C. Lanzi,[a] C. Aieta,[a] M. Ceotto,[a] R. Conte[a]

[a]*Università degli Studi di Milano, Via Golgi 19, 20133 Milano, Italy*
cecilia.lanzi@unimi.it

Semiclassical vibrational spectroscopy is based on the evolution of classical trajectories and is able to reproduce quantum effects with good accuracy at the cost of a reasonable computational effort.[1-5] Nevertheless, semiclassical vibrational power spectra do not simulate all the features of the experimental IR spectra, since intensities in power spectra are not directly related to IR absorptions. Therefore, we developed a new semiclassical approach to the calculation of molecular IR spectra, by employing the time average technique upon symmetrization of the quantum dipole-dipole autocorrelation function.[6,7] We tested the accuracy of this new method on a few simple analytical systems and small molecules in the gas phase. In particular, spectra in the limit of infinite or zero temperature were investigated. Overall the method features excellent accuracy in calculating absorption intensities and provides estimates for the frequencies of vibrations in agreement with the corresponding power spectra.

*federico.coppola@unina.it

Modern scientific research heavily relies on time-resolved vibrational spectroscopic techniques, specifically infrared (IR) and Raman spectroscopies for probing the intricate photoinduced non-equilibrium dynamics of molecular systems and elucidating the underlying mechanisms driving various chemical reactions and biological processes.[1,2] In this contribution we will present an innovative computational approach combining *ab-initio* molecular dynamics (AIMD) with transient vibrational analysis, establishing a time-dependent density functional theory (TDDFT)-based protocol.[3] This protocol offers a groundbreaking capability: the simultaneous description of transient IR and Raman active vibrational modes. To achieve this, we incorporate recent advancements in assessing higher-order TDDFT properties and employ multiresolution time-frequency analysis techniques based on the Wavelet Transform of specific time-series extracted from AIMD simulations, pushing the boundaries of vibrational spectroscopy. To demonstrate the practical utility of our protocol, we will show representative case studies in gas and in condensed phase where we applied these methodologies for investigating the complex interplay between time resolved signals and excited state photodynamics .[4] Through the meticulous analysis of vibrational signatures, we gain a deeper understanding of how nuclear motions act as mediators in the photodynamics of diverse photo-active systems, shedding light on the molecular mechanisms governing these processes. In summary, our computational approach, grounded in TDDFT and advanced vibrational analysis techniques, marks a paradigm shift in the study of ultrafast chemical processes.[5] It allows researchers to delve into the transient structural dynamics of molecules in real time, bridging the gap between theoretical predictions and experimental observations in materials and systems of biological interest.

Excited-state dynamics in Non-Fullerene Acceptors for Organic Photovoltaics

Samuele Giannini,[a] Alexander J. Gillet,[b] Giacomo Prampolini, [a] Fabrizio Santoro,[a] David Beljonne[c]

[a]*CNR-ICCOM, Pisa, Italy*
[b]*University of Cambridge, Cavendish Laboratory, United Kingdom*
[c] *University of Mons, Laboratory for Chemistry of Novel Materials, Mons, Belgium*
samuele.giannini@cnr.it

The efficiency of organic photovoltaics (OPVs) has exceeded 19% with the introduction of non-fullerene electron acceptor (NFA) materials such as Y6 and its derivatives. Despite this progress, a lack of understanding hampers further advancements in material design. This presentation centers on a computational-experimental characterization of application-relevant NFAs. I will discuss how first-principles-based model Hamiltonians and state-of-the-art non-adiabatic molecular dynamics simulations[1,2], which couple the electron-nuclear motion, allow for the accurate reproduction of experimental optical properties in large molecular aggregates and provide important insights. For example, the interplay of charge transfer excitations and Frenkel exciton states in some NFAs was identified as responsible for the broadening and red shift in the absorption spectrum from solution to solid state, contrasting common causes like J-aggregation. These simulations, along with evidence from transient absorption spectroscopy and magnetic resonance spectroscopy, enabled the disentanglement of the complex excited state dynamics in these systems[3]. I will discuss a set of strategies based on our understanding of the solid-state packing's influence on NFA properties for intelligent material design to enhance OPV performance.

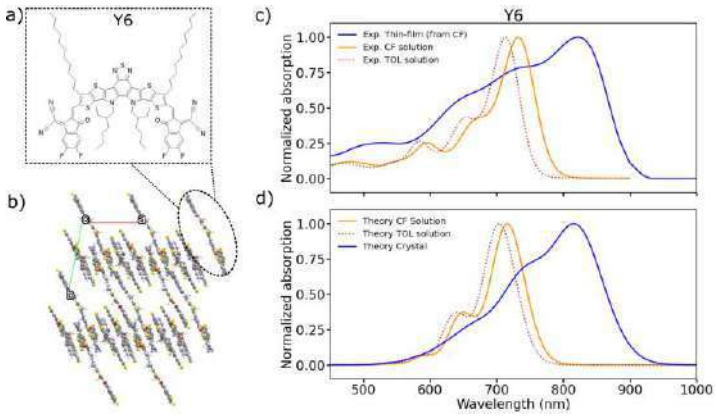

Figure 1: Molecular and **b)** single-crystal structures of Y6, respectively. **c)** Experimental absorption spectra of Y6 in TOL (dashed brown line) and CF solution (solid orange line). **b)** Computed absorption spectra in the same solvents.

Computational modeling of gas-phase reactions: the role of intersystem crossing in the reaction between O(^{3}P) and pyridine

S. Alessandrini,[a] C. Puzzarini[a]

[a]*Dipartimento di Chimica "Giacomo Ciamician", Via Francesco Selmi 2, Bologna*
silvia.alessandrini7@unibo.it

Spin-forbidden processes, such as intersystem crossing (ISC) occur on longer time scales than those where the spin is conserved, thus they are recognized as secondary processes. The entity of these phenomena can be tuned and, as an example, ISC is enhanced in presence of heavy atoms, like transition metals, bromine, or iodine.

In a recent paper,[1] the discovery of a dominant ISC that controls the reaction between atomic oxygen O(^{3}P) and pyridine (C_5H_5N) was reported. This ISC occurs in the presence of only light atoms (H,C,N,O) making the process relevant in atmospheric chemistry, as well as in combustion processes, and astrochemistry. The discovery was made thanks to a joint theoretical and experimental study of the title reaction, in the gas phase. In particular, the experimental data from crossed molecular beams for the reaction show that the reaction C_5H_5N+O(^{3}P) forms a 98% isomer with molecular formula C_4H_5N (pyrrole or one of its isomers) together with the CO molecule. These products belong to a singlet surface, while the reactants are on the triplet surface, thus testifying the importance of the spin-forbidden channel controlled by the ISC between the triplet and singlet surfaces. This is large contrast with the isoelectronic system benzene+O(^{3}P), where the entity of the ISC is in the order of 30% [2]. The ISC was characterized using accurate computational approaches, which have been used to uncover the reaction networks, the geometries at the ISC, the various products (about 30) and the kinetic of the process at moderate-low temperatures.

The key features of this new ISC were interpreted using frontiers orbitals and other energetic considerations, opening the way towards the characterization of this ISC in other reactions where one of the reactants bears an N-atom.

Shining Light on Inverted Singlet-Triplet Emitters

M. Bedogni,[a] D. Giavazzi,[a] F. Di Maiolo,[a] A. Painelli[a]

[a]*Parma University, Department of Chemistry, Life Sciences and Environmental Sustainability Parco Area delle Scienze 17/A, Parma*
francesco.dimaiolo@unipr.it

The inversion of the lowest singlet and triplet excited states, observed in several triangle-shaped organic molecules containing conjugated carbon and nitrogen atoms, is an astonishing result that implies the breakdown of Hund's rule.[1] The phenomenon attracted interest for its potential toward triplet harvesting in organic LEDs. On a more fundamental vein, the singlet-triplet (ST) inversion sheds new light on the role of electron correlations in the excited-state landscape of π-conjugated molecules.[2-5] Relying on the celebrated Pariser-Parr-Pople model, the simplest model for correlated electrons in π-conjugated systems, we demonstrate that the ST inversion does not require triangle-shaped molecules nor any specific molecular symmetry.[6] Indeed, the ST inversion does not require strictly non-overlapping HOMO and LUMO orbitals but rather a small gap and a small exchange integral between the frontier orbitals.

Ultrafast excited-state dynamics of Luteins in the major light-harvesting complex LHCII

Laura Pedraza González ,[a] Davide Accomasso,[a] Lorenzo Cupellini,[a] Giovanni Granucci,[a] Benedetta Mennucci[a]

[a]*Dipartimento di Chimica e Chimica Industriale, Università di Pisa, Via G. Moruzzi 13, 56124, Pisa, Italy*
laura.pedraza@unipi.it

Carotenoid pigments are known to present a functional versatility when bound to light-harvesting complexes. This versatility originates from a strong correlation between a complex electronic structure and a flexible geometry that is easily tunable by the surrounding protein environment. In this work, we investigated how the different L1 and L2 sites of the major trimeric light-harvesting complex (LHCII) of green plants tune the electronic structure of the two embedded luteins, and how this reflects on their ultrafast dynamics upon excitation. By combining molecular dynamics and quantum mechanics/molecular mechanics calculations, we found that the two luteins feature a different conformation around the second dihedral angle in the lumenal side. The s-cis preference of the lutein in site L2 allows for a more planar geometry of the π-conjugated backbone, which results in an increased degree of delocalization and a reduced excitation energy, explaining the experimentally observed red shift. Despite these remarkable differences, according to surface hopping simulations the two luteins present analogous ultrafast dynamics upon excitation: the bright state S_2 quickly decays (in ~50 fs) to the dark intermediate S_x, eventually ending up in the S_1 state. Furthermore, by employing two different theoretical approaches (i.e., Förster theory and an excitonic version of surface hopping), we investigated the experimentally debated energy transfer between the two luteins. With both approaches, no evident energy transfer was observed in the ultrafast timescale.

The nature of carotenoid S* state and its role in the nonphotochemical quenching of plants

D. Accomasso,[a] G. Londi,[b] L. Cupellini,[b] B. Mennucci[b]

[a]*Faculty of Chemistry, University of Warsaw, Warsaw, Poland*
[b]*Department of Chemistry and Industrial Chemistry, University of Pisa, Pisa, Italy*
d.accomasso@uw.edu.pl

Light-harvesting complexes (LHCs) of oxygenic photosynthetic organisms serve a dual function in photosynthesis. Under low-light conditions LHCs absorb sunlight and transfer the excitation energy to the reaction center, whereas in high-light situations they switch to a quenched state, dissipating the excess of the absorbed energy as heat to avoid photodamage. While the processes underlying the light-harvesting function are now rather well known, the quenching mechanisms of LHCs are still under debate. In CP29, a minor LHC of plants (Figure 1), spectroscopic investigations have proposed that quenching mainly occurs via excitation energy transfer (EET) from specific chlorophylls to a debated carotenoid S* state of lutein (Lut).[1,2] In this work, we performed simulations of the nonadiabatic excited state dynamics for Lut in CP29. Our simulations indicate that the minor s-trans conformer of Lut in CP29 shows all the spectroscopic features ascribed to the S* state, and the EET quenching by Lut is more energetically favored for the s-trans conformer, compared to the dominant Lut s-cis conformer. These findings allow us to elucidate the nature of the quencher S* state and to associate it with a specific carotenoid conformation.[3]

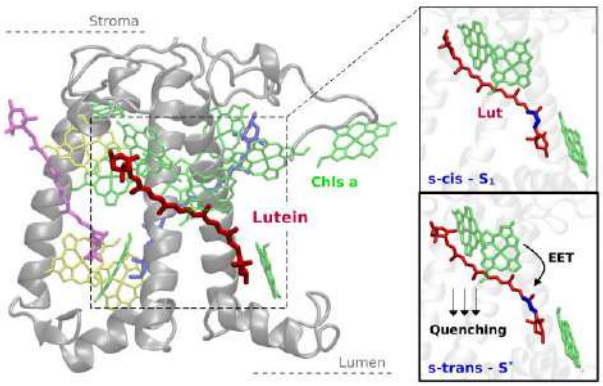

Figure 1: Side-view of CP29 and its L1 site for both Lut s-trans and s-cis conformers.

Multiscale Modeling of the Photoinduced Enantioselective Radical Cyclization of α-Chloroamides in Flavin-Dependent Ene-Reductases

G. Dell'Orletta,[a] M. Capone,[a] G. D. Scholes,[b] T. K. Hyster,[b] M. Aschi,[a] I. Daidone[a]

Photobiocatalysis has recently emerged as a valuable strategy for conducting chemical reactions that are challenging with conventional organic chemistry tools. This approach involves the use of photenzymes, i.e. enzymes that absorb light to promote substrate transformation. The photexcitation of these catalysts enables access to electronic excited states with different properties compared to the ground state, thus providing new reaction modes. Additionally, the chiral active sites of these enzymes can control the stereoselective outcomes of these processes.

While there are only few natural photoenzymes, irradiating non-natural photoenzymes, which are enzymes dependent on cofactors with latent photochemical properties, can broaden the range of available catalysts. Notably, Todd Hyster and coworkers discovered that the photoexcitation of flavin-dependent ene-reductases (EREDs) can facilitate non-natural transformations involving radical intermediates, such as the 5-exo-trig radical cyclization of alkene-tethered α-chloroacetamides to yield a chiral γ-lactam.[1] Specifically, they found that two enzymes from this family, the triple mutant T36A-K317M-Y343F of *Gluconobacter oxydans* ene-reductase (GluER-G6) and the Old Yellow Enzyme 1 (OYE1), produce opposite enantiomers.[1,2]

We present a computational study of this reaction catalyzed by GluER-G6, employing a multiscale approach based on Molecular Dynamics (MD), Quantum Mechanics (QM), and the Perturbed Matrix Method (PMM)[3]. Firstly, we focused on the initial step, namely the mesolytic cleavage of a C-Cl bond triggered by photoexcitation. We observed that productive mesolytic cleavage occurs only in certain conformations of the substrate, while the others undergo back electron-transfer. Then we addressed the subsequent radical cyclization step using the same tecniques. On the base of our results, we proposed an enatioinduction scenario in which the relative stability of prochiral transition states is not determined by direct interaction with the protein but is rather dependent on a degree of freedom within the substrate, which is controlled by the enzyme through conformational selection.[4]

Computational insight on monoterpenoids antifungal activity

S. Pezzola,a P. Galloni,a V. Conte,a F. Sabuzia, G. Bocchinfuso, a M. Venanzi,a
[a]*Dipartimento di Scienze e Tecnologie Chimiche, Università di Roma Tor Vergata, via della Ricerca Scientifica, Roma*
silvia.pezzola@uniroma2.it

Natural terpenoids and their derivatives are raising new interest as antifungal agents, inspired by traditional medicine and plant protection strategies. Among all, thymol and carvacrol are widely investigated for their activity as antibacterial/antimycotic agents1. Recently, tailored modifications, such as acetylation or bromination, led to thymyl acetate and 4-bromothymol, respectively, which have been synthesized and purified through eco-friendly approaches2. Interestingly, 4-bromothymol antimycotic activity resulted up to 6 times higher than that of thymol on 8 yeast strains3, even in the case of acclaimed resistant species. To elucidate the 4-bromothymol mechanism of action, a thorough computational study has been performed, exploiting Quantum Mechanics (QM) and Molecular Dynamics (DM). QM afforded the characterization of the reactivity, the moieties acting as hydrogen bonds donor/acceptor in water, and the partition coefficients. MD, through the Minimum Bias Approach (MBA), showed out the "real" pose of active compounds into the simulated double layer of eukaryotic-like membrane, meanly 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine (POPC). MBA confirmed the density alteration of the leaflet into which monoterpenoids are inserted, the shrinkage of the membrane thickness, and the alteration of the order parameter of the double layer. Overall, the computational findings were in terrific agreement with the experimental results3, and they clarified, for the first time, the mechanisms of action of thymol, carvacrol, and 4-bromothymol, likely explaining their different antimicrobial efficiency (Figure 1).

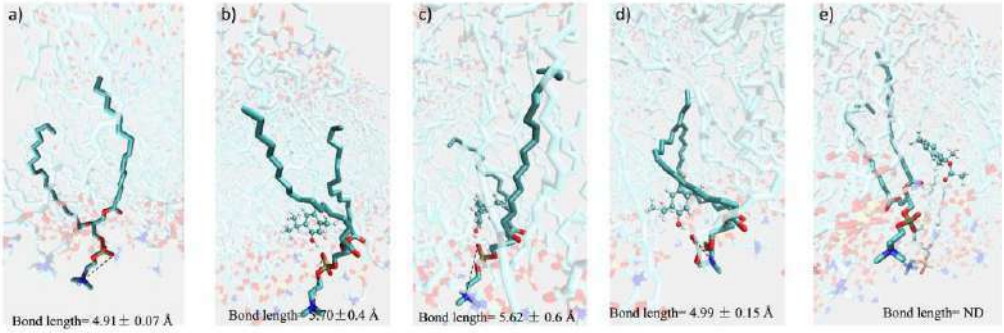

Figure 1: Analysis of the bond length in lipid between the nitro-group and the phosphate oxygen, in the presence or not of the investigated compounds, dotted line. a) POPC alone, and POPC with b) thymol, c) carvacrol, d) 4-bromothymol, e) thymyl acetate.

Breast cancer is the second leading cause of mortality in adult women, accounting for more than 500,000 deaths every year[1]. Although significant improvements in the prognosis of this tumor have been achieved, innovative strategies able to further increase the patients' survival rate are still required. Theoretical-computational approach can be of crucial importance in several stages of discovery and design of new drugs. Extra-cellular vesicles (EVs) isolated in the sera of breast cancer patients show, on their membrane, high levels of the Gremlin-1 protein[2-4] that has been associated with poor prognosis and promotion of lung metastasis. In this scenario, our research group has recently identified, through the SELEX procedure[5,6], an RNA aptamer (Ex-50T) able to selectively recognize breast cancer EVs by interacting with Gremlin-1. In this work, a theoretical-computational investigation of the structural properties of this aptamer and of its binding mechanism to Gremlin-1, is presented. In particular, a complete modeling procedure is built to obtain the tridimensional structure of Ex-50T from its primary sequence. Then, the interaction with Gremlin-1 has been modeled through molecular docking and microseconds-long molecular dynamics (MD) carried out to characterize at atomic resolution the RNA aptamer interaction with the biologically relevant forms of Gremlin-1. Our results show that an integrated computational approach spanning from bioinformatic tools to predict the 2D and 3D aptamer structure to molecular docking and MD simulations to investigate its interaction with the protein, is crucial to provide the insight necessary to understand how to chemically modify the aptamer to improve its binding with Gremlin-1. In this way, another step toward the design of more efficient and pharmacokinetically stable aptamers that might be further developed both as therapeutic and as diagnostic tools, is taken.[7]

A Machine Learning tool for Pathway Analysis in Molecular Dynamics Simulations

S. Motta,[a] L. Callea,[a] L. Bonati,[a] A. Pandini[b]

[a] *Department of Earth and Environmental Sciences, University of Milano-Bicocca, Milan 20126, Italy*

stefano.motta@unimib.it

Understanding molecular mechanisms, such as ligand binding, protein unfolding, and conformational changes, is crucial for deciphering complex biological processes and accelerating drug discovery. Molecular dynamics (MD) simulations, boosted by enhanced sampling methods, provide a robust computational framework to investigate dynamical events at atomistic level. However, there is a challenge in processing the large-scale data produced by MD simulations and extracting important conformations from noisy trajectories.

To address this, we developed PathDetect-SOM[1], a flexible tool for in-depth analysis of pathways sampled during MD simulations. The tool employs Self-Organizing Maps (SOMs), a well-established algorithm in unsupervised machine learning. PathDetect-SOM facilitates the visualization and interpretation of MD simulation pathways, helping in the identification of pivotal states and examination of energy landscapes. It simplifies complex molecular processes into intuitive 2D representations through geometric clustering and trajectory mapping.

Recently, we designed and implemented, an R package that extends PathDetect-SOM, providing functions to develop workflows for MD simulation analysis within the R statistical environment. This upcoming package will support reading and writing trajectories in the GROMACS format and includes a suite of analysis functions for pathway reconstruction, property mapping and network analysis.

Applications of PathDetect-SOM to different molecular mechanisms are presented, demonstrating its suitability to reconstruct pathways and to detect critical events in simulations of ligand binding[2,3], protein unfolding[4,5], and protein-protein interaction[6]. These tools facilitate the analysis of complex pathways, thus accelerating the understanding of key biological processes.

adriano.pierini@uniroma1.it

The demand for high-performance and sustainable energy storage solutions has led increasing research efforts towards the development of novel materials for next-generation batteries. Glyoxal acetals have been recently proposed as a promising innovation to electrolyte formulations for Li-ion batteries[1], holding as a potential solution to many problems related to the large volume changes occurring in high-capacity anode materials like Si and Si/graphite[2]. However, optimizing the formulation of the glyoxal acetals-containing electrolyte requires a fine understanding of their interaction with co-solvents and salts at a molecular scale.

Molecular dynamics (MD) is widely exploited to study local molecular properties of condensed phases which are hardly accessible to experiments. Polarizable MD force fields have shown to generally outperform fixed point-charge models in yielding a good description of structural and dynamical properties of either gas-phase, cluster-size and liquid bulk systems with a same set of parameters[3]. This holds in particular when a system is characterized by a large amount of mobile charge carriers, like in electrolytes and ionic liquids[4].

In this work we present an extension of the polarizable AMOEBA force field for the simulation of glyoxal acetals-based electrolytes for new Li-ion batteries. The force field was first validated with reference ab-initio calculations of ion-solvent and ion-ion pairs potential energy surfaces and molecular clusters formation energy in gas-phase. Calculated bulk properties were also compared to the available experimental data. The MD simulations investigated the effect of different solvent/co-solvent formulations in LiTFSI and LiFSI electrolytes, highlighting in particular the impact on ions solvation, ion-pair dynamics and ionic transport mechanisms. The results allow to elucidate the relation between the electrolyte structure and its electrochemical performances and to design practical strategies for their improvement.

Computational Study of Glassy Solid Electrolytes for All-Solid-State Batteries

M. Bertani,[a] A. Pedone[a]

[a]*University of Modena and Reggio Emilia, Via G. Campi 103, 41125, Modena*
marco.bertani@unimore.it

The global growing demand for energy storage is pushing the research for new battery materials with improved properties. These materials must allow high performances of the batteries and guarantee a safe and ecological synthesis, usage, and disposal. Moreover, the need for raw materials whose supply comes from areas where human rights are not guaranteed must be eliminated.

All-Solid-State-Batteries (ASSB) are emerging as promising alternatives in terms of safety and energy density but new highly conductive, yet electrochemically stable Solid-State Electrolytes (SSE) must be developed. In particular, Glassy Solid Electrolytes (GSE) are gaining growing interest in the research and industrial community because of their low-cost manufacturing and robust chemical stability which can avoid the known safety problems, like fires and explosions, caused by the organic liquid electrolytes in Li-ion batteries[1].

The tremendous increase in the battery market has made lithium a critical material. Its extraction from mines comes with ethical issues and the supply chain could face a shortage in the near future. Sodium-based batteries are possible alternatives, but a huge effort is needed in the study of suitable SSE. Nowadays, the most studied GSEs for Na-ASSB are based on sulfide because of their high ionic conductivity, wide compositional range, and lack of grain boundaries[2]. Unfortunately, these materials can react with atmospheric compounds and are electrochemically unstable with electrode materials hampering their synthesis and usage. In the last decade, mixed oxy-sulfide (MOS) glasses have been demonstrated to maintain the optimal ionic conductivity of pure sulfide GSE while having the chemical and electrochemical stability of oxide-based ones[2].

This study aims to understand the atomistic structure of MOS-GSE as the link between the composition and properties of these materials. To do so, DFT ab-initio molecular dynamics (MD) simulations were performed on several Na-based MOS-GSE with increasing substitution of sulfur with oxygen. The high computational cost of this technique limits the simulation to a few hundred atoms and very short timescales that do not allow the investigation of ionic conduction mechanisms at low temperatures. To overcome these limitations the DFT data were used to train a Machine Learning (ML) potential which was applied to the MD simulations of larger simulation boxes to investigate the Na conduction.

This method has the potential to become a standard method for the accurate investigation of GSEs by means of MD simulations as it allows minimizing the ab-initio calculations and simulating large models for long timescales which makes conduction events accessible at low temperatures.

eleonora.ascrizzi@unito.it

Nowadays there is an urge to transit from fossil fuels to clean energy sources: a crucial role in this process can be played by the oxygen evolution reaction (OER), hydrogen evolution reaction (HER) and oxygen reduction reaction (ORR)[1]. The main problem in the worldwide diffusion of the catalysts for these reactions is their high costs. The most efficient catalysts are in fact made of noble metals[2,3]. An alternative based on earth abundant metals would be needed and for this we propose and study FeOx /Au systems. The structure of supported FeOx layers is nonetheless still to be determined since a wide range of structures can be formed depending on the operating conditions (mainly the applied potential and the pH of the solution)[4,5].

In such framework, computational chemistry can play a relevant role in identifying conceivable structures based on Fe oxides and hydroxides with different oxidation numbers. Relevant structures have been fully analysed by considering their electron/magnetic properties and their relative stability at the operating conditions. The major interest is to establish the relationships between structure and properties in order to identify the active species taking part to the catalytic reactions.

The VASP code[6] has been used for calculations in combination with the DFT+U approach and PBEsol as functional since this computational set up guarantees a proper description of the transition metals centers and related (electro)chemical processes. Experimentally acquired STM images and water adsorption energies are used to compare theoretical data with experimental one, validating our model and highlighting different structure-reactivity-properties relationships in the three high-symmetry domains of the FeO/Au moiré.

N-Heterocyclic Molecules for Tunable Functionalization of Oxide Surfaces

Sergio Tosoni[a]

[a]*Università di Milano-Bicocca, Dipartimento di Scienza dei Materiali, Via Roberto Cozzi 55, 20125 Milano*

N-Heterocyclic carbenes (NHCs) have superior properties as building blocks of self-assembled monolayers, or as carriers of functional groups to functionalise surfaces. Understanding the influence of the substrate in the molecular binding is a fundamental step before employing these ligands in technological applications. NHCs have been widely studied on metallic substrates such as Au(111)[1] or Cu(111).[2] Recently, it has been shown how, on oxidized copper, these molecules tend to bind preferentially to oxygen atoms, rather than copper atoms.[3] This is an important finding, since it is the first time that a direct bond formation between a carbene centre and an oxygen atom is observed in the context of adsorption on surfaces. Interestingly, the subsequent desorption of cyclic urea promotes the reduction of copper under relatively mild conditions.[4]

Based on these findings, it is hereby shown how NHCs can bind to oxide surfaces, recurring to Density Functional Theory calculations. The following oxidic supports are studied: MgO, cuprite, titanium dioxide in the form of rutile, and silica. Both normal carbenes and mesoionic carbenes (displaying a more pronounced electron donor character) are considered. Two different binding modes are found: i) the carbene centre binds to a metallic cation and ii) the carbene binds to an oxygen anion. Depending on the chemical nature of the oxide and the electron-donating capability of the NHC molecule, either C-metal bonds or C-O bonds are preferentially formed. In case of C-metal bond formation, the charge transfer is related to the balance between the sigma donation and pi back-donation mechanisms, where the chemical structure of NHC plays a role. When C-O bonds are formed, the NHC molecule is oxidized, with consequent reduction of the surface: this mechanism is very unfavourable on large-gap oxides such as MgO, while it is possible on reducible oxides such as TiO_2. These findings will help in designing the employ of NHC ligands to functionalize oxide surfaces.

francesca.fasulo@unina.it

Single-chromophore single-molecule photocatalysts have emerged as promising agents for the conversion and storage of solar energy into chemical bonds.[1-4] Recently, Turro and co-workers reported a single-molecule dirhodium photocatalyst (DiRh(II,II)) bound to nickel oxide (NiO) photocathode able to generate hydrogen from acidic solutions with red light.[5] Its unique design makes this complex also a highly promising sensitizer for Dye-sensitized photoelectrochemical cells (DSPECs) when coupled with p-type semiconductors such as NiO. The efficient development of DSPECs calls for a thorough understanding of all properties and processes occurring at the molecule/solid interface, only partially achievable by experimental techniques. In this context, this contribution presents new insights into structural and electronic features of the DiRh(II,II)/NiO interfaces from state-of-the art Density Functional Theory (DFT)-based calculations. Besides, we also compute molecule/surface electron injection rates and identify preferential charge transfer channels via the projection-operator diabatization (POD) approach.[6] Our results show that DiRh(II,II) complex interacts strongly with the NiO surface through the formation of COO-Ni bonds, leading to stable mono- or bi- anchored configurations, with the mono-anchored DiRh(II,II) complex presenting the most promising features from the electronic and charge dynamics points of view. Regarding H_2 production, we find that surface anchoring to NiO facilitates efficient charge separation but barely impacts hydrogen binding to the DiRh(II,II) complex. Overall, our findings provide valuable insights into the nature of DiRh(II,II)/NiO interactions, guiding the design of advanced catalysts (e.g. containing asymmetric ligands) with enhanced photo-electrochemical performance for applications in renewable energy conversion and storage.

A DFT study on the Red-Light Photocatalytic Activation Of Pt(IV) Anticancer Drugs Using Methylene Blue

Stefano Scoditti,[a] Luca Salassa[b] Emilia Sicilia[a]

[a] *Department of Chemistry and Chemical Technologies, University of Calabria, Arcavacata di Rende (CS), 87036, Italy*
[b] *Donostia International Physics Center, Paseo Manuel de Lardizabal 4, Donostia, 20018, Spain*
stefano.scoditti@unical.it

In recent years, Salassa and colleagues have discovered new catalytic reactions in which flavins, such as riboflavin (Rf) and certain flavoproteins, mediate, under light irradiation, the transformation of Pt^{IV} prodrugs into the corresponding active Pt^{II} drugs, such as clinically-approved cisplatin, oxaliplatin, and carboplatin, with unanticipated efficiency.[1] In these photocatalytic reactions, the catalyst needs an electron source (e.g., NADH) to be reduced into the active hydroquinone form, which can rapidly convert Pt^{IV} into Pt^{II} complexes. In these bioorthogonal reactions, metal complexes act unconventionally as substrates, rather than catalysts, changing a well-established paradigm in catalysis. However, the main limitation of flavin-catalyzed reduction of Pt^{IV} prodrugs is the wavelength necessary for being photoactivated. Indeed, the absorption profile of flavins does not fall within the therapeutic window (600-900 nm), which is not conducive to optimal tissue penetration. For this reason, we have researched new photocatalysts possessing photo-redox properties similar to flavins but capable of absorbing light within the therapeutic window range. Our research has led us to study methylene blue (MB), a phenothiazine with a rich medical history and an intense absorption band between 600-700 nm. The mechanism of reduction by MB-catalysis, showed in Figure 1, has been studied using Density Functional Theory (DFT). Firstly, we explored the NADH to MB hydride-transfer mechanism both in the dark and under light irradiation for the formation of the LeucoMethylene Blue (LMB). Then, we have investigated the reduction of Pt^{IV} prodrugs by LMB, focusing on elucidating the possible activation pathways.

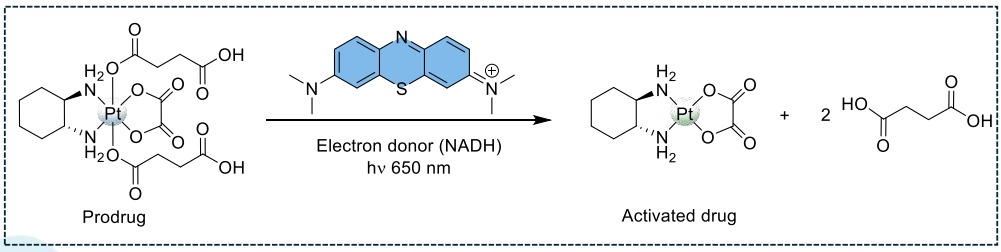

Figure 1: Catalytic reduction of PtIV promoted by MB in the presence of NADH

Modelling Single-Atom Catalysis

G. Di Liberto,[a] G. Pacchioni,[a]

[a]*Dipartimento di Scienza dei Materiali, Università degli Studi di Milano Bicocca, Milano, Italy*
giovanni.diliberto@unimib.it

Single Atom Catalysts (SACs) are emerging as new frontier in the field. Computational chemistry offers a valid framework to access the atomistic details of electrocatalytic processes and to rationalize of even predict novel systems. Recently, a lot of attention has been dedicated to the reactions of evolution and conversion of molecular hydrogen and oxygen from or to liquid water.[1] The activity of SACs is usually rationalized or predicted using the Computational Hydrogen Electrode (CHE) approach, where the free energy of key intermediates adsorbed is used to explain the catalytic activity.[2]

In this presentation we discuss the key ingredients to model electrocatalytic processes on SACs. SACs differ substantially from metal surfaces and can be considered analogues of coordination compounds. In coordination chemistry, at variance with metal surfaces, stable complexes of hydrogen and oxygen can form.[3] We show that the same can occur on SACs and their formation may change the kinetics of the process.[4,5] We propose an approach to predict the stability of SACs under working conditions of pH and applied voltage.[6] Needless to say, the adopted DFT functional affects the accuracy of the predictions, and we show evidence suggesting that self-interaction corrected schemes should be adopted.[7] DFT numerical simulations demonstrate that these ingredients may lead to different conclusions about the activity of SACs in the water splitting reaction. This work provides an example of the important analogies between the chemistry of SACs and that of coordination compounds, and underlines the key ingredients to be accounted when attempting to provide predictions with computational frameworks.

Using photons to control the properties of molecules: an *ab-initio* study

Enrico Ronca[a*]

[a] *Author affiliation: Università degli Studi di Perugia, Dipartimento di Chimica, Biologia e Biotecnologie, Via Elce di Sotto 8, 06123, Perugia, Italy*
enrico.ronca@unipg.it

Manipulation of matter properties using strong coupling to photons is becoming a hot research topic in physics and chemistry [1,2]. Recent experimental studies demonstrated that strong-light matter coupling in optical cavities can be used to inhibit, catalyze and increment the selectivity of chemical reactions[1].

In the past few years, a lot of progress has been made in the field, but a complete understanding of the possibilities offered by cavity QED in chemistry is still far from being achieved.

In this talk, I will present some recent studies we performed using new *ab-initio* theoretical techniques developed in the group.[3-4] The predictive potential offered by these techniques will be exploited. The effects induced by quantum fields on several chemical phenomena going from photochemistry to chemical reactivity will be analyzed and discussed.[3-5] In the last part of the talk I will also mention how the chirality [6,7] and magnetic properties [8] of molecules can be manipulated inside and optical cavity.

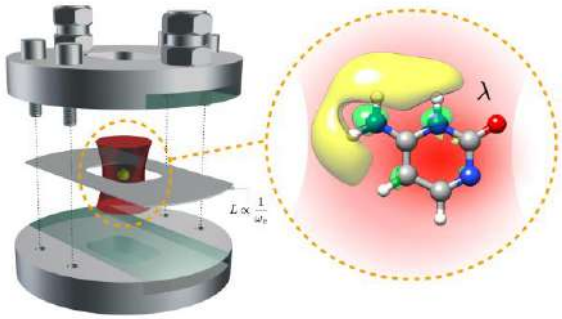

Figure 1. Chemical processes in optical cavities.

A machine learning approach for the prediction of atomic charges of metal- organic frameworks

Herald Paja[1], Lorenzo Donà[1], Mattia Raimondo[1] and Bartolomeo Civalleri[1].

Department of Chemistry, University of Turin, via Pietro Giuria 7, 10125, Torino TO, Italy
herald.paja@unito.it

Metal-organic frameworks (MOFs) are very versatile materials due to their modular structure, as the framework is formed by the combination of two secondary building units (SBUs): an inorganic unit (metal ion or cluster) and an organic ligand. As a result, a wide range of combinations are possible, thus allowing MOFs to cover a huge chemical space. High-throughput computational screening is then useful to explore all the chemical and physical properties of such materials but low-cost computational methods such as bespoke tailored force-fields are needed to speed up the calculations [1]. To this end, accurate atomic charges are crucial to predict long-range electrostatic interactions correctly. These can either be derived from quantum-mechanical calculations or generated on the fly through simplified geometric schemes or, more recently, through Machine Learning (ML) prediction models. The latter requires suitable databases of structures and properties to be used to train the ML model. Several databases of MOFs and their properties are now available such as CoReMOF [2], QMOF [3] and ARC-MOF [4].

In this work, we present the results of predicting atomic charges derived from the QMOF database. We trained different ML models by using XGBoost and RandomForest with atomic and environmental descriptors. On the one hand, the QMOF database, which contains more than 20000 cleaned-up experimental structures (< 300 atoms in the unit cell) for which DDEC charges are available, was analysed to understand how the size and composition (i.e. metal ion types) of the training dataset affects the prediction of the atomic charges. On the other hand, we built datasets with randomly extracted structures ranging from 500 to 1500 MOFs. We compared them with more balanced one with an equated composition in terms of different metal ions.

This strategy allows us to achieve good results using a reduced number of MOFs compared to the largest dataset (i.e. 1500 vs 20375 structures of the entire QMOF database) with the RandomForest ML models giving better performance to XGBoost. We were also able to predict with higher accuracy the charges of the metallic species in the node which are less abundant compared to the other species present in the structure (e.g. H, C, O and N). Based on this result, Hirshfeld-I charges were also calculated using the low-cost hybrid HF/DFT sol-3c composite methods [5] on the reduced dataset and an ML model was trained. The CRYSTAL program [6] was used to exploit the space group symmetry and the efficient parallelization of the code.

Building reactive potentials through machine learning and enhanced sampling: from methods to catalytic applications

L. Bonati and M. Parrinello

Atomistic Simulations, Istituto Italiano di Tecnologia, 16163 Genova, Italy
luigi.bonati@iit.it

Machine learning potentials for atomistic simulations have enormous potential for modeling chemical reactions and materials, offering *ab initio*-like accuracy but being orders of magnitude faster than density functional theory (DFT) calculations. Unlike interatomic potentials based on fixed functional forms, they learn to reproduce energies and forces directly from large datasets of quantum-mechanical calculations.

However, many reactive processes, such as chemical reactions, occur on longer time scales than we can simulate. This makes it challenging to construct a set of reference configurations, especially if the reactions occur in a complex and dynamic environment. To address this problem, we take advantage of enhanced sampling methods such as Metadynamics. Integrating these methodologies with active learning strategies, we can construct robust and reliable potentials for studying rare events. In particular, active selection of configurations in the transition region proves critical to describe reaction rates with machine learning-based potentials accurately[1]. In addition, by leveraging efficient architectures such as equivariant graph neural networks and Bayesian approaches to measure the uncertainty, we can construct uniformly accurate potentials along the entire reaction path in a data-efficient way.

The synergistic combination of these families of approaches allows us to simulate for the first time in a realistic way the dynamics of heterogeneous catalytic processes under *operando* conditions. A revealing example is the study of the dynamics of the Fe(111) surface at high temperatures and its influence on the decomposition of N_2, which is believed to be the limiting step in the famed Haber-Bosch process[2]. At high temperatures, surface iron atoms become highly mobile, jumping between lattice sites. Consequently, active sites are continuously formed and destroyed, altering the free energy profile of adsorption and dissociation. If we also include the effect of lateral interactions with adsorbed nitrogen, we again find two different behaviours[3]. At room temperature, nitrogen atoms poison the catalyst by blocking the active sites. In contrast, at high temperatures, poisoning is greatly reduced by the surface reconstruction induced by the adsorbates with the formation of local motives that cluster the nitrogen atoms and stabilize the remaining active sites. These simulations highlight the danger of extrapolating low-temperature results to *operando* conditions and indicate that the chemical reactivity can only be inferred from calculations that take dynamics fully into account.

A General Perturbative Route to Anharmonic Vibro-Rotational Spectroscopy in Internal Curvilinear Coordinates

M. Mendolicchio,[a]

[a]*Scuola Normale Superiore, Piazza dei Cavalieri 7 – 56126, Pisa*
marco.mendolicchio@sns.it

The quest for a reliable yet practical modelling of large molecular systems has always played a central role in the field of theoretical and computational chemistry.[1] In this framework, despite the undisputed effectiveness of static structure-property correlations and the fundamental rigid-rotor/harmonic-oscillator model, results that are directly comparable to experiment can only be achieved through a more advanced description either at the electronic or nuclear level. Among the various methods for the inclusion of anharmonic effects, the vibrational second-order perturbation theory (VPT2)[2,3] allows the effective study of medium-to-large size molecular systems.

While VPT2 can be successfully applied in many cases, it is also characterized by some intrinsic drawbacks that prevent its use in some situations, in particular when large amplitude motions (LAMs) are present. Unfortunately, variational approaches such as the vibrational configuration interaction (VCI)[4] become rapidly prohibitive as the size of the molecular systems increases. On the other hand, reduced-dimensionality methods tailored for describing one or a limited number of LAMs require an effective separation from the rest of vibrations, usually referred to as small amplitude motions (SAMs). As shown in previous studies,[5-8] the definition of a suitable set of internal coordinates able to decouple these two classes of vibration allows to treat each normal mode through the most appropriate method. Based on this premise, a general and effective VPT2 framework in terms of curvilinear coordinates was developed.

In this contribution, the versatility of internal coordinates and their application in the fields of rotational and vibrational spectroscopy will be described, starting from the calculation of transition energies, and proceeding up to thermochemistry and vibro-rotational interaction parameters. The performance of the new engine will be illustrated by its application to systems of biological and technological interest.

[*] *alessio.petrone@unina.it*

Light induces non equilibrium time evolving molecular phenomena. The computational modelling of photoinduced processes in large systems, embedded in complex environments (i.e. solutions, proteins, materials), demands for a quantum and statistical mechanic treatment to achieve the required accuracy in the description of both the excited state energy potentials and the choice of the initial conditions for dynamical simulations.[1] On the other hand, the theoretical investigation on the atomistic scale of times and sizes of the ultra-fast photo-induced reactivity and non-equilibrium relaxation dynamics right upon excitation requests tailored computational protocols. Additional challenge is the theoretical study of the interplay between molecules at finite temperature and their related non-equilibrium time-resolved spectroscopies, such as time-resolved infrared (IR), femtosecond stimulated Raman, and transient absorption.[2]

In this work we will show several methodologies exploiting hierarchic computation schemes, where a large part of the degrees of freedom are treated explicitly to achieve the right accuracy. Additionally, part of the explicit system is described at *ab initio* level, using density functional theory, employing hybrid functionals and its time-dependent formulation (TD-DFT),[3] given the good compromise between accuracy and computational cost. Finally, we will present several theoretical-computational protocols for the accurate characterization of the photo-induce charge recombination and excitons dynamics, along with their related non-equilibrium vibrational/dynamical properties. For this aim, the time dependent electronic structure of excited electronic states and their interconnection with time-resolved spectroscopic signals in materials (dyes for light harvesting) and biological systems (photo-probes) will be analyzed.[4]

Novel computational strategies for the study of chemical selectivity: Combining high accuracy and chemical insight

G. Bistoni[a]

[a] *Dipartimento di Chimica, Biologia e Biotecnologie, Università degli Studi di Perugia, Via Elce di Sotto, 8, 06123 Perugia, Italy*
giovanni.bistoni@unipg.it

In this contribution, local correlation methods,[1] advanced conformational sampling strategies,[2-3] innovative electronic structure analysis tools[4-5] and machine learning models are combined to establish accurate computational protocols for the study of chemical selectivity in complex transformations. These protocols are employed to elucidate the mechanisms that govern the selectivity of challenging processes, encompassing for example asymmetric catalytic reactions for the synthesis of important pharmaceuticals and natural products.[6] The knowledge gained is then used to identify simple rule of thumbs for the design novel catalysts with tailored selectivity, and to provide insights into their potential validity across diverse chemical scenarios.[7]

Unravelling the complex dynamical behavior of heterogeneous catalysts during reactants exposure

U. Raucci,[a] M. Yang,[a] A. Tosello,[a] F. Mambretti,[a] M. Parrinello[a]

[a] *Italian Institute of Technology, via E. Melen 16152, Genoa*
umberto.raucci@iit.it

The complex dynamical behavior of industrial catalysts during their high-temperature exposure to reactants represents a critical yet frequently disregarded factor in the study of heterogeneous catalysis, which is traditionally dominated by the static active site paradigm.

Here, thanks to the progress in the construction of DFT quality machine learning (ML)-based interatomic potential and enhanced sampling techniques, we unravel the complex dynamic behavior of catalytic processes under *operando conditions* by investigating ammonia decomposition on lithium imide[1,2] (Li_2NH) and ammonia synthesis on barium hydride[3] (BaH_2). Our ML-driven molecular dynamics simulations reveal that when the catalyst is exposed to the reactants, the dynamical state of the top layers changes, inducing the formation of a few diffusive, almost liquid-like interfacial layers[1,3]. Such a modified and highly fluctuating interfacial state is responsible for catalysis. Indeed, the large fluctuations observed in the top layers of the surfaces allow a series of reactions to occur enabling ammonia synthesis or decomposition on these transition-metal-free catalysts. Once started, the process is self-sustained, with different reaction steps further contributing to the surface dynamical behavior, and therefore, to its catalytic efficiency[1].

In conclusion, our microscopic analyses underline the dynamic nature of heterogeneous catalysts, which do not merely serve as static platforms for reactions but, rather represent dynamic entities that evolve under reaction conditions. We suggest the rational design of more efficient catalysts by appropriately engineering their interfacial behavior.

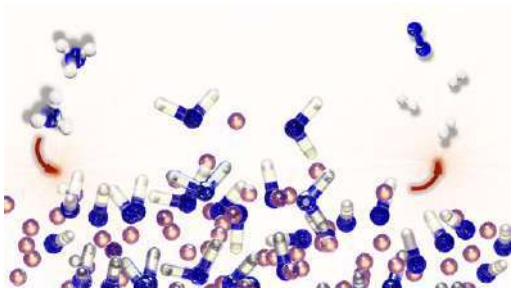

Figure 1: A representative snapshot of the Li_2NH (111) surface during ammonia exposure.

A graph theory-based order parameter for the structural and dynamic characterization of supercooled water

N. Di Fonte,[a] C. Faccio,[b] L. Zanetti-Polzi,[c] I. Daidone[a]

[a]*Department of Physical and Chemical Sciences, University of L'Aquila, via Vetoio (Coppito II), L'Aquila*

nico.difonte@graduate.univaq.it

Our work is focused on the development of a graph theory-based order parameter for the characterization of liquids. In particular, we applied it to the delicate framework of the Liquid-Liquid Phase Transition (LLPT) in supercooled liquid water, simulated via molecular dynamics (MD). In the LLPT scenario, liquid water exists in two states, the high-density liquid (HDL) and the low-density liquid (LDL).

Despite the structural, dynamic and thermodynamic differences between the HDL and LDL state, distinguishing between the HDL and LDL state, distinguishing them even with computational methods is challenging and, therefore, several order parameters have been introduced to differentiate the two phases.

We recently proposed the Node Total Communicability (NTC) as an order parameter, testing its ability to distinguish between HDL/HDL-like and LDL/LDL-like molecules at high pressure where the coexistence line is crossed [1], and at ambient pressure, where the Widom line is crossed[2].

This descriptor, borrowed from graph theory, yields information about the local connectivity of each water molecule within a simulation box and highlights the influence of the medium-to-long range effects, allowing us to characterize the structural and dynamical behaviour of the system at the microscopic level[1,2].

We found that HDL-like forms are not homogeneous but rather characterized by the presence of high connectivity patches composed of molecules with an increased local density and mobility. Small highly connected patches are also found in the LDL phase (Fig. 1), and we hypothesize that they could function as initial sites from which the HDL phase starts forming and growing during a phase transition.

Expanding on this hypothesis, we are currently using the NTC to study and characterize the transition of an LDL system to an HDL-like composition with a spinodal-like decomposition mechanism.

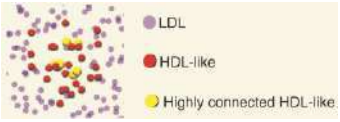

Figure 1: Visualization of highly connected patches and HDL-like patches in an LDL environment.

Assessing the catalytic mechanism of the horse-liver alcohol dehydrogenase with a biomimetic cofactor through a multiscale computational study

M.Farina[a], E. Bodo[a], I. Daidone[b], M. Aschi[b], M. Capone[b], A. Marrone[c]

In recent years, there has been a significant interest in redox enzymes due to their ability to exert crucial chemo and stereoselective control over the reactions they catalyze. Moreover, enzymes operate under mild conditions, making them particularly attractive for the design of green chemical processes.[1] Here, we focus on horse liver alcohol dehydrogenase (HLADH), an enzyme exhibiting a wide substrate tolerance. Specifically, in its catalytic action of the reduction reaction of ketones, the enzyme mediates the hydride transfer (HT) from NADH to the re-face of the carbonyl group, resulting in the formation of S alcohols as products.[1,2]
The utilization of biomimetic cofactors presents an appealing strategy, given their notable advantages in versatility, efficiency, and tunability. These attributes render them invaluable instruments for propelling advancements across diverse domains of chemistry and technology[1]. However, the catalytic reaction mechanisms are not yet known. In a previous study,[1] a mechanism was proposed for the reduction of 2-pentanone catalyzed by HLADH, employing 1,4-dihydro-N-benzylnicotinamide as biomimetic cofactor. Differently from the mechanism with NADH (which implies an initial, direct HT), this mechanism involves as first step the detachment of His67 from the catalytic Zn(II) metal ion center followed by formation of a complex that involves η^2-coordination of the 5,6 double bond of the biomimetic to the zinc, followed by HT. We study the catalytic mechanism of this system here using a multiscale approach, specifically the Perturbed Matrix Method-Molecular Dynamics (PMM-MD) approach.[3] By calculating the free energy changes along the possible mechanisms, we can ascertain whether the alternative mechanism (involving detachment of His67 and formation of the η^2 complex) or the direct-HT mechanism is the most thermodynamically and kinetically favorable.

Design and set up of Machine Learning force fields of characterization and development of next generation solid state battery electrolytes

A. Azzali,[a] E. Bodo [a]

[a]*Sapienza, università di Roma, Piazzale Aldo Moro 5, Rome*
alessandro.azzali@uniroma1.it

All-solid state (ASSB) batteries are one of the most promising alternatives of Li-ion liquid technology. ASSB have several advantages[1], such as greater stability, better safety, and higher energy density[2], but also an intrinsic, and still unsolved, problem caused by their solid nature, the low ion mobility. Amorphous Lithium thiophosphates, LPS (xLi_2S-$(1-x)P_2S_5$) and their oxidised form LPSO (with Li_2O and/or P_2O_5) are among the most promising[3] electrolytes. Optimizing their performances by tuning their composition in order to achieve high ion conductivities (at least 10^{-3} S/cm to be competitive with liquid electrolytes) is an extremely complicated task because we do not yet know the structure-properties relation and the optimization process require laborious trial-and-error laboratory procedures. Using molecular modelling we can help making this process much quicker. Typically, computational approaches to electrochemistry involve ab-initio molecular dynamics (AIMD) methods, that, despite their accuracy, are very slow and computationally intensive, compared to classical molecular dynamics (MD), that instead relies on parametric force fields (FF). Classical MD calculations on LPS and LPSO are, at the moment, difficult to perform because they would need the development of a suitable FF whose analytical form is complicated due to the different states of chemical coordination that Li^+ assumes in the amorphous solid. Nevertheless, it is important for the electrochemical community to have access to a quick and efficient way to model electrolytes such as LPS and LPSO.

We have used deep learning molecular dynamics[4], to generate the FF. The deep neural network[5] has been trained using accurate ab-initio data and a deep learning force field (DLFF)[7-8] has been produced. The FF has the high accuracy[6] of the ab-inito level chosen for the training set and, being parametric, a high efficiency (classical MD level). Using this DLFF we have performed fast ed accurate simulations on model systems beyond the actual limits of AIMD. This approach will be crucial to determine electrochemical properties of LPS and optimize their composition to make this technology competitive in a large-scale industry environment.

A computational approach to the study of carbon dots for the determination of their structure and properties

Francesca D'Ambrosio, Enrico Bodo

Chemistry Department, University of Rome "La Sapienza", Piazzale Aldo Moro 5, 00185, Rome, Italy
francesca.dambrosio@uniroma1.it

Recently, carbon dots (CDs) have emerged prominently in the family of carbon-based nanoparticles for their unique properties, such as intense photoluminescence, low toxicity, excellent biocompatibility, and easy surface functionalization[1]. In addition, they involve simple synthetic approaches that include bottom-up and top-down methods[2] that, in turn, determine the functional groups of the surface, their size, and their photoluminescence response. For all these reasons, CDs have found applications in various fields, being mostly used for biological and biomedical applications[3]. To date, a detailed understanding of the atomic-level structure of these compounds and the relationship between the structure and their properties has been only partially established[4]. Therefore, it is necessary to develop an efficient computational method to fill these gaps. Preferably, this approach should maintain an explicit description of the electronic degrees of freedom, to assess optical properties from first principles and to investigate electron density and, ultimately, the surface charge of the nanoparticle.

We present results on the application of a computational multiscale approach based on *ab-initio* DFT (Density Functional Theory) and semi-empirical (TB-DFT, tight-binding density functional theory) methods to the class of carbon dots. The advantage lies in reducing time and cost of the research compared to experimental methods, while considering a wide range of structures and maintaining a good level of accuracy. Our study begins with the CDs with an amorphous carbogenic core, the variant which is less explored in literature. Several model structures based on amorphous carbon functionalized with nitrogen or oxygen atoms, with a number of atoms ranging from 20 to 200 have been studied and will be presented.

r²SCAN derived composite methods for solid state calculations

M. Raimondo,[a] L. Donà,[a] B. Civalleri[a]

[a]*University of Turin, Department of Chemistry, Via Pietro Giuria 7, Turin, Italy*
mattia.raimondo@unito.it

In the last decades, methods derived from Density Functional Theory (DFT) have been used as workhorse computational tools for many applications. Recently, there has been a growing interest in moving from the modelling of small and medium-sized systems to investigating increasingly large and complex systems. However, for systems characterized by weak bonds the current semi-local or hybrid DFT methods do not show sufficient accuracy and predictive power due to their pitfall in describing dispersive interactions. To cope with this, it would be necessary to use either the 5th-rung exchange-correlation (XC) functionals or wavefunction-based methods, which are very accurate but extremely expensive for large-scale calculations. To overcome this limitation, Stefan Grimme proposed the so-called "3c" composite methods[1] which combine DFT with semiclassical corrections to include dispersive interactions and correct for the basis set incompleteness error. After their initial application to molecules and molecular crystals, the originally proposed methods have been revised and optimized for solid-state calculations. This has resulted in a set of methods referred to as "sol-3c"[2].In this work, we have extended the existing "sol-3c" composite methods to mGGA XC functionals using the r²SCAN one[3]. The corresponding r²SCAN-based composite methods in their pure and hybrid HF/DFT variants have been developed in combination with double-ζ (sol-def2-mSVP) and triple-ζ (pob-TZVP-rev2) quality basis sets[4] specifically adapted to solids. The r²SCAN "sol-3c/pob-3c" methods were validated and tested on benchmark sets containing both intermolecular adducts (s66x7[5]), molecular crystals (X23[6], DMC8[7]) and simple inorganic solids (SS20[8]). They were then applied to the study of the energetic and structural properties of layered materials, the mechanical, electronic and vibrational properties of α-quartz, TiO2 (and its polymorphs), all-silica zeolites and the adsorption of small molecules on inorganic surfaces and meta-organic frameworks. The new methods show broad applicability with accurate results and an adjustable and affordable computational cost.

The effect of locally concentrated RTILs on low temperature aluminium-sulfur batteries, a computational investigation

S. Russo,[a] E. Bodo[a]

[a]*Università di Roma "Sapienza", P.zale Aldo Moro, 5, 00185 Roma*
stefano.russo@uniroma1.it

In modern days, battery usage is expanding since mobile systems like smartphones, electric vehicles, etc. rely on stored energy[1]. Aluminium-sulfur (Al-S) has been considered a promising energy storage device due to the theoretical capacity and the high abundance of their components. However, these batteries are notoriously flawed by sluggish ionic transport and cathode convertion rates[2]. Recently[3], a mixture of room temperature ionic liquids (RTILs) and aromatic diluents has been used showing improved ionic transport, offering high coulombic efficiency.

We have employed molecular dynamic simulations to study locally concentrated RTILS electrolytes (LCILEs). The aggregation behaviour of LCILE have an important role in the ionic transport and stripping/plating mechanism on the electrodes. The advantage of using a parametrized simulation make the dimension scales of nano-aggregations easily achievable giving us a tool to better understand the experimental results of those novel batteries.

Modeling Single Atom Catalysts

Clara Saetta, Ilaria Barlocco, Giovanni Di Liberto, Gianfranco Pacchioni

Dipartimento di Scienza dei Materiali, Università degli Studi di Milano Bicocca, Milano, Italy
c.saetta@campus.unimib.it, ilaria.barlocco@unimib.it, giovanni.diliberto@unimib.it, gianfranco.pacchioni@unimib.it

Single Atom Catalysts (SACs) are considered to be the new frontier in the field, since they establish a bridge between the homogeneous and heterogeneous catalysis. Computational chemistry shows the atomistic details of electrocatalytic processes, and it is extremely helpful to rationalize of even predict systems'properties. A lot of attention has been dedicated to the reactions of evolution and conversion of molecular hydrogen and oxygen from or to liquid water.[1] The Computational Hydrogen Electrode (CHE) approach is the key to predict the activity of SACs, where the free energy of key intermediates adsorbed is used to explain the catalytic activity[2], or even predict the reaction mechanism.

In this presentation we discuss a computational screening of Single Atom Catalysts (SACs) bound to titanium nitride (TiN), an emerging supporting matrix. The catalysts were tested against the Hydrogen Evolution Reaction (HER), based on density functional theory (DFT). We explore the role of fundamental ingredients to consider for a reliable screening of SACs. Namely, the formation of H_2-complexes[3,4] besides the classical H* one has an important impact on the predicted HER activity. Also, the results indicate that one needs to adopt self-interaction corrected functionals[5], including the Hubbard parameter on d electrons. Once unconventional intermediates in a self-interaction corrected scheme, the number of potential good catalysts for HER is strongly reduced, since the formation of unconventional intermediates lead to thermodynamic barriers. This study highlights the importance of including the key ingredients for the prediction of new systems, as the formation of unconventional intermediates and the adoption of self-interaction corrected functionals[5]. Also, this study highlights some interesting candidate deserving more dedicate work.

aniello.langella@unina.it

Layered Transition Metal Oxides (Na_xTMO_2) hold promise as high-energy cathode materials for Na-ion batteries[1]. Their general structure consists of TMO_6-octahedra 2D slabs sandwiched between Na layers, wherein the arrangement and packing of oxide layers define distinct material morphologies such as P2- and O3- structures[2]. While mixed transition metal oxides in this class of cathodes have shown promising performances and enhanced anion redox activity[3,4], ongoing research aims at improving their long-term stability, which is often hampered by solid-state phase transitions occurring during Na^+ insertion and extraction cycles, with structural collapse and significant capacity loss. Understanding and controlling these structural transformations is therefore of outmost importance to boost the electrochemical performance of layered oxides.

Employing the solid state nudged elastic band (ss-NEB) method[5] combined with state-of-the-art density functional theory (DFT) calculations, we address the prototypical case of P2 ↔ P2'/OP4 transitions in Na_xMnO_2[6]. We provide an atomic-level perspective on the glide-driven processes in these compounds, confirming the key role of Cooperative Jahn-Teller effects (CTJE) and Na^+ ordering at low state of charge as driving forces for these phase transitions[7]. Moreover, we highlight the utility of the ss-NEB method in finely charactering these subtle processes. Leveraging the same methodology, we also elucidate how partial substitution of Mn with Ni extends the of P2 phase, delaying the direct transition from P2 to O2 at higher voltages.

In conclusions, our new structural and electronic insights will provide a solid scientific framework for designing new layered transition-metal oxides with enhanced stability for long term battery operations.

Activity of Single Atom Catalyst for Nitrogen Reduction: The More Reactive the Better Does Not Always Holds True

Matteo Spotti, Ilaria Barlocco, Giovanni Di Liberto, Gianfranco Pacchioni

Dipartimento di Scienza dei Materiali, Università degli Studi di Milano Bicocca, Milano, Italy

m.spotti1@campus.unimib.it

Single Atom Catalysts (SACs) are emerging as a new frontier in heterogeneous catalysis.[1,2] They are made of metal atoms atomically dispersed on a matrix. Computational chemistry allows to study catalytic processes with an atomic detail and to rationalise, and even predict, the properties of systems. A lot of attention has been dedicated to the electrochemical Nitrogen Reduction Reaction (NRR) to ammonia, because of the key role that it could have in energy transition.[3] The activity of SACs is usually rationalized by using the Computational Hydrogen Electrode (CHE), a thermodynamic approach proposed by Nørskov and co-workers, making possible to explain the catalytic activity evaluating Gibbs free energies of key adsorbed intermediates.[4,5] In this presentation we rationalise the activity of Single and Dual Atom Catalysts made of a set of transition metal atoms for NRR. We show the importance of using self-interaction corrected functionals. We also observed that DACs are more active than SACs, an aspect in line with the nature of the real catalyst (nitrogenase) for NRR in ambient condition.[6] Also, the highest thermodynamic barrier decreases from 3d to 5d metals. Interestingly, if one combines the two positive effects, this results into too strongly stable intermediates, showing that *"the more reactive the better"* does not always hold true in single atom catalysis. We, finally, show that the NRR mechanism cannot be limited to the classical. This work highlights *i)* the importance of using self-interaction corrected functionals, *ii)* DACs could be a valid option for NRR, and *iii)* the combined effect of DACs with 5d metals does not necessarily lead to an increment of the activity.

Hydrogen Complexes on Single-Atom Alloys: A combined DFT-Kinetic Monte Carlo Study

E. Colombi Manzi[a], Giovanni Di Liberto[a], Michail Stamatakis[b], Gianfranco Pacchioni[a]

[a] *Dipartimento di Scienza dei Materiali, Università degli Studi di Milano Bicocca, Milano, Italy*
[b] *Physical and theoretical chemistry laboratory, University of Oxford, Oxford, UK*

e.colombimanzi@campus.unimib.it

Single-atom alloys (SAAs) are emerging in the field of catalysis, offering a new paradigm for enhancing catalytic performance. These materials, composed of isolated metal atoms dispersed on a metal substrate, represent a class of single-site catalysts with exceptional properties[1], exhibiting enhanced catalytic activity by breaking the Brønsted–Evans–Polanyi relationship[2].

SAAs are widely studied for processes involving hydrogen, such as water splitting or hydrogenation reactions. Previous studies have shown that dihydrogen and dihydride complexes can form on SAAs, indicating the potential for non-conventional intermediates in catalytic reactions. These complexes play a crucial role in modelling studies aimed at screening new materials, identifying descriptors, and predicting novel catalysts[3].

The combination of DFT calculations with kinetic modelling makes it possible to capture trends in activity and selectivity. The Kinetic Monte Carlo (KMC) approach is attracting growing interest for the study of catalytic reactions, due to its versatile framework and its ability to provide unique insight, by bridging molecular scale processes (micro) and observable phenomena[4].

In this work we investigate the adsorption of hydrogen on a set of 14 SAAs. We show that in 4 cases: CoRh(111), PdRh(111), CoAu(111), NiAu(111) the formation of the dihydrogen intermediate (H_2*) is observed. Importantly, the H_2 adsorption process necessarily passes through that intermediate and it is barrierless. On the other hand, the breaking of the bond and the formation of H* ad-atoms entail a sizeable reaction barrier.

The static information is used as input for KMC simulations to capture information about overall reaction rate and hydrogen coverage and to provide insight into the role of the H_2* kinetics in H_2 adsorption.

Sodium chloride (NaCl) represents the principal component of atmospheric particulates of marine origin.[1] To gain a molecular-level understanding of the adsorption process of water vapor on the NaCl surface, Monte Carlo simulations performed in the Grand Canonical ensemble were carried out, considering the water adsorption at different water pressures on a NaCl(001) surface.[2] The calculated adsorption isotherm shows four different regions, whose coverages correspond to those of the low-, transition-, high-, and pre-solution-coverage regions experimentally observed. Detailed analysis, leveraging unsupervised machine learning for water clusters detection, revealed how the structure of the adsorbed water molecules (islands, layer, and multi-layer) changes depending on water pressure, and how their orientation with respect to the surface varies with the distance from the surface. This detailed information further supports the picture coming from previous experimental IR absorption spectroscopy studies.

The aerobic oxidation of carbon monoxide to carbon dioxide is catalysed by the Mo/Cu-containing CO-dehydrogenase enzyme in the soil bacterium *Oligotropha carboxidovorans*, enabling the organism to grow on the low-weight gas molecule as a carbon and energy source [1]. It was shown experimentally that silver can be substituted for copper in the active site of Mo/Cu CODH to yield a functional enzyme. In our laboratories, we employed QM/MM calculations to investigate whether the reaction mechanism of the silver-substituted enzyme is similar to that of the native enzyme. Due to remarkable consistence with experimental findings, our theoretical results indicate that the Ag-substituted enzyme can oxidize CO and release CO_2 following the same reaction steps as the native enzyme. Surprisingly, lower activation energies for C–O bond formation have been found in the presence of silver. We also evaluated the effects that differences in the water-active site interaction may exert on the overall energy profile of catalysis. Finally, the formation of a thiocarbonate intermediate along the catalytic pathway was found to be energetically unfavorable for the Ag-substituted enzyme. This finding aligns with the hypothesis proposed for the wild-type form [2], suggesting that a step corresponding to the formation of such species may not be necessary for the enzymatic catalysis of CO oxidation. Further perspectives in terms of investigations on engineered forms of the enzyme active site will be also considered in our presentation.

Role of Key Intermediates of Oxygen Evolution on IrO_2, RuO_2 and TiO_2 catalysts: A Computational Electrochemistry study

E. Inico, G. Di Liberto, L. Giordano

Università degli Studi di Milano-Bicocca, Dipartimento di Scienza dei Materiali, Via R. Cozzi, 55, Milano, Italy
elisabetta.inico@unimib.it

Water electrolysis is a key reaction for the transition to sustainable fuels and green energy production.[1] The Oxygen Evolution Reaction (OER) still needs to be improved in terms of efficiency and fundamental understanding of its chemistry. In terms of efficiency, RuO_2 is considered a promising candidate. OER is typically assumed to occur through the path OH*, O*, OOH*.

Previous studies demonstrated that on RuO_2 unconventional intermediates can form. For instance, instead of forming OOH*, the oxygen bond changes from hydroperoxide type (OOH) to superoxide ($OO^{-}H^{+}$) one.[2]

In the presentation we systematically investigate the role of key reaction intermediates on three relevant metal oxides for electrocatalytic and photoelectrocatalytic OER, TiO_2, RuO_2, IrO_2.[3-4] This study was conducted by first, investigating the stability by means of ab-initio thermodynamics, and then by looking at the critical role of solvation. Finally, static calculations were complemented by ab-initio molecular dynamic simulations.

Results allow to rationalize both the role of solvation in the stability and reactivity of OER intermediates, as well as the role of the electronic structure of the metal oxide, giving an interesting overview of the intermediates formation and stability.

davide.moscato@unimi.it

It is now common knowledge that solvation can play an important role in many areas of chemistry, such as reactivity and the study of biomolecular processes. What is less obvious and still remains an open problem for the theoretical community is how to properly model and describe such processes. In this work[1] we take as an example the case of water solvated thymidine. We chose this system due to its peculiar experimentally observed behavior in the vibrational spectrum,[2,3] where in gas phase the signal relative the pyrimidinic rings' C4 = O and the one to the C5 = C6 are well separated while upon water solvation the same two signals are degenerate. To investigate the reason of this concerted shift of signals and gain a new atomistic physical picture of this phenomenon we use the Divide and Conquer Semi-classical Initial Value Representation (DC-SCIVR)[4] which allows us to add Nuclear Quantum Effects (NQEs) to classical molecular dynamics. Furthermore, to retain an high accuracy on such a complex and massive system we combined our semiclassical approach with the cutting edge QM/AMOEBA potential.[5] During this presentation it will be shown how the use of these tools allowed us to build a new physical picture of water solvation which keeps in account for the atomistic details in a dynamical way.

Light-matter interaction plays an essential role in many aspects of life and technology, including biologically relevant photochemical processes (e.g., photosynthesis, bioluminescence, vision), light-induced chemical reactions, photovoltaics, photonics, materials engineering. The advent of spectroscopy provided chemists and physicists with a powerful tool to investigate the interaction between matter and electromagnetic radiation. An accurate study of such interaction, however, is also possible with the application of rigorous ab-initio electronic structure methods which are employed to perform computer simulations of molecular systems. These studies are particularly important for the interpretation of complex experimental spectra and a better understanding of electronic properties of matter.

The most common procedure used to calculate molecular properties is based on linear response theory[1], which allows for the direct simulation of spectroscopic properties. The computation of these quantities requires the solution of the so-called "response equations" which are casted in the form of a generalized eigenvalue problem. However, the determination of its solutions can become expensive and, in many cases, could lead to numerical instabilities[2][3].

In this talk, I will present an improved version of the well-established Davidson direct diagonalization approach[4], able to fix those instabilities at a reduced computational cost. This new algorithm is referred to as Swapped Metric-Orthogonal Generalized Davidson (SMO-GD)[5]. In its first formulation it has been applied by us to simulate spectra at the CASSCF level of theory but it can be also applied, without lack of generality, to time-dependent density functional theory (DFT) and Hartree-Fock (HF)[6] approaches.

This algorithm represents a stable and efficient eigensolver that can be, in principle, applied to the solution of response equations both for molecules and solid state systems.

Electronic excitations in complex and multichromophoric systems with machine learning

Lorenzo Cupellini,[a] Edoardo Cignoni,[a] Amanda Arcidiacono,[a] Elena Betti,[a] Benedetta Mennucci[a]

[a]*Dipartimento di Chimica e Chimica Industriale, Università di Pisa, Via G. Moruzzi 13, 56124, Pisa, Italy*
laura.pedraza@unipi.it

Photophysical processes of biological interest occur in condensed phase, within "complex" systems where chromophore-environment interactions shape optical properties and excited-state dynamics. Faithful quantum chemical (QM) modeling of these processes requires a multiscale QM/classical strategy that accounts for all such interactions [1], as well as a thorough sampling of the configurational ensemble. The computational cost of QM methods however limits the number of calculations, forcing a compromise between statistical accuracy and feasibility. Machine learning (ML) techniques hold great promise in alleviating the computational burden of QM calculations, and have been successfully employed for the prediction of excited-state properties and dynamics [2]. However, much less attention has been paid to environment effects on excited states [3].

Here I will outline potential ML strategies to model excited states within complex systems, showing that the effects of the environment can be incorporated in a physically sound way within ML models. I will focus on light-harvesting pigment-protein complexes, as examples of complex environments where excitations are delocalized over multiple chromophores and also tuned by the interactions with the protein [4]. The obtained ML models [5] not only can faithfully predict the effect of the environment on electronic excitations, but can be used to simulate the excited-state dynamics of large multichromophoric complexes [6]. Finally, physically sound ML models can also assist the interpretation of solvatochromic effects, effectively complementing traditional QM/classical methods [7].

Four component relativistic calculations at reduced cost: a Cholesky decomposition implementation

D. Cianchino,[a] Tereza Uhlirova,[b] T. Nottoli,[a] J. Gauss, [b] F. Lipparini[a]

[a]*Dipartimento di Chimica e Chimica Industriale, Università di Pisa, Via G. Moruzzi, 13, 56124, Pisa, Italia*

d.cianchino@studenti.unipi.it

Including relativistic effects[1] in the computational description is paramount when dealing with molecules containing heavy-metal atoms. Such effects can be divided into scalar relativistic and spin-orbit effects. The former have a large impact on the overall energy, while the latter are responsible for fine effects on the electronic states. In this contribution, we pursue a computationally efficient, but rigorous description of scalar relativistic effects by adopting the four-component spin-free Dirac-Coulomb Hamiltonian[2] in combination with Coupled-Cluster with single and double excitations (CCSD)[3] as an electronic structure method. A four-component treatment introduces a major computational bottleneck, because the 4-component structure of the wave function leads to a sizeably larger number of two-electron integrals that need to be computed and processed when compared with the non-relativistic case. The additional two-electron integrals are not only affecting all computationally intensive step of a quantum chemistry calculation, but are also *per se* expensive to compute. However, they are numerically smaller than the non-relativistic integrals, which makes them an ideal problem for rank reducing techniques. In this contribution, we apply the Cholesky Decomposition (CD)[4] to the spin-free, relativistic two-electron integrals to accelerate the computation. We present an efficient, two-step[5] implementation of the CD, and discuss possible approximations that can be adopted when selecting the Cholesky basis, and in particular, the neglect of pivots stemming from the small component integrals. Using the CD has several advantages: it reduces the cost of computing the integrals themselves, accelerates the SCF and integral transformation computations, which further become trivially parallelizable, and, due to the effective compression of the two-electron integral tensor achieved by the technique, allow for an efficient MO implementation of the CCSD treatment that is not memory limited. This is particularly attractive, as it allows to use the same machinery used for non-relativistic CD-CCSD calculations, making thus it possible to perform the correlation calculation, which is the most expensive overall computational step, at no additional computational cost with respect to the non-relativistic counterpart. Various numerical experiments are presented to show in detail the possibilities and performance of the CD-SFDC-CCSD implementation.

The accurate simulation of environmental effects in the formation and relaxation of electronic excited states (ESs) is essential for efficient design of new materials with target properties.[1] The consideration of non-equilibrium effects is a crucial aspect but the quantum mechanical (QM) approach must flexibly address the diverse descriptions of the environment's polarization response.[2] While numerous studies have explored singlet ESs,3 less is known about the impact of solvent effects to triplet transitions, that have garnered considerable attention due to their potential applications in optoelectronics[4,5] and their role in the photoprotection mechanisms in plants and bacteria.[6] Here, we delve into the challenges of accurately characterizing the polarization response of the environment to triplet excitations, surpassing the limitations of the standard linear response framework in continuum dielectric models. The latter indeed fails to incorporate solvation effects arising from singlet-to-triplet transitions. Notably, the state-specific polarization (ss-pol) response also plays a crucial role in determining the ESs structure minima, facilitated by analytical gradients through a lagrangian formulation in a TDDFT framework.[7] Since it has been shown by an open quantum systems approach[8] that the delayed solvent response due to the solute charge density reorganization evolving in a time regime naturally include both ss-pol and dispersion interactions, both of them have been included in our effective protocol here presented. Simulations in the study of systems with inverted singlet-triplet gap[9] in solution for thermally activated delayed fluorescence applications will show the pivotal role of an accurate solvent response description.[10]

e-mail: luca.melega@phd.unipi.it

In recent years, rank-reducing techniques have seen a surge of interest by the quantum chemistry community, due to them being able to mitigate the intensive computational cost associated with electronic structure methods, thus extending their applicability to larger molecular systems. In that regard, we exploit the Cholesky decomposition (CD) of the electron repulsion integrals (ERI) tensor[1], reducing the impact of its manipulation on the cost of quantum chemical calculations. CD is not only able to compress the information stored within the ERI tensor, making it possible to manipulate it without recomputing or reading the integrals from disk, but also affords a strict control over the accuracy of their representation, since the approximation error is bound to be lower than the predetermined threshold used for the decomposition.

Here we applied the CD of ERIs and their derivatives to the computation of analytical geometrical gradients at the Coupled Cluster (CC) level of theory[2-4]. We present an efficient and parallelized implementation of CD, using a two-step algorithm[5] that can fully exploit Abelian point-group symmetry[6] and compute not only the Cholesky vectors, but also their derivatives with respect to nuclear displacements, also fully exploiting point-group symmetry. We use the Cholesky vectors and their derivatives to achieve an efficient and parallel implementation of the CC density matrices and for the intermediates in the *Z*-vector equations, along with their contractions with Cholesky decomposed differentiated integrals, yielding optimized molecular structures at the CCSD and CCSD(T) levels. The capabilities of our new implementation are tested on a range of systems, for which we compute the energies and molecular structures.

silvia.digrande@sns.it

Quantum chemistry plays an increasing role in complementing experimental studies since its accuracy and feasibility for large systems are constantly increasing. Several procedures have been developed for the generation of accurate thermochemical data[1]. For small molecules, among the most successful approaches are the Weizmann-*n* series (e.g. W4[2]) and the extrapolated *ab initio* thermochemistry (HEAT) protocol[3], providing results with sub-chemical accuracy but with a very unfavorable scaling with the system size. Alternative protocols have been proposed, which employ explicitly correlated (F12) approaches[1], that can save some computer time thanks to their faster convergence to the complete basis set limit. For larger molecular systems, more approximate composite methods are unavoidable, which aim at reaching chemical accuracy. The most well-known are the last versions of the G*n*[4] and CBS-*x*[5] families employing conventional methods or the W1-F12[2] and SVECV-F12[6] models with F12 approaches. Recently, an accurate computational protocol rooted in the F12 coupled cluster method, referred to as the Pisa composite scheme (PCS), has been developed and tested for structural and energetic data[7]. Two PCS variants with different accuracy and computational requirements are proposed, PCS3 and FPCS3, which can be employed for the study of medium-to-large molecules. Particular attention has been paid to core-valence contribution, extrapolation recipes, and optimization of the cost/performance ratio of the approach. The PCS3 variant can be applied to systems containing about 15 atoms, while the FPCS3 scheme, with the introduction of the frozen natural orbital approximation, permits to obtain accurate electronic energies for systems containing up to about 50 atoms, without the use of local correlation methods. These schemes have been benchmarked and applied to the calculations of atomization energy and heat of formation of systems of increasing size, from benzene (12 atoms) to a molecular motor (47 atoms), and open new frontiers for accurate characterizations and studies of energetic and biological interest.

Gold nanoparticles hold great promise in a myriad of advanced applications across chemistry, material science and biology, owed largely to their advanced optical and electrical properties. These intrinsic qualities have positioned nanoparticles as key players in sensing, catalysis, and drug delivery. However, a pivotal challenge lies in the design and engineering of gold nanoparticle monolayers that feature specific, high-affinity binding sites. It is this ability to tailor selective binding that underpins much of the practical applications of gold nanoparticles' unique properties, representing a significant hurdle in reaching their full potential.

Computer-aided rational design has proved invaluable in the effort to design and tailor nanoparticle monolayers for specific binding [1]. Yet, as with drug design, computer-aided rational design of nanoparticle monolayers requires a detailed understanding of the desired systems to allow researchers to make rational choices. Within drug development, preliminary screening techniques such as docking are routinely employed to swiftly identify and eliminate inferior candidates, thereby concentrating efforts on molecules with the most promise. However, such docking methods are inapplicable to nanoparticle systems due to the highly dynamic and evolving nature of the monolayers [2].

Here, we introduce a rapid screening approach, combining molecular dynamics simulations with machine learning, to explore the interactions between gold nanoparticles and small molecules. Utilising Nanomodeler [3], which allows the automated creation of monolayer-protected gold nanoparticles *in silico*, our approach facilitated the efficient evaluation of thousands of gold nanoparticle ligands for their binding affinity to small molecules, demonstrated through the case study of 3-methoxytyramine, a vital neuroblastoma biomarker.

While our immediate aim is the development of nano-based chemosensors for early neuroblastoma detection, the versatility of our method shows potential for broader applications in catalysis, drug delivery and energy harvesting with gold nanoparticles.

On-surface synthesis of organic structures is a convenient bottom-up approach for tailoring both the chemistry and the morphology of surfaces and for the synthesis of complex hybrid interfaces of potential interest in the development of organic based devices[1,2].

The unexpectedly rich surface chemistry of trinaphtylboroxine (TNB) deposited on the Au(111) support has been monitored through X-ray Photoemission and B K-edge NEXAFS. Through computational screening of a set of possible structures, by exploiting the element sensitivity and site specificity of core-electron spectroscopies we were able to uncover the role of adsorbed O atoms in promoting B-C bond cleavage which resulted in the on-surface formation of a stable B-O-B motif. Furthermore, the synthesis of the B-O-B motif allows for tuning the electronic properties at the interface between molecules and gold substrate. This work has been carried out in close collaboration with experimental groups of the CNR-IOM in Trieste.

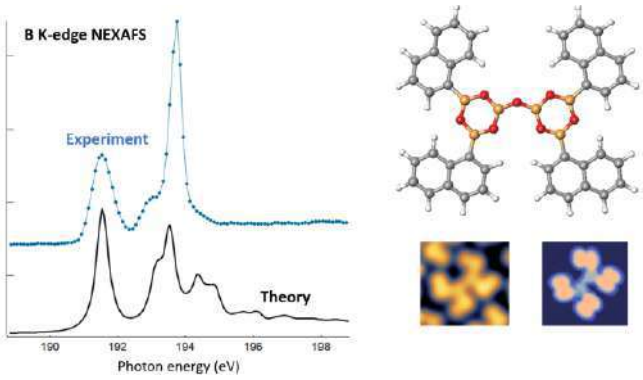

Figure 1: Left panel: experimental and calculated B K-edge NEXAFS spectra of TNB/Au(111). Right panels: top: model of the H-shaped molecule proposed in the present work; bottom: comparison between experimental and simulated STM image of the molecule.

Marco.trinari@sns.it

Spectral properties of isolated molecules can be drastically different from those of the same molecules dissolved in aqueous solution[1]. Multiscale Quantum Mechanics (QM)/Classical models are highly effective for simulating solvated molecules by partitioning the system into two components: the solute, which is treated at the QM level, and the solvent, which is modelled classically[2-4]. Among these methods, QM/Molecular Mechanics (MM) approaches have undergone a great expansion in recent decades and have become widely used to study spectroscopic properties of systems in solution[1-3]. The success of this type of theory lies in retaining the atomistic details of the solvent and the ability to describe the hydrogen bonding[1,3].

In this work, we study several spectroscopic properties of Zwitterionic L-Tryptophan in aqueous solution, by using fully polarizable QM/MM and QM/Frozen Density Embedding (FDE)/MM approaches[5-7]. The MM portion is in all cases described employing the Fluctuating Charges (FQ) and Fluctuating Charges and Dipoles (FQFμ) force fields[8,9], and the coupling to classical molecular dynamics allows the sampling of the solute/solvent configurational space[1]. While QM/ FQFμ well describes long-range electrostatic interactions, the use of a three-layer QM/FDE/ FQFμ approach permits an accurate ab initio description of short-range non-electrostatic interactions[6]. The simulated properties are UV-Vis absorption, Nuclear Magnetic Resonance, and Electronic Circular Dichroism, which are all very sensitive to solvent effects. The work aims to demonstrate the improved accuracy of the methodology by increasing the level of sophistication which is employed to model solute/solvent interactions, through comparison with experimental data.

giacomo.ambrogio@unito.it

We present a new version of the CRYSTAL ab initio simulation software designed to use graphics processing units (GPUs) and meet the escalating computational demands of theoretical materials science. CRYSTAL[1] is a solid-state simulation software that allows to perform calculations on materials, making use of the Density Functional Theory (DFT) framework, including hybrid functional approaches.

In present days, the accurate description and prediction of material properties rely heavily on the computational power and efficiency of simulation programs. Traditional CPU-based approaches encounter substantial challenges in terms of hardware demand and execution time. In this regard, a valuable alternative is to use GPUs, which are the most powerful components in computers and HPCs.[2] Our work leverages their high throughput capabilities to significantly accelerate the execution of DFT simulations, particularly for large-scale systems encountered in real-world applications.[3]

Employing publicly available GPU-accelerated libraries for linear algebra operations, we achieve remarkable performance enhancements. In the case of the Metal Organic Framework ZIF-8 (supercell containing 2208 atoms, 22176 atomic orbitals), we reduced single-point energy calculation time by 86% (128 CPU cores vs 1 NVIDIA A100 GPU) while maintaining numerical precision.[4] The incorporation of GPUs into CRYSTAL not only enhances computational efficiency but also expands the scalability, enabling the handling of huge size system that were previously prohibited with the conventional CPU-based approach.

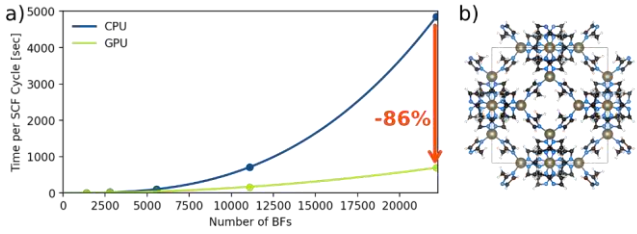

Figure 1 a) Execution time vs system size (series of supercell) of CPU and GPU codes. b) Unit cell of ZIF-8.

Spectroscopic characterization of water clusters is a powerful tool to gain insight into the hydrogen bonding structure of water. New experimental advances have made it possible to record the vibrational spectrum of clusters of increasingly higher dimensionality,[1] such as the water octamer,[2] which exhibits a behavior characteristic of the solid-liquid phase transition of water.

On the theoretical side, anharmonicity has to be taken into account to correctly assign the vibrational features of water clusters.[3]

In this work, we study the OH-stretch region of the water octamer spectrum using the quasi-classical trajectory (QCT) technique,[4] which is a computationally affordable classical method capable of providing very accurate anharmonic frequencies. Differently from the conclusions of the previous scaled harmonic assignment,[2] which invoked the contribution of 5 conformers and a solvated form of the water heptamer in the spectrum, we find out that the spectroscopic features can be related to the 4 lower energy conformers of the octamer.[5]

Clean energy is one of the big demands of this century, driven by the need to mitigate human impact on the planet's ecosystems.[1] Weather-dependent renewable sources require advancements in energy storage technologies.[2] Molten carbonate electrolysis cells (MCECs) are a prime example of devices able to convert surplus energy from a renewable source into gaseous energy carriers, like H_2.[3-4] To further improve the efficiency of these devices, we require reaching a deeper understanding of each step involved in the functioning process. Here, we start with a thorough structural investigation of the electrolyte of choice for MCECs, namely the molten $Li_{1.24}K_{0.76}CO_3$ eutectic mixture. We employ explicit polarization molecular dynamics to show that the structure of this molten mixture is characterized by tight lithium-carbonate interactions, giving rise to a structural network in which the K^+ ions are loosely embedded. Using the knowledge of the melt structure at an atomic level, we can rationalize the conductivity trends we see experimentally in molten carbonate mixtures. Finally, from our simulation we provide the first theoretical prediction of the static structure factor, S(q), of the $Li_{1.24}K_{0.76}CO_3$ melt at the typical operating temperature of MCECs ($923\ K$, see Figure 1). This work will be the first step in a larger endeavor to characterize at an atomic level each element of the chemical processes involved in these devices. The polarizable force field developed here will be a steppingstone towards more advanced studies: on the role of the electrolyte first, and the rest of the cell later.

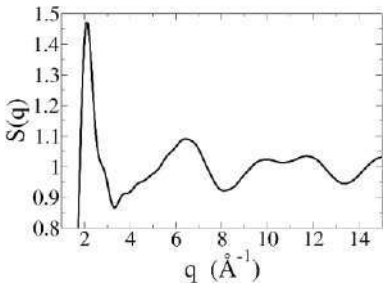

Figure 1: Static structure factor (S(q)) of the $Li_{1.24}K_{0.76}CO_3$ melt, calculated from our simulation.

Exploring the Time-Scale Complexity of Molecular Dynamical Systems: A Novel Refined Clustering Approach

Doria,Domiziano; Cioni,Matteo; Becchi,Matteo; Massimo dellePiane; Giovanni M. Pavan

Department of Applied Science and Technology, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129 Torino, Italy
domiziano.doria@polito.it

Molecular systems display both complexity and dynamism, undergoing continuous changes and interactions that are challenging to fully anticipate or comprehend. Over time, they demonstrate diverse behaviours driven by molecular interactions, feedback processes, and external factors, aligning them closely with the characteristics of complex dynamical systems.

In the quest to unravel the complexities of these dynamical systems, the ability to distinguish and categorize a wide range of signal behaviours poses a significant challenge, one that traditional clustering methods struggle to meet.

This study introduces an advanced methodology designed to enhance the classification of complex dynamical systems, specifically by refining the analysis of segments traditionally deemed non-classifiable. Building upon the foundational principles of "Onion Clustering" [1], and its feature which allow us to catch non-classified signals data, due to their high fluctuations, our approach delves deeper into the data, revealing previously obscured layers and offering a richer understanding of the system's inherent dynamics. Like its predecessor, which efficiently discerned statistically relevant fluctuations from noise through an iterative detect-classify-archive strategy, our methodology extends this paradigm by further classification and optimization of the clustering time window.

These refinements enable a precise yet comprehensive analysis, capable of uncovering subtle dynamical events across different scales. In this paper, we outline the development of our methodology, the analytical framework, and the wider implications of this sophisticated approach for revealing the complex and concealed patterns within complex systems.

anna.ranaudo@unimib.it

Niemann-Pick C1-Like 1 (NPC1L1) is a transmembrane protein, involved in cholesterol absorption in the intestine, whose activity can be modulated by ezetimibe, a drug that prevents cholesterol transport from the lumen to the membrane. The structure of the complex NPC1L1-ezetimibe was recently resolved[1]: ezetimibe localizes in a tunnel which is the path for cholesterol transport from the N-terminal domain (NTD), where cholesterol is first recognized, to the sterol sensing domain (SSD), where cholesterol leaves the protein and is released in the membrane.

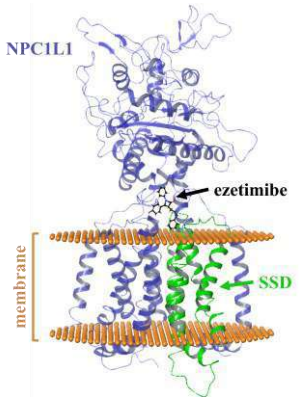

Figure 1: Structure of the NPC1L1-ezetimibe complex.

Molecules such as sterols and polyphenols, contained e.g. in plants, have been shown to act against NPC1L1 activity[2]. However, it is still unknown where they bind NPC1L1, and which is the mechanism by which they manage to prevent cholesterol absorption. In this study, we aim to predict the structures of the complexes the aforementioned molecules could form with NPC1L1. Computational approaches such as protein-ligand docking and all-atoms molecular dynamics simulations, with explicit modelling of the membrane[3], are used. Structural information on the binding of other molecules to NPC1L1 and NPC1 proteins, a structural homologous which is also involved in cholesterol transport, is exploited to drive the modelling procedure.

giacomo.darcangelo@sns.it

Surface-Enhanced Raman Spectroscopy (SERS) is a powerful analytical technique that has garnered significant attention thanks to its capability to amplify the Raman signals of molecules adsorbed on nanostructured metal surfaces up to the detection of a single molecule[1]. However, one challenge to the interpretation of the data is the difficult reproducibility of the results, complicated by the multitude of effects that contribute to the enhancing factor.[2] This complexity makes it difficult to predict both the level and the effect of enhancement on the analyzed compound. One potential enhancement factor may be purely related to the response of the molecule itself, especially when dealing with chromophores.

In this contribution, to discern this effect, we propose a combined experimental-theoretical study of enhancement processes using the methylene blue molecule as a test case. From an experimental point of view, the compound is examined under various conditions to obtain a comprehensive picture of the enhancement effects. This includes utilizing non-conventional state-of-the-art spectroscopy setups, as well as standard analytical methodologies with bench instrumentation. Concurrently, the proposed computational study relies on density functional theory (DFT) calculation are used to provide an accurate insight into the molecular nature of the Raman enhancement effect[3].

This work represents a step for systematic modeling of SERS spectra under real experimental conditions. Its aim is to establish a theoretical methodology that supports the interpretation of Raman enhancement phenomena.

Photosystem-II (PSII) is a multi-subunit protein complex that harvests sunlight to perform oxygenic photosynthesis. Initial light-activated charge separation takes place at a reaction center consisting of four chlorophylls and two pheophytins. Understanding the processes following light excitation based on experimental results remains elusive due to spectral congestion as well as to the ultrafast nature and multi-component behavior of the charge-separation (CS) process. Using advanced computational multiscale approaches, based on all-atom molecular dynamics simulations coupled with the Perturbed Matrix Method[2], we were able to achieve the first direct calculation of the kinetics of the charge separation processes in the reaction center (RC) of PSII[1]. Our results indicate the presence of a multi-path scenario for the primary charge separation that, eventually, leads to the formation of the $SP^{+}Pheo_{D1}^{-}$ pair. We identified two primary radical-pair formation components that considerably differ in their respective time constants. The dominant faster channel starts from Chl_{D1}* and leads to the formation of a $Chl_{D1}^{+}Pheo_{D1}^{-}$ charge-separated pair subsequently evolving to the $SP^{+}Pheo_{D1}^{-}$ couple. In the second and slower path a long-range ET event occurs starting from SP* and leading directly to $SP^{+}Pheo_{D1}^{-}$. We also found an energy transfer pathway between the Chl_{D1}* and the SP* localized excited states, the efficiency of which is tuned by the protein environment. This observation can also explain the experimental heterogeneity measured for $Pheo_{D1}^{-}$ formation ranging from picoseconds to tens of picoseconds. The presence of a preferential channel for CS and shortcuts from different localized excited states in the RC, consistently leading to the same rapidly formed radical pair, is crucial for efficient light harvesting.

Spectroscopic characterization of the interface between tripyrenboroxine and Au(111) surface

S. Pistillo,[a] D. Toffoli,[a] A. Cossaro,[a] S. Micheloni[a], G. Fronzoni[a]

[a]*Department of Chemical and Pharmaceutical Sciences, University of Trieste, via L. Giorgieri 1, 34127, Trieste, Italy*
simone.pistillo@phd.units.it

Boroxines represent a class of compounds extensively employed as templates on metal surfaces[1]. Their exceptional mechanical properties and thermal stability have sparked significant interest in utilizing them for the development of new electronic devices. In this study we performed a combined experimental and theoretical study to characterize the interface between tripyreneboroxine (TPyB) and Au (111) surface in term of its electronic properties through NEXAFS core spectroscopy studies. Density Functional Theory (DFT) calculations were performed to describe the geometry of the system (shown in Figure 1) and elucidate the nature of TPyB /surface interaction. A finite cluster was then cut out from the periodic relaxed structure for the calculations of the NEXAFS spectra at both B and O K-edge. The calculations suggest the presence of unoccupied orbitals strongly hybridized with gold atoms, close to the Fermi level. The coupling of these orbitals with the Au substrate demonstrates the importance of the boroxine group to mediate possible charge transfer between molecule and surface. These findings suggest that such systems, typically utilized as templates for the growth of organic films, can also serve as active interlayers, establishing an efficient electronic transport channel that bridges the inorganic substrate and organic overlayer.

Theoretical study of charge and energy transfer processes in materials for organic electronics

D. Mangatia,[a] R. Borrelli,[a]

[a]*University of Turin, Department of Chemistry, Via Pietro Giuria 7, Turin, Italy*
damiano.mangatia@unito.it

Nowadays, a myriad of organic semiconductors (**OSCs**) have been proposed across diverse domains, including electronics, flexible displays, and cost-effective solar cells. [1] Since early investigation on their charge mobility it has been clear that i) local vibrations are strongly coupled to the charge-transfer process ii) the fluctuation in the transfer integrals can significantly affect the transport mechanism, because their magnitude is comparable to the average value of the transfer integrals. [2] Therefore the study of charge mobility in **OSCs** can be tackled by developing quantum dynamical models in a system where electronic and nuclear degrees of freedom exhibit strong coupling. Starting from this point we propose a study of electron dynamics in emerging hole-transport materials (**HTM**) devices. Using specific atomistic models of the materials we compute the relevant parameters that controls the charge transfer (**CT)** process: site energy, electron transfer integrals and electron-vibrational coupling using state-of-the art methodologies. [3,4] These parameters are used as input for a subsequent studyof the electron-nuclear dynamics using a properly defined **Holstein-Peierls** model Hamiltonian. Using this approach we show how these parameters affect the various regime of charge-mobility in organic **HTM**.

Isolation of transient nucleoprotein complexes in their biological conformation is a challenging task: a promising technique for this goal is to induce in vivo crosslinking between the nucleic acid and the protein, by UV light (UV-CL). The photo-cyclization of 5-benzyluracil (5BU) to 1,2-indaneuracil has been proposed as a model reaction for studying the mechanism of UV-CL.[1] In this context, we present a combined experimental and theoretical study of the thermal equilibrium, the photophysics and the ultrafast photo-activated dynamics of 5BU in methanol,[2] exploiting the framework of the DFT and TD-DFT.[3] We adopted the ADMP[4] method and an hybrid QM/MM ONIOM partition scheme, enforcing non-periodic boundary conditions.[5] We recorded the UV absorption spectrum in methanol solution and simulated the band shape through TD-DFT calculations performed on the structural ensemble given by the AIMD trajectory, finding a good agreement between experiments and simulation. With respect to previous studies,[6] we uncovered that first two excited states are indeed the ones responsible for the absorption preceding the photoreaction; that their brightness is strongly influenced by the accessible conformations of the 5BU at room temperature and the microsolvation of its oxygen and nitrogen atoms. After excitation, 5BU exhibits an ultrafast non-radiative decay (probed by fluorescence upconversion experiments), which competes with the reactive path and is debated to be due either to a de-excitation to the ground state or a relaxation within the excited state.[6] To give a molecular interpretation of the photo-induced relaxation, we conducted a mixed quantum/classical non-adiabatic molecular dynamics, by adopting the Surface Hopping[7] approach; we finally performed a vibrational analysis through an innovative protocol, based on the wavelet transform of time resolved generalized modes extracted from the trajectories.

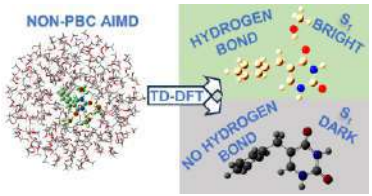

Figure 1: Left: a snapshot from the AIMD of 5BU in methanol. Right: two sampled configurations of 5BU.

Novel Theoretical and Computational Approaches for Modelling Photoinduced Proton-Coupled Electron Transfer Reactions in Complex Environment

G.Amante[a], N. Rega[a,b]

[a]*Scuola Superiore Meridionale, Largo S. Marcellino 10, Napoli*
[b]*Università degli Studi di Napoli Federico II, Complesso Universitario di Monte Sant'Angelo, Via Vicinale Cupa Cintia 26, Napoli*
g.amante@ssmeridionale.it

Proton-Coupled Electron Transfer (PCET) reactions represent an important class of reactions of fundamental importance in both biological and technological contexts [1,2]. In these reactions, a transfer of electrons and protons between two molecular species occurs, which may involve different sites. A challenging case regards the proton transfer from a solute towards a solvent molecule. A reasonable classification of PCET reactions is based on the degree of electronic, vibrational and vibronic adiabaticity between the transferred electron and proton [3]. Recently, our research group [4] has introduced an innovative procedure to discriminate between different degrees of adiabaticity in mechanisms.

In this contribution, we aim to characterize the mechanism of photoinduced PCET reactions between tyrosine and tryptophan in oligopeptide models [5] in solvent. In this context, theoretical/computational methodologies significantly contribute to the atomistic/molecular-level interpretation of the processes involved. The solvent plays a key role as proton acceptor species, thus requiring an accurate description of the solute/solvent interaction potential and the main configurations assumed by it around reactive sites. We therefore aim to develop a generalized protocol based on hybrid multiscale methods, where the solute is described at the quantum mechanics level, the first two/three solvation shells at the molecular mechanics level, while the bulk properties of the solvent are described using a continuum dielectric model (QM/MM/Continuum) [6]. For the QM/MM clusters thus described, we will assess the possibility of characterizing stationary points of the potential energy surface and finally address the development of a new flexible methodology for ab initio molecular dynamics simulations of solute/solvent systems using non-Periodic Boundary Conditions in non-spherical cavities (e.g., elliptical) for the description of non-spherical solutes such as oligopeptides and linear polymers. The high computational efficiency of this procedure promises to analyze and provide evidence on PCET mechanisms that regulate the reactivity of numerous biological systems.

Artificial molecular machines represent a hot research topic directly linked to the development of nanoscale devices.[1] Among the molecular machines synthesized, the light-driven molecular rotary motors represent an elegant way to transform the electromagnetic radiation in a unidirectional rotary motion. In this work, we focused on a Feringa-type motor.[2] This molecule is characterized by two parts, the *stator* and the *rotor*, connected by a carbon double-bond axle, and performs a full unidirectional rotation about this latter, in an isomerization cycle characterized by two photochemical and two rate-limiting thermal steps. In order to unveil the photophysics of the system and providing a molecular interpretation of the photorelaxation process, we performed *ab-initio* molecular dynamics simulations[3-7] in both the ground and excited electronic states, within density functional theory and its time-dependent version formalism[8,9] along with a transient vibrational analysis based on the Wavelet transform[10,11] of specific quantities. An accurate, calibration of the potential with a detailed balance of the environment effects, was carefully addressed. Then, relying on the electronic excited state trajectories, we extracted generalized normal modes and collective structural rearrangements to shed light on the main molecular determinants involved in the vibrational dynamics. Within the early stages upon excitation, a clear mechanism emerges, a bi-phasic energy decay from the Franck-Condon region occurs and is modulated by coupled vibrations involving the central carbon-carbon double bond. Our findings contribute to expanding the knowledge of processes that underlie the photorelaxation and provide a detailed interpretation of time-resolved spectroscopic experiments.

Insights into the rate limiting step of the natural water oxidation reaction from all-atom molecular dynamics simulations of Photosystem II

G. Parisse,[a*] D. Narzi,[a] L. Guidoni[a]

[a] Department of Physical and Chemical Sciences, University of L'Aquila, Via Vetoio – 67100 Coppito, L'Aquila, Italy
gianluca.parisse@graduate.univaq.it

In nature the manganese cluster (Mn_4Ca) located inside the enzyme Photosystem II (PSII) catalyses the water oxidation reaction, which represents a key step of the whole photosynthetic process. The complex reaction takes place along the five steps (S_0-S_4) of the Kok-Joliot cycle. The slowest step in oxygen evolution has been recently identified after the S_3 state by a combined experimental and computational study, highlighting a significant entropic slowdown.[1] Classical molecular dynamics (MD) simulations allow to get insights on the H-bond network sampled by the solvent molecules around the Mn_4Ca cluster on timescales inaccessible to quantum chemical calculations, thus representing a suitable tool for investigating at molecular level on the origin of this entropic slowdown. Here, starting from the experimentally determined structure of PSII in Thermosynechococcus vestitus BP-1,[2] we simulated the wild-type (WT) form of PSII in the oxidized S_3 state, embedded in a lipid bilayer, and the respective D1-N298A variant. Firstly, by following a recent approach,[3] we developed a new classical force field derived by Ab Initio Molecular Dynamics simulations[4] of the manganese cluster in the oxidized S_3 state. Thereafter, by means of classical all-atoms MD simulations, we started working on the origin of the entropic contribution associated with the bottleneck of photosynthetic oxygen evolution. Our MD simulations reveal pronounced fluctuations regarding the H-bonded protein-water network in the surrounding of the Mn_4Ca cluster. Starting from the simulated trajectories, we carried out several analyses to sample the water molecules distribution and take into account their intrinsic mobility in the oxygen evolving complex (OEC) over the simulation time. Our results show an increased mobility of the closest water molecules to the Mn_4Ca and a concomitantly more flexible protein environment upon N298A mutation, thus resulting in a weaker H-bond network in the OEC when compared to the WT form. These results could explain both the experimentally found increased entropic and decreased enthalpic contributions to the activation free energy of the S_3 to S_4 transition in the mutated PSII.

How Machine Learning enhances simulation of energy transfer in Light-harvesting Complex II

E. Betti,[a] P. Saraceno,[a] E. Cignoni, [a] L. Cupellini [a], B. Mennucci [a]

[a] *Dipartimento di Chimica e Chimica Industriale, Università di Pisa, via G. Moruzzi 13, 56124 Pisa, Italy*
elena.betti@phd.unipi.it

In plant photosynthesis, the harvesting of solar energy is made possible by aggregate of pigments embedded in specialized membrane proteins, called light-harvesting complexes (LHCs)[1]. Specific interactions with the protein and electronic couplings with other chromophores alter the optical properties of individual pigments, and light absorption in the aggregate is followed by a cascade of energy transfer processes. Because of the complex nature of LHCs, the simulation of such excited state dynamics is challenging and requires expensive multiscale methods[2] to estimate all the involved parameters. Structural disorder adds on top, requiring calculations to be repeated over many configurations of the system. Machine learning (ML) can represent a valuable alternative to traditional approaches in the simulation of the energy transfer events. Here, we show that a ML strategy[3] can be applied to estimate excitonic quantities of LHCII of higher plants with accuracy comparable to standard multiscale methods, with the advantage of an extremely higher speed which allows wide sampling of the configurational space of the system when coupled to molecular dynamics. The resulting estimated parameters are robust and allow simulation of the excited state dynamics which closely reproduces the experimental one, as demonstrated by comparison to transient absorption[4,5]. New insights on the most relevant pathways and associated characteristic times are achieved through this integrated model.

Computational investigation on the Hydrogen Evolution Reaction mechanism by Chini complexes

F. Rizza,[a] F. Arrigoni,[b] R. Della Pergola,[a] C. Greco,[a] U. Cosentino[a]

fabio.rizza@unimib.it

The transition from fossil fuels to renewable energy sources necessitates the development of efficient energy storage methods to address the spatiotemporal challenges posed by the limited ability to store this energy for use when it is most needed. Chemical bond energy storage, particularly through electrochemical conversion of renewable resources into carbon-neutral fuels, emerges as a promising solution.[1,2] Metal Carbonyl Clusters (MCCs) with their tailored electronic structures present as ideal candidates for electrocatalysis, notably in hydrogen evolution reaction (HER) and carbon dioxide reduction (CDR). The utilisation of MCCs as homogeneous electrocatalysts offers distinct advantages over conventional catalysts, owing to their unique properties.[3] Their high proton affinity in the reduced state facilitates hydride intermediate formation at low potentials, while the flexibility in substitution reactions enables precise tuning of catalytic properties.[4] Here, we present a comprehensive Density Functional Theory (DFT) study focusing on a specific class of platinum carbonyl clusters with general formula $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n \leq 10$), known as Chini clusters (Figure 1).[5] Our computational approach delves into the efficacy of Chini clusters in prompting the reduction of protons and (possibly) CO_2 to produce molecular hydrogen and (hopefully) formate utilising metal hydride intermediates. We assess the accuracy of various levels of theory in describing the structure and infrared spectra of Chini clusters and explore the reaction profile for the hydrogen evolving reaction.

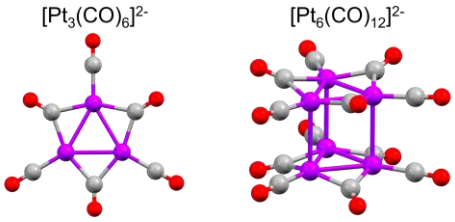

Figure 1: Structures of monomer and dimer Chini clusters.

The Interconnectedness of Sustainable Development-oriented Critical Challenges, Chemistry Teaching and Systems Thinking

S. Delaney[a]

[a]*School of Education, Deakin University, Burwood, Victoria, Australia*
s.delaney@deakin.edu.au

School science and chemistry curricula around the world are beginning to incorporate the critical challenges that society faces today into teaching, sometimes presented alongside the potential solutions that chemical science can offer. However, it should be recognized that this shift isn't always occurring within the 'core' curriculum; rather, it's often only suggested in as 'engaging' real-world scenarios related to green chemistry and sustainable development for educators to integrate into their instruction. Even though this integration is a subject of debate in curricula that are already overloaded with content, the objective remains crucial. It is essential for all students to feel equipped and capable of participating in vital societal decisions that will determine their uncertain future in the Anthropocene era.

The international chemistry education community has rallied around holistic approaches such as systems thinking, which leverage sustainable development-oriented contemporary science innovations to generate a self-sense of teacher and student agency towards addressing critical challenges facing society today. The IUPAC project Systems Thinking in Chemistry for Sustainability: Toward 2030 and Beyond (STCS 2030+) and other associated implementation projects promote systems thinking as a vital tool to assist chemistry to make connections with Earth and societal systems. However, teaching and learning resources and available professional learning have not kept up with the rapid increases in innovation taking place in industry. This presentation describes some recent examples of schoolteacher professional learning programs that have taken place in different countries, focussed on supporting educators to embed systems thinking-oriented activities into their classrooms. The presentation will also encompass insights from both students and teachers on the implementation of systems thinking within the chemistry classroom. In addition, it will contemplate the necessary support structures that should be established to enhance professional learning initiatives in the future.

Acids and bases from Arrhenius to Brønsted and Lowry: a story with many protagonists

M.V.Barbarulo,[a] F. Calascibetta[b]

[a] *Liceo classico Eugenio Montale, Roma*
[b] *Presidente del GNFSC*
franco.calascibetta@fondazione.uniroma1.it

During our previous studies aimed at better specifying the independent paths which in 1923 brought J. N. Brønsted and T.M. Lowry to the definition of acids and bases, which goes by their name [1], we have had the opportunity to reflect more carefully on the framework of knowledge in which their research was placed. Starting from the statement of the theory of electrolytic dissociation by Arrhenius in 1887 [2], which led to a first definition of acids and bases as substances that release into water ions H+ e OH- respectively, in the following years several authors added their contribution, by globally examining other important properties of the two classes of substances, such as their ability to change the color of indicators and act as catalysts in many organic reactions. The research by these scientists, among whom we can mention R. Abegg [3], A. Werner [4] and L. Micaelis [5], ended up leading to an expansion and greater articulation compared to the initial definition of Arrhenius. In this sense the two publications by Brønsted [6] and Lowry [7] can be seen as the culmination of a process to which others also contributed significantly.

Inclusion through the disciplines: the case of chemistry

E. Aquilini,[a]

[a]*Liceo Artistico "F.Russoli" 1, Via San Frediano,13, Pisa*

ele.aquilini6@gmail.com

In recent years, schools have become familiar with acronyms such as DSA, BES, PDP that categorize the casuistry of disadvantage and dispensatory and compensatory modes of intervention. Without detracting from the recognition that certain functional characteristics of individuals exert on learning, there is an excessive cataloging of discomfort forms that proves paralyzing of the educational action of curricular teachers. As Maurizio Muraglia[1] reports, a dangerous drift of medicalization of all discomfort forms is detected, in view of an ideal state of well-being that in reality does not exist. In fact there is instead a continuum between so-called "normality" and the most severe forms of distress[2]. The impression is that the concept of inclusion, which should characterize daily schooling because it is understood as a way of promoting learning by taking into account the peculiarities of each student, is being fragmented into bureaucratic classifications which are followed by pedagogical interventions entrusted to non-experts in the discipline. In schools, the intervention of neuropsychiatrists and social workers tends to exert a deresponsibility action on teachers. Faced with diagnoses that spare no one, teachers retreat from their mandate to teach those who need it most. Collaboration between support teachers and curricular teachers is often non-existent or occasional.

This contribution reports on an effective collaboration between support and curricular teacher in a third grade class of an art High School, which led to good results in terms of "possible" learning, with respect the degree of discomfort of the three students considered. The topic of the study was Lavoisier's fundamental 1772 discovery[3] in which he understood that air is involved in the combustion of phosphorus and sulfur. Storytelling[4] played an essential role in learning for all students in the class and particularly for the most fragile subjects.

DID-OR-002

Ten Fashionable Years – Keeping Dyeing Chemistry from Dying

Sergio Palazzi

ISIS di Setificio "P. Carcano", Como
studio@kemia.it

Almost ten years have passed since the first cycle of "reformed" Italian High School was completed. The laws of 2010-2012 strongly rearranged every curricula[1], and had a very harsh effect on the *Istituti Tecnici*. The two former courses of *Perito Chimico Tintore* (Dyeing Chemistry Engineer) and *Perito Tessitore* (Weaving Engineer) merged into a brand new interdisciplinary path, that a bad marketing strategy baptized *Tecnico di Sistema Moda* (Fashion System Technician), or S.M. It has two subsection (for textile and for leather industry); our *Setificio*, unique in Italy, also has a section for Fabric Designers, inherited from an older tradition, that faces disrupting innovations in printing.

Oddily, those of S.M. are the only schooling paths in Italy that have Applied Chemistry among the characterizing subjects for the final exam, other than the "true" chemical course (*Chimica e Materiali*). But the latter is mostly focused on general items, so, despite their name, *Sistema moda* graduates are in practice the only specialists surfing the waves of innovation that dyers and printers, finishers and weavers, QC and certification labs are struggling to keep up with. And textiles are everywhere, fashion is only the tip of the iceberg. It is relevant that the majority of S.M. students continue their studies, and not only in STEAM; a good number then comes back in the textile field with widened experiences.

The world of textile covers almost all the branches of chemistry and is less than halfway through a radical transformation, due to changes in materials, procedures and approaches, driven by sustainability instances[2]. Italy is leading in most of these fields, but there is a dramatic lack of people with a sound technical background, so we need to motivate young people also with more adequate teaching procedures. After a decade, it is worth reflecting on what we did in the meanwhile. There seems to be a new push toward more substantial changes in secondary and tertiary education, developing integrated and advanced curricula, so it could be useful to collect and share any effective idea.

In this oral communication, that also looks at some already published works[3] and others still in progress, we will propose several suggestions on how to introduce, in more effective ways, the chemistry and technologies of dyes, formulations, pigments and ligands, finishing agents, new and/or recyclable fibers, digital colour science, water and energy saving etc, supporting a lab-centered teaching along the five years (or soon 4+2?). Learning approaches often lean on real-life references, from historical documentation to the ZDHC and REACH databases and new production quality protocols, in close interaction with academic and industrial environments. We also reflect on the pros and cons arising from these experiences.

The Chemistry of Macromolecules in the stories of Primo Levi

V. Villani

Science Department, Università della Basilicata, Campus Macchia Romana, Potenza, Italy
Vincenzo.villani@unibas.it

Primo Levi was a macromolecular chemist. Director of SIVA (1953-1973), a paint and similar industry, he dealt for a long time and with passion with all the problems connected with the synthesis, production and use of products based on thermoplastic vinyl polymers or phenolic thermosetting polymers. His work as a chemist represented an inexhaustible source of literary inspiration which not only sheds light on the complexity of the human soul, but is a source of scientific reflection, useful from an educational point of view for the new generations.

In *La chiave a stella* (Einaudi, 1978) the worker Faussone, a sort of *alter ego* of the Author, deals with things that are only apparently elementary: he assembles pylons and mechanical structures. To Levi's perceptive eye, this hard and intelligent work becomes a metaphor for the work of the macromolecular chemist who on an infinitely smaller scale with invisible forceps, and with even greater difficulty, neatly assembles the monomers into macromolecules with a structure no less elaborate than the immense oil derricks.

In *Il sistema periodico* (Einaudi, 1975) the macromolecular ideas are numerous and intriguing. Like the worker Lanza who engages in an all-out night fight with the red-hot autoclave of phenolic resin that is under pressure and on the verge of exploding. Small, great daily heroisms that Levi recounts with involvement, glimpses of industrial life unknown to those who have not experienced that world from within. Lanza, after having tamed the crazy baekelizer with strokes of the key and inventiveness, finally smugly pours the resin produced, shining like a mirror, and as if nothing had happened, passes the deliveries to the day shift worker saying that everything is fine.

And then the artisanal lipstick that drools on the lips, and the paints that have undergone an unwanted sol-gel transition, the thermosetting enamel that mysteriously detaches from steel cans, the unusual preparation of boiled linseed oil ... All cases that seem like thrillers, solved with brilliant chemical acumen, in which the Author is always aimed at understanding the microcosm of man and nature.

Design and testing of a teaching sequence on the notions of permanent and instantaneous dipole

N. Cimadamore [a], M. Ghirardi [a,b], A. Regis [a], E. Ghibaudi [a]

[a] *Gruppo SENDS, Dept. of Chemistry, University of Torino, Via Giuria 7, I-10125, Torino (Italy)*
[b] *ITIS Quintino Sella, Via Fratelli Rosselli, 2, 13900 Biella (Italy)*
e-mail: elena.ghibaudi@unito.it

Educational research shows that the notions of permanent and instantaneous dipole referred to the atomic-molecular realm are difficult to understand and a source of alternative conceptions[1-3]. Difficulties include: the identification of dipolar systems with charged species; the misinterpretation of symbols $\boldsymbol{\delta}+/\boldsymbol{\delta}-$; the lack of correlation between electron mobility (thought in the frame of a shell atomic model) and the onset of intermolecular interactions; the inability to perceive the systemic nature of these interactions.

A teaching sequence focused on dipolar interactions and their interpretation at the nucleus-electron level was designed with the aim to tackle the above-mentioned teaching problems. The didactic transposition addressed the following conceptual issues: (1) description of the molecular dipole as a consequence of electron motion within an overall electrically neutral chemical species; (2) development of the issue of intermolecular interactions starting from the concept of instantaneous dipole, which is present in all atomic-molecular systems (3) conceptualization of dispersion forces as a result of a systemic process in a particle ensemble, rather than the sum of intrinsic properties of individual molecules; (4) treatment of the concepts of instantaneous and permanent dipole within a unified, non dualistic theoretical framework that emphasizes the temporal variable.

The teaching action is based on the use of several didactic tools: individual worksheets aimed at introducing new concepts through problem-situations, formulation of interpretive hypotheses, identification etc.; collective discussions in the classroom, moderated by the teacher; slides for recap and synthesis of the newly learned concepts. This teaching sequence was tested on three classes of a technical secondary school (ITIS “Q. Sella” in Biella, Italy) over a period of 7 weeks. The individual answers provided by students and their contributions to collective discussions were analysed, in order to monitor the learning process and identify strengths and weaknesses of the teaching sequence. Such analysis shows that this sequence was effective in overcoming several obstacles, e.g. the difficulty to distinguish between phenomena and their interpretive models, or to identify causal relationships. The results of a test administered before and after the experimentation, showed that a significant percentage of students achieved the learning objectives. Overall, the sequence was effective in promoting the understanding of the notions of permanent and instantaneous dipole within a coherent and unitary theoretical frame.

Three-Dimensional Structures in Late Nineteenth and Early Twentieth Century Chemistry Textbooks

Matteo Chioccioli[a]

[a]*Istituto Scolastico "Marsilio Ficino", Piazza S. Francesco, 10, 50063 Figline e Incisa Valdarno (FI)*
matteo.chioccioli@tiscali.it

Graphical representations of three-dimensional structures play a pivotal role in the field of chemistry education. Their correct interpretation is indeed essential for a full understanding of basic concepts that are central for both organic and inorganic chemistry. Students should have a deep knowledge of the correct meaning of the symbolic representations that appear in school and university manuals in order to avoid misunderstandings and a meaningless learning of the discipline.

The aim of the present work is to analyse two important historical examples: the three-dimensional representations of tetrahedral carbon, proposed by van't Hoff and Le Bel 150 years ago to describe the stereoisomerism of organic compounds, and the geometry of metal complexes introduced by Werner in 1893.[1-3] This work investigates in detail the way in which these three-dimensional representations were received and presented in school and university textbooks, published in Italy and abroad in the late nineteenth and early twentieth centuries, before the introduction of techniques of structural investigation such as X-ray crystallography.

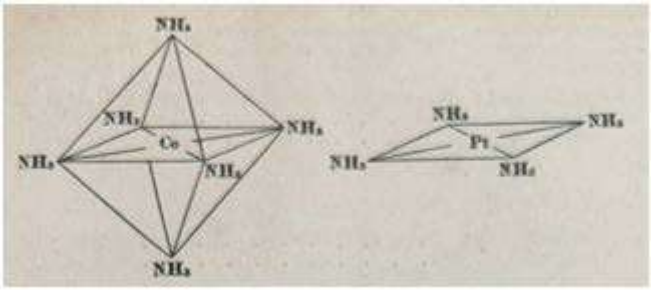

Figure 1: Representation of coordination geometries of metal complexes.[4]

Computing in Class for Chemistry Teaching and Learning

Laura Orian,[a] Leonie Lieber,[b] Nicole Graulich,[b] Giulia Licini[a]

[a] *Dipartimento di Scienze chimiche Università degli Studi di Padova Via Marzolo 1 35131 Padova (Italy)*

[b] *Justus-Liebig University Gießen, Institute of Chemistry Education, Heinrich-Buff Ring 17, 35392 Giessen (Germany)*

In the last two decades, computers have gained increasing importance in almost of all aspects of our life, including education. At different levels, STEM disciplines can benefit of computer support, ranging from presentations and lectures, data analysis, code development, self-evaluation and examination, but also modeling, simulations and visualization and, more recently, artificial intelligence tools. Our interest is focused on the use of computer modeling, i.e., calculations and simulations, in chemistry teaching and learning. Several cases are presented and discussed, including activities developed and organized in the secondary school classes in the framework of Piano nazionale Lauree Scientifiche Chimica [1] and PNRR Orienta [2].

A recent project, including tasks of organic chemistry designed for bachelor students and proposed to the third-year students of the Chemistry degree in Padova, is also reported. This project uses the idea of creating cognitive conflicts to engage students in working with computational data to derive claims about structure-property relationships. The qualitative analysis provides insights into the role of computational chemistry for understanding fundamental chemical concepts.

How Science on Stage contributes to improving STEM education

Paola Ambrogi
Consiglio Direttivo della Divisione di Didattica
paola.ambrogi2206@gmail.com

Science on Stage Italy1 (SonS It), to which the Italian Chemistry Society cooperates through its Didactic Division, is part of Science on Stage Europe2 (SonS Eu) an international network of 35 nations for the dissemination of best practices in Science, Technology, Engineering, and Mathematics or STEM education. STEM permeates and moulds a great part of our lives and STEM skills are crucial to take a critically active part in society and make informed decisions with responsibility and autonomy. Chemistry, physics, biology, astronomy, mathematics, technology, and earth sciences, to quote some of the STEM components the students face through the curricula, contribute to the education of future citizens. The Italian Ministry of Education and Merit, in 2023, released guidelines for STEM education3 stressing its importance at every school level.

The aims of SonS are the promotion of quality STEM education and the enhancement of students' interest in STEM by promoting teachers' professional development. One motto of Science on Stage states: "*Teachers make the difference*". SonS offers professional development based on the exchanges of best practices "*from teachers to teachers*". Every year the activities of SonS reach approximately 100,000 teachers in different countries members of the network offering them the possibility of meetings, professional enrichment, and exchange of effective and useful teaching practices. SonS offers teacher training and releases teaching materials. Its best-known activity is probably the biennial European Science on Stage Festival. The 13th edition will take place from 12-15 August 2024 in Turku, Finland, attended by 450 teachers of primary and secondary schools from all over Europe. During the Festival, the participants who won a national selection will present the most creative STEM ideas at stands, in workshops or highlight sessions, and on stage. The eleven Italian projects that will be present in Turku, have been selected at the Italian SonS Festival, which took place in September 2023 at Città della Scienza in Naples.

This communication reports on a short history of SonS, its activities and the outcomes of the last European SonS Festival, in which Italian delegates will present several innovative Chemistry-based projects.

Since 1984, Società Chimica Italiana (SCI), to promote the dissemination of basic chemical culture and support and enhance the overall growth path of girls and boys, has organized the "Giochi della Chimica", competitions aimed at Second Degree Secondary Schools [1]. Starting from 2024, the "Giochi della Chimica" has been organized into two competitions: the "**Individual Competition**" and the "**Team Competition**" with a total of more than 35,000 participating students and 800 schools from all over Italy.

The individual competition is divided into 3 categories. *Class A* involves the participation of students of the first two years of Second Level Secondary Schools; *class C* is dedicated to students of the following three years of Technical Institutes on Technological sector (Chemistry, Materials and Biotechnology); *class B* is reserved for all the other students of the last three years of Second Level Secondary Schools. For each class, the competition includes three phases: i) ***Institute Phase***, consisting of a unique national competition held in all participating Secondary Schools; ii) ***Regional Finals***, performed in Universities of each region; iii) ***National Final***, reserved to the best 100 students at regional and national level. In the 2024 edition, for the first time the team competition has been also organized, where Second Degree Secondary Schools can participate with teams made up of 4 students.

Questions and problems for both competitions are elaborated by a Questions Working Group, involving delegates of SCI Divisions, based on a dedicated Syllabus. Such Syllabus has been prepared by the National Organizing Committee of "Giochi della Chimica", with the collaboration of the Chemistry Teaching Division of SCI, starting from the National Guidelines for the lyceum and technician and professional high school and the Guidelines for teaching civic education.[2, 3]

The most talented students who participated in the National Final of the Individual Competition are selected by National Organizing Committee for participating in the Italian delegation of International Chemistry Olympiad (IChO). The training of these students is conducted by experts of different fields of chemical sciences and includes theoretical preparation and laboratory practice according to the topics of the "Preparatory Problems "published on the IChO website [4].

The present communication will present and analyze the results obtained, starting from the gender and age distribution of the participants, then moving on to the type of questions proposed in the competition sessions and their respective answers.

I Giochi di Avogadro: Analysis of an Experience in Promoting Chemical Culture in First Degree Secondary Schools in Italy

Alessandro Abbotto,[a] Paola Ambrogi,[b] Sabrina Donghi,[c] Luigi Falciola,[d] Roberto Fattorusso,[e] Alice Severi,[f] Margherita Venturi[g]

[a]Università di Milano-Bicocca, Milano; [b]"IIS L. Nobili", Reggio Emilia (retired); [c]"I. C. Galvani"- Scuola Secondaria di I grado, Milano; [d]Università di Milano, Milano; [e] Università della Campania "L. Vanvitelli", Napoli; [f] "ISIS Follonica" - Scuola Secondaria di II grad, Follonica (Gr); [g] University of Bologna, Bologna
sabrina.donghi1@gmail.com

Since 1984, the Società Chimica Italiana (SCI), to promote the dissemination of basic chemical culture and support and enhance the overall growth path of girls and boys, has organized "I Giochi della Chimica", competitions aimed at Second Degree Secondary Schools. The achievements of the latest editions have initiated, within the SCI, a reflection on the importance of the medium of the Giochi to involve new actors (be they students or their teachers), also with the aim of conveying a more modern and captivating vision of the discipline, often experienced only in its most mnemonic aspects and little connected with everyday life. Therefore, for the academic year 2023-2024, with the patronage of Ministero dell'Istruzione e del Merito (the Ministry of Education and Merit), SCI has decided to also address the first cycle of education and the national competition called "I Giochi di Avogadro" was proposed and organized.[1] Participation was open to all students attending the second and third classes of First Degree Secondary School. The first edition involved 14 regions for a total of over 1700 students. There were two computer-based competition phases. The first one, at the school level, which included 20 multiple-choice questions to be completed in 45 minutes, and the national final, in which the top 4 students from each school participated, with 30 multiple-choice questions to be completed in 60 minutes. The questions for both competitions were developed based on a framework elaborated in light of the National Guidelines for the curriculum of the first cycle of education (D.M. 254/2012 of the Ministry of Education, University, and Research), the Guidelines for teaching civic education (Attachments A and B to D.M. n. 35/2020 of the Ministry of Education), reflections carried out within the National Organizing Committee of Giochi di Avogadro, and shared experiences in the journal "La Chimica nella Scuola" (Chemistry in School). The communication will present and analyze the results obtained, starting from the gender and age distribution of the participants, then moving on to the type of questions proposed in the two competition sessions and their respective answers.

Serious games on chemistry and sustainability for schools and the citizens

F. Deganello,[a] M. L. Testa,[a] C. Aliotta,[a] M. Russo,[a] A. Ienco,[b] C. D' Errico,[c] V. Grasso,[c] A. Torreggiani [d]

[b]*Consiglio Nazionale delle Ricerche, ICCOM, Via Madonna del Piano 10, Sesto Fiorentino, Firenze*
[c]*Consiglio Nazionale delle Ricerche, IBE, Via Madonna del Piano 10, Sesto Fiorentino, Firenze*
[d]*Consiglio Nazionale delle Ricerche, ISOF, Via Gobetti 101, Bologna*
francesca.deganello@cnr.it

Sustainability education may be challenging due to the complexity of the matter that relies on multidisciplinary and interdependent knowledge.[1] Serious game could be a successful methodology to educate a broad audience on sustainability issues. As a continuation of our work on chemistry dissemination[2], here, we present three educational and ludic activities, based on serious games, designed for schools and the citizens, with the aim of increasing interest towards Chemistry and Sustainability.

Figure 1: The serious games: a) "Verso la sostenibilità…e oltre", b) "Celle a combustibile a ossidi solidi: il puzzle"; c) "Libri in Tavola"

In the board game called "*Verso la sostenibilità…e oltre*", participants are engaged by answering question cards featuring multiple choices to learn some key concepts about chemistry and sustainability while playing. The 3Dpuzzle called "*Celle a combustibile a ossidi solidi: il puzzle*" is crafted from scraps and waste-derived components. Participants have some time to study the puzzle image and the technical information required to correctly assemble the device as fast as possible. Through this activity participants can learn what a solid oxide fuel cell is, its basic components, and their primary roles within the cell. In the interdisciplinary challenge called "*Libri in Tavola*" participants need to place each book title into the right position on the EuChemS periodic table of critical elements[3]. Depending on the audience, three different difficulty levels are proposed. Following each participant's response, an experiment, a technical information, or a curiosity is shared and explained in association to the chemical element.

The National Chemistry Project of the Piano Lauree Scientifiche

U. Cosentino

University of Milano-Bicocca, Piazza della Scienza 1, 2026, Milano, Italy
ugo.cosentino@unimib.it

The Piano Lauree Scientifiche (PLS) is a plan of the Ministry of University and Research aimed at promoting enrollments in scientific degree courses, reducing university dropouts, improving the careers of university students, and the professional growth of the School's teachers Upper secondary [1].

All 32 Italian universities where there is a course of study in class L-27 Chemical Sciences and Technologies participate in the PLS National Chemistry Project [2].

In the imminent prospect of the decrease in high school students who will enter the university path due to the demographic decline, both the theme of orientation and that of reducing dropouts and improving the careers of our students are of great importance.

This contribution will present the work carried out in the first year of the project on the topic of the transition of students from secondary schools to university, illustrating the intervention strategies developed in the field of orientation and the reduction of dropouts and improvement of careers.

DID-OR-012

Laboratory activities of the PLS Chemistry: an opportunity for teachers and students.

M. Funicello

Dipartimento di Scienze, Università della Basilicata, Via Ateneo Lucano 10, 85100 Potenza

maria.funicello@unibas.it

For many years now, PLS has offered teachers and students in the three-year period of secondary school the opportunity to practically try their hand at various chemistry topics. The aim that has accompanied these activities since its inception is both to bring out scientific vocations in students (in our case particularly in the chemical field) and to contribute to the training of science teachers with new teaching proposals.

The common thread in the PLS Chemistry activities of the current academic year was "The colors of chemistry" and was divided into three laboratory activities which involved different disciplines present on site. In this communication will be discussed the educational ideas offered as part of the project and the students’response.

DID-OR-013

Should I enroll or not? A profile of freshmen in Chemistry and Industrial Chemistry undergraduate courses in Italy and analysis of the impact of the activities of the "Piano Lauree Scientifiche" on university study course enrollments.

Oreste Tarallo[a], *Silvia Galano*[b], *Italo Testa*[b]
(a) Department of Chemical Sciences, (b) Department of Physics "E. Pancini"
University of Naples Federico II, Complesso Universitario di Monte Sant'Angelo, Napoli (Italy)
oreste.tarallo@unina.it

The decline in enrolments in chemistry-related degree courses observed internationally is a matter of great concern, as it could lead to a loss of expertise and competitiveness in an extremely important field for both research and productive system[1]. For many years, several EU countries have been implementing orientation actions for high schools' students aiming at guiding them towards a more conscious choice of university studies, with particular emphasis on STEM areas. In this framework, the Italian "Piano Lauree Scientifiche"[2] - Chemistry Area (PLS-Chem), for two decades now, has played a leading role, implementing numerous activities aimed at high school students to introduce them to Chemistry oriented degree courses, with particular reference to those in Chemistry and Industrial Chemistry.

In this context, during 2023, a questionnaire aimed at investigating the reasons underlying the choice of their university study course has been administered to 1163 freshmen (44.3% female students) enrolled in Degree Courses in Chemistry or Industrial Chemistry of 21 Italian Universities. The questionnaire employed various psychometric scales to examine the motivations for the university choice, the attitude towards the discipline, the awareness of a generic "scientific" disciplinary identity, or of a specifically chemical" one. To estimate the impact of the activities of the PLS-Chem on the choice of the university study course, the questionnaire also asked which extracurricular activities the student had participated in and how much the activities had influenced their subsequent choice.

The results show that the motivations that most led the interviewed freshmen to enrol in the degree course in Chemistry or Industrial Chemistry are "*interest and passion for the subjects covered by the course*" (mean = 3.80/5), "*desire to understand the world around me*" (3.79/5), and "*propensity towards the subjects covered by the course*" (3.71/5), thus indicating a strong attitude toward the discipline. On average, freshmen demonstrate a significantly higher attitude towards chemistry than perceived self-efficacy (4.22 vs. 3.50, $p < .001$) and a significantly higher "scientific" disciplinary identity than "chemical" identity (3.81 vs. 3.67, $p < .001$). The impact of PLS-Chem activities was particularly significant: although only 26% of freshmen who responded to the questionnaire participated in PLS-Chem labs, for 73% of these, such participation was "very important" in the degree choice. Students who participated in PLS activities seem to have a higher chemical identity (3.80 vs. 3.62 of non-participants, $p < .001$), suggesting that PLS-Chem activities develop in students a greater self-perception as "future chemists". This contribution will present in detail the profiles of freshmen and discuss the correlations with the participation in the activities of PLS-Chem.

From the periodic system to the recognition of carbohydrates

P. Fonte
Patrizia.fonte@tin.it

"The Periodic System" by Primo Levi, which represents a key to understanding the periodic system, table of elements. Our guys reviewed the text in an original way, through a podcast. Contents of the podcast: We are chemists, we must not surrender to incomprehensible matter. This is why we are here, to make mistakes and correct ourselves, to take hits and return them. The profession of chemist teaches us that by making mistakes we learn and improve. Making a mistake in an improvised electrolysis experience, Levi guides us through a reflection on the importance of hydrogen, the same one that burns in the sun and stars. Nature is immense and complex, but it is not impervious to intelligence. Chemistry is not an abstract subject, because it sets our reasoning in motion, both in the laboratory and in everyday life. Primo Levi talks about his first falling in love, his teenage life and his relationship with his work colleagues. Experimenting helps us analyze and predict the effects of our actions. Just as carbon, such a simple element, can be transformed into valuable and precious substances, in adverse situations we have the ability to adapt and find beauty in our environment. Chemistry serves to awaken consciences in the dark and sad context of World War II and the Holocaust. Doctor Müller was head of the chemical laboratory at Auschwitz, where Levi also worked. Müller was considered the redeemer of Nazism, he was described as a monster, but Levi knew the human side of him. At the end of the war Müller called Levi, saying he wanted to meet him; he accepted but 8 days later he received the announcement of his death. "I didn't feel capable of representing the dead of Auschwitz, nor did it seem sensible to me to see Müller as the representative of the executioners." The soft and delicate zinc, so succumbing to acids, behaves very differently when it is very pure: then it stubbornly resists attack. Two philosophical consequences can be drawn from this: the praise of purity that protects from evil; the praise of impurity that generates changes, that is, gives life. Impurities are therefore necessary, dissent and diversity are needed, but fascism does not want them, it prohibits them and for this reason you are not a fascist; he wants everyone to be the same and you are not the same. We must not conform to fashion or bad habits, we must not be alienated by prejudices, but be ourselves even when it means not being taken seriously. Impurities make us feel free. Here's what Levi says when talking about his friendship with Sandro: the diversity of our origins made us rich in goods to exchange, like two merchants who meet coming from remote and unknown areas. Our activity is part of another of an experimental nature, starting from the Chapter relating to Carbon:1 "Now our atom is inserted: it is part of a structure... a ring structure, an almost regular hexagon, which however is subject to complicated exchanges and equilibria with the water in which it is dissolved; because it is now dissolved in water, or rather, in the sap of life....It has become part of a glucose molecule... which prepares it for first contact with the world.Recognition Carbohydrates2

Laboratory activity activity 1.Compilation of the table relating to the general information of some commonly used carbohydrates, assisted by 'tasting' and solubility tests; activity 2. Bread making with different types of yeasts and flours and construction of the leavening curve; activity 3. Separation of gluten and starch from a dough of water and wheat flour; activity 4. Colorimetric test for the evaluation of the presence of starch in foods; activity 5. Colorimetric test for the evaluation of the presence of proteins in foods.

Using Interrupted Case Studies to Enhance Argumentation Skills

Salete Linhares Queiroz[a], Raíla Raiany de Sá Almondes[a], Pablyana Leila Rodrigues da Cunha[b]

[a]*University of São Paulo, São Carlos, São Paulo, Brazil*
[b]*Federal University of Ceará, Fortaleza, Ceará, Brazil*
salete@iqsc.usp.br

Fruits mainly comprise living tissues and are characterized by a high level of water availability, which makes them highly perishable. Edible film and coating applications show promising results in increasing the shelf-life, as well as preserving their quality. This study reports on the implementation of three interrupted case studies[1], and the use of edible film and coatings in fruit conservation. The case studies, entitled 'The delicious crimson grapes', 'Mr. Jairo´s pears' and 'Guavas, edible films and minerals', were undertaken by undergraduate chemistry students. Implementing the case study as a teaching strategy focused on students utilizing data provided in case studies to formulate a written scientific argument in defense of the best solution for the cases. This work utilizes the Leitão's framework[2] to investigate the students' written arguments regarding solutions for the case studies. Leitão[2] outlined a unit of analysis, which is meant to capture how dealing with opposition affects the speakers' position. The unit of analysis includes three basic elements: argument (justified claim), counterargument and reply. According to Leitão[2], there are three types of replies: dismissing the counterargument (speakers find themselves able to dismiss a piece of information a counterargument conveys), local agreement (speakers normally start by stating their agreement with the content of a counterargument and then they keep defending their previous position by adding to it some new support), integrative (integrating both positions and rejecting the initial view). The reply is made up of points of view and justifications. The research questions investigated in this study was "What are the types of replies in the student's written texts when faced with counterarguments presented by the case studies characters about the best edible films to use in each problem situation? The results show that the majority of the counterarguments was dismissed. To do this the students took a position regarding counterarguments, being forced to revise them carefully. Almost all the students effectively used evidence to formulate their replies. Indeed, students cited data by linking specific inscriptions (e.g., graph representing changes in weight of grapes over time, tables presenting information on various properties of fruit after edible coatings/films, etc.) to their argumentative texts. In conclusion, using an interrupted case study method facilitates written argumentative texts based on using evidence. FAPESP (Grant 2023/01936-1); CNPq (Grants 304974/2020-0 and 420662/2023-5).

Paving the way to a sustainable stationary energy storage system: The development of aqueous zinc-ion batteries

F. La Mantia[a,b]

[a]*Universität Bremen, Bibliothekstraße 1, 28359 Bremen, Germany*

lamantia@uni-bremen.de

In the last few years, aqueous Zn-ion batteries have attracted a great attention as energy storage devices for stationary applications, thanks to their high safety and environmental friendliness, together with low toxicity and costs[1]. Their working principle (see Figure 1) is based on shuttling of zinc ions in solution from the negative to the positive electrode (discharge) and vice versa (charge). Although promising, still several challenges, which limit their cycle life and therefore their commercialisation, remain unsolved.

On the negative electrode side, the major problems are related to: (I) the hydrogen evolution reaction occurring in parallel to the Zn deposition reaction[1,2], and (II) the formation of isolating layered double hydroxides, which block the surface of the zinc[3].

On the positive electrode side, Prussian blue analogues (PBA) show extremely promising performances thanks to their excellent rate capability, which is strongly required in the case of stationary applications, and high operating potential, leading to competitive energy densities of the final battery[1]. However, they suffer from a relatively short cycle life, mostly related to unwanted changes in their structure upon cycling[2].

Here, an overview of some recent strategies adopted to optimise the cycle life of both metallic zinc negative electrodes and PBA positive electrodes will be shown, emphasizing how, by understanding the fundamental mechanism leading to degradation, it was possible to specifically operate on them in order to enhance the cycle life of the battery from 20 to 1000 cycles.

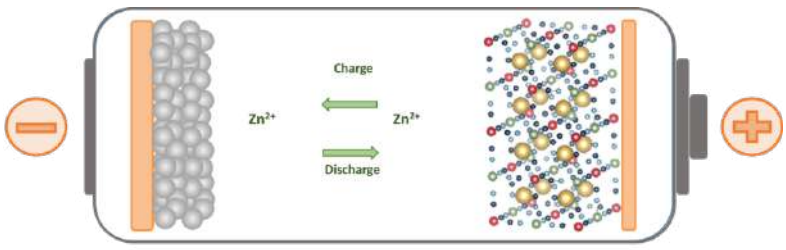

Figure 1: Working principle of an aqueous zinc-ion battery.

Addressing key challenges in the development "beyond Li-ion" chemistries

Giuseppe Antonio Elia

GAME Laboratory, Department of Applied Science and Technology (DISAT), Politecnico di Torino, Corso Duca degli Abruzzi 24, Torino 10129, Italy
National Reference Center for Electrochemical Energy Storage (GISEL) - INSTM, Via G. Giusti 9, Firenze 50121, Italy
e-mail presenting author: giuseppe.elia@polito.it

Renewable energy production is characterized by intermittent power output and requires large-scale applications to improve energy storage capability (currently, less than 1% of the electrical energy production can be stored). Developing low-cost and environmentally friendly electrochemical storage systems characterized by high performance is of fundamental importance for a sustainable energy economy. The currently most mature battery technology is the lithium-ion battery, which is considered one of the most appealing candidates for power sources for electric vehicle applications. However, the large-scale application of lithium-ion batteries is currently under discussion due to the limited lithium and certain transition metals such as Co and Ni resources. Several other metallic anodic materials such as sodium, potassium, calcium, magnesium and aluminium [1-3], characterized by a higher abundance of lithium, have been considered suitable candidates for electrochemical storage devices in replacing lithium systems. Notably, significant efforts are being devoted to understanding and addressing key challenges in developing these so-called "beyond Li-ion" chemistries, and substantial insights into their storage and failure mechanisms have been obtained over the past few years thanks to advanced characterization and computation/modelling techniques. An overview of our activity in "beyond Li-ion" batteries field and an evaluation of the capability of this technology will be presented. [4–9]

Since their serendipitous discovery in 2004, carbon quantum dots (CDs) gained increasing interest from the scientific community because of their outstanding optical properties, which make them suitable for a plethora of applications, going from sensing to bioimaging, optoelectronics, photovoltaics, etc., as an alternative to the classic chalcogenide-based quantum dots. Their production is simple, low-cost, sustainable, and could employ precursors recycled from biomass and biowaste. Furthermore, through the modulation of the synthesis parameters, it is possible to produce CDs with desired properties, and a recent work by Patel et al.[1] gives an interesting example of the possibility of modulation of the properties of CDs for theranostic applications through the proper setting of the reaction parameters. Starting from those considerations, here we aim to give an insight into the effect of the synthesis parameters on the optical, chemical, and structural properties of blue-emitting CDs. We selected the hydrothermal approach owing to its feasibility for future large-scale industrial applications, and we employed eco-friendly precursors that could be obtained from biowaste, like citric acid (CA) and glucose (Glu) as carbon sources, and urea as both nitrogen source and base (Figure 1). Through spectroscopic, electrochemical, and structural investigations, we studied and discussed the effects of the reaction parameters considering the formation of graphitic nitrogen *N*-oxides[2] and their role.

The use of intact, metabolically active, photosynthetic bacteria for the development of sustainable photoelectrodes allows converting solar energy into electrical energy without requiring long purification processes of the biocatalysts.[1] To this end, the photoinduced electrons generated following the charge separation event must be transferred from the photosynthetic apparatus located inside the bacterial membrane to the electrode surface. Our group recently developed a sustainable approach to obtain a redox-adhesive polydopamine matrix that simultaneously facilitates the photoinduced extracellular electron transfer, with a 5-fold enhanced photocurrent production, while maintaining the bacteria in close contact with electrode surfaces. [2] Additionally, we recently developed free-standing biobased electrodes that allowed enhancing bacterial colonization and a further 18-fold increase in current generation from the biobased electrodes.

Herein, the possibility to employ these biohybrid photoelectrodes for the on-line, early monitoring of different contaminants is presented. The high versatility of the photosynthetic organism utilized (i.e., the purple bacterium *Rhodobacter capsulatus*) allowed studying the influence of both organic and inorganic contaminants on the obtained photocurrent. Electrochemical and spectroscopic investigations revealed a complex interaction between bacterial cells and the contaminants, paving the way for the use of these biohybrid systems as self-powered biosensors.

As the market for energy storage system expands, safety and production sustainability of lithium ion batteries (LIBs) have become new concerns in addition to battery performance. Many battery components are synthesized from critical raw materials (CRMs) that are at risk of depletion, and alternative materials based on highly abundant and readily available elements need to be developed. Lignocellulose, composed of cellulose, hemicellulose, and lignin, is one of the most abundant and environment-friendly feedstocks. Their use is expected to be an effective way to reduce the energy consumption and negative environmental impact during the production of batteries.

In the present study, battery components have been developed based on commercially available Kraft lignin, sodium carboxymethyl cellulose (CMC), the lignin extracted from poplar wood, and cellulose extracted from pistachio shells. Two types of lignin were utilized to synthesize hard carbon (HC) through hydrothermal treatment at 250 °C with the presence of citric acid and/or pyrolysis at 600 °C. The synthesized materials were examined as the anode material for LIBs and found to exhibit a specific capacity around 200 mAh/g at C/10.

In the case of cellulose, it was investigated as a binder for $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO). CMC is frequently utilized as a binder in aqueous electrode fabrication processes. In our study, cellulose extracted from biomass has been mixed with CMC in different ratios. A highest capacity of 125 mAh/g at 1C was obtained when the binder composition was cellulose:CMC=2:8 w/w, which was higher than the specific capacity of LNMO having solely CMC as the binder. By increasing the concentration of cellulose, the capacity value decreased, which was probably due to inhomogeneity of electrodes caused by poor solubility of cellulose in water.

Development of cellulose-based separator was also attempted. However, due to amphiphilic property of cellulose, the membrane being able to absorb traditional electrolytes was not obtained. To solve this issue, two different types of membranes were prepared: one is composite membranes based on poly(ethylene oxide) and CMC, and the other is CMC-membrane with an enhanced porosity prepared by lyophilization. Both membranes were soaked in 1M $LiPF_6$ in ethylene carbonate and dimethyl carbonate 1:1 v/v mixture and examined in Li|LNMO cells. The porous CMC-membrane allowed the cell showing a discharge capacity above 100 mAh/g at C/20. Combining all these results, it is possible to design LIBs based on highly abundant and easily accessible materials, enabling more sustainable production of LIBs.

mattia.longo@polito.it

The continuous increase in energy consumption worldwide has catalysed the attention of research players on the production of safer and more efficient energy storage systems. A possible strategy to reduce the leaking of liquid electrolyte is the employment of solid or semi-solid polymer electrolytes. Gel polymer electrolytes (GPEs) present the best compromise between mechanical and electrochemical properties, as well as an improvement of the cell safety[1]. The UV mediated radical polymerization is a common GPE fabrication strategy due to its low reaction time and economic advantages. However, the polymerization can only occur in the presence of an initiator, and is hindered by oxygen, thus impeding the industrial scale up of the GPEs production. In this work, an UV mediated thiol-ene photopolymerization, employing polyethylene glycol diacrylate (PEGDA) and two different thiols (trimethylolpropane tris(3-mercaptopropionate) - T3 and pentaerythritol tetrakis(3-mercaptopropionate) - T4) as oligomer and crosslinkers, respectively, was carried out in a liquid electrolyte solution (1 M LiTFSI in EC/DEC) to obtain a self-standing GPE (noted as PT3 and PT4). The thiol-ene polymerization mechanism enables an easily up-scalable, fast, cheap and environmentally friendly GPE production, eliminating the need for a photoinitiator and an inert atmosphere[2]. A comparative study between the properties of membranes cured in an inert Ar atmosphere (AR), as well as GPEs produced in a dry atmosphere (DR), was performed. All the produced GPEs present an excellent room temperature ionic conductivity above 1 mS cm^{-2}, as well as a wide electrochemical stability window up to 4.5 V. The full cells were tested to evaluate the rate capability of the GPEs comparing between membranes produced as self-standing and subsequently sandwiched between anode and cathode (referred to ex-situ), and GPEs directly cured on the cathode surface (referred to as in-situ). The assembled cells display stable cycling, reaching a specific capacity up to 140 mAh g^{-1}, when tested at a current density of C/10 for 300 cycles.

Characterization of hybrid DMSO-aqueous electrolytes for non-flammable lithium-ion batteries

I. C. Pellini,[a] E.Polato,[a] S.Khalid,[a] R.Ruffo[a,b]

[a]*Department of Material Science, University of Milano-Bicocca, via Roberto Cozzi 55, 20125*

The most commonly used electrolytes in lithium-ion batteries (LIBs) present serious problems of flammability and environmental impact, due to the organic solvents that are employed. In order to overcome this problem, one of the most promising current research lines about LIBs electrolytes is focused on the replacement of these solvents with water-based electrolytes[1]. Unfortunately, water present a narrow electrochemical stability window (ESW) of only 1.23 V, which limits the maximum potential that can be reached by a full cell and the choice of the possible electrodes that can be employed. In the last years, two different strategies were adopted with aim of expand di ESW of water: (I) the use of high amount of salts, up to a superconcentrated solution and (II) the addition of some non-flammable solvents. The addition of salts causes molecules to get caught in the solvation shells of ions, hindering their reactions[2], while the solvent can make it more difficult for the water molecules the access to the electrodes, where the decomposition reaction occurs, giving H_2 and O_2. Moreover, the right choice of these two component can promote some reaction of the electrolyte, from which the Solid Electrolyte Interphase (SEI) layer is generated. This layer is able to protect the electrolyte from degradation reaction and increase in this way the durability of the full device.

The non-flammable co-solvent chosen for this work is dimethyl sulfoxide (DMSO), that is highly miscible with water, quite cheap and low toxic[3]. Instead, the ideal salts that can promote the SEI layer generation are those containing F atoms, because they decomposes giving LiF, that is on of the components of the layer.

The main focuses of this work are the physicochemical and electrochemical characterizations of aqueous electrolytes made of superconcentrated solution of fluorinated salts, dissolved in a mixture of water and DMSO in a 1:1 molar ratio. In order to complete the electrochemical studies, a full-cell device was built, by using $LiMn_2O_4$ as the positive electrode and $LiTi_2(PO_4)_3$ as the negative electrode.

alessandro_piovano@polito.it

Li- (LIBs) and Na-ion batteries (NIBs) play a crucial role as energy storage devices for electric vehicles and smart grids. It's widely recognized that all the components contribute to the overall performances, not only the active materials, but also conductive carbons, current collectors, electrolyte separators and binders, so that the optimization of each component is likely to result into huge economic and environmental benefits [1].

In this context, we explored the possibility of repurposing in batteries the recycled polyvinyl butyral (PVB) from post-consume laminated glasses (from automotive and construction) that cannot be reused in glasses because of degraded optical properties. Indeed, nowadays most of the PVB collected after disposal is incinerated or landfilled, causing tons of losses every year [2].

Two strategies were pursued: either using recycled PVB as binder in the electrodes composition or transforming it into a membrane to be used as electrolyte separator.

In the case of PVB as binder, we investigated the electrochemical and structural properties of polymer blends of PVB with standard binders, as polyacrylic acid (PAA) and poly(vinylidene fluoride) (PVDF), producing hard carbon (HC) anodes for both LIBs and NIBs.

On the other side, the membrane preparation required the conversion of PVB into a cross-linked polyurethane by reaction with a diisocyanate, controlling the morphology of the produced membranes by changing the conditions of the coagulation bath used for their casting [3]. Many parameters must be considered for the preparation of an optimal separator, including electronic insulation, low ionic resistance, mechanical stability, chemical resistance to degradation, wettability and uniform thickness.

Preliminary results are highly encouraging and pave the way to the development of more sustainable separators and binders from waste products for safe, low-cost energy storage devices.

Designed Solutions to Face the Bigger K-ion Challenge in Potassium Organic Batteries

S. Trano,[a] D. Mantione,[b] G. Lingua,[b] M. Armandi,[a] C. Francia,[a] D. Mecerreyes,[b] F. Bella[a]

Sabrina.trano@polito.it

Our world is grappling with an energy transition vital for planet survival. For this reason, Li-ion batteries (LIBs) have reached unprecedent attention from the research community and the global market. Nonetheless, lithium scarcity prevents LIBs from covering the entire demand of storage at global scale. As a result, potassium-ion batteries (PIBs) are strongly emerging as a viable technology for stationary storage and large-scale production for its features: abundancy, low costs, the closest redox potential to Li, the smallest Stokes radius, and compatibility with aluminium current collector at every voltage. Nonetheless, desolvated K-ions show the biggest radius, arising some challenges: once intercalated in rigid inorganic electrode material structures, K-ion may cause their distortion, resulting in drastic capacity decay, like in commercial graphite and Prussian blue. And yet, the latter two are still the best option as anode and cathode materials for PIBs.

From this starting point, our group has focused on possible solutions to address these issues in both anode and cathode, keeping always into account the imperative of lower impact PIBs production since they are meant for the large-scale. Indeed, here we report a highly porous carbon material, prepared from lignin and potassium carbonate, with X-Ray diffraction evidences of no stacking of graphene layers, and thus no limited interlayer volume. Its disordered structure allows the K-ions to insert in the carbonaceous anode without causing any damage to the structure, but instead, upon cycling, they may cause its rearrangement to a structure perfectly suitable for K-ion hosting. This behaviour is electrochemically translated in an increase of capacity for the first cycles and null decay of capacity, the values of which are comparable to commercial carbon blacks[1].

On the cathode site, in potassium battery field very few satisfying options have been published to now, due to the challenging bigger K-ions. Organic electrodes are not-critical raw materials-based, cheap, environmentally friendly, tunable, and - above all – their intrinsic mechanical flexibility can lead to the reversible and damage-free accommodation of large sized K-ions, resulting in stable PIB performance. Their biggest drawback is the high solubility in organic solvents. In consideration of this, stable aminoxyl radicals like TEMPO have been investigated to exploit its tunability both as monomeric unit and polymeric materials, in pristine for and also functionalized in order to reduce its solubility in organic electrolytes. In our work, we also considered the effect of the amount of free radicals on the electrochemical properties, as well as the possibility to integrate the redox activity of an n-type material in a TEMPO-like-based electrode on an aluminium current collector.

Water electrolyzers based on Anion Exchange Membranes (AEMs) are the new frontier for green hydrogen production. This enable the use of platinum group metal-free catalysts and reduce the capital cost of hydrogen. Despite intensive research over the last decade the commercial use of AEMs is hindered by the poor alkaline stability of polymer electrolyte, lower conductivity compared to the Proton Exchange Membranes (PEMs) and non-trivial synthesis procedure. The poor alkaline stability is due to several degradation mechanisms. The main one is Hoffman elimination, which occurs in the presence of beta hydrogens with respect to conductive quaternary ammonium groups and leads to a decrease in ionic conductivity[1].

Recently, Olsson et al. discovered a new class of AEMs known as Poly(aryl piperidinium) (PAP)[2]. These combine a heteroatom-free aromatic backbone with the piperidinium group. The N,N-Dimethyl Piperidinium shows a longer half-life than any other quaternary ammonium grups. Stability in alkaline einvironment is due to the stiff six-members chair conformation that disfavour the Hoffman elimination process[3].

A simple approach for the production of AEMs is the functionalization of commercial polymers (e.g. PE, PP, PS ecc.). by radiative grafting[4] and chemical modification[5]. To the the best of our knowledge the effect of the average polymer molecular weight on functional properties of AEMs has been poorly investigated[6].

Inspired by the recent work of Olsson et al. on chemical grafting of polystyrene by superacid hydroxyalkylation[7] we investigated the effect of PS molecular weight variation on electrochemical and functional properties.

A strategy to atomically disperse the Fe-N-Cs active sites in the micro-mesoporous environment facilitating the mass transportation for oxygen reduction reaction (ORR) is presented. Herein, in-house prepared silica nanoparticles (ca. 70 nm) were functionalized with atomic Fe via amino ligands namely 3-aminopropyltriethoxysilane (APTES) and N-(2-Aminoethyl)-3-aminopropyltrimethoxysilane (EDTMS). The derived materials i.e SAFe (silica functionalized with Fe via APTES) and SEFe (silica functionalized with Fe via EDTMS) were then used as porosity templates, as well as an iron precursor with a potential to restrict the coalesce of Fe into metallic nanoparticles. Subsequently, SEFe and SAFe were impregnated with methylimidazole (carbon and nitrogen source). The achieved sludge after drying was then pyrolyzed for 1 h at 900 °C to develop the basic Fe-N-Cs structures (SEFe_M_P1 and SAFe_M_P1) followed by etching with HF solution to remove silica and produce porous structures (SEFe_M_P1A and SAFe_M_P1A). Lastly, samples were again pyrolyzed under a reducing atmosphere to confirm atomically dispersed active sites in the defect-rich graphitic frameworks (SEFe_M_P1AP2 and SAFe_M_P1AP2). Analyzing the ORR activities under acidic and alkaline conditions, it was witnessed that activity evidently enhanced as the synthesis steps proceeded. High surface area, atomically dispersed active moieties in the defective architecture along with the absence of undesired metallic nanoparticles gave rise to excellent ORR electrocatalysis of the final Fe-N-Cs samples. Therefore, SEFe_M_P1AP2 and SAFe_M_P1AP2 outpaced the other samples in terms of performance by realizing the uppermost onset potentials of 950 mV vs RHE and 965 mV vs RHE, respectively in 1 M KOH while 772 vs RHE and 808 mV vs RHE, respectively in 0.5 M H_2SO_4 while following an obvious 4 electron ORR route. Eventually, the alkaline exchange membrane fuel cells (AEMFC) were configured using them as cathode electrocatalysts and noted open circuit voltage (OCV) of 0.825 V for SAFe_M_P1AP2 and 0.845 for SEFe_M_P1AP2. Whereas the peak power densities came out to be 219 mW cm^{-2} (at 500 mA cm^{-2}) and 103 mW cm^{-2} (at 230 mA cm^{-2}) for the above-mentioned Fe-N-Cs, respectively. These findings emphasize the significant potential of employing an engineering approach to Fe-N-Cs synthesis to bolster progress in green energy production via fuel cells.

Near-infrared sensors for the determination of the state of charge in all-copper redox flow batteries

R.Petruzzelli[a], G. Lacarbonara[a] , C. Arbizzani[a]

[a]*Alma Mater Studiorum - University of Bologna, Dept. of Chemistry "Giacomo Ciamician", Via F. Selmi 2, 40126 Bologna, Italy*

Redox flow batteries (RFBs) are affected by the crossover of the active species, leading to electrolyte unbalancing and self-discharge. For this purpose, is fundamental to monitor the state of charge (SoC) during the RFB operation to recognize the need for rebalancing or restoring the electrolyte and prevent system failure[1]. UV/Vis/NIR spectroscopy is a suitable technique for real-time SoC monitoring. The development of sensors that could be integrated into the electrolyte reservoir, capable of detecting the oxidation state of species in solution is facilitated by the independence of absorption spectroscopy from temperature and electrochemical processes of the system[2,3].

In an all-copper RFB, the electrochemical conversion of Cu(I) to Cu(II) occurs in the positive half-cell and can be efficiently monitored by UV/Vis/NIR spectroscopy. The Cu(II) absorption spectrum is characterized by two prominent bands of different electronic natures. A ligand-to-metal charge transfer transition in the UV part of the spectrum is present, which strongly depends on the copper solvation shell and gives information about the Cu(II) chloro-complexes speciation. Meanwhile, a broad transition present in the NIR region can be assigned to Cu(II). In this transition, the chloride coordination can be ignored, and the magnitude of the absorption mostly depends on the Cu (II) concentration.[4]

According to the Lambert-Beer equation, NIR bands allow studying highly concentrated systems (up to 2M) by tuning b thickness thanks to the low molar extinction coefficient of Cu(II) in this region. In this work, the SoC monitoring system for both negative and positive half-cells with the NIR spectrophotometric monitoring of Cu(II) will be presented and discussed.

francesco.cazzadori@phd.unipd.it

Electrochemical Scanning Tunnelling Microscopy (EC-STM) has proven to be a powerful technique to study the electrocatalytic behaviour of molecular model catalysts for the "in situ" monitoring of single-atom sites and of the electrocatalytic process dynamic.[1] In fact, provided that the deposited molecules self-assemble on the ideal crystal substrate at the electrode-electrolyte junction, an EC-STM analysis can bring fundamental information regarding the electrochemical double layer.

Metal-substituted macrocycles have recently attracted a lot of attention due to their numerous applications spanning from electrocatalysis, molecular microelectronics, photoemission, and sensing. It is known that metal-substituted octaethylporphyrins deposited on Au(111) and highly oriented pyrolytic graphite (HOPG) substrates can be studied with EC-STM in aqueous electrolyte to characterize their self-assembling into ordered domains; plus, the interaction between the metal center and molecular oxygen dissolved in solution was proven to cause a change in the STM image profile measurable as a ΔZ in the molecular height, due to the coordination with the metal center of the porphyrin.[2,3] From volcano plot analysis of different transition metal octaethylporphyrins OEPs, chromium-based ones are placed in the strong-binding side of the plot, indicating that oxygen should poison the active site by forming a strong coordination bond with the metal center.[4] Chromium tetrapyridyl-porphyrin was observed on Ag(111) substrate with STM in Ultra High Vacuum conditions.[5] However, to our knowledge no chromium porphyrin was studied with EC-STM at the electrode-electrolyte junction.

Here, CrOEP was successfully synthesized from free-base H_2OEP and deposited on Au(111) and HOPG single crystal substrates to characterize the self-assembled molecular monolayers with EC-STM in 0.1 M $HClO_4$ electrolyte. The electrochemical response of the so formed Au(111)-monolayer interphase was evaluated by combining voltammetric and EC-STM measurements in Ar and O_2 atmosphere.

PHOTO-ELECTROCHEMICAL DETECTION OF EMERGING POLLUTANTS WITH TITANIA BASED ELECTRODES

D. Fumagalli,[a] V.Pifferi,[a] L. Falciola,[a]

[a]*Università degli Studi di Milano, Via Golgi 19, Milano*
daniele.fumagalli@unimi.it

Titanium dioxide is a widely used semiconductor known for its bio-compatibility and high photoactivity, which can be exploited for the preparation of photo-renewable surfaces.[1] The preparation of hybrid electrodes, combining TiO_2 with catalytic metal structures,[2] can further improve the properties of the devices, widening their range of application in the analytical chemistry field. Different procedures can be exploited for the synthesis of the materials: in this work, metal structures (gold and silver) were prepared both chemically and electrochemically, immobilized on conductive glass slides and then covered with a titanium dioxide layer via dip-coating in a TiO_2 sol.[3]

Electrochemical (EC) and Photo-electrochemical (PEC) characterization of such devices, performed mainly via cyclic voltammetry and electrochemical impedance spectroscopy, helped gain a better understanding of the complex relations between the TiO_2 sol aging time and the morphology of the layer, the interaction between the semiconductor and the metal structures and the stability of the electrodes.

Detection of the analytes (e.g. ciprofloxacin, cetirizine, bisphenol-A) was performed both via pulsed electroanalytical techniques (such as differential pulse voltammetry) and photo-electrochemical techniques, achieving in both cases good detection limits and selectivity. The combination of EC and PEC measurements allowed the realization of bimodal sensors able to achieve self-validation. Furthermore, the stability and photo-renewability of the electrode prove the device could be applied for in-situ monitoring of emerging contaminants in the environment.

elena.mariani@unifi.it

In contemporary galvanic industries, direct current electroplating stands as the prevailing technique. Nevertheless, the emergence of novel methods such as unipolar and bipolar pulse plating, enabled by modern electronics, introduces promising possibilities. Despite challenges in theoretical modelization and technological aspects, pulsed current finds practical application due to its capacity to influence electro-crystallization mechanisms, directly impacting the mechanical and physical properties of deposits[1]. By simply adjusting pulse amplitude and duration, control and enhancement of various deposit properties, including composition, thickness, grain size, porosity, and homogeneity, become achievable.

This work aims to thoroughly investigate the correlation between deposition parameters and deposit properties, integrating theoretical analysis with experimental evaluations. The focus lies on a process aiming to achieve products with comparable, if not superior, characteristics to current standards but with reduced metal thicknesses, crucial for fostering a more sustainable industry. In pulse electroplating, the electrodeposition of nanostructures hinges on two fundamental processes: nucleation rate and the growth of existing grains. Favorable factors induce a high nucleation rate (current density) and inhibit grain growth (through specific molecules)[2].

Notably, pulsed currents have demonstrated the capability to yield shinier and brighter films compared to steady currents, thereby enhancing deposition efficiency. Additionally, pulsed currents show promise in augmenting deposit characteristics. Conversely, bipolar currents exhibit remarkable homogeneity across the deposition area and demonstrate reduced susceptibility to edge effects. This research illuminates the potential of pulsed current deposition techniques in electroplating applications, paving the way for advancements in industrial processes[3]. By comprehending the effects of deposition parameters on deposit properties, we can stimulate innovation and optimization in electroplating practices, ultimately leading to improved product quality and performance across various industrial domains.

Environmental pollution poses a multifaceted challenge, endangering the well-being of ecosystems worldwide.[1] The scientific community is paying an increasing effort to address this pressing issue, particularly concerning water pollution for which new engineered materials have been designed, synthesized, and tested to enhance wastewater treatment processes.[2]

In this study, we describe an interesting application of Ni-hexacyanoferrate (Ni-HCF) nanocubes, synthesized through a co-precipitation method, aimed at removing metronidazole (MDZ) as the standard pollutant by means of a photocatalytic process. The photocatalytic activity of Ni-HCF toward MDZ was assessed in aqueous solutions under simulated solar irradiation, leading to a degradation as high as 94.3% of the target pollutant within a 6-hour timeframe.[3] We attribute this remarkable performance of Ni-HCF nanocubes to a higher ability in separating the charge carriers and to a lower resistance toward charge transfer, as confirmed by the electrochemistry.

Further investigation into the catalyst's stability and recyclability revealed exceptional performance, even after undergoing three cycles of reuse. This characteristic is crucial for potential applications in water remediation. Additionally, scavenger tests revealed that the active radicals involved in the photodegradation mechanism might predominantly be OH radicals.[3] These achievements highlight the possibility to combine the performance of an earth-abundant catalysts with a renewable energy source for environmental remediation, thus meeting the requirements for a sustainable development.

fiammetta.vitulano@unimi.it

In order to address environmental concern and contamination issues, numerous strategies have been developed to remove water pollutants, although it is still necessary to enhance their effectiveness against toxic and biorefractory organic molecules. Electrochemical reduction offers considerable advantages over conventional degradation methods. When applied to the wastewater treatment of harmful halogenated compounds, it can offer a double benefit, allowing the elimination of the pollutant and the recovery of the valuable halogen species. In this scenario, the electrochemical reductive dehalogenation of 3,5-dihalogenated derivatives of salicylic acid, chosen as model molecule, is examined in this study as a green technique that, through the cleavage of C-X bonds, makes the transformation products more biodegradable and less bioaccumulative.[1,2] Cyclic voltammetry (CV) was used to study the electrochemical behaviour of the halogenated compounds in aqueous system, comparing different cathode materials.

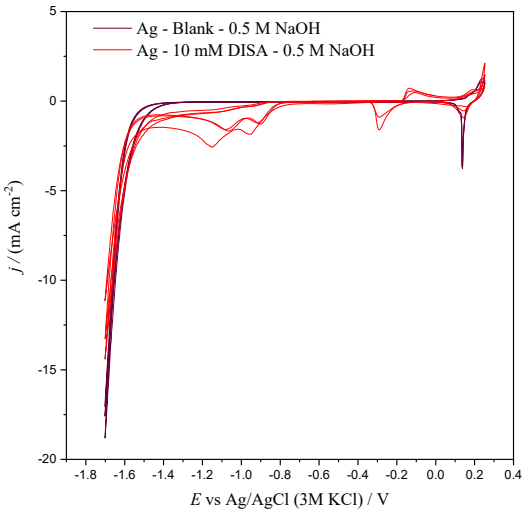

Figure 1: CV of 10 mM 3,5-diiodosalicylic acid (DISA) on Ag electrode in 0.5 M NaOH aqueous solution.

After identifying silver as the most promising cathode,[3] electrolysis was performed, both in batch and flow conditions. The results showed that reductive electrochemical dehalogenation is an efficient process, providing more insights into the mechanism of halogenated compounds degradation in reductive processes.

Plethora of gas sensing systems for environmental monitoring, food spoilage and non-invasive medical diagnostics have been developed so far[1,2]. Recently, carbonaceous-based sensors have attracted huge attention thanks to their unique properties giving rise to various nanocomposite materials. However, they still suffer from several problems concerning for instance the low sensitivity, which could be overcome by their coupling with metal oxides (MOS), and the scarce selectivity, especially in relatively high humidity environments as the human breath[1,2]. Besides, porphyrin-based macrocycles can play a dual role in gas sensing thanks to both their high chemical versatility and good electrical conductivity, especially when combined to MOS[3].

The present work is aimed at evaluating and comparing the sensing at mild temperatures (120 °C) of SnO_2 coupled with different porphyrins toward the sensing of acetone molecules, *i.e.* the breath biomarker of diabetes type 1. Specifically, zinc tetraphenylporphyrin (ZnTPP) and its perfluorinated derivatives were chosen[3]. Interestingly, the ZnTPP does not seem to give any significant response upon exposure to the analyte, whereas perfluorinated derivatives showed a boosted signal with respect to pristine SnO_2. In addition, the effect SnO_2/porphyrins weight ratio was explored (4:1, 32:1, 64:1). In all cases, 32:1 gave optimal performances also resulting in a detection limit of 200 ppb. Hence, aiming at unveiling the sensing mechanism, DFT calculations were performed. From preliminary results, we may infer that the sensing behavior of theses nanocomposites is mainly based on a balance between the number of accessible MOS states in the conduction band and the electron transfer from the porphyrin's HOMO to the CB of SnO_2. When SnO_2 is coupled to a system that has a high tendency to donate electrons (ZnTPP) a saturation of the accessible states occurs, so there is no room for electrons coming from the interaction with acetone molecules, resulting in the signal quenching. Conversely, when SnO_2 is coupled to perfluorinated porphyrins, that are less prone to donate electrons due to the fluorine presence, a lower number of carriers is injected, and acetone is more liable to interact with the MOS surface. Therefore, we believe that these findings can provide useful guidelines to achieve a boosted light-free gaseous sensing.

Design rule hidden from the eye in S/N-bridged ancillary ligands for copper(I) complexes applied to light-emitting electrochemical cells

Luca M. Cavinato,[a] *Ginevra Giobbio,*[a,b] *Sylvain Gaillard,*[b] *and Rubén D. Costa,*[a]

e-mail: luca.cavinato@tum.de

Light-emitting electrochemical cells (LECs) are of high interest for soft-lighting applications and disposable (opto)electronics. Here, the transition towards sustainable and/or "green" LECs is becoming urgent.[1] In this context, recently, fully Cu(I)-based white LECs have been achieved *via* host:guest approach, reaching on par performances of the Ir(III) based counterpart.[2,3] However, the poor performance of the low-energy guests is still a current bottleneck.[4] In this context, this work explored conventional strategies (*i.e.,* π-extension and change of heteroatom-bridge in N^N ligand) that resulted in a series of complexes, in which the PLQY enhances from <1% to 21% in thin-films. Conversely, the success in enhancing the photophysical features is not reflected in efficient LECs that feature a very poor performance with the brightest candidate. Thus, the conventional chemical design rules fail to provide good performing devices.

To fill the gap of knowledge between an optimal photoluminescence-driven ligand design and poor device performance, this work capitalizes the use of a multivariate analysis using a dataset based on all the prior-art $[Cu(N^N)(P^P)]^+$-based thin-film lighting (>90 papers). Success and versatility of our multivariate model were confirmed with close prediction/experiment match across the series of novel complexes. What is more, comparison with the reference complexes allow us to unveil a new design rule: the need to consider the ligand polarization features (*i.e.,* clogP and tPSA) that rule the dielectric constant and ion conductivities in thin-films as confirmed by electrochemical impedance spectroscopy. In detail, the model suggests that high clogP are beneficial for both, PLQY and device efficiency, while the device efficiency is mainly enhanced with ligands featuring low tPSA value. This nicely match the experimental device data and the complex design, rationalizing that only the π-extension strategy can lead to devices with one order enhanced performances (*i.e.,* 0.35 cd/A@117 cd/m^2) despite the PLQY of the thin-films was less promising (*ca.* 10 %).[5]

All-in-all, this work provides fresh insights for the design of Cu-iTMCs fueling research on sustainable ion-based lighting sources.

Hybrid fluorescent protein-polymer derivatives for stable deep-red lighting devices

S. Ferrara,[a] D. Gutiérrez-Armayor,[a] M. Nieddu, [a] R. D. Costa[a]

[a]*Technical University of Munich, Chair of Biogenic Functional Materials, Schulgasse, 22 94315 Straubing*
sara.ferrara@tum.de

Recent progress in the field of bio-hybrid light-emitting diodes (Bio-HLEDs) have shown mCherry fluorescent protein as the main candidate for highly stable deep-red devices. We recently revealed that the deactivation mechanism of mCherry embedded in polymer matrices is highly dependent on oxygen permeability and residual water content upon preparation.[1] Here, we report a mCherry functionalization with hydrophilic polymer chains as a strategy to reduce the chromophore deactivation pathways by *i*) acting as a protective shell and *ii*) potentially reducing the H-transfer driven chromophore protonation resulting in emission quenching. First, we ruled out the effect of the chain length on the stability of the FP inside reference coatings upon mild continuous irradiation conditions (55 mW cm^{-2}). Secondly, we refined the overall device performance through the stabilization of the best performing hybrid mCherry-polymer adduct in previously reported PVA-based matrix, preparing first class deep-red Bio-HLEDs (*x/y* CIE color coordinates of 0.6/0.3) stable >200 h upon harsh driving conditions (600 mA, 150 mW cm^{-2}). This overcomes the prior art for mCherry-based Bio-HLEDs (50/~15 h at 55/150 mW cm^{-2}).[1, 2] Thus, this work not only *i)* identifies a novel strategy to protect low-energy emitting proteins from the detrimental effect of the environment in solid state upon irradiation stress, but also *ii)* settles record performances in the field of deep-red Bio-HLEDs.

Layered materials have many potentials for use in applications requiring (semi)conducting behavior, coupled to anisotropy or preferential orientations. In our group, we try to incorporate them into energy devices of different types, ranging from solar and photoelectrochemical cells up to energy-storage and piezoresistive systems.

In general, we choose to resort to highly scalable methods for their production and their processing, mostly solution-based, through the preparation of inks that can undergo further chemical processes or be deposited *via* spin/spray/dip-coating.

In this talk, we will give a collective view of some of the recent projects we are carrying on: we will discuss some uses of 2D transition metal dichalcogenides in electrochemical capacitors and we will show some recent results in the production and testing of layered heterojunctions based on two different semiconductors for use in photoelectrochemical hydrogen evolution.

alessia.pollice4@unibo.it

The water splitting reaction and the carbon dioxide conversion into energy dense molecules could cooperate to meet the supply of industrial energy demand using clean and renewable strategies. The electrochemical reduction of the molecules such as CO_2 and H_2O into building blocks or fuels, such as H_2, CO and HCOOH, is a possible solution to meet future energy needs and decrease the carbon footprint. To do that, the most important aspects are the design of the device and the smart synthesis of the catalyst.[1,2,3]

The most important factor for the successful implementation of the reaction lies in the meticulous design and optimal functionality of the reaction device.[3]

In this study, we focus on the development and optimization of a novel flow device known as *MicroFlowCell*. The MicroFlowCell is designed for precise control and manipulation of fluid dynamics, presenting promising applications in industrial fields. The device is coupled with a Gas Diffusion Electrode system, which allows to have higher currents and to maximize the substrate-electrode interactions. The investigation includes a thorough examination the key parameters such as the effects of liquid and gas flow rates, solution pH, electrolyte concentration and gas diffusion layer design on the MicroFlowCell's functionality.[4] Experimental methodologies are employed to systematically explore the interplay between these parameters and the device efficiency.

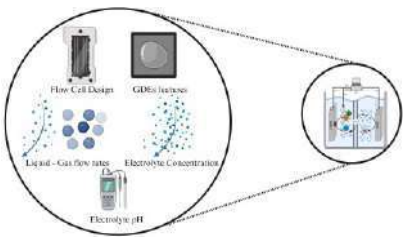

Figure 1: Key parameters associated with MicroFlowCell functioning: FlowCell design, Gas Diffusion Electrodes features, fluids flow rates, solution pH and electrolyte concentration.

The significance of this study lies in the potential advancements in using the reactor to test new electrocatalyst designs within a well-functioning system.

Metal Organic Frameworks (MOFs) as catalysts for CO_2 conversion

Eleonora Astolfi, Simone D'Agostino, Arianna Quintavalla, Giovanni Valenti [a]

[a] *Department of Chemistry "G. Ciamician" University of Bologna, via Francesco Selmi, 2 Bologna 40126, Italy*

eleonora.astolfi2@unibo.it

The overreliance of fossil fuels has determined a rapid rise in atmospheric CO_2 concentrations and disrupted the natural balance of the carbon cycle. The protection of the ecological environment by developing advanced technologies and methods to close the carbon loop is a key to this solution. Among them, the electrochemical conversion of carbon dioxide to value-added products could be an interesting way for the carbon capture. Aside from the advantage of working at room temperature and ambient pressure, the carbon dioxide reduction reaction presents problems related due to the thermodynamic stability of the CO_2 molecule. Significant efforts are due to the limited solubility of CO_2 in water under the working conditions. Furthermore, the CO_2 reduction reaction (CO_2RR) mechanism involves (multi) proton coupled electron transfer (PCET) pathway generating many different reaction intermediates resulting in a large variety of products which means to poor selectivity (Figure 1) [1].

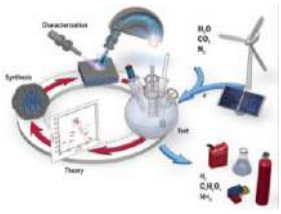

Figure 1: Electrochemical conversion coupled with renewable energy sources [2].

Metal Organic Frameworks (MOFs) used as catalysts show promising results due to their structure and organization in the space. They are composed by metal ions coordinated by organic ligands forming a highly porous and crystalline coordination polymers with facilitated exposure to active sites and structural order [1]. Herein, a copper-based coordination polymer (Cu^{2+}-CP) using (E)-4-aminocinnamic acid (4-ACH) as organic ligand was synthetised and deposited onto the Gas Diffusion Layer (GDL) used as working electrode of a MicroFlowCell with a three electrodes configuration. This design could be a strategic way to achieve high current densities and overcome both mass transport limitation and CO_2 solubility.

Electrocatalytic materials and devices for the water splitting

Davide Gramigni, Alessia Pollice, Massimo Marcaccio, Giovanni Valenti, and Francesco Paolucci
Department of Chemistry "G. Ciamician", University of Bologna, via Selmi 2, 40126, Bologna, Italy
E-mail: davide.gramigni@studio.unibo.it

Electrolytic water splitting is one of the most promising ways to harness intermittent renewable power sources, store the provided energy as a clean-burning and sustainable fuel and mitigate greenhouse gas emissions. However, in the water splitting reaction, the hydrogen evolution reaction (HER) rate is often limited by that of the oxygen evolution (OER) due to the more sluggish kinetics and the large overpotential of the latter, which lowers the overall energy conversion efficiency. In this context, nanostructured catalysts have emerged as a promising avenue to address these limitations.

This research project, in collaboration with Dr. Ferdinand Hof from the Material Science Laboratories in Bordeaux, is focused on the study and characterization of nanostructured electrocatalysts for the OER, based on non-precious metals such as Ni, Co or Cu, at different pH values, aiming to elucidate the pH-dependent catalytic behaviour [1,2]. Electrochemical techniques such as CV, LSV and EIS have been used for catalyst activation, oxygen production and ohmic drop corrections.

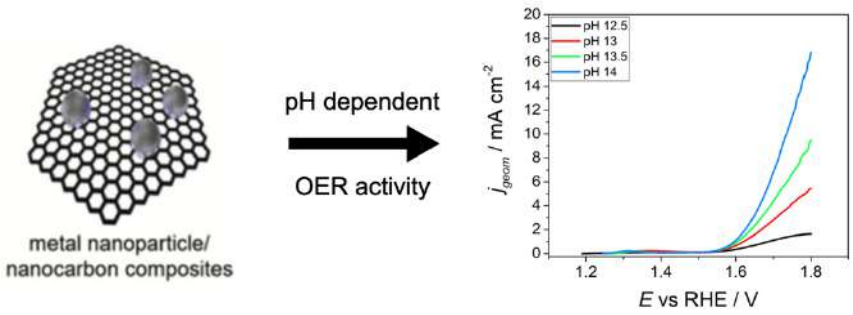

Figure 1: *Representation of nanostructured catalysts and the observed pH-dependent OER activity.*

Overall, this research has the potential to enhance the understanding of the underlying pH dependent OER mechanism, paving the way for the design of more efficient and sustainable electrochemical devices for hydrogen production.

Indoor photovoltaics have gathered growing interest amongst researchers, as a mean to exploit the indoor lighting we use in our daily life to power small devices. Dye-sensitized solar cells (DSSCs) represent good candidates for such applications[1]. However, when it comes to indoor applications, there is an increased demand for non-toxic and non-flammable solvents for electrolytes. The implementation of water-based electrolytes is a promising way to address these issues, whilst also ensuring the eco-friendliness and sustainability of these devices[2]. In this work, aqueous gel electrolytes incorporating a iodide/triiodide redox couple were made with a bio-sourced polymer, xanthan gum[3]. DSSCs were assembled using screen-printed TiO_2 semiconducting layers treated with $TiCl_4$ and sensitized with an organic dye, D149. As counter electrode, Pt sputtered FTO was used. The performance of the cells was investigated under indoor light intensities between 500 and 2000 lux.

Hydrogen, a key energy carrier for a sustainable future, faces challenges in efficient production via water electrolysis due to the sluggish kinetics of the Oxygen Evolution Reaction (OER). To overcome this, catalytic materials are essential to reduce the high overpotential. Operating in alkaline conditions, non-noble metal electrocatalysts such as nickel oxide, have shown promise for the hydrogen production at lower cost.[1]

In this work, we investigate $LaNiO_3$ for the OER in alkaline water, selected for its cost effectiveness and scalability.[2] $LaNiO_3$, synthetized by the co-precipitation method, shows good OER activity and electrochemical stability. The powder was characterized from a structural, morphological, and electrochemical point of view and also *operando* X-Ray Absorption Spectroscopy (XAS) for a better understanding of the reaction mechanisms.[3] Moreover, to enhance our understanding of the surface behavior of the perovskite during the OER, High Resolution Electron Transmission Microscopy (HR-TEM) was used. The investigation was done on the *as prepared* perovskite (**Figure 1A**), on the same material after having worked under OER conditions (**Figure 1B**) and on the material kept in KOH 1 M overnight (**Figure 1C**). These three-step allow us to confirm that the there is an increasing disorder on $LaNiO_3$ surface, and that it is caused by the electrochemical treatment. In summary, combining XAS, HR-TEM and electrochemical evidence, the study unveils a disordered layer on the $LaNiO_3$ electrocatalyst surface. Under cathodic conditions, a Ni(II) layer forms and oxidizes under anodic potentials, creating Ni(III) sites potentially serving as active sites for the OER. The disorder enhances active sites for improved OER performance.

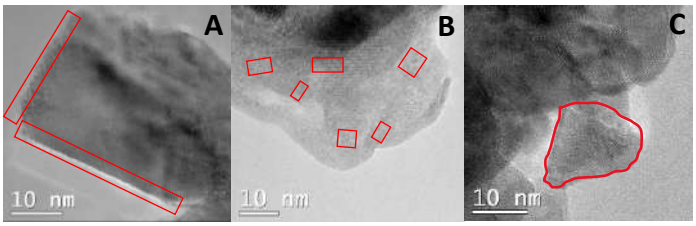

Figure 1: **A)** HR-TEM images of $LaNiO_3$ *as prepared* **B)** after worked under OER **C)** after treatment in KOH 1M

marco.cattelan.3@phd.unipd.it

Battery-based energy storage systems with high power / energy densities and excellent cycle efficiency are expected to play a key role in our everyday life. Even though Lead-Acid Batteries (LABs) are the oldest electrochemical energy storage technology, they still attract a lot of interest thanks to their properties: stability, reliability, recyclability and low cost of raw materials. Precisely for these reasons, LAB technology will retain its strong position at least until 2030 and it remains very competitive, but ongoing investments are needed in order to improve production and performances.

A well-known problem of LABs is the limited charge efficiency and cyclability, due to an important degradation of electrodes during the discharging-charging process. It was observed that small addition (0.5 – 2 $\%_{wtPbO}$) of carbons in the Positive Active Mass (PAM) of LABs improves the battery performances and specifically the weight, mechanical strength, and conductivity, which is beneficial for uniform current distribution during the charge-discharge process.[1] A series of carbon-based materials were selected and they were screened on the bases of physicochemical and electrochemical properties such as surface area, porosity, graphitization degree, conductivity, contact angle (wettability), and the overpotential versus the hydrogen evolution reaction.[2] The best candidates were mixed and tested at different loadings in the positive active mass to prepare positive plates from scratch.

A 1+/2- test cell was developed for the electrical, electrochemical, and chemical characterization of the novel electrodes in AGM configuration. The prepared cells were tested under standard charge-discharge protocol and then tested with a homemade procedure for waterloss using coupled electrochemical polarization and gas analysis, adapted for the AGM configuration, in accumulation mode instead of flux mode.[3] The incorporation of carbonaceous materials is evaluated as impact in the charge/discharge performances, in oxygen recombination and plate corrosion of LAB cell under test, when compared to commercial plates. The effect of increased carbon loading was also considered.

matteo.gandolfo@polito.it

Lithium-ion batteries (LIBs), despite being a rather recent invention, gained a dominant role in the field of energy storage due to their high energy density, long cycle life and low self-discharge. LIBs experienced a dramatic improvement since the first studies in this field in the past century. However, the current technology still requires further improvement to meet the market needs. Concerning next-generation anodes, lithium metal is the most promising candidate, owing a specific capacity (3860 mAh g^{-1}), which is about ten times higher than the presently used graphite (372 mAh g^{-1}), and a very low redox potential (-3.04 V *vs.* SHE). Nonetheless, lithium metal electrodes are suffering a high reactivity with commonly used electrolytes and dendritic lithium deposition, causing severe safety issues[1]. Polymer electrolytes can be a suitable replacement for liquid electrolytes due to their ability to limit dendrite growth and the improved stability against lithium metal anode[2]. An increased electrochemical performance, high thermal stability and extended electrochemical stability window have been observed when introducing ionic liquids (ILs), i.e., room temperature organic molten salt, into the polymer matrix. These ionogels (IGs) are a promising class of polymer-based electrolytes for next-generation lithium-metal batteries. Unfortunately, fast Li^+ kinetics are still a challenge due to the high viscosity and low transference number of ILs[3]. A possible solution is given by a hybrid approach as the insertion of active and passive filler can further boost the electrochemical performances of IGs.

Herein, we present composite IGs prepared via a one-pot preparation protocol by mixing the polymer precursors butyl methacrylate (BMA) and poly(ethylene glycol) diacrylate (PEGDA) with the IL PYR14FSI and, in addition, LLZTO nanoparticles. The inorganic filler is fully integrated in the polymer matrix by using an organosilane functionalization which allows for the formation of covalent bonds during the polymerization step. Three functionalized LLZTO nanoparticles were investigated, differing by the silane content, resulting in a maximum ionic conductivity of $6 \cdot 10^{-4}\ S\ cm^{-1}$ at 20 °C and an anodic electrochemical stability up to 5.3 V (*vs.* Li^+/Li). Li|IG|LFP cells delivered a stable cycling with a specific capacity of 120 mAh g^{-1} at room temperature for hundreds of cycles owing to a high compatibility of the IG composite with lithium-metal anode.

margherita.verrucchi@unifi.it

The electrodeposition of palladium for decorative applications has become widespread in the last decades as a substitution for nickel and it is now used both as a final coating and as an intermediate layer to improve corrosion resistance, increase the adhesion of subsequent precious deposits, and act as a diffusion barrier layer. However, palladium and palladium alloy deposits easily undergo micro-cracking due to the evolution of large quantities of hydrogen during the metal reduction and its consequent co-deposition. Indeed, palladium is able to dissolve hydrogen forming two bulk hydride phases known as α-PdHx (x ~0.02) and β-PdHx (~0.67). Microfractures result from hydrogen desorption associated with the lattice contraction that occurs in the transition from the β-PdHx to the thermodynamically stable α-PdHx phase. On the other hand, high-hydrogen palladium hydrides are of great interest for different industrial sectors, especially in the energy field for hydrogen storage[1]. Identifying the working conditions necessary to ensure the selective formation of the two phases would therefore be of crucial importance for both the electroplating industry and the energy field. We focused on the two parameters that we think have the greatest influence in incorporating and retaining hydrogen during electrodeposition, testing five different current densities (from 0.25 to 4 A/dm^2) and three thicknesses (0.25, 0.5 and 1 μm). The experiments were carried out in a pure Pd galvanic bath (Fe < 1%) at a temperature of 50 °C and pH ranging 7 and 7.3. Brass plates were used as substrates, and subsequent analyses of the samples were performed using the X-ray diffractometry (XRD) technique that allows the two phases to be easily identified thanks to the diagnostic peaks associated with α-PdHx and β-PdHx at 40.1° and 38.34°, respectively[2]. Measurements were performed using a powder diffractometer equipped with a Euler cell and scanning from 35° to 45°. To roughly estimate the kinetics of the desorption process, the XRD analysis were performed 10 minutes, 1.5, 3, and 24 hours after the end of the deposition process. Finally, we identified a heat treatment that can be used by the electroplating industry to facilitate the desorption of hydrogen and quickly obtain the α-phase. The authors acknowledge MUR and EU-FSE for financial support of the PhD fellowship PON Research and Innovation 2014-2020 (D.M. 1061/2021) XXXVII Cycle in Chemical Sciences.

claudia.carbone@unimi.it

Gadolinium-based contrast agents (GBCAs), which are gadolinium complexes, are used worldwide in magnetic resonance imaging (MRI) to enhance the contrast of images and have a clearer visualization of the disease [1]. In the present research, the advantages of electrochemistry are exploited for the synthesis of a new possible GBCA. The project was inspired by the research on metal-ion batteries (MIBs), for which Prussian blue analogues (PBAs) are among the most promising cathodes, thanks to their simple synthesis, non-toxicity, stability, and their high capacity for the electrochemical-driven insertion of several metal ions [2]. For their biocompatibility, they have been considered also in the medical field [3]. The aim of this study is to electrochemically intercalate Gd^{3+} ions into nanometric spherical Zinc-hexacyanoferrate (s-ZnHCF), which was synthesized with a high-temperature coprecipitation method found in literature [4]. After its characterization by XRD and TEM (Fig. 1), it was deposited on FTO (Fluorine-doped Tin Oxide) and used as working electrode in cyclovoltammetries. Successive chronoamperometries in a solution of gadolinium ions allowed to create gadolinium-rich particles.

Since electrochemistry allows a fine control of experimental parameters, with further studies the amount of intercalating gadolinium could be controlled, and so its ability to enhance the MRI signal. Furthermore, the presence of Gd^{3+} in the superficial layer of nanoparticles would improve its interaction with H_2O, which is essential for the functioning mechanism of contrast media.

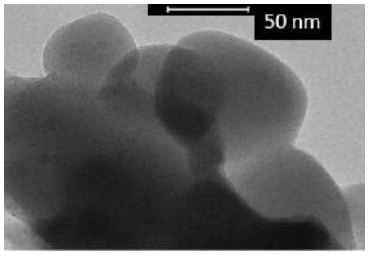

Figure 1: TEM image of synthetized s-ZnHCF

matteo.gastaldi@polito.it

Solid polymer electrolytes (SPEs), composed of a lithium salt dissolved in a polar polymer matrix, are promising candidates for replacing liquid electrolytes in lithium-ion batteries (LIBs)[1]. SPE suffer from low ion mobility at room temperature, which restricts their practical use. Polyethylene oxide (PEO) can reach, in formulation with lithium salts, high conductivity values at elevated temperatures, and its low glass transition temperature (T_g) makes it a good candidate for SPE. PEO presents some drawbacks, like the strong dipolar interaction and complexation of Li^+ that prevent the migration of lithium ions and segmental mobility in crystalline phase[2-4]. Polycarbonates (PC) show moderate interaction between carbonate groups and Li^+ that ensure ions and segmental mobility and wide electrochemical stability window, but they have high T_g values, which makes these materials semicrystalline and restricts ion transport[5]. We selected three PCs, characterized by an increasing chain length, to blend with PEO in different proportions. Through a design of experiment (DoE), we compared the chemical, mechanical and electrochemical properties of polymer electrolytes composed of PEO blended with PCs at fixed LiTFSI salt concentration. The study helps identifying the best PC and the ideal ratio at which the ionic conductivity, the electrochemical stability window and the elastic modulus are optimal. All formulations were prepared by exploiting a mini-extrusor, which enabled us to avoid the use of organic solvents, minimizing polymer degradation phenomena by using an inert atmosphere. Finally, UV-cured PEO and PCs matrixes are investigated to enhance the mechanical and electronic properties of the final electrolytes.

Fuel cells are devices that convert chemical energy into electric energy with higher efficiency compared to thermal engine. Thus, fuel cells are generating attention for their use in transportation and power generation. Among the other, the proton exchange membrane (PEM) fuel cell (FC) results to be the ideal candidate for the commercial application because they can operate at low temperatures (50-100°C) and low pressure (0.3 MPa), and moreover are generally lightweight and small-sized.[1] Unfortunately, PEMFC rely heavily on the utilization of platinum on both anode and cathode. The oxygen reduction reaction (ORR) occurring on the cathode of the fuel cell is the bottleneck of the device therefore greatest effort is devoted to this reaction. Very recently, with the development of anion exchange membrane (AEM), AEM fuel cells have grown exponentially. AEMFC can substitute efficiently Pt supported over carbon on the cathode side with platinum group metal-free (PGM-free) electrocatalysts. These electrocatalysts are also called single atom electrocatalysts and have a structure of a first raw transition metal (TM) coordinated with nitrogen and integrated in a carbon backbone.

State of the art and commercially available ECs use Fe-based electrocatalysts of the type Fe-N_x-C. These electrocatalysts are produced using sacrificial support method (SSM) by the mixing an organic matrix containing nitrogen atoms, silica as a hard templating agent and a Fe salt. This mixture is then subject to pyrolysis with controlled temperature and atmosphere. Silica is then removed through the use of HF.[2] The templating removal etched out not only the silica but remove also undesired oxides and nanoparticles, producing an highly porous carbon containing the active side desired. Due to its lipophilicity, use of HF represents a serious hazard for health and thus safer etching procedure are needed. In this work, an Fe-N_x-C electrocatalysts have been developed exploiting in situ production of HF for the silica etching step, avoiding the direct use of HF. Two salts (NaF and NH_4HF_2) have been used as HF precursor and the safer etching method was optimized. The samples were characterized in terms of composition, morphology and electrocatalytic activity and compared with the HF etched EC.

Interestingly, in alkaline environment (0.1 M KOH), the best performing electrocatalyst was the one etched with NH_4HF_2 possessing an onset potential (E_{on}) of 0.97 V vs RHE and a half-wave potential ($E_{1/2}$) of 0.88 V vs RHE. The electrocatalyst etched with HF had a E_{on} of 0.95V vs RHE and a $E_{1/2}$ of 0.87 V vs RHE.

Critical Aspects in Lithium-Mediated Nitrogen Reduction Reaction for Electroproduced Ammonia

Anna Mangini, Noemi Pirrone, Sara Garcia-Ballesteros, Federico Bella

Department of Applied Science and Technology, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129 - Turin, Italy
anna.mangini@polito.it

Ammonia is a fundamental building-block for fertilizers as well as for many other commodities, and its production *via* the Haber-Bosch (HB) process is responsible of around 1.4% of the global greenhouse gas emissions due to the severe conditions (200 atm) of these few huge, centralized plants. Finding a renewable-driven and delocalized electrochemical process for NH_3 production, complementary to HB, could be a key solution for our society that is facing climate change crisis and that is demographically growing[1].

In view of process electrification, the Li-mediated pathway represents the most promising solution in the N_2 reduction reaction challenging field. Exploiting the unique reducing power of this alkali metal, this strategy achieves the highest Faradic efficiency (FE) and NH_3 production rate[2]. Different strategies, both continuous and step-by-step systems, are under evaluation in current literature.

In the first, Li^+ ions from the aprotic electrolyte are electrodeposited on the cathode, where N_2 is reduced and protonated into NH_3 directly in the same environment. On the plated Li, a solid electrolyte interphase (SEI) unavoidably forms due to electrolyte degradation on the interface, and the different diffusion rate of Li^+, N_2, and H^+ trough the SEI layer determines the selectivity towards NH_3 formation[3]. In the latter, the formation of Li_3N is the key intermediate step. The exploitation of a Li-N_2 galvanic cell, inspired by lithium-air batteries, could maximize Li_3N formation[4]. Even in this case, nevertheless, practical aspects are delaying the rising of this innovative research filed, and a critical eye on interferents and impurities should be adopted for a correct NH_3 quantification. Our laboratory is currently addressing these challenges within the SuN_2rise project, and an overview of electrochemical and engineering-related crucial aspects will be presented in this contribution.

Since the discovery of the first Oceanic Hydrothermal Vent field in the 1970s, these geological formations have been proposed as possible cradles for the emergence of life on our planet. In the Archean era, Alkaline Hydrothermal Vents were generated by the reaction between alkali, metal, and hydrogen-rich fluid, originating from the oceanic crust, with a slightly acidic and CO_2-rich ocean. Within this environment, a mineral barrier precipitated, composed of iron oxide and hydroxide, green rust, iron sulphide, along with Ni, Zn, Co, and Mn ions. The surface of this material, jointly with the structure of the vent itself, can efficiently promote the coupling of CO_2 reduction reaction (to simple organic molecules) with hydrogen oxidation. [1]

On the other hand, material scientists and chemists worldwide are frenetically searching for an effective material capable of performing CO_2RR at affordable prices. Could the minerals that performed carbon dioxide reduction 4.4 billion years ago be utilized in today's industry to address the environmental challenges of the new millennium? Here is the idea of "emergence of life inspired material" for CO_2 conversion.

Recently, a new approach to the study of Hydrothermal Vents has emerged from electrochemistry. [2][3]

New electrodes based on mineral materials have been tested to determine their effective catalytic ability for CO_2 reduction and product distribution. In our research, Mackinawite (Fe-S) and Violarite (Fe-Ni-S) were tested by performing electrolysis in a CO_2 environment, revealing the production of formic acid, methanol, and carbon monoxide at -1.1 V vs SHE (HCOOH and MeOH had never been identified before on such materials [4]).

The geological system is modelled as a fuel cell where a continuous supply of carbon dioxide and hydrogen is provided. The electrode material is composed of the vent's minerals, with the anode and cathode short-circuited in a configuration that recall a corrosion process. The system, capable of coupling CO_2RR and HOR (or other oxidation process), is ultimately powered by the pH difference between the two compartments (simulated inner vent fluids and oceanic waters). An electrochemical analogue of the vent has been created in an H-type cell to study the current and electrical potential trends during operation. The results are then compared using an Evans-type diagram.

A new era of electrochemical energy storage devices is required to meet the increasing demand for energy storage capacity at lower costs. Furthermore, because the number of batteries produced is constantly increasing, developing more sustainable chemistry without consuming limited resources is an actual research challenge.[1] In recent years there has been growing interest in batteries based on fluoride-ion shuttle. This interest stems from the potential to utilize a cost-effective, high-capacity conversion cathode, taking advantage of multi-electron transfer processes, and use a metal anode without the risks caused by dendrite formation, resulting in enhanced safety and performance.

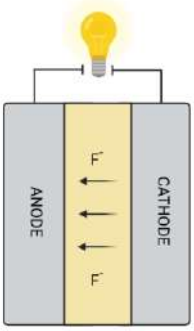

Figure 1: Fluoride-ion batteries working principle

Today, finding a suitable electrolyte is one of the most significant challenges for developing a fluoride-ion battery capable of competing with modern lithium-ion batteries[2,3]. This work attempts to use a novel solution in the electrolyte technology, to ensure ionic conductivity and high chemical and electrochemical stability, enabling cyclability between metal-metal fluoride electrodes at room temperature[4].

Feasibility and challenges of the electrochemical ammonia production from nitrogen and nitrate in a flow cell reactor

Noemi Pirrone,[a] Sara Garcia-Ballesteros,[a] Simelys Hernández,[b] and Federico Bella[a]

[a]Electrochemistry Group, Department of Applied Science and Technology, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129-Turin, Italy; [b]CREST group, Department of Applied Science and Technology, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129-Turin, Italy
noemi.pirrone@polito.it

The Haber-Bosh process is the most optimized and only known way to produce the quantities of NH_3 needed to satisfy the overall world demand. Despite that, the urge to reduce as much as possible greenhouse gases emission paved the way for the discovery of alternative and cleaner paths towards the production of such a fundamental molecule indispensable to sustain agriculture in this period of demographic growth. The research has focused on the possibility of producing NH_3 from direct N_2 electrochemical reduction (NRR) in aqueous electrolytes under ambient conditions, the limitations of which are the low selectivity at high current densities and low yield, due to the high dissociation energy of N_2 triple bond and the unavoidable hydrogen evolution reaction (HER).[1] On the other hand, NO_3^- can be easily converted into NH_3 thanks to the lower activation energy and it is one of the most abundant contaminants of underground waters. Thus, the use of NO_3^- to produce NH_3 under ambient conditions can also address the water pollution issue.[2] The research on such topics is still in the first stages and very few literature reports reliable and consistent results.

Our work is divided into different lines: i) the NO_3^- electrochemical reduction using commercial MoS_2 in a gas-diffusion electrode flow cell of 10 cm^2, ii) NRR tests using different catalysts in different conditions, iii) the study of different sources of contamination, among all that coming from Nafion membrane. Regarding the first line, the design of experiments and surface response methodology (DoE/RSM) revealed the possibility of having stable operations for over 100 h with low NO_3^- concentration (500 mg L^{-1}), with FE and productivity rate for NH_3 stable at values around 60% and 19.6 µg h^{-1} cm^{-2}, respectively. Unfortunately, even with the hardest effort, we were not able to obtain reliable and good results for NRR in all the explored conditions. False positives have been demonstrated to be related to the presence of contaminants, especially the one coming from the Nafion membrane, which can absorb NH_3 in a magnitude dependent on the electrolyte composition and on the cell conditions.

The design of efficient catalysts for the Oxygen Reduction Reaction (ORR) continues to be a crucial point in the development of clean energy technologies, particularly in fuel cells. Here we present our latest findings on an innovative atomic precision catalyst, called MWCNT-LPd. This catalyst consists of a Pd(II) tetraazacycloalkane complex anchored to multi-walled carbon nanotubes (MWCNTs) obatained through a supramolecular approach[1]. Our investigation explores the structural and electrochemical characteristics of MWCNT-LPd, to elucidate its catalytic mechanism and performance. Through comprehensive analyses, including quantum-mechanical calculations, electrochemical and spectroscopic techniques, we examine the role of coordination geometry in catalytic activity, shedding light on the need for unoccupied coordination sites for efficient ORR. A tetraazacycloalkane ligand was intentionally chosen to occupy all four coordination sites of the conventional square planar coordination geometry of Pd(II). This choice was made to investigate a fundamental question: whether the metal ion requires unoccupied coordination sites to effectively catalyse the oxygen reduction reaction (ORR) or whether, as suggested by quantum mechanical calculations, catalytic activity may result from O_2 interactions occurring at the fifth coordination position[2]. Remarkably, our results show that the tetracoordination of Pd(II) within the complex does not compromise its catalytic activity, achieving ORR performance comparable to that of Pt commercial bulk electrodes and introducing new notions of the structure-function relationship in ORR catalysis. In this way, the results obtained open new possibilities for the design of inexpensive and highly efficient catalysts that are crucial for the advancement of sustainable energy technologies. Authors thank Project 2022NW4P2T CUP B53D23013890006 "From metal nanoparticles to molecular complexes in electrocatalysis for green hydrogen evolution and simultaneous fine chemicals production (FUTURO)" PRIN2022 Progetti di Ricerca di Rilevante Interesse Nazionale funded by the Italian Ministry of University and Research and NextGenerationEU.

NiO Nanoparticles as Electrocatalyst for Nitrates Reduction

L. Sibella, O. Tammaro, S. Garcia Ballesteros, S. Esposito, F. Bella

Department of Applied Science and Technology, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129 Torino, Italy.

lorenzo.sibella@polito.it

The introduction of the Haber-Bosch (HB) process in the early twentieth century enabled the large-scale production of NH_3, swiftly becoming one of the most crucial chemical products worldwide due to its extensive application in agriculture as a fertilizer. Moreover, NH_3 has recently garnered significant interest as a potential renewable energy storage system, given its capacity to serve as a source of hydrogen.[1]

However, the Haber-Bosch process, reliant on atmospheric nitrogen and fossil fuel, requires H_2 for NH_3 production, as well as high process temperature and pressure, contributing to approximately 1.6% of the annual global CO_2 emissions.[2] A promising alternative lies in the electrochemical nitrogen reduction reaction (E-NRR) to synthesize NH_3 under ambient conditions.[3] However, to date, this process has a limited yield production and a low selectivity due to the high stability of the N_2 molecule and the presence of parasitic reactions, primarily leading to water (solvent) conversion into hydrogen.[4]

A more recent focus has emerged towards the reduction of NO_3^-, as it can be more easily converted into NH_3 with a significant Faradaic efficiency (FE) and high yield. Moreover, owing to the prevalent use of nitrogen-based fertilizers, this process possesses a significant real-case application towards wastewater treatment were high NO_3^- levels have often been detected.[3]

This study presents the utilization of a nanostructured NiO electrocatalyst, prepared by precipitation in aqueous medium and calcinated at 600 °C, for the reduction of NO_3^- into NH_3, achieving an average FE of 36% and a production rate ranging from 28 to 107 μg h cm^{-2}, depending on the initial NO_3^- concentration. The experiments were conducted in a H-type cell, utilizing three different concentrations of KNO_3 (NO_3^- source), i.e. 0.1, 0.05, and 0.008 M. A second investigated experimental parameter was the concentrations of the supporting electrolyte (i.e., K_2SO_4), that was used at 0.4, 0.45, and 0.492 M. The tests were conducted under an applied potential (E) of –1.4 V vs. Ag/AgCl for a duration of 2 h.

In this contribution, we will show the main outcomes derived from this newly explored electrocatalysts, highlighting the main structure-performance correlations.

matteo.milanesi@polito.it

The Green Deal sets ambitious goals for EU climate neutrality by 2050, enabled by a increase of renewable energy share, pursued by the 'FIT for 55% package, and based on more affordable, secure, and clean energy systems. Achieving these targets requires the development of sustainable, interconnected, sector-coupled, and flexible Electrochemical Energy Storage (EES) systems. Metal-air batteries present several advantages, including using aqueous electrolytes with inorganic salts, cheap and abundant active materials (e.g., zinc), high gravimetric energy density, and long-term stability. The main goal of the HORIZON EUROPE project "HIPERZAB" is to develop an Electrically Rechargeable Zn-Air Battery (ERZAB) ideal for mid-term storage to be coupled with renewable power sources and electrolysers. HIPERZAB will achieve an actual paradigm shift with respect to the battery performance, lifetime, safety, sustainability, and costs of liquid electrolyte-based Zn-Air Batteries through the investigation of three innovative components: a 3D porous Zn/biopolymer composite anode, an eco-friendly bilayer gel biopolymer electrolyte[1], and a CRM-free structured cathode. The ultimate goal of the project is to integrate these components in a single device, proposing a radically new gel-electrode-assembly (GEA) battery design with a channelled current collector. HIPERZAB will further focus on understanding the mechanisms behind the unique integration of these innovative components by developing advanced operando techniques and atomistic as well as multiscale modelling for the discharge/charge processes and to control/monitor the durability/performance of the materials. More specifically, our research group is working on the development of the acidic side of an aqueous Gel Polymer Electrolyte (GPE) that, coupled with the basic one[2], will increase the battery operating potential from 1.65 V in alkaline-based electrolytes to 2.55 V and, hence, the overall device energy density from ≈ 1353 to 2091 Wh/kg. The electrolyte preparation is based on the use of natural bio-polymers[3], such as cellulose derivatives and low-cost, sustainable chemicals, with also the exploration of the use of redox mediators to modulate the kinetic of OER and ORR processes. Particular attention is also paid to the regulation of Zn ion conduction/transport across the interfaces by adjusting the amount of water and the polymer crosslinking density coupled with mechanistic understanding. The idea is to design a membrane-less battery in which ion mixing is avoided thanks to the proper selection of pH-sensitive polymers for both the acidic and basic environments, separately[4].

Bio-based separators represent an important opportunity for next-generation sustainable batteries, and, in the next years, it will become fundamental to investigate more in details these systems to guarantee the best performance of energy storage devices.

The separator is a critical component of batteries since it prevents electrical short circuits, being a physical barrier between the anode and the cathode, but it also serves for ion transportation. Traditional polyolefin-based separators are widely used in lithium-ion technologies thanks to their price and chemical stability[1]. However, this stability determines a high resistance to biodegradation[2]. Consequently, the use of these technologies increases the plastic pollution that is a formidable threat to the sustainable development of human society. To overcome this problem, the use of a bio-based separator is needed.

The aim of this work is the realization of a bio-based separator by means of a green process. After a deep evaluation of several natural polymers, calcium alginate (CA) has been chosen to realize a composite separator for green energy storage. CA is obtained from sodium alginate (SA), a cell wall component of brown algae. In presence of divalent cations (especially calcium), the low viscosity solution is turned immediately into a gel. CA was selected thanks to its thermal and chemical stability that make it a promising candidate for the realization of a new generation separator[3].

The most promising alternative to the current fossil-fuel cantered system is a hydrogen-based circular economy This requires the conversion of hydrogen into electricity in proton exchange membrane fuel cell (PEMFC) using perfluorosulfonated polymer (e.g. Nafion® and Aquivion®).

The main limit of these devices is their relatively low lifetime due to the degradation of the polymeric chains[1] caused by radical species (•OH •OOH) generated at the cathode. The best strategy to improve the device's lifetime is the introduction of radical's scavenging species in the (MEA)[2]. State of the art radical scavengers include cerium oxide nanoparticles, either embedded in the membrane[3], or in the catalyst layer[4].

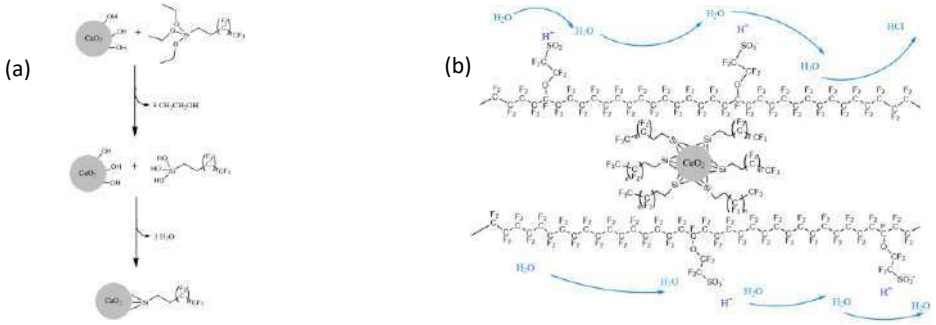

Figure 1: schematic representation of: (a) the grafting procedure and (b)the resulting nanocomposite membrane

To improve the compatibility between the inorganic filler and the organic polymeric matrix we fabricated CeO_2 NPs decorated with 4 different fluorinated silanes through a surface grafting process of the nanoparticles that are then dispersed in the polymeric film (figure1). The success in the fabrication of nanocomposite membranes was proved trough IR spectroscopy, XRD analysis and microscopic imaging. Thereafter the samples were thoroughly physicochemically characterized showing improved thermal, and mechanical properties with comparable electrochemical behavior.

Electrochemical Iodination as a Green Alternative for the Synthesis of X-ray Contrast Media

L. Sorti,[a] C. F. Morelli,[a] F.Uggeri,[b] L. Lattuada,[b] A. Minguzzi,[a] A. Vertova[a]

letizia.sorti@unimi.it

Iodinated contrast media (ICM) exploit the radiopacity of the iodine they contain to enhance tissues contrast in X-ray-based analyses. Their usage has widely increased in the last 20 years,[1] but SARS-CoV-2 related lockdowns caused a troubling shortage of ICM in 2022.[2] The solutions adopted to deal with the problem were mainly implementing the conservation strategies and reduce the dosages, but also novel and more efficient synthetic routes must be considered as a possible solution to prevent the problem in the future. This also provides an opportunity to rethink the process to be more consistent with the green chemistry principles.

In this work, the successful electrochemical tri-iodination of N,N'-bis(2,3-dihydroxypropyl)-5-hydroxy-1,3-benzenedicarboxamide, an important intermediate for the synthesis of iomeprol, is reported. This reaction is currently carried out using corrosive and difficult-to-handle reagents (e.g. ICl), the production of which also implies an increase in time and costs.[3] In particular, the possibility of using less hazardous reagents, such as iodides or molecular iodine, that are electrochemically oxidized to the iodinating I_2/I^+ species was explored.[4]

The goal was to have a one-step in situ iodination process, in which the generation of the iodinating agent and iodination itself occurred in the same reaction environment. The final optimized synthesis involves a first stage of chemical iodination with I_2 and a second stage of electrochemical recycling of the iodides formed.[5] For the electrochemical part, working in pH control (pH 10-12) and potentiostatic conditions (+ 0.65 V vs SCE) is the best solution to both avoid the formation of oxidation by-products and enhance the current efficiency. The setup involves a divided cell equipped with a cation exchange membrane and leads to an almost complete iodination of the substrate using stoichiometric iodine and a faradic efficiency of almost 100%. The electrodes selected are inexpensive and robust carbonaceous anode and stainless steel cathode, meeting the industrial requirements. Industrial-scale implementation of this electrochemical iodination could therefore help in the direction of green synthesis and environmental protection in the pharmaceutical field.

Nowadays, the integration of renewable energy sources (e.g. photovoltaic) with efficient electrochemical energy storage systems (EESS), such as batteries and supercapacitors, is dramatically important to store the possible excess of energy produced and supply additional power in case of insufficient electricity supply [1]. Yet, EESS are usually based on not sustainable electrolytes, which should be progressively phased out [2].

Here, the exploitation of Deep Eutectic Solvents (DES) based on NaCl as Hydrogen Bond Accpetor (HBA) and glycerol as hydrogen bond donor (HBD) as sustainable [3] and effective alternative to conventional electrolyte is proposed [4]. Indeed, the establishment of the supramolecular hydrogen bond network typical of DES seems to dramatically impact the electrochemical stability of the electrolyte: the 1:10 HBA:HBD molar ratio shows an extremely wide electrochemical stability window (up to 3 V) and faradic efficiency close to 100% when implemented as electrolyte in supercapacitors. Additionally, this system was also fruitfully tested in thermoelectric devices.

Reling on these very promising results, we developed a multi-technique approach also taking advantages of measurement campaigns at large-scale facilities) to thoroughly characterize our electrolytes and to get meaningful insights toward the design of a second generation of Deep Eutectic Electrolytes. As a result, we decided to further widen the chemistry of our solvent by the (i) engineering of the HBD and/or (ii) the replacement of the sodium salt with the zinc counterparts. The former was reached by selective etherification of one or two hydroxyl moieties of the glycerol with alkyl chain (e.g. methyl, ethyl, trifluoromethyl…)[5].

This study could be seen as a thoughtful effort in the design, characterization and implementation of innovative and sustainable electrolytes in line with the 7th sustainable development goal of the United Nations.

Nanocomposite Oxides from High Entropy MAX-phases $Ti_3Al_xSi_ySn_zC_2$ as Negative Electrode for Lithium-Ion Batteries

N. Vallana[1], A. Gentile[2], C. Ferrara[1], I. Ostroman[1], S. Marchionna[2], R. Ruffo[1]

n.vallana@campus.unimib.it

In recent years, batteries have significantly influenced societal advancements, with the lithium-ion battery (LIB) standing out for its impressive electrochemical capabilities. However, the commonly negative electrode, graphite, has encountered challenges related to aging and safety, particularly under high current densities.[1]

An alternative worth exploring for the negative electrode in LIBs is the utilization of Li-alloy systems such as Li-Sn and Li-Si (theoretical reversible capacity of Sn and Si are, respectively, 783 mAh g^{-1} and 4212 mAh g^{-1}). However, the significant volume changes during cycling pose obstacles to their practical use.[2]

To mitigate this challenge, one potential strategy is the adoption of corresponding conversion oxides like SnO_2 and SiO_2, which, through a conversion mechanism with lithium ions, potentially create smaller metal particles embedded within the Li_2O framework. Despite the promise of this approach, managing volume fluctuations remains a critical concern.[3]

Within this framework, a less explored route involves employing solid solutions of conversion oxides with intercalation oxides, such as TiO_2, capable of providing a robust framework. Regarding this, we have introduced an innovative approach to produce nanostructured solid solutions of oxides by thermally treating MAX-phase systems and we have shown that controlled oxidation of these Sn-containing phases ($Ti_3Al_{1-x}Sn_xC_2$ with x= 0.4 or 0.7) at 600°C in air yields a composite material capable of very good electrochemical performance as a negative electrode in lithium-ion batteries.[4] Moreover, in this context, we have also studied how the final temperature of the oxidation step can modify the final product and how these related differences can affect its electrochemical properties.

With an analogous approach, here it's proposed a novel parallel study starting from Si-based MAX-phases, both $Ti_3Al_{1-x}Si_xC_2$ and $Ti_3Al_xSi_ySn_zC_2$ (with x+y+z=1). First, their physical-chemical properties were investigated; then their electrochemical performances were evaluated as possible negative electrodes for LIBs.

Tailoring the self-assembly properties of $Au_{25}(SR)_{18}$ atomically precise clusters in the solid state

A. Conte,[a] S. Antonello,[a] S. Bonacchi[a]

[a]*University of Padova, Department of Chemical Sciences, Via F. Marzolo 1, Padova*
andrea.conte.5@phd.unipd.it

The manipulation of Atomically Precise Clusters (APCs) stands as a key objective in the quest to deliver responsive nanomaterials for catalysis, sensing, and optoelectronic applications.[1-4] A pivotal breakthrough in this pursuit involves the precise adjustment of ligand within $Au_{25}(SR)_{18}^0$, enabling the modification of cluster assembly properties in the solid state.[5-7] Through deliberate variation of the ligand length (SC_4H_9, $SC_{10}H_{21}$, $SC_{18}H_{33}$), we achieved a precise control over cluster interactions, inducing consequential alterations in their aggregation properties of $Au_{25}(SR)_{18}^0$. Notably, we found, employing scanning electron microscopy (SEM) and atomic force microscopy (AFM), that $Au_{25}(SC_{18}H_{33})_{18}^0$ exhibited anisotropic self-assembly in the solid state, thus forming ultralong fibers having a length of hundreds of micrometers and an average diameter of 850 nm. Moreover, XRD and Selected Area Electron Diffraction (SAED) analysis suggested that the $Au_{25}(SC_{18}H_{33})_{18}^0$ fibers displayed crystallographic order and a high degree of symmetry in the three dimensions. This study not only provides insights into the fundamental principles governing cluster self-assembly in the solid state but also offers a pathway to engineer tailored materials with customized properties. By gaining the ability to fine-tune APCs' self-assembly through ligand manipulation, a new era of nanomaterials design emerges, promising enhanced performance and versatility in diverse applications.

Polymers are a leading class of functional material suitable for high-value applications, prized for their adaptability and suitability for a wide range of high-value applications, including biomedical engineering, food packaging, and electrochemical energy storage (EES) sectors[1]. In the pursuit of reducing environmental impact and diminishing reliance on fossil fuels, there has been a significant drive to replace synthetic polymers with biopolymers, composed of repeated chemical blocks derived from renewable resources that may also be degraded in the environment. As a result, numerous types of natural or biopolymers have been developed to address the growing needs across the various applications[2]. Among the different classes of biopolymers, poly ethylene furanoate (PEF) derivatives has attracted increasing attention from the scientific community due to its potential to replace poly(ethylene terephtalate) (PET), mainly used in the packaging, film and fibre sectors. PEF can be 100% bio-based since both its monomers can be produced from biological resources, and exhibits superior mechanical properties compared to PET[3]. The purpose of this study has been to develop electrospun membranes of PEF derivatives, and perform a physico – chemical and electrochemical characterization, to evaluate the potential applications of this biopolymers in both biomedical and EES fields.

Sodium-ion batteries (SIBs) are being considered as a viable alternative to lithium-ion batteries (LIBs) due to their similar physical and chemical properties. However, it is crucial to recognize the distinct differences between SIBs and LIBs, particularly in terms of ionic radii.[1]

The research presented here focuses on iron-manganese-based oxide materials doped with bivalent elements as positive electrodes for SIBs. The synergistic effect of its two elements, Fe and Mn, and their abundance make this class of material environmentally appealing.[2] Nevertheless, the material exhibits air instability and undergoes multiple phase transitions during charging and discharging. To overcome these challenges, dopants can be introduced. Our focus is on materials with an O3-type structure, which allows for higher sodium content compared to P2-type structures, thus enhancing battery performance.[3]

This project pursues two main objectives. First, to optimize the co-precipitation synthesis process by considering various factors that influence it;[4] second, to comprehensively investigate the effects of various dopants from multiple perspectives, including electrochemical performance, structural stability, and moisture sensitivity. The study aims to contribute to the advancement of SIB technology by comprehensively analyzing the aspects mentioned above.

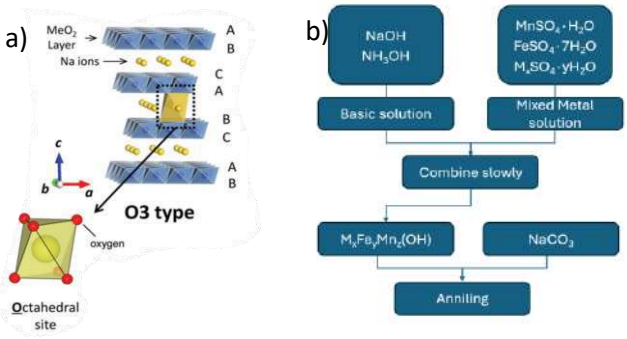

Figure 1: a) O3-type structure; b) synthesis protocol.

High entropy alloys (HEAs) are a new class of materials[1] that has attracted an increasing interest in recent years, in the form of thin films, because of their outstanding properties such as high strength/hardness, good wear resistance, high temperature strength, exceptional corrosion resistance[2]. In this work, we used pulsed direct current (DC) magnetron sputtering to fabricate HEA thin films of TiVNbMoAl 15-15-20-25-25 at%, starting from a single target of the same alloy composition. The films of 900 nm thickness were deposited on a 30 mm diameter 100Cr6 steel disk at two different temperatures of 25°C and 400°C. X-ray diffraction (XRD) analysis (Fig.1) was performed to prove the formation of a crystalline high entropy alloy film. The results showed that the films were well-crystallized (Body-Centered Cubic (BCC) Structure solid solution) at both temperatures, but the crystallite size increases with an increase of deposition temperature from 16 to 38 nm. In addition, no intermetallic phase was detected. The roughness was less than 10 nm, indicating that all the films have comparatively smooth surfaces. The chemical composition obtained by SEM-EDX analysis of the film appears to be in line with that of the starting target. The corrosion tests show an increase resistance of HEA-coated samples compared to the bare substrate, confirming the possible application of this class of materials as protective films.

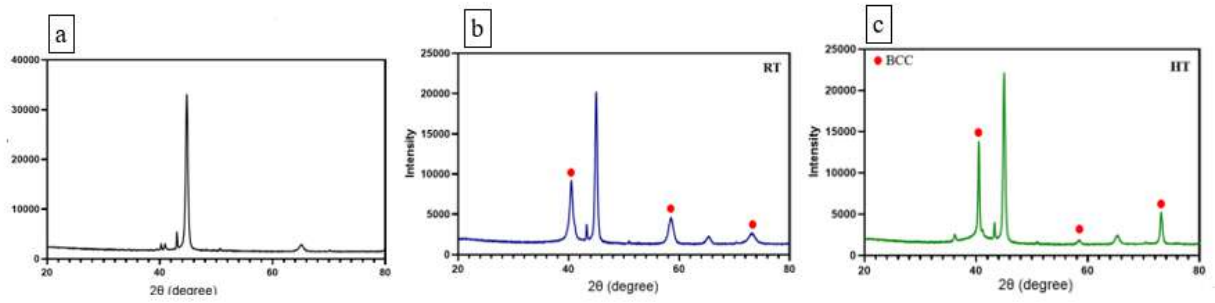

Figure 1: Comparison of XRD patterns of pristine 100Cr6 steel substrate (a), and of TiVNbMoAl HEA coatings deposited at 25°C (b) and 400°C (c). Body-Centered Cubic (BCC) Structure

Electrochemical Nitrogen Conversion into Ammonia in the SuN2rise ERC-StG Project

Andrea Giarrizzo, Anna Mangini, Noemi Pirrone, Lorenzo Sibella, Lucia Fagiolari, Sara Garcia Ballesteros, Federico Bella

Department of Applied Science and Technology, Politecnico di Torino Corso Duca degli Abruzzi 24, 10129 – Torino, Italy
andrea.giarrizzo@polito.it

The preservation of our planet is the most urgent issue in the world and the scientific community is pushing a lot of researchers to work on technologies for the storage/conversion of CO2 into chemicals. However, it is easier not to produce CO2 than setting-up plants to treat it.

In this framework, the ERC-StG project SuN2rise proposes an alternative breakthrough based on a versatile solar-driven strategy leading to redesign industrial processes. Facing the Haber-Bosch process for ammonia production (one of the most impactful chemical processes today), we propose the electrochemical fixation of dinitrogen into ammonia, by simply using air, water and ambient conditions. The scientific aim is that of demonstrating an integrated device where a photovoltaic (PV) unit will power a regenerative electrocatalytic cell converting dinitrogen to ammonia (E-NRR). A newly proposed Li-mediated approach under mild conditions, derived from an interdisciplinary contamination between electrocatalysis and Li-batteries, will be the key towards N2 conversion, bypassing both the competitive hydrogen reduction reaction and the complete irreproducibility of recent E-NRR approaches attributed to N-contaminations or degradation of N-based catalysts.

The team will further move beyond the state-of-the-art by fabricating transparent devices, that can be integrated in greenhouses, allowing the production of ammonia and ammonium fertilizers directly in farms, bypassing the known issues related to the massive infrastructure of ammonia plants and difficulties in reaching remote communities. The proposed approach will significantly impact also the field of liquid fuels, being ammonia safer and with higher energy density than hydrogen. Achieving these goals will require multidisciplinary expertise in the field of chemical, material, process and device engineering.

Electric Response and Conductivity Mechanism of Solid State Hybrid Inorganic Organic Polymer Electrolytes for Sodium Secondary Batteries

G. Pagot,[a] F. Brombin,[a] K. Vezzù,[a] E. Negro,[a] V. Di Noto[a]

[a] *Section of Chemistry for the Technology (ChemTech), Department of Industrial Engineering, University of Padova Via Marzolo 9, I-35131 Padova (PD), Italy*
gioele.pagot@unipd.it

The widespread adoption of electric vehicles, smart grids, and portable electronics is foreseen to necessitate a substantial quantity of energy storage devices, surpassing the capabilities of Li-ion batteries alone. Consequently, there is an ongoing exploration for innovative electrochemical energy storage technologies [1]. Among these alternatives, sodium secondary batteries (NaBs) emerge as promising solutions due to the abundant and cost-effective nature of raw materials, the low sodium standard reduction potential, and the chemical similarities between sodium and lithium, facilitating their implementation. Currently, state-of-the-art electrolytes for reversible sodium deposition rely on flammable organic solvents, which are unstable when in contact with sodium metal.

Drawing inspiration from the groundbreaking work conducted by Di Noto and colleagues [2-4], this study introduces a family of hybrid inorganic-organic polymer electrolytes (HIOPEs) designed for advanced solid-state NaBs. The HIOPE is synthesized by reacting zirconium ethoxide with polyethylene glycol (PEG400) and sodium perchlorate, resulting in a 3D hybrid network. This network features interconnected inorganic zirconium metal nodes and organic PEO chains, ensuring structural flexibility. To further enhance flexibility and ion conductivity, the HIOPE is doped with the poly(ethylene glycol) dimethyl ether (PEGDME250) plasticizer, achieving a room temperature value exceeding 10^{-4} S cm^{-1}. The proposed solid-state electrolytes undergo comprehensive analysis of thermal and structural properties, focusing on interactions within the HIOPE components. Additionally, the conduction mechanism is elucidated through broadband electrical spectroscopy studies in a wide range of temperatures and frequencies. This comprehensive exploration provides valuable insights into the utilization of non-traditional solid-state electrochemical functional components for NaB applications.

Oxygen Reduction Reaction *"Core-Shell"* Hierarchical Carbon Nitride Electrocatalysts: Correlation between the Features of the Precursor and the Physicochemical Properties of the Final System

V. Di Noto, E. Negro, S. Boudjelida, A. Nale, G. Pagot, K. Vezzù
Department of Industrial Engineering, University of Padova, Via Marzolo 9, 35131 Padova, PD, Italy
e-mail address: vito.dinoto@unipd.it

The oxygen reduction reaction (ORR) is a major bottleneck in the operation of proton-exchange membrane fuel cells (PEMFCs). Furthermore, the electrocatalysts (ECs) exhibiting the lowest ORR overpotentials are based on Pt, a very scarce critical raw material (CRM). Hence, the development of high-performing and durable ECs for the ORR is a major stepping stone towards the large-scale rollout of PEMFCs.

Our research group developed a new approach for the synthesis of ORR ECs, consisting in the pyrolysis and subsequent treatment of a precursor obtained by coupling suitable carbon species/sacrificial supports with a zeolitic inorganic-organic polymer electrolyte (Z-IOPE). The latter comprises organic binders bridging anionic complexes including the Pt *"catalyst"* and other *"co-catalysts"*. The proposed approach is extremely flexible, especially with respect to the synthesis of the initial EC precursor. In principle, it is possible to modulate a number of crucial features of such EC precursor: (i) the chemical composition (*e.g.*, in terms of Pt, other *"co-catalysts"* and N; the latter plays a crucial role to stabilize the active sites); and (ii) the morphology, that can be *"templated"* on suitable species. The very flexibility of the proposed synthetic process needs to be leveraged appropriately to maximize the performance of the final ORR ECs.

Herein it is elucidated how the modulation in the parameters involved in the synthesis of the EC precursor impact the physicochemical and electrochemical properties of the final ECs. An extensive characterization of the final ECs is carried out. ICP-AES and microanalysis are adopted to determine the bulk chemical composition. Near-ambient pressure XPS (NAP-XPS) elucidates the surface chemical composition and the chemical states of the surface elements. Cyclic voltammetry with the rotating ring-disk electrode method (CV-TF-RRDE) is used to clarify the *"ex-situ"* electrochemical performance and ORR reaction mechanism. Finally, the most promising ECs are used in the fabrication of single PEMFCs. In comparison with the Pt/C benchamark, some ECs are characterized by a much higher intrinsic kinetic performance due to the electronic and bifunctional effects bestowed by the carbon nitride support and the *"co-catalysts"*. Finally, the binder has a marked effect on the stoichiometry, size, and distribution of the PtM_x aggregates bearing the active sites.

Repurposing discarded porphyrin wastes as electrocatalysts for the oxygen reduction reaction

N. Giulini,[a] M. Muhyuddin,[a] S. Mattiello,[a] L. Beverina,[a] and C. Santoro[a]

[a] *Department of Materials Science, University of Milano-Bicocca, Via Cozzi 55, 20125 Milan, Italy*
n.giulini@campus.unimib.it

Hydrogen is a potential alternative to fossil fuels. The broad deployment of this technology requires the development of a reliable, affordable, and efficient supply chain of water electrolyzers (WEs) and fuel cells (FCs). The latter efficiently converts hydrogen into green electricity. However, the key bottleneck in their spreading out lies at the cathode where Oxygen Reduction Reaction (ORR) exhibits sluggish kinetics and requires a high loading of precious metals (e.g., Pt). In this view, Transition Metal-Nitrogen-Carbons (TM-N-Cs) are promising electrocatalysts (ECs) to replace Pt currently used for the ORR, especially for Alkaline Exchange Membrane Fuel Cells (AEM-FCs) technology.[1]

Nowadays, TM-N-Cs are typically synthesized through pyrolysis treatment mixing transition metal, nitrogen-rich organic precursors, and carbonaceous substrates of diverse nature.[2] Among the possible metal-containing precursors, metal-porphyrins are of interest as they contain already the desired structure of single-atom transition metal coordinated with nitrogen.

The Adler-Longo method is the standard and cheapest methodology widely used to synthesize porphyrins.[3] It consists of refluxing pyrrole and an aldehyde (e.g., benzaldehyde) in propionic acid, with yields in moles around 20% in the best-case scenario, and prices around 20-40 €/g. After the product purification, the remaining mass is considered waste and discarded. However, the latter is mainly composed of polypyrromethenes, molecules with chemical structures that resemble open porphyrin rings. Interestingly, they show the same chemical composition and the ability to coordinate metal cations, due to the presence of nitrogen atoms.

This study aims to synthesize both porphyrins and polypyrromethenes, integrate them into a carbon matrix, and investigate them as TM-N-C-based electrocatalysts. A comprehensive structural and morphological characterization is provided, and the electrocatalytic activity towards ORR in an alkaline environment (0.1 M KOH) is discussed. Notably, Iron-containing precursors were investigated, and the effect of a second metal, like Manganese, was studied as well. The possibility of upcycling the as-considered waste material is shown, demonstrating the capability of polypyrromethenes to be employed as a green and cost-effective alternative to porphyrins in ECs.

Organic Co-Solvent Mediated Electrolyte Engineering for Improved Performance of Aqueous Sodium-Ion Batteries

S. Khalid, [a] I. Pellini, [a] A.Tos,[a] G. Conte,[a] R. Ruffo,[a]

[a]*University Of Milano Bicocca,Via Roberto Cozzi 55, Milano*
s.khalid3@campus.unimib.it

While modern lithium-ion batteries demonstrate impressive performance and market dominance, significant safety concerns persist due to their reliance on highly flammable organic electrolytes, posing substantial risks for large-scale storage deployment. Moreover, the limitations surrounding lithium availability and distribution underscore the necessity of investigating alternative battery technologies[1]. Aqueous sodium-ion batteries offer promise as a viable solution to these challenges, particularly in applications where gravimetric energy density is not the primary consideration. However, widening the electrochemical stability window (ESW) in aqueous electrolytes necessitates the use of high salt concentrations, typically ranging from 21-55 mol kg^{-1}. Although these concentrated electrolytes effectively facilitate the formation of artificial solid-electrode interfaces and enhance water stability, issues related to cost and toxicity emerge[2]. To tackle these concerns, we propose the integration of an organic solvent into the aqueous electrolyte to effectively decrease water activity by modifying hydrogen-bonding structures. In this investigation, we explore a novel hybrid electrolyte system consisting of sodium bis(trifluoromethanesulfonyl)imide (NaTFSI) and a water-miscible polymer, poly(ethylene glycol) (PEG), acting as the organic co-solvent to reduce water activity. As a result, we achieve an extended ESW reaching up to 3V, with a moderate salt concentration of 5 mol kg^{-1} (PEG:H_2O=80:20), coupled with an impressive conductivity of 2.47 mS cm^{-1} at 25°C. Thermal behaviour and flow properties of these electrolytes were examined using techniques such as differential scanning calorimetry (DSC) and Rheometry. Initial full-cell investigations employing $NaTi_2(PO_4)_3$/$Na_3V_2(PO_4)_2F_3$ yielded a specific capacity of 48 mAh g^{-1} at 0.5 C, demonstrating a favorable columbic efficiency exceeding 98%.

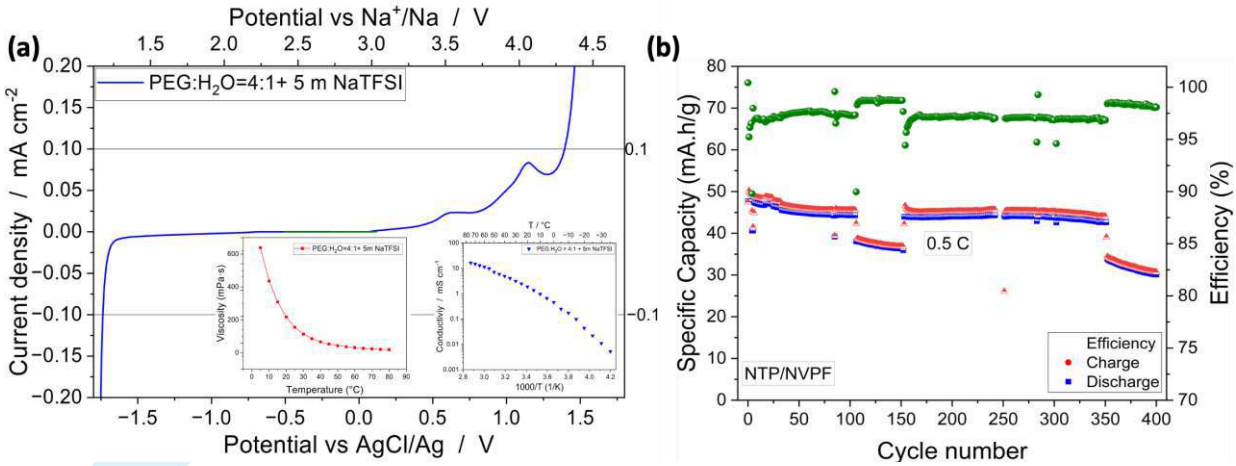

Figure 1: (a) Estimated ESW of PEG:H_2O:$NaTFSI_{5m}$ via LSV at 0.5 mV Sec^{-1} , Inset (conductivity & viscosity) (b) long cycling of NTP/NVPF full cell at 0.5 C in the PEG+H_2O + 5 m NaTFSI

Enhancing Lithium-ion Battery Anode Performance: Challenges and Solutions

G.Conte,[a] S.Khalid,[a] N.Pianta,[a] R.Ruffo[a]

[a]*University of Milano Bicocca, Via R. Cozzi 55, Milano*
g.conte15@campus.unimib.it

The quest for optimal anode materials in lithium-ion batteries has led to extensive exploration of various elements, with lithium metal, offering a theoretical capacity of approximately 3860 mAh/g, standing out as an ideal choice. However, practical constraints hinder its widespread adoption. Silicon emerges as a promising alternative due to its abundance and high nominal capacitance (3579 mAh g^{-1}), promising enhanced anode performance. However, its significant volumetric expansion (> 300%) during lithiation poses a major challenge, limiting its industrial viability[1]. Graphite, despite its lower capacity, remains favored for industrial applications owing to its abundance, cost-effectiveness, and satisfactory electrochemical properties. Recent efforts have concentrated on augmenting graphite's performance, with combined graphite-silicon electrodes gaining traction. Nonetheless, the integration of silicon introduces swelling issues, leading to the pulverization of electrode materials and subsequent performance degradation[2]. The current study aims to propose strategies for mitigating silicon-induced swelling and enhancing the performance of graphite-silicon composite electrodes. Proposed approaches include using graphene cages, surface modification, and specific binders. For instance, preliminary investigations suggest that electrodes incorporating a polymer composed of 5% by weight of a poly rotaxane (PR) and linear polyacrylic acid have shown promising results, achieving an areal capacity of 2.68 mAh cm^{-2} [3]. Furthermore, combining such binders with ionic liquid electrolytes containing lithium salts, such as LiVSi, has shown potential in significantly enhance the performance of this anode material to a capacity of 3.5 mAh cm^{-2}.

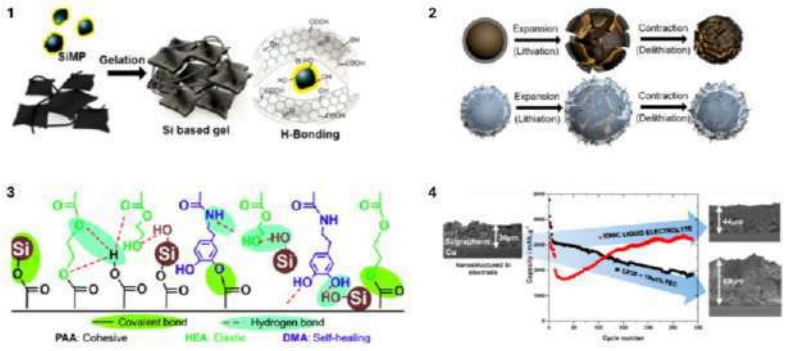

Figure 1. Possible approaches for solving the swelling problem in Silicon-based electrodes[5]

mattia.reato@phd.unipd.it

Since Professor Whetten's groundbreaking work on "Nanocrystals Gold Molecule" in 1996,[1] atomically precise nanoclusters (NCs) protected by ligand shells have emerged as a fascinating class of molecule-like species. Today, metallic NCs are a driving force in materials science, fueled by the ability to create novel functional materials with precisely tailored properties through ligand design.[2]

This work highlights the crucial role of ligand chemistry in manipulating NC behavior. We demonstrate how meticulous ligand design allows precise control over a broad spectrum of NC properties, including solubility, biocompatibility, electron transfer kinetic in both solution and solid state,[3] and chemosensing response for volatile organic compounds (VOCs). We also explore their potential for monolayer formation using the Langmuir-Blodgett (LB) technique. Furthermore, we report the first high-yield synthesis of a Au_{25} dimer bridged by a metal-complex moiety, that is a modified Ru(II) complex, achieved without by-product formation. This multicomponent, redox-active molecule exhibits unique properties such as quenched emission and intriguing spectroelectrochemical behavior. This feat was accomplished through a novel ligand exchange reaction (LER) strategy leveraging electrostatic forces and product precipitation.

This work underscores the importance of ligand design for synthesizing functional NCs with tailored properties, paving the way for the development of advanced materials with vast application potential.

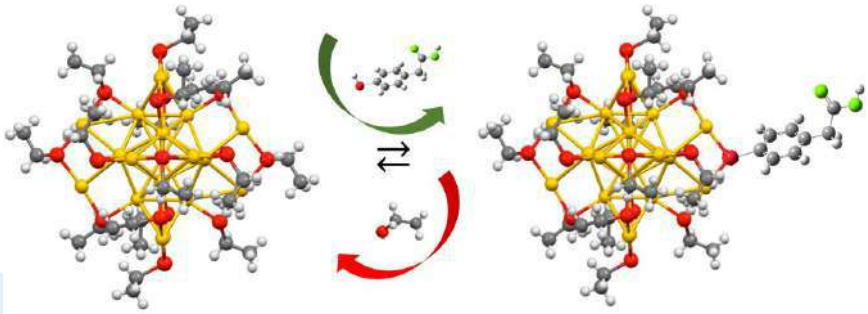

Figure 1: Example of surface modification by LER strategies on Au_{25} NC.

Development of a Fully Automated Method HS-SPME-GC-MS/MS for the Determination of Odor-Active Carbonyls in Wines: a "Green" Approach to Improve Robustness and Productivity in the Oenological Analytical Chemistry

M. Piergiovanni,[a] S. Carlin,[b] C. Lotti,[b] U. Vrhovsek,[b] F. Mattivi[a,b]

[a]*Center Agriculture Food Environment (C3A), University of Trento, via Edmund Mach 1, San Michele all'Adige (TN)*
[b]*Center Research and Innovation, Edmund Mach Foundation, San Michele all'Adige (TN)*
maurizio.piergiovanni@unipr.it

Volatile carbonyl compounds (VCCs) are the principal products of oxidation and are related to the characteristic pleasant scents of oxidized wines. However, apart from cases where it is a deliberate process, oxidation is commonly a side reaction whose uncontrolled advancement determines a relevant accumulation of VCCs resulting in undesirable odour defects. Accordingly, VCCs concentration represents a quality parameter for the evaluation of the correct winemaking style and proper bottling and storage[1]. To date, several analytical procedures have been developed for the quantitation of VCCs in wines but their application to the routine laboratory context is often limited by a laborious sample preparation involving the use of disposable labware and solvents, making them economically unattractive and environmentally impactful.

To overcome these limitations, an HS-SPME-GC-MS/MS method was optimised and validated. This protocol was based on a solvent-free extraction, in compliance with the Green Analytical Chemistry principles, and utilized the autosampler to perform the entire sample preparation, simultaneously achieving productivity, performance, and robustness. A total of 44 VCCs (linear, Strecker and unsaturated aldehydes, ketones, and numerous other compounds) were investigated. In solution derivatization with O-(2,3,4,5,6-pentafluorobenzyl) hydroxylamine hydrochloride (PFBHA) was used to promote recoveries especially for more complex VCCs; a mixture of 4 internal standards allowed to correct analytes of different volatilities.

All compounds exhibited satisfactory linearity ($R^2 > 0.99$) and a broad linearity range (from 0.05 to over 1000 µg/L for most VCCs), suitable intra-day and inter-day repeatability evaluated at two concentration levels (RSD < 25% in most cases) and satisfying recoveries measured in spiked samples. The method was applied to determine the evolution of VCCs in white (Gewürztraminer) and red (Teroldego) wines after accelerated ageing for 5 weeks at 50°C.[2] In all samples, furans and non-aromatic Strecker aldehydes increased in accordance with the state-of-art of ageing models. Some VCCs like many linear aldehydes and benzaldehyde accumulated at the beginning and then decreased in the second part of the ageing, being reasonably involved in equilibriums which depend on temperature and pressure. Finally, numerous VCCs exhibited no significative variation, indicating that their formation is not necessarily related to oxidation and ageing.

Lipids, proteins, cells: advanced spatial multiomics to delve deeper into the complex molecular and cellular landscape of the tumour microenvironment

G. Bindi[a], N. Monza[a], G. Santos de Oliveira[a], V. Denti[a], V. L'Imperio[b], F. Pagni[b], F. Magni[a], A. Smith[a]

g.bindi@campus.unimib.it

The advent of mass spectrometry-based spatial multiomics has enabled the possibility to map different classes of biomolecules, such as lipids, N-glycans, and proteins, all within a single tissue section[1]. In the context of tumour biology, the application of these techniques is of particular interest when it comes to the characterisation of the Tumour MicroEnvironment (TME), which comprises heterogeneous sets of cell populations including tumour cells, immune cells, fibroblasts, endothelial cells, and more, along with their specific molecular signatures[2]. The possibility to map tumour-infiltrating lymphocytes, while also understanding their altered molecular mechanisms, could potentially unveil which factors are major contributors in the tumour-immune cell interplay which is known to mediate immunosuppression and influence the outcome of cancer treatments such as immunotherapy[2]. In this work, we apply a MALDI Mass Spectrometry Imaging (MSI) trimodal spatial omics approach for the subsequent mapping of lipids, immune cells, and proteins within a single clear cell Renal Cell carcinoma (ccRCC) tissue section. The visualization of immune cells was performed with MALDI-HiPLEX-IHC, a targeted imaging approach which is aided by immunostaining with antibodies linked to photocleavable mass tags. This targeted imaging step was used to map the relative position of different cell populations within the TME, and to subsequently individuate regions of interest on tissue where the presence of regiospecific lipids and proteins could be assessed in an untargeted way to understand the molecular alterations which characterise aberrant cell-cell communication. The application of this protocol on lymphocyte-rich ccRCC samples enabled the relative distribution of tumour cells and lymphocytes, including immunosuppressive T regulatory cells, to be mapped. Moreover, their lipidomics and proteomics alterations could be characterised and features of interest tentatively annotated by higher resolution mass spectrometry-based techniques. Whilst preliminary, our results are promising in determining the molecular signals which are crucial in determining the immunosuppressive state which characterises the TME and that could contribute to failure to immunotherapy.

l.santorelli@tigem.it

Functional interactions among proteins are fundamental in driving regulatory activities for cell biology, including mechano-transduction, cell-to-cell communication/recognition, endocytosis and secretion. Since the plasma membrane proteins (PMPs) constitute ~30% of the mammalian proteome and 60% of all drug targets [1], have access to the complete "membranome" PPIs network would represent an unbiased approach to depict regulatory pathways controlling cell behaviour.

Recently, cross-linking mass spectrometry (XL-MS) has emerged as a powerful and versatile technique in the field of structural and functional biology, enabling the elucidation of protein-protein interactions (PPIs), protein conformational changes, and the mapping of intricate networks within biological systems [2].

Hence, we decided to apply an XL-MS approach to map, on a system-wide scale, the PMPs networks of He-La cells, used as cellular reference model. Our strategy included cross-linking of PMP-enriched fractions, label-free nanoLC-MS/MS analysis, and bioinformatics data elaboration.

Specifically, we present a cross-linked MS dataset of cells before (native) and after (disrupted) plasma membrane (PM) dissolution, applying the MS-cleavable cross-linker disuccinimidyl dibutyric urea (DSBU). We defined the best experimental settings in terms of DSBU concentration, cross-linking reaction time, PM enrichment, MS acquisition and elaboration. Based on all detected inter-links, we constructed a global network composed of unique residue-to-residue pairs originating from more than 300 proteins assigned to the PM compartment. The comparison to known interactions revealed an overlap of 25%, confirming the accuracy of our dataset. With respect to PM-associated proteins, we detected the highest number of PPIs for specific PM member families: ATP-binding cassette (ABC) transporters, solute carrier (SLC) transporters family, ATPase Na^+/K^+, Cu^{2+} and phospholipid transporters. The remaining cross-links were identified for proteins which are currently not described as interacting with each other, presenting potentially *de novo* partners.

At present, we are applying XL-MS for the characterisation of PPIs changes occurring at the PM in response to micro-environment stimuli and in cell models of inherited metabolic diseases.

Pollution and Exposome: description of search for biomarkers of effect of oxidative stress; preliminary results

C. Maccari[a], R. Andreoli[a]

[a]*Laboratory of Industrial Toxicology and Advanced Analytical Methods, Department of Medicine and Surgery, University of Parma.*
Mail: chiara.maccari@unipr.it

Pollution and oxidative stress have characteristics in common: both are originated by several factors, for their characterization it is necessary to quantify and compare more biomarkers, differing are the adverse effects on health and exposure to pollutants causes oxidative stress. To describe the contribution of both (air pollution and oxidative stress) in healthy subjects compared to patients with respiratory diseases are important identify specific biomarkers of exposure to environmental toxics and of effects to oxidative stress [1].Asthma is one of the most common respiratory diseases in the world, with an estimated 300 million asthmatic patients of all ages; for this type of pathology, the pollution probably causes a direct irritating effect and a consequent oxidative damage to the neuroreceptors and the epithelium of the airways, resulting in chronic inflammation, remodelling and increased risk of hyper-bronchial reactivity, aggravating pre-existing respiratory diseases such as asthma or inducing its occurrence. The role of air pollutants in triggering asthma exacerbations in young and adult asthma patients was established and investigated by several studies that support the role of air pollution in the development of asthma in childhood [2].For this purpose, the study design provides for the recruitment of both healthy subjects (200 adults and 100 children) and asthmatic ones (100 adults and 50 children) and for both the collection of spot urine samples and brush samples. Urinary concentration levels of Benzene, Toluene, Ethylbenzene and Xylenes (BTEX), Styrene and Methyl-tert-butylether (MTBE) and their metabolites will be quantified to characterize the environmental exposure; as biomarkers of nucleic acids damage, the oxidative forms of guanine, guanosine and 2'deoxyguanosine, and the methylated forms of cytosine, cytidine and deoxycytidine will be determined in urinary samples. All the analyses will be performed by GC-MS and LC-MS/MS techniques [3]. In the brush the main polymorphisms of biotransformation enzymes involved in the metabolization of toxic related to pollution were characterized in order to describe the individual susceptibility of the subjects recruited. The non-invasiveness of the matrices allows to quantify the levels of the biomarkers also children and in fragile subjects. We had validated the analytical methods used to the quantification of biomarkers of exposure and of effects, we quantified in urinary samples HMGB-1, markers of inflammation, and we found a different between healthy and asthmatic subject.

The metabolic role of trehalose in autophagy induction in central nervous system

S. Serrao[a], D. Camazzola[b], V. Denti[a], E. Bossi[a], E. Limo[a], A. Esposito[b], G. Martano[b], F. C. Guarnieri [b,c], L. Murru[b], G. Paglia[a]

simone.serrao@unimib.it

Trehalose is a non-reducing disaccharide made of two glucose molecules linked by an alpha-1,1-glycosidic bond. In the last years, trehalose applications increased exponentially, and now it is widely used in various industrial applications[1], leading to an increased "involuntary" intake. Different works indicated that trehalose reaches the central nervous system, where it is probably metabolized by neurons[2] and exerts neuroprotective roles since its ability to induce m-TOR-independent autophagy[3], but the molecular mechanism behind the autophagy activation is still unclear. Preliminary experimental data highlighted that trehalose might induce autophagy through a metabolic mechanism occurring in lysosomes organelles.

In this study, we propose to clarify the molecular pathways underpinning trehalose-induced autophagy. Rat hippocampal neurons were treated with trehalose, and with glucose as control. At the same time, lysosomes were isolated from treated and non-treated rat hippocampal neurons with immunoprecipitation assay protocol.

Neuronal cell and isolated lysosomes have been analyzed with untargeted LC/MS-based lipidomics and metabolomics approaches. Our preliminary results showed an augmented concentration of short-chain carnitines and a down-regulation of metabolites involved in energetic metabolism and aminoacidic metabolism in trehalose-treated cells. We also highlighted increased levels of lysophosphocholines and lysophosphatidylethanolamines in cells treated with trehalose, suggesting that the mobilization of membrane lipids happened, probably due to phosphatases activity. Results on lysosomes exhibited variations in polar metabolites involved in aminoacidic and energy metabolism.

Overall, our preliminary results show that the trehalose perturbation cause important metabolic variations that could be linked to autophagy induction.

pdellasala@unisa.it

Non-covalent molecular interactions are crucial in both biological systems and their synthetic counterparts, facilitating various applications like drug delivery, nanoreactor development, and molecular sensor innovation.[1] Within this domain, supramolecular chemistry has been pivotal in crafting bioinspired architectures for many applications in different fields.[2]

The primary advantages of MALDI-MS or ESI-MS for studying host-guest complexes lie in their ability to ionize under relatively mild conditions. This facilitates the direct ionization of solution-phase samples under native conditions, enabling the preservation of secondary interactions. Additionally, these techniques offer rapid response times, enhancing efficiency in analysis.[3]

Regarding supramolecular systems, mass spectrometry can give crucial insights into supramolecular associations in the gas phase,[4,5] the kinetic stability of complexes, and reactions occurring within molecular containers. [6]

In this communication, we will show our recent results regarding the characterization of supramolecular systems utilizing high-resolution mass spectrometry. Our aim is to show novel aspects pertaining to the encapsulation phenomena in gas phase within supramolecular systems.

A new comparative metabolomic approach to characterize the standardization of the UVCB production process

M.Burico,[a] B. Gironi,[a] C.M. Quintiero, [a] S. Tamimi [a], M. Stocchero[b], D. Decarli [a], M. Gianni [a], L. Mattoli[a]

[a]*Metabolomics and Analytical Sciences, Aboca S.p.a., Loc. Aboca 20, 52037, Sansepolcro, Italy*

mburico@aboca.it

REACH is the regulation (CE n. 1907/2006) which governs the registration, evaluation, authorization and restriction of chemical substances. Substances can be divided between "*well-defined substances*" with a 100% defined qualitative and quantitative composition and "*UVCB substances*".

Substances of unknown or variable composition, complex reaction products or biological materials (UVCB) represent all complex chemical mixture whose number of constituents is high, whose composition is largely unknown or the variability of the composition is unpredictable. In this case, a complete identification based on chemical composition is not possible. Typical examples of UVCB are natural complex matrices (NCMs), essential oil, resins and petroleum products[1]. The challenge regulatory framework is to find the way to characterize the whole substance by developing new analytical approaches. Here we present the workflow for metabolite fingerprint and profiling (untargeted metabolomics) and relative quantification (targeted metabolomics) of the principal characteristic metabolites in NCMs. In untargeted metabolomic approach a huge number of known and unknown metabolites are detected and all the obtained variables are considered simultaneously, in agreement with the minimum reporting standard of the Metabolome Standard Initiative (MSI), allowing the detection of interactions between variables (e.g. synergic effects). This approach can be useful both to develop new complex products with NCMs, to monitor the standardization of their production process and to confirm the maintenance of the quali-quantitative profile from batch to batch. By Variable Selection algorithms[2], it is possible to select a sub-set of relevant features representative of the entire initial dataset. In this work, we focused the attention on a selected number of compounds and we demonstrated that statistically the data set of the relevant features has the same trend of the original one. The most relevant features of the untargeted model were than selected for a targeted metabolomic approach that was further relative quantified with respect to a reference sample serially diluted to gain corresponding calibration curves. This innovative workflow is the rapid and less expensive way to characterize NCMs by the screening of identified or annotated suspect compounds[3].

The interplay between UV spectroscopy and high-resolution mass spectrometry for the confident identification of Cucurbitacins in unexpectedly bitter Scopatizzo melons

A. Castellaneta[a], I. Losito[a,b], O.D. Palmitessa[c], M. Renna[c], B. Leoni[c], P. Santamaria[b,c], C.D. Calvano[a,b], T.R.I. Cataldi[a,b]

andrea.castellaneta@uniba.it

Have you ever experienced a surprisingly bitter taste when biting into a Scopatizzo melon (*Cucumis melo* L.)? Apulian producers have faced this issue since 2022, due to the appearance of Scopatizzo fruits exhibiting such an unpleasant characteristic[1]. The bitterness is caused by the production of cucurbitacins, *i.e.*, a natural defence mechanism found in cucurbitaceous plants. Cucurbitacins are a group of bitter and highly oxygenated tetracyclic triterpenes, that are mainly produced in plants belonging to the Cucurbitaceae family such as cucumbers, melons, and watermelons. These secondary metabolites make the plant unappealing to predators, protecting its stems, leaves, and fruits. However, the ingestion of cucurbitacins can be harmful to humans. It might determine the outbreak of gastrointestinal disorders and even lead to more serious health risks[2]. For generations, careful plant breeding has ensured Scopatizzo melons to be deliciously sweet[3]. Nevertheless, the distinctive unpleasant taste of the wild ancestors can still appear due to random genetic backmutation and cross-pollination phenomena[1]. Hence, it is crucial to assess the presence of cucurbitacins in these fruits to protect both the consumer's health and the economic losses of local producers.

In this communication, the hyphenation of hydrophilic interaction liquid chromatography (HILIC) with UV detection and atmospheric pressure chemical ionization (APCI) high-resolution mass spectrometry (HRMS) was successfully exploited for the identification of all the major cucurbitacins occurring in bitter-tasting Scopatizzo samples. The UV spectra interpretation of cucurbitacins, along with the rationalization of MS/MS spectra resulting from the collision-induced dissociation of carbocations resulting from the in-source fragmentation of cucurbitacin ions as protonated molecules, returned precious information about the discriminating structural traits between the diverse cucurbitacin molecules. Four cucurbitacins were recognized in Scopatizzo fruits, *i.e.*, cucurbitacin R, cucurbitacin D, cucurbitacin B, and 23,24-dihydrocucurbitacin B. The identification was corroborated by the few available analytical standards, and the comparison with the cucurbitacin profile of the cucumber *Ecballium elaterium* L., representing a well-known and studied natural source of cucurbitacins.

Advances in thyroglobulin measurement: exploring dried blood spot mass spectrometry for enhanced clinical utility

N. Monza,[a] V. Denti,[a] C. Chinello[a], I. Piga[b,] F. Magni[a]

[a] *University of Milano Bicocca, School of Medicine and Surgery, Vedano al Lambro (Monza), Italy*
[b] *Department of Biomedical Sciences, University of Cagliari, Cagliari, Italy*
n.monza@campus.unimib.it

In contemporary medical practice, human thyroglobulin (Tg) represents the primary tumour biomarker for detecting the recurrence of differentiated thyroid carcinoma (DTC) in patients who have undergone thyroidectomy[1]. Tg is a large and highly glycosylated tissue specific protein exclusively produced by both healthy and tumour thyroid follicular cells in the thyroid gland[2]. Different techniques, including immunometric assays (IMA) and radioimmunoassays (RIA), have been implemented in clinical settings to gauge Tg levels in blood samples collected through venipuncture[3]. However, the reliability of these methods is compromised by the presence of antibodies, including antithyroglobulin antibodies (TgAbs) and heterophile antibodies (HAs), resulting in frequent inaccuracies in the quantification of T due to either the under or overestimation of the actual values[4,5]. In recent years, liquid chromatography tandem mass spectrometry (LC-MS/MS) has emerged as a distinctive and alternative tool aimed at overcoming the challenges posed by antibody interference[6]. Despite its potential, the effectiveness of LC-MS/MS has yet to be fully explored and, if performed, could improve our knowledge regarding the potentiality of this tool for the detection of Tg[3, 6].

In this work, we present a workflow, based upon LC-MS/MS and Stable Isotope Standards and Capture by Anti-Peptide Antibodies (SISCAPA®) technology, to quantify Tg in patients with thyroid cancer, indicating greater sensitivity and specificity with respect to the routinely available protocols. Moreover, this workflow is also currently being translated and tested for use with samples obtained with DBS (dried blood spot) devices, a simple, cost effective, and minimally invasive alternative to those obtained by venipuncture[7]. Based upon these findings, this LC-MS/MS and SISCAPA® based approach not only shows the potential for improving the accuracy of Tg quantification but may also simplify this process for patients living in remote areas who could independently collect DBS samples for Tg monitoring.

angelicarebecca.zizzamia@unibas.it

The erectile dysfunction drug sildenafil has attracted a great deal of attention in recent years due to its widespread legal and illegal use around the world and its increasing use by young people for recreational rather than medical purposes[1]. Due to sildenafil's high stability in various environmental conditions and its accumulation or phototransformation in receiving waters, this dangerous trend poses a significant risk to both human health and the environment[2]. Therefore, in-depth studies are needed to find innovative methods for completely removing sildenafil from the aquatic environment, while limiting the formation of more toxic derivatives. This study investigated the efficacy of photooxidation processes for removing sildenafil and its potentially toxic derivatives from water. Distilled water and synthetic wastewater were treated with three different oxidants: peroxymonosulphate (PMS), peroxide sulphate (PS) and hydrogen peroxide (H_2O_2), and a heterogeneous catalyst, TiO_2. The investigation also considered the formation of potentially toxic phototransformation products, performing a tentative structural identification by LC-ESI-MS and MS^n. The results proved that the Sunlight/PMS system is the most effective for entirely and environmentally friendly removal of this drug and its transformation products from aquatic environments, achieving complete degradation in distilled water and synthetic wastewater after 80 and 130 minutes of irradiation, respectively. Toxicity bioassays on *Vibrio fisheri* and *in silico* tests using the software ECOSAR confirmed the non-toxic nature of the phototransformed products. This study highlights the potential of Sunlight/PMS photooxidation as a promising strategy for mitigating the environmental risks associated with sildenafil contamination.

sara.avesani@unipd.it

Plants are members of communities inhabiting an environment within which they can share or compete for resources as well as communicate [1,2]. Plants have evolved various mechanisms to explore the environment and interact with neighbouring plants. Among these the most effective being the release of arrays of volatile organic compounds (VOCs) from their leaves, flowers, and fruits into the atmosphere and from the roots into the soil[1].

These communicative responses are well documented[1,2,3,4], but what precedes them and the mechanisms that are actively involved, have yet to be identified. To fill this gap the present work will measure the changes in VOC emission of pea plants acting with either a cooperative or competitive attitude.

Two varieties of *Pisum sativum*, L. (*sativum sativum* and *sativum macrocarpon*), were chosen as model plants, to compare the behavior and emissions within the same or different genotypes belonging to the same species or genus. Pea plants were grown in a phytotron with eight climatic chambers. An untargeted metabolomics approach was applied using a Proton Transfer Reactor - Time of flight - Mass Spectrometer (PTR-MS-TOF) analysis. Preliminary results reveal differences in VOC emissions when comparing cooperating and competing pea plants. This study shed definite light on the physiological and molecular events occurring in interacting plants.

maria.acquavia@unibas.it

Packaging plays a crucial role in facilitating modern food systems. Although conventional plastics find wide applications in the field of food packaging, the negative environmental impact caused by the disposal of "single-use plastics" is currently driving the market towards alternative solutions[1]. Consequently, the demand to develop and produce eco-friendly alternatives for food packaging is increasing. The most recent research concerning bioplastic production focuses on by-products and waste materials from food industries[2]. In this work, tea waste (TW) extract has been added to a polylactic acid (PLA) polymeric matrix in order to fabricate new active bio-materials for packaging applications, able to extend food shelf-life avoiding moisture loss and colour and textural changes. Liquid chromatography coupled to tandem mass spectrometry with electrospray ionization in negative ion mode (LC-ESI(-)-MS/MS) has been used to provide an untargeted characterization of the bioactive compounds occurring in TW extract, which could be freely released in the head-space of packaging, acting as antioxidants. Data-dependent acquisition offered the possibility to get selective MS/MS spectra, allowing the identification of several metabolites with well documented biological activity that accounted for the high antioxidant properties of the fabricated bioplastics (radical scavenging activity up to 60% against DPPH radical). As food contact materials should comply with the specific conditions described in the EU Regulation 10/2011, which lists all the permitted substances that can migrate into food or food simulants[3], an evaluation of the non-intentionally added substances (NIAS) released from TW based plastics was carried out. An HS-SPME-GC-MS method, using a polydimethylsiloxane fiber (100 µm), was optimized to analyse the volatile organic compounds released from PLA and PLA/TW composites. The results obtained from the molecular fingerprint of PLA volatiles, mainly comprising aldehydes and few substances of health concerns, showed that VOC emission was reduced by TW extract addition, thus increasing the safety of the fabricated materials for food contact purposes.

NIR and HR-MS techniques for the prediction of physical, chemical and biological properties of honey

B. Gironi,[a] C.M. Quintiero,[a] M. Burico [a], S. Tamimi[a] ,M. Gianni[a] ,L. Mattoli[a]

[a] *Metabolomics and Analytical Sciences, Aboca S.p.A, Loc. Aboca 20, Sansepolcro, 52037, Italy*
bgironi@aboca.it

Natural Complex Products (NCPs) based on Natural Complex Matrices (NCMs), derived from medicinal plants are used to realize substance-based medical devices. In recent years, thanks to the evolution of the regulatory framework about medical devices in EU (Reg 2017/745) is of great importance increasing the knowledge about complex systems emerging properties that can be related to their biological activity. Therefore, new analytical approaches need to be applied for a complete characterization of NCPs that is not limited to a single compound[1,2].

In this scenario, an exhaustive characterisation of the physical, chemical and biological properties of honey as NCMs, which depend on its botanical origin and geographical production area, is of growing interest to monitor the quality of the product and guarantee its characteristics[3].

Despite the number of studies on honey, a comprehensive approach that describes with analytical tools the specific physical, chemical and biological properties associated with its composition is still lacking.

To identify an approach that describes the complexity of honey as much as possible, in the present work NIR and HR-LC-MS fingerprint analyses on several samples of honey (blend of polyfloral and Acacia) coming from different geographical areas (Europe and South America) were carried out and their correlation with various physical, chemical and biological properties were evaluated. In particular, electrical conductivity, glucose and fructose content, antioxidant activity, abiotic adhesion were measured.

Unsupervised multivariate statistical analysis on NIR and UHPLC-qToF metabolomic fingerprint was applied for a preliminary description of the behaviour of the different types of honey.

Partial Least Square regression (PLS-r) was used to correlate electrical conductivity, glucose and fructose content, antioxidant activity, abiotic adhesion with NIR and UHPLC-qToF data. The statistical models created highlighted the presence of some different honey samples, which were further subjected to targeted analyses of phenolic compounds.

In conclusion, the studied approach is suitable for identifying the correlation existing between chemical and physical/biological characterization data.

cmquintiero@aboca.it

It has estimated that plants produce from 90,000 to 200,000 different compounds classified into primary and secondary metabolites. To define the plants metabolome, it is necessary the development of metabolomic approaches, to increase the identification and quantification of plants metabolites, their patterns and relationships as part of Natural Complex Matrices (NCMs)[1]. In this way untargeted and targeted metabolomics approach using hyphenated methods, such as UHPLC-qToF, are widely applied to obtain high resolution mass data.

Untargeted metabolomic data obtained by HR-LC-MS techniques are affected by intra-batch and inter-batch effects, which are the major confounding factors in data interpretation[2]. Batch effects lead to results that are not reproducible along the analytical sessions; this is why experimental data-processing and data pre-treatment strategies are necessary to minimize its impact.

In this study fourteen samples composed by NCMs were analysed in three different analytical sessions. Each sample was stored at -80°C before acquisition and acquired in randomized sequences. The following correction strategies for batch effect were applied:

- The use of different internal standards (ISTD)[3] added to the samples to normalize the response in specific regions of the entire chromatogram depending on chemical similarity associated to the analytical method.

- The use of quality controls sample (QC) at the same concentration randomly included along the analytical session as reference for apply the substraction of the mean responses to all the compounds detected (mean centering) and the probabilistic quotient normalization (PQN)[4].

- The use of quality controls sample (QC) at different concentrations randomly included along the analytical session that generate for each compound a linear regression model to estimate the compound response.

This study highlights the best way to correct batch effect to characterize and monitor the quality and manufactoring process of products based on NCMs.

antonella.difrancesco@unict.it

Lupin belongs to the legume family (*Fabaceae*) and it has both health and commercial values in the food industry in relation to their high protein content, high concentration of essential amino acids and dietary fiber, and negligible starch contents.[1] In addition, lupin seeds have many nutraceutical properties, including hypoglycemic activities or the ability to maintain low-level of both cholesterol and blood pressure. Therefore, during the last years there has been a growing interest for this legume which is considered as a target food for healthy living.[2] On the other hand, with the rapid introduction of novel foods and new ingredients in traditional foods, the number of people allergic to lupin is also rising, but the frequency of sensitization and allergic reactions to lupin in the general population is still unknown.[3] All legumes contain various anti-nutritional substances but, unlike other legumes, lupin has anti-nutritional components which are represented by quinolizidine alkaloids causing a bitter taste. They can be toxic and therefore are removed through specific technological processes.[4] Taking into account consideration that lupin seeds are recognized as a protein-rich crop and their use as a dietary protein source is of increasing interest, in the present work a comparative proteomic analysis, both at a qualitative and quantitative level, of two different cultivars of narrow-leaf lupin (*Lupinus angustifolius*), namely "Polo" and "Boregine", was carried out. Particularly, the "Polo" variety is naturally free or almost free of quinolizidine alkaloids. These cultivars show a good resistance to water stress, lodging, and are mainly, but not only, used for the production of feed and fodder. The preliminary results of this investigation highlighted that, although the two cultivars show a very similar protein composition, some differences related to the different expression level of some genes are still present. Particularly, "Boregine" shows a higher amount of a group of proteins having allergenic properties, whereas "Polo" contains a higher amount of proteins involved in antioxidant activity. These finding might be correlated to a major resistance of the cultivar for "Polo" against biotic and abiotic stresses, and to a potential major allergenic property of the cultivar "Boregine".

lucia.cioffi@unimi.it

Neuroactive steroids are steroid hormones, such as pregnenolone, progesterone, testosterone, and their metabolites, with important modulatory actions on behavior and nervous functions[1]. They are produced both in peripheral glands and in the nervous system through the steroidogenic process[1]. Previous studies have reported that plasma neuroactive steroid levels do not exactly reflect what occurs in the central nervous system and those levels are different based on the brain region analyzed[3] and sex[2]. These concepts have been described in physiological and in pathological situations[3], and even after a period of gonadectomy, suggesting that other factors may be involved in the regulation of their levels[2]. Interestingly, sex steroid levels are influenced by sex chromosome complement[4]. However, the effect of sex chromosomes on neuroactive steroids in the two sexes has not been evaluated yet.

The four core genotype (FCG) mouse is an experimental model in which the sex chromosome complement is unrelated to the animal's gonadal sex[5]. Therefore, this experimental model allowed us to investigate the effect of gonads in relation to chromosome complement on the levels of neuroactive steroids in plasma, hippocampus, and hypothalamus assessed by liquid chromatography coupled with tandem mass spectrometry[6].

Data obtained showed a tissue-specific involvement and a regional-specific interaction of sex chromosomes and gonads, resulting in neuroactive steroid level differences in plasma, hippocampus, and hypothalamus based on the genotype.

Due to the high number of neurological and psychiatric disorders associated with sex- and regional-specific alterations of neuroactive steroid levels and the implication of sex chromosome genes in pathological conditions, the results of this study may help to improve the knowledge of related brain disorders.

Oral fluid as a new investigative matrix to determinate IGSR and OGSR exposure

F. Pagano[a,b,c], M. Masella[c], F. Vincenti[a], C. Montesano[a], R. Curini[a], M. Sergi[a]

[a]*Chemistry Department, University La Sapienza, Rome, Italy*
[b]*Public Health and Infectious Disease Department, University La Sapienza, Rome, Italy*
[c]*Delta APS Service, Rome, Italy*

The increased use of ammunition without lead and heavy metals was observed, leading to a growing interest in the detection of organic gunshot residues (OGSR) as evidence of firearms related crimes; however metal determination helps us to determine the type of ammunition used.[1,2]

The purpose of this work is the development of a reliable analytical method by means of ICP-MS for the determination in oral fluids (OF) of the most common metals used found in ammunition and gun cleaning oils.

For this purpose, acid extraction in microwave was used for the OF clean-up and metals extraction before ICP-MS analysis.

The method was tested on real samples: a shooting session was performed in an open shooting range; the shooters fired from 2 to 200 rounds with a 9x21 caliber, after which they were sampled. Samples were analyzed confirming that metals explosives may be detected in OF, the use of this matrix may be of great interest for investigative purposes as it is not affected by secondary transfer. and the sampling is fast, not invasive and can be performed by non-medical staff. The study demonstrates how the most commonly used metals both in the ammunition and in the primer are found in different concentrations depending on the type of cartridge used and the number of shoots. The study also showed that people in close contact with the shooters (example: shooting instructor) still inhaled a large amount of metals and allows us to assess the presence of the risk factors of the exposed subjects. The presented method allows the determination of very low traces of analytes, providing evidence of a direct contact with IGSR.

This represents an interesting starting point for the assessment of the potential exposure to IGSR or the use of firearms at a crime scene.

In this work also the persistence of IGSRs in OF was investigated. The preliminary results obtained during this trial are very promising, as a close correlation between the concentration of IGSR in saliva and the time elapsed between sampling and exposure was observed.

Method optimization for the analysis of thyroid hormones and their main metabolites

G. Barone[a,b], D. Martinez-Brito[a], X. de la Torre[a], F. Botrè[a,c]

[a] *Laboratorio Antidoping, Federazione Medico Sportiva Italiana, Largo Giulio Onesti, 1, 00197, Rome, Italy*
[b] *Dipartimento di Scienze e Tecnologie Chimiche, Università di Roma "Tor Vergata", 00133 Rome, Italy*

g.barone@labantidoping.it

In recent years, the number of athletes subjected to doping control who have declared the use of thyroid hormones has significantly increased[1,2]. There appears to be a necessity to investigate and assess whether the use of thyroid hormones could constitute a substance of abuse in sports, along with the potential consequences that this may provoke. The present study aims to develop an analytical method with an adequate recovery of all the components of the thyroid metabolic pathway and then apply it to real urine and serum samples from individuals who have assumed thyroid hormones[3]. Indeed, the purpose is to investigate if, compared to euthyroid subjects, there are different metabolic ratios, i.e. T3AA (3,3′,5-triiodothyroacetic acid) /T4AA (3,3′,5,5′-tetraiodothyroacetic acid), T3/T3AA and T4/T4AA that could indicate an abuse of these hormones[3]. The evaluation of different organic solvents, with or without additives, for the mobile phases, comparison between liquid-liquid extraction, with different solvents and at different pH, and solid phase extraction, with different types of cartridges, were evaluated. Raw data were acquired in positive and negative electrospray ionization modes using an Agilent Technologies 1290 Infinity II series HPLC coupled to an Agilent QTOF 6546 acquiring in Full scan and Product Ion Scan acquisition modes and an Agilent Technologies 1290 Infinity II series HPLC coupled to an Agilent Ultivo LC/QT operating in MRM (Multiple Reaction Monitoring) acquisition mode. Preliminary results suggest that a good compromise for the recovery of the main thyroid hormones and their acidic and basic metabolites was obtained using Oasis WAX (Weak Anion Exchange) cartridges, applying two different elutions that enable the differentiation between neutral and basic compounds and acidic compounds (including acidic metabolites containing carboxylic functional groups). The Full scan mode was used to optimize parameters as capillary voltage, nebulizer gas pressure, nozzle voltage, sheath gas flow, sheath gas temperature, drying gas flow, and drying gas temperature for the ionization source. In particular, the parameters were set to avoid in-source fragmentations, especially for acid metabolites such as T3AA and T4AA. The Product Ion Scan mode was used to study the analytes fragmentation process to find the most abundant fragments formed. This step was necessary to select the most relevant transitions in the MRM acquisition method. Adding ammonium formate, ammonium fluoride, and acetic acid to the mobile phase showed no improvement in responses compared to classic 0.1% formic acid. In conclusion, thyroid hormones and their derivatives are structurally related to the non-essential amino acid tyrosine. However, physicochemical differences make it challenging to apply an analytical procedure for their simultaneous extraction and detection. In this study, an LC-MS/MS method was optimized to detect TH and derivatives with a unique pretreatment procedure and in a single chromatographic-mass spectrometric run.

Occurrence of ChloroPerFluoroPolyether Carboxylates (PFPECAs) in environmental and biota samples: evaluation of toxicity profile of ClPFPECA-N2 by lipidomics approach

S. Moretti[a], E. Artino[a], G. Cruciani[a],L. Goracci[a]

e-mail: simone.moretti@unipg.it

Per- and Poly-FluoroAlkyl Substances (PFASs) constitute a broad class of man-made chemicals related to some human diseases[1]. In the last years, alternative compounds deemed safer than the called "legacy" PFASs (PFOA, PFOS...) were synthetized. An example is the "emerging" class called ClPFPECAs which were recently founded in both environmental[2] and biota[3,4] samples. Herein, we report the evaluation of toxicity profile of ClPFPECA-N2 by lipidomics approach. HepG2 cells were expose to increasing concentrations and after extraction, lipidomics analysis was performed by UHPLC-HRMS. Data were elaborated using Lipostar2[5] (Molecular Discovery Ltd.) and the obtained results shown lipids dysregulation for ClPFPECA-N2 compared to the control samples. Particularly, MUFA and PUFA cardiolipins and triacylglycerols were the lipidic classes mainly responsible for the separation in the multivariate statistical analysis (PCA and PLS-DA) between treated samples and control.

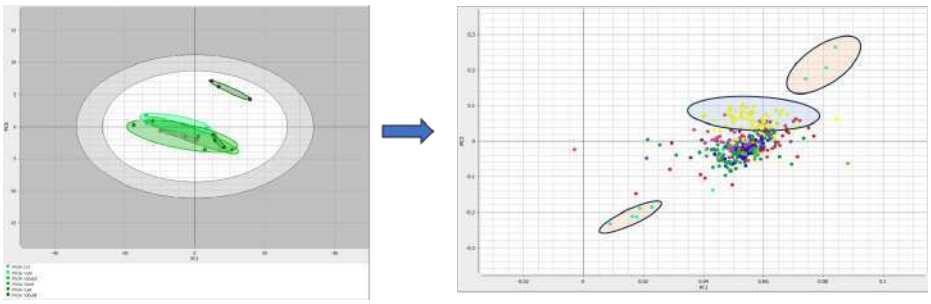

Figure 1: Multivariate statistical analysis (PCA) of HepG2 cells treated with ClPFPECA-N2.

In the field of public health, a pressing concern is antimicrobial resistance, a significant global threat[1]. Plant natural products offer promise in combating multi-drug resistance by acting as antibacterial agents through various mechanisms[2]. Widespread natural product classes, such as terpenes, flavonoids, alkaloids, and phenolics have demonstrated antimicrobial activity[3].

Morus alba L. (Moraceae) twigs have historical use in traditional medicine for muscle-related symptoms, yet their chemical constituents and clinical potential remain underexplored[4]. Here, we conducted a metabolomic-guided phytochemical investigation, based on a LC-HRMS/MS and Molecular Networking combined approach, of an industrial extract of *M. alba* L. twigs, obtained in the field of our scientific partnership with Indena Spa (Milan, Italy). Molecular networking uncovered different clusters of prenylated polyphenols, glycosylated phenolic compounds and Diels-Alder dimers guiding the phytochemical profiling of this extract. Our analysis allowed us to swiftly annotate and isolate 17 secondary metabolites including stilbenoids, flavonoids, and flavanones.

Isolated metabolites were tested for their antimicrobial activity against *Staphylococcus* spp. The most active compound resulted to be kuwanon C, exhibiting a MIC of 8 µg/mL against *S. aureus* ATCC 43300 (methicillin resistant, MRSA) and *S. epidermidis* ATCC 3598 (a biofilm producers' strain). The same concentration resulted bactericidal. We also observed an additive interaction between 4 µg/mL kuwanon C in combination with low oxacillin dosage against the MRSA. Due to the high chemical structure similarity of isolated metabolites, structure-activity relationships of these versatile scaffolds have been postulated.

carmen.tesoro@unibas.it

Broad bean (*Vicia faba* L.) is a vegetable belonging to Leguminosae family and nowadays it's consumed worldwide for human and animal nutrition because of its low cost, ease of cultivation and edible seeds, which are rich in several nutritional compounds, e.g. carbohydrates, proteins, fibres and some specific secondary metabolites i.e. polyphenols. It's also well known as an important natural source of L-Dopa, the dopamine precursor to be used in first-line treatment of Parkinson's symptoms[1]. Due to the neurotoxic effect of synthetic L-dopa and its side effects, natural sources of this bioactive compound should be preferred for the "on-off" motor fluctuations inhibition. Recent studies confirmed that also broad bean by-products could be an attractive natural source of bioactive compounds[2]. Because of the huge presence of health beneficial compounds also in *Ribes rubrum* L., *Punica granatum*, *Phyllanthus emblica*, this work was focused on the characterization of pod valves extracts in these acidic aqueous matrices. 2D van Krevelen diagrams were used as a tool to obtain molecular formula maps useful for a rapid and comprehensive analysis of the more representative metabolite classes[3-5]. An LC-ESI/LTQ-Orbitrap/MS^2 approach was used to identify L-dopa and major polyphenolic compounds in each extract. This study confirmed the higher content of L-dopa in pods compared to beans, with values even comparable to those of *Mucuna pruriens*[1]. It also highlighted the very low content of pyrimidine glycosides vicine and convicine, the two metabolites responsible for the haemolytic crisis in favism patients[6]. To evaluate the potential use of pod valve extracts as an adjuvant in the treatment of Parkinson's disease, a neuroprotective assay was carried out against the human neuroblastoma cell line SH-SY5Y. All different tested extracts showed to be good candidates as adjuvants as no cytotoxic activity even at relatively high concentrations was observed.

vanna.denti@unimib.it

Thyroid nodules present a diagnostic challenge due to their diverse morphological appearances, which often overlap between benign and malignant entities. In this study, we aimed to define the molecular profiles of different thyroid lesions, ranging from benign to malignant, that could aid in the better characterisation of the indeterminate thyroid lesion named as non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP). Our group have previously shown the potentiality of MALDI-Mass Spectrometry Imaging (MSI) in the characterisation of NIFTP lesions using both cytological[1] and histopathological tissue samples[2].
In this work we analysed a tissue microarray (TMA) containing 88 cores from 44 donors, using a MALDI-MSI approach using a TIMS-TOF-FLEX instrument, and we investigated the tryptic peptides profiles of papillary thyroid carcinoma (PTC), follicular variant of PTC (FVPTC), follicular adenoma (FA), Hürthle adenoma (HA), and NIFTP thyroid lesions. Our analysis provided high-resolution proteomic profiles specific to each lesion type, along with spatial characterization within the tissue microenvironment.
Characterizing NIFTP poses a challenge due to its histological similarity to both benign FA and malignant PTC and this overlap could find confirmation in our results when comparing their proteomic signature. The subtle morphological differences between NIFTP and encapsulated follicular variant of PTC further complicate diagnosis, necessitating additional molecular markers for accurate classification. Hence, integrating molecular profiling techniques like MALDI-MSI could provide valuable insights to enhance the diagnostic accuracy of NIFTP lesions. The integration of these findings into a larger patient cohort, as part of an ongoing project initiated several years ago, promises to enrich our understanding of thyroid pathology and facilitate more accurate diagnostic and therapeutic strategies in thyroid cancer management[1]. This work underscores the value of molecular characterization in complementing morphological assessments for improved diagnostic accuracy in thyroid nodules.

Hydroxyanthracene derivates citotoxicity: A differential evaluation between single molecule and whole plant extract

L. Tinti[a], V. Cicaloni[a], P. Nezi[a], G. Isoldi[b], P. Etiope[a], B. Barlozzini[c], R. Pecorari[c], L. Salvini[1]

[a] *Fondazione Toscana Life Sciences, Siena, Italy,*
[b] *Materia Medica Processing, Siena, Italy,*
[c] *Linneus Consulting, Roma, Italy*
p.nezi@toscanalifesciences.org

Hydroxyanthracene derivates (HADs) are a group of natural or synthetic compounds with a wide range of biological activities (for instance, anti-inflammatory, antibacterial, and antiarthritic). In addition, because of their properties for helping the normal bowel function, HADs are widely used in constipation as pharmacological drugs and nutritional supplements. Nevertheless, during the past years, a safety usage of HAD products has been placed under consideration from European Food Safety Authority (EFSA) because some scientific studies reported that HADs are not lacking toxicity. In particular, the safety of the use of medicinal plants containing HAD in dietary supplements was re-evaluated concluding that HAD emodin, aloe-emodin, and the structurally related substance danthron have been shown to be genotoxic and carcinogenic until proven otherwise based on other studies. Thus, the first objective of this study was to shed light on the large variability in composition of botanical food supplements containing HAD by a systematic analysis of the qualitative and quantitative composition of a cohort of extracts and raw materials of plants with high levels of anthraquinones commercially available (Cassia angustifolia, Rhamnus purshiana, Rhamnus frangula, Rheum palmatum, and Rheum raponticum) using UPLC-MS/MS[1]. Specifically, the targeted analysis was performed by parallel reaction monitoring (PRM). Since, the current investigations of HAD toxicity were based on in vitro and in vivo studies conducted mainly on the use of the single molecules (emodin, aloe-emodin, and rhein) rather than on the whole plant extract, the qualitative quantitative characterization was the starting point to select the most appropriate products for the treatments for an in vitro cell studies. Thus, the second objective of this study was the investigation, for the first time, of the toxic events of HAD used as single molecule in comparison with the whole plant extracts containing HAD occurring in an intestinal in vitro model of human colorectal adenocarcinoma cells (Caco- 2). A shotgun proteomics approach followed by a bioinformatic elaboration was applied to investigate the differential protein expression in the Caco-2 cells after a single-HAD or whole–plant extract treatment to fully understand the potential targets and signaling pathways. In conclusion, the combination of a detailed phytochemical characterization of HAD products and a largely accurate analysis of the proteomic profile of intestinal cells treated with HAD products provided the opportunity to investigate their effects in the intestinal system.

Evaluation of Protein Aggregation Capture Protocol for Thermal Proteome Profiling Analysis

A. Giuliano[a], C. Gabriele[a], M. Gaspari[a]

[a]*Department of Experimental and Clinical Medicine, Magna Græcia University of Catanzaro, 88100 Catanzaro, Italy*
annarita.giuliano@studenti.unicz

Thermal proteome profiling (TPP) is an emerging strategy that combines the cellular thermal shift assay (CETSA) with quantitative proteomic mass spectrometry (MS) to investigate proteome-wide interactions of therapeutic molecules[1]. Ligand-target engagement is determined by detecting changes in protein thermal stability, which requires high quantitative accuracy and reproducible analysis for construction of successful melting curves[2]. Thermal denaturation curves are profiled by using isobaric tandem mass tags (TMT) that enable to multiplex samples and increase quantification precision[1]. A crucial step prior TMT labeling is to remove compounds of lysis buffer, such as detergents, chaotropic agents, and salts, which may affect the labeling efficiency. However, the removal of interferents represents a major source of sample losses and experimental variability[3].

In this study, protein aggregation capture (PAC) approach[3] was employed to provide a rapid and efficient sample preparation for TPP analysis and the performance of quality data was compared to the traditional in-solution digestion method. Protein identifications were comparable for both protocols, but PAC yielded an increased number of peptides (4626 protein groups; 35226 peptides) compared to in-solution protocol (4686 protein groups; 26824 peptides).

Although the melting curves were fitted for all proteins quantified with minimum 2 valid fold changes, only sigmoidal curves with a minimum coefficient of determination (R^2) of 0.8, indicating how well the fold changes fit the melting curve, and a plateau of < 0.3 were included in the statistical analysis[2]. Thus, the number of well-modelled proteins for each experiment was investigated. PAC protocol accurately quantified melting temperature in 88% of proteins identified, versus 83% for the in-solution method. Furthermore, reproducibility was assessed by correlating the melting point (T_m) values of replicate samples. A high correlation of 0.87 was achieved with PAC protocol which outperformed 0.71 for the in-solution method.

Results showed the ability of PAC protocol to profile melting curves with high quantitative accuracy and reproducibility.

Blood microsampling is a promising tool for blood collection as it is simple and minimally invasive. It allows multiple sampling and is optimal for longitudinal studies[1]. For these reasons, it has gained attention and has been applied to metabolomics studies. Physical activity induces metabolic changes and a correlation between metabolism and cardiovascular risk has been demonstrated. For example, physical exercise has been shown to improve the catabolism of branched-chain amino acids (BCAA)[2]. The involvement of BCAA in ischemic cardiomyopathy is well known: their plasma levels correlate with the presence and severity of the disease[3]. In this preliminary study, blood samples were collected with Dried Blood Spots (DBS) from patients affected by myocardial infarction participating in a physical rehabilitation program. Blood was collected at 7 time points: before the start of the rehabilitation protocol, before and after the first training, before and after training halfway through the rehabilitation protocol, and before and after the last training. Untargeted metabolomic analysis was performed to assess exercise-induced changes, correlation with clinical outcome and cardiovascular risk factors in these patients. Polar metabolite analysis was performed on DBS with UHPLC-MS. The results showed the most altered metabolic pathways were associated with purine metabolism and histidine metabolism. In particular, xanthine and histidine levels were high at the beginning of rehabilitation and gradually decreased with the training time. Comparing the metabolic phenotype at the beginning and at the end of rehabilitation highlighted a reduction of xanthine, urocanic acid and C5-carnitine. Overall, the use of DBS simplified longitudinal blood sampling and allowed the investigation of metabolic changes during the physical rehabilitation program after myocardial infarction.

GC-MS Investigation of Endogenous Lactonization of 2-Hydroxyglutarate in Acute Myeloid Leukemia Patients

S. Liuzzi,[a] F. Chiara,[a] M. Puccinelli,[b] G. Mengozzi[b]

[a]*University of Turin, Turin*
[b]*A.O.U. Città della Salute e della Scienza, Clinical Biochemistry Laboratory "Baldi e Riberi", Turin*
simona.liuzzi@unito.it

Introduction: 1/5 cases of acute myeloid leukemia (AML) are affected by a mutation relating to genes encoding for isocitrate dehydrogenase (IDH), responsible for oxidative decarboxylation of isocitrate to alpha-ketoglutarate (α-KG). Instead, the mutated IDH enzymes catalyze reduction of α-KG to the metabolite 2-hydroxyglutarate (2-HG), an oncometabolite.[1] A certain amount of R-2-HG-lactone is known to be present in urine specimens of IDHmt brain tumor patients after 2-HG derivatization with (trimethylsilyl)diazomethane for GC-MS analysis.[2] However, it is yet to be clarified whether this metabolite has an endogenous or exogenous origin and the related diagnostic implications. Thus, aim of the study was to ascertain the origin of R-2-HG-lactone comparing lactone formation in solvent, plasma matrix and PBMCs suspension.

Materials and Methods: The analytical workflow has been designed in accordance with UNI EN ISO 15189:2022 and Eurachem Guidelines. The chromatographic run was performed on Crossbond 5% diphenyl / 95% dimethyl polysiloxane and performed with GCMS-QP2020 (Shimadzu) in SIM mode. Identified ions for TMS-derivative of 2-HG were 247 (quantifier), 203, 129, 157 m/z; whilst 159 (quantifier), 115, 131, 85, 101 m/z were the selected ions for TMS-derivative of lactone. Known amounts of 2-HG, at two concentration levels, were spiked in aqueous solution, plasma and PBMCs of healthy subjects and AML IDHmt patients. Subsequently, samples were incubated at 37 °C and GC-MS analysis was performed at three timings: T0, T1 (1h-post), T2 (3h-post).

Results and Discussion: A different decrease in the concentration of 2-HG has been observed at T2, reaching 15%, 35% and 47% in solvent, plasma and PBMCs suspension, respectively. Conversely, there was an increase in lactone proportional to the decrease in concentration of 2-HG. These measurements were elaborated through a Michaelis-Menten kinetic model, obtaining v_{max}, k_{cat} and Km values for each biological matrix. Our data seemed to confirm the hypothesis of an endogenous enzyme capable of catalyzing the 2-HG lactonization. The decrease of 2-HG in non-biological environment also suggested lactone formation *via* autoxidation process.

Conclusion: Lactone appeared to be present endogenously. However, a small amount formed spontaneously even *in vitro*. Further investigations will be necessary to establish with certainty the endogenous origin of lactone and its usefulness in the diagnosis of AML IDHmt.

Nano/micro composite polysaccharide-based stimuli-responsive hydrogels for release of antimicrobial agents in the treatment of skin wounds

C. Fiorica,[a] G. Biscari, F.S. Palumbo,[a] G. Pitarresi

[a]*Dipertimento di Scienze e Tecnologie Biologiche Chimiche e Farmaceutiche (STEBICEF), Università Degli Studi di Palermo, Via Archirafi 32, Palermo*
calogero.fiorica@unipa.it

Skin wound healing is a physio-pathological process that involves various steps with the function of restoring the physiological barrier-role of skin (1).

Bacterial infections represent one of the main factors that plays a significant role in delaying the healing of both acute and chronic wounds. This phenomenon has becoming particularly challenging because of the emergence of multi-antibiotic resistant bacteria that makes ineffective the topical administration of common antibiotics (2).

For this reason, there is an urgent need to develop new molecules with broad-spectrum antimicrobial effect or to develop drug delivery systems capable of potentiate the effectiveness of available drugs.

For several decades, hydrogels, particularly those obtained using polysaccharide as starting biomaterial, have been regarded as the gold standard for treating cutaneous wounds, owing to their chemical, physical, and morphological properties that make them exceptionally well-suited for interfacing with tissue lesions and serving as a vehicle for the release of bioactive molecules that stimulate tissue regeneration (3).

In the past years our group has focused high effort in the development of polysaccharide hydrogels (mainly using gellan gum and xanthan gum derivatives) with stimuli responsive features, that be exploited to potentiate the effect of commonly used antibiotics, or with peculiar rheological, physicochemical and morphological properties to release wide spectrum antimicrobial agents (4).

For example, loading the hydrogel with photothermal nanoparticles enabled to obtain near infrared (NIR) sensitive materials capable to generate local heat after laser irradiation that adjuvate and potentiate the pharmacological effect of antibiotics. Still, we have demonstrated that composite hydrogels, obtained by dispersing in the gelling solution nano or microparticles, can give rise to production of therapeutic tools with high versatility and application potential (5).

TEF-KN-02

Rational design of intra-articular drug delivery systems

F. Selmin, G: Frigerio

Department of Pharmaceutical Sciences, University of Milan, via G. Colombo, 71, Milan (Italy)
francesca.selmin@unimi.it

Local administration of drugs by intra-articular (IA) injections represents one of the major treatments for arthritis, osteoarthritis or musculoskeletal disorders to reduce pain and inflammation, facilitate motion and function. However, in most cases, the systemic bioavailability of after IA and intra-muscular administration overlaps[1] due to the rapid elimination of drugs and macromolecules through the microvasculature and/or the lymphatic pathway, respectively.

The maintenance of an effective therapeutic concentration of the drug in the joint for prolonged time cannot be achieved by frequently repeated injections which present some risks, such as bacterial infection, bleeding, nerve damage and synovial membrane inflammation. To address this issue, several successful strategies have been proposed, including the synthesis of water insoluble prodrugs and the design of drug delivery systems.

In other words, to deliver sufficient therapeutic doses to the site of action a drug suspension has to be injected tacking into account the following parameters. First, the particle size determines fate of the drug in the joint: nano- and microparticles sizing lower than 3 μm are easily drained by the lymphatic system in both inflamed and naïve models; whereas 10 μm-particles are essentially retained, even if they can activate the biological response of macrophages. However, particle size up to 50 μm should be avoided due to difficulties in injections (i.e. needle diameters range from 25 to 22 G depending on the location) and those up to 100 μm can cause abrasion of the synovia. Thus, the optimal size falls within the narrow 30-50 μm range. Secondly, the optimization of the drug release rate from a suspension or a drug delivery system is challenging because (i) *in vitro* testing methods are not described in the main Pharmacopoeias, (ii) long evaluation time is required and (iii) animal models to establish an *in vitro in vivo* correlation are lacking[2]. Moreover, the achievement of this goal is complicated not only by the features of anatomical district, but also by the quali-quantitative differences of joints synovial fluids of healthy subjects and osteoarthritic patients[3].

Through the presentation of case material taken from our experience on methylprednisolone[2-4], an in-depth analysis on the IA administration of insoluble pro-drugs or long acting injectables will be provided in the attempt to highlight the critical points in the prediction of drug release and in vivo biodistribution.

How to assess the quality of complex drug products and their copies: the case study of semisolid preparations

U.M. Musazzi, P. Volontè

University of Milan, Department of Pharmaceutical Sciences, Via G. Colombo 71, 20133 Milan
umberto.musazzi@unimi.it

Nonbiological complex drugs (NBCDs) are medicinal products that exhibit intrinsic complexity in terms of their active substance, formulation, or route of delivery, and that cannot be fully characterized using conventional physicochemical analytical methods. An example of NBCDs is topically applied drug products (e.g., semisolid preparations for cutaneous application), where even slight changes in formulation components can significantly impact the quality target profiles of the drug product. Recognizing this complexity, both the FDA and the EMA have recently updated their guidelines for assessing the equivalence of topically applied drug products. According to the FDA, copies of these products must demonstrate both qualitative (Q1) and quantitative (Q2) equivalence to the reference product [1]. In addition, similar semisolid preparations must prove their structural and functional similarity (Q3). This involves comparing their in vitro release and rheological patterns. In 2018, the EMA introduced a draft guideline proposing the concept of "extended pharmaceutical equivalence" as an alternative to traditional bioequivalence studies [2]. This extended approach requires demonstrating the sameness of two formulation in terms of the pharmaceutical form, the qualitative and quantitative composition, the equivalence of the microstructure/physical properties, and in vitro release profile (IVRT). However, if dealing with complex formulations (e.g., creams), equivalence can be established through permeation kinetic studies [e.g., in vitro permeation studies (IVPT)], pharmacodynamic equivalence tests or clinical trials. This work contributes to the existing knowledge on how to assess the Q3 similarity of not Q1/Q2 equivalent semisolid preparations, in terms of in vitro release studies (IVRT), in vitro permeation (IVPT) and rheological behaviour [3]. In this light, Ibuprofen (IB) creams at two different strengths (i.e., 1% and 10%) were used as a model formulation. Starting from reference formulations two changes were made simulating: a minor variation (addition of the humectant), and a major variation (modification of the surfactant). The experimental results highlighted that these variations impacted only in 1% IB formulations where both the equivalences of rheological data and J-values failed. At the highest concentration, the presence of IB crystals broke down the differences in rheological patterns and lead the IB thermodynamic activity at the maximum figuring out an overlapping of the J-values. Such data suggest the combination of these studies, which are thought for the development of copies, could be also applied to the management of post-marketing variations that involve product composition.

Nanomedicine advances medical research through improved drug delivery for challenging diseases. Surface modifications enhance NMeds' biodistribution and effectiveness. However, personalized nanomedicine systems are necessary due to disease complexities. TeFarTI's projects focus on tailoring NMed targeting for better therapeutic outcomes. For instance, we optimized hybrid NMeds for retinal targeting[1], delivering a neuroprotective peptide with precision. In another project targeting Huntington's disease (HD)[2], we developed hybrid NMeds with consistent efficacy, eventually transitioning to cholesterol-based NMeds. Moreover, we synthesized novel ligands to improve BBB penetration. Our BBB and GBM co-targeting project[3] tested four ligands, revealing enhanced uptake in GBM cells, particularly with one antibody promoting astrocyte growth. This augmented the efficacy of paclitaxel-loaded NMeds, with successful BBB penetration observed in vivo. These projects underscore the importance of understanding disease and microenvironment intricacies for effective NMed design.

Leveraging (bio)active lipid nanoparticles for biomaterials design and drug delivery applications

V. Nele[a]

[a] *Department of Pharmacy, University of Naples Federico II – Via D. Montesano, 49 – 80131 Naples (IT)*
valeria.nele@unina.it

The design of (bio)active nanoparticles which undergo changes in response to an applied stimulus or possess intrinsic therapeutic activity is particularly relevant for biomedical applications. In this talk, I will discuss two key examples: (i) the development of ultrasound-responsive nanoparticles to control enzymatic activity and hydrogel formation and (ii) the use of nanoparticles with bioactive lipidic and inorganic components for the treatment of neurodegenerative diseases.

In a first example, we propose lipid nanoparticles able to trigger the formation of hydrogels[1]. An underexplored trigger for hydrogelation is ultrasound, which is well-established in clinical settings for imaging purposes. We used calcium-loaded liposomes able to release their payload upon ultrasound exposure were used to activate a calcium-dependent tissue transglutaminase, which could in turn catalyze the formation of fibrinogen hydrogels. Precise control over these processes could be achieved, with the calcium release, catalysis rate, and hydrogelation rate all shown to be dependent upon the ultrasound exposure time[2].

(Bio)active nanoparticles can also be exploited for drug delivery purposes in the context of neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS), whose complexity demands multi-functional therapeutic approaches. Here, we engineered lipid self-assembling nanoparticles (SANP) with bioactive lipidic and inorganic components, which we combined with RNA payloads. We used a phosphatidylinositol (PIP) derivative which could restore lysosomal calcium homeostasis and autophagy flux and an antisense microRNA (anti-miRNA) able to prevent the progression of neurodegenerative damage. We further modified the SANP core with cerium to scavenge reactive oxygen species (ROS), which are involved in ALS pathology. *In* vitro, cerium-SANP were able to prevent ROS-induced death of neuronal cells[3], while SANP co-encapsulating PIP and anti-miRNA yielded a synergic reduction of the expression of an ALS protein marker on motoneurons (unpublished). *In vivo* studies in a mouse model of ALS showed that the PIP-SANP formulations were able to improve the overall survival of the mice, which also retained part of their motor skills (unpublished).

Taken together, these examples highlight the tremendous potential of (bio)active lipid-based nanoparticles in tuning the properties of biomaterials and enabling combinatorial drug delivery approaches.

maria.carafa@uniroma1.it

Medulloblastoma (MB) is a pediatric brain tumor often associated to activating mutations of the Sonic Hedgehog (SHH) pathway [1]. Inhibitors of SHH pathway are available on the market but have shown limited clinical efficacy, due to compensatory mechanisms restoring downstream activation. We have previously demonstrated that the antidiabetic drug phenformin significantly inhibits the downstream hedgehog-dependent transcription factor Gli1 in preclinical models of SHH MB, causing a substantial reduction of tumor growth. However, phenformin is also associated with high risk of lactic acidosis, due to its intrinsic ability to inhibit hepatic gluconeogenesis. Hence, phenformin loading into carriers, specifically able to bypass the liver and target the brain, would be a suitable strategy.

Here we tested both liposomes and liposome-like delivery systems (niosomes) and showed that encapsulating phenformin into these formulations efficiently allows its delivery to SHH medulloblastoma tumors.

Compared to liposomes, niosomes show several advantages for drug delivery such as lower costs, higher stability and ease of preparation [2]. In particular, Phen loaded liposomes and niosomes have been prepared with suitable characteristics to load proper amounts of the lipophilic drug and to be administered intravenously. We show that phenformin-loaded vesicles are efficiently incorporated into Med1-MB SHH medulloblastoma cells, where they induce a significant decrease of cell proliferation, associated to the activation of the energy stress pathway at the highest concentrations. Consistently, both phenformin-loaded nanocarriers induce a robust decrease of Hedgehog signaling, as documented by the significant decrease of the Hh target gene Gli1. Remarkably, when phenformin-loaded vesicles are administered to mouse models of SHH MB, the concentrations of phenformin are strongly reduced in liver and plasma but significantly increased in the cerebellar tumors, compared to the drug alone, being the effect stronger with niosomes. Accordingly, the intratumor levels of Gli1 mRNA are strongly downregulated, documenting the efficacy of this approach in targeting the Hh signaling *in vivo*.

Together, these data illustrate a novel nanodelivery-based approach to inhibit the oncogenic Hedgehog signaling and to improve the biodistribution of phenformin, potentially reducing its side effects.

Lipid-based nanocarriers to target brain tumours: recent evidences from preclinical studies

L. Battaglia,[a]

[a]*University of Turin, Department of Drug Science and Technology, via Pietro Giuria 9, Turin*
luigi.battaglia@unito.it

Gliomas are the commonest brain tumours, which can be classified in low or high grade according to their invasiveness. Surgery is the first treatment, followed by adjuvant radio and chemotherapy. However, high grade gliomas are characterized by a poor prognosis, because of fatal relapses. Indeed, despite the recent advances in surgery (neuronavigation, use of 5-aminolevulinic acid, and intra-operative magnetic resonance imaging), recurrences can derive either from incomplete resection of the primary mass or from tumour cells migrating into the health tissues, the so called brain adjacent-to-tumour (BAT) zone[1]. Within this concern, current chemotherapy, based upon oral temozolomide, is only a palliative care. Its efficacy is limited by chemo-resistance, while the brain-blood barrier (BBB) prevents the brain access of nearly 98% of alternative potential drug candidates. Nonetheless, despite intact BBB overcoming is needed to target cells in the BAT zone, tumour mass growth promotes the formation of an altered BBB, the so called blood-to-brain tumour barrier (BBTB), with a leaky vascularization[2]. Therefore, passive, active and homotypic targeting mechanisms can be exploited for brain delivery of multiple chemotherapeutic agents to the brain, acting on glioma proliferation, vascularization and differentiation.

Among available nanocarriers suitable for drug targeting to the brain, lipid-based ones (nanoemulsions and solid lipid nanoparticles – SLN) show several advantages in terms of biocompatibility and versatility. Indeed, lipids are either physiological compounds or substances endowed with an approved status, such as GRAS (Generally Recognized As Safe) substances. Moreover, they are either liquid or low melting, allowing an easy processing on a large scale. Finally, they can be surface functionalized owing to different strategies[3,4]. Nonetheless, several hurdles still limit the clinical translation of such nanocarriers for glioma chemotherapy. Among them the preclinical efficacy assessment in cell and animal models, suitable to truly recapitulate the human condition. In this presentation the main evidences obtained at the University of Turin in the last years about the usage of lipid-based nanocarriers for drug delivery against glioma in preclinical models are shown.

giuseppe.racaniello@uniba.it

Three-dimensional printing (3DP) has now been widely used to produce customizable dosage forms useful for adherence to personalized medical therapies[1]. With this easily obtainable geometric variation and dosing flexibility, 3D-printed formulations could closely meet patient needs. This enables the development and growth of precision medicine, which involves optimizing drug doses based on a patient's age, sex, weight, disease severity, and genetic profile[2]. Out of the several 3D printing techniques explored for drug delivery applications, direct powder extrusion (DPE) represents one of the most innovative 3DP techniques for personalized pharmaceutical forms production[3]. It enables the production of finished solid pharmaceutical forms in a single step, directly from mixtures of excipients and active pharmaceutical ingredients (API), extending the possibility of printing even mixtures with high dosages of API, reducing their risk of degradation when exposed to double thermal stress, and accelerating the development of the formulation by lowering costs and waste production[4].

The novel 3DForMe® printer, based on DPE, was developed by our workgroup in collaboration with Farmalabor Srl to improve the preparation processes of highly personalized 3D-printed solid pharmaceutical forms. The 3DForMe® printer and the DPE 3DP technique have been effectively employed in scientific research operated by our workgroup to develop new solid pharmaceutical forms presenting improved chemical-physical characteristics. This technology was employed in different case studies on drugs belonging to classes II and IV according to the Biopharmaceutical Classification System. In the reported studies, the 3DP DPE technique was combined with the use of polymer blends containing cyclodextrin, selected for its ability to enhance the aqueous solubility, stability, and bioavailability of the printed investigated drugs.

Specifically, the different possibilities given by this technology were investigated in the creation of customized drug delivery systems for paediatric patients, with the production of mini-tablets for the immediate release of Captopril or sustained release of Budesonide, in the development of buccal delivery systems such as mucoadhesive orodispersible films for the release of Clobetasol or Lidocaine, or for drug repurposing with the development of Niclosamide-based tablets.

Importance of dissolution testing for IVIVC in drug product development

Mansuroglu, Yaser

SOTAX AG, Switzerland

IVIVC (*In vivo in vitro correlation*) is an essential tool for predicting the *in vivo* performance of a drug based on *in vitro* drug release profiles. Physicochemical and biopharmaceutical properties of the drug as well as the physiological conditions in the body must be considered to develop a reliable correlation. Key parameters for this include solubility and permeability of the drug, LogP and pKa values as well as ambient conditions in the area of the body the drug is distributed in like pH and presence of enzymes. The aim of IVIVC is therefore to establish a correlation between either the full dissolution profile and *in vivo* absorption curve or between any parameter derived from *in vitro* data and *in vivo* data. Based on these definitions, three main levels of correlation are defined, according to their ability to reflect the entire plasma drug concentration vs. the time profile. Level A is the highest level of correlation and represents a point to point relationship between *in vitro* dissolution and cumulative *in vivo* absorption. Level B is based on the principle of statistical moment analysis where the mean *in vitro* dissolution time is compared either to the mean *in vivo* residence time, to the mean *in vivo* absorption or mean *in vivo* dissolution time. Level C relates one dissolution result, such as the time to achieve a certain percent dissolved or percent dissolved at a certain time point to one pharmacokinetic parameter (AUC, tmax, cmax…). IVIVC enables to pre-optimize the drug product on base of these (dissolution) *in vitro* results without the need of animal/clinical studies and saves both time and money. The importance of IVIVC for drug product development is therefore undeniable. Dissolution testing is a widely used *in vitro* testing tool in both Academia and Pharmaceutical industry as it provides an indication of how well a dosage form will dissolve in the patient and thus be available for absorption in the small intestine. Depending on the drug product and site of action in the body, various methods for dissolution testing are possible.

Formulation strategies for pulmonary delivery of biopharmaceuticals

A. Bianchera,[a,b], R. Bettini[a,b]

[a]*Food and Drug Department, University of Parma, viale delle Scienze 27/a, 43124, Parma*
[b]*Biopharmanet-TEC, University of Parma, viale delle Scienze 27/a, 43124, Parma*
annalisa.bianchera@unipr.it

Biopharmaceuticals represent a significant and growing share of new drugs entering the market, but their administration is somewhat limited to parenteral injection, due to their instability when administered orally. Protein inhalation could represent an interesting alternative especially for the treatment of lung diseases or for the prevention of pulmonary infections. In any case, the successful development of inhalable protein therapeutics, in the form of nebulized solutions or dry powders, must take into consideration the risk of degradation of these products during formulation and administration. Both processes can damage proteins, so a thorough characterization of the respirable fraction, as well as of the preservation of biological activity and aggregation of the protein, is mandatory to correctly estimate the therapeutic potential of the preparation.

Alpha-1 antitrypsin (AAT) is administered intravenously to treat genetic AAT-deficiency. Only a small part of the injected dose reaches the lungs, which are the main organ affected by the deficiency. To achieve a higher local concentration and improve patient compliance, an inhalable formulation of AAT, as a nebulized solution or as a dry powder, would be highly desirable. Starting from the injectable solution of human AAT, we compared the effect of a jet nebulization system with an electronic active vibrating membrane nebulizer on nebulization efficiency, protein activity and aggregation. Protein activity and aerosolization performances were comparable between the two nebulizers, but dose delivery efficiency was higher with the mesh nebulizer[1]. A recombinant version of AAT, overcoming the limitations due to the availability of blood donors, was formulated as a dry powder in the presence of different excipients with the aim of prolonging its stability during storage. The combination of mannitol and leucine proved to be the most effective in preserving rAAT activity after storage in oxygen-free conditions and after aerosolization[2].

Dry powders for nasal inhalation have also been prepared from a hyperimmune serum against COVID-19 to be administered as a pre-exposure or early post-exposure prophylaxis in case of contact with the virus. Drying serum with trehalose did not alter the ability of immunoglobulins to bind the Spike protein and to neutralize pseudoviral preparations of different variants of concern of SARS-CoV-2. In vitro aerodynamic evaluation suggested the possibility of targeting both the upper and lower airways via nasal inhalation, providing broad coverage against viral spread in the airways.

A heat-generated polymeric matrix technology transferred to drug delivery and cell culture systems

S. Baldassari,[a] G. Ailuno,[a] G. Caviglioli,[a,b]

[a]*Dept. of Pharmacy, University of Genova, Viale Cembrano 4, 16148 Genova, Italy*
[b]*IRCCS Ospedale Policlinico San Martino, Largo R. Benzi 10, 16132 Genova, Italy*
sara.baldassari@unige.it

Our research group have developed and patented[1] a matrix system, suitable for drug delivery and 3D cell culture, based on the application of a technology consisting in performing a thermal treatment on compact units including as excipients a specific type of cross-linked, water-insoluble polyacrylic polymers; the thermal treatment, under appropriate conditions, generates a monolithic hydrophilic matrix able to swell in aqueous medium at neutral or alkaline pH, forming a hydrogel very resistant to erosion.

This versatile matrix may be employed in systems for drug delivery. Indeed, the inclusion of a hydrophobic component, such as ethylcellulose, in the composition makes the matrix able to control the release rate of active substances in the intestinal medium. Moreover, when including in the composition a pH regulator, the polymer forming the matrix manages to swell even in the stomach's acidic environment. Tablets with this composition manage to float immediately in the gastric fluid owing to their low density, to absorb water and to enlarge, creating the conditions for gastroretention, associated to drug controlled release for up to several hours[2].

The technology has also been employed and patented for the preparation of matrices for 3D cell cultures[3]: in this case, compacts including the polyacrylic polymer, sodium bicarbonate and sodium chloride, subjected to thermal treatment and subsequent leaching of the water-soluble components, create a porous hydrophilic scaffold, moist heat sterilizable, transparent and biocompatible, which has been successfully employed for 3D culturing of different cell types, and suitable for drug testing.

Our technology can be manufactured with easily available, low-cost components, and the heating process, fundamental for matrix formation, may be carried out using the common industrial heating systems. The temperature to which the compacts are heated and the duration of the thermal treatment may be set to modulate the features of the matrix, achieving either the appropriate drug release rate or the mechanical properties most suitable for the cultured cells, depending on its application.

Probiotic Microencapsulation: Exploring with Spray Drying and Prilling/Vibration Techniques to Enhance Performance Through Precision Polymeric Mixtures

Angela Assunta Lopedota,[a] Vita D'Amico,[a] Ilaria Arduino, Antonio Lopalco, Rosa Maria Iacobazzi, Massimo Franco, Nunzio Denora,[a]

Department of Pharmacy-Pharmaceutical Sciences, University of Bari "Aldo Moro", Via E. Orabona, 4, I-70125 Bari, Italy

angelaassunta.lopedota@uniba.it

The human gut microbiota plays a crucial role in maintaining overall health and well-being, with oral probiotics recognized for their ability to promote a healthier gut microbiota. Probiotics, live microorganisms consumed in sufficient quantities, offer various health benefits, and contribute to the balance of the gut microbiota [1]. These microorganisms compete with pathogens, regulate inflammatory responses, produce beneficial metabolites, and support microbiota balance. Ensuring a minimum viable count of approximately log 6 CFU/mL is crucial for their optimal colonization at the intended site [2].

However, research on the viability of commercial probiotic products has revealed lower concentrations and deficiencies in probiotic strains' viability during passage through the gastrointestinal tract (GIT). This raises significant concerns about the effectiveness of many products currently available on the market, as they may not survive processing, GIT transit stress and storage processes [3].

To address these challenges, two approaches have been explored. Firstly, microparticles were developed using the prilling/vibration technique to encapsulate the probiotic strain Lactiplantibacillus plantarum 4S6R [4]. A specific polymeric mixture, selected for its responsiveness to colonic stimuli, was identified as an effective carrier for these microparticles. Secondly, a microencapsulation formulation was developed for the probiotic Bifidobacterium longum (strain 22348) to protect it from environmental and physiological factors (e.g., pH, oxygen, and temperature). The probiotic cells were encapsulated via spray drying using a polymer mixture consisting of Eudraguard® biotic, inulin, and alginate with or without maltodextrin as wall materials.

Both strategies yielded microparticles with high yield and encapsulation efficiency. The first approach suggests that the selected triggered dependent polymer mixture holds promise for enhancing probiotic survival and efficacy in the gastrointestinal tract, paving the way for advanced probiotic product development. The second study concluded that the characteristics of the powders were suitable for protecting probiotic viability during production and under gastrointestinal conditions, thereby extending their shelf life without compromising their health benefits. Spray drying of probiotic microcapsules shows significant potential in functional food, benefiting both industry and consumers alike.

ilaria.ottonelli@unimore.it

The production and development of the Covid-19 vaccines by Pfizer and Moderna have brought the microfluidic (MF) technique in the spotlight for the production of nanomedicines, thanks to the possibility of having high reproducibility and automation while also reaching large scale production.[1] This technique is based on the fine mixing of different solutions in microchannels with precise geometry, creating a controlled microenvironment that can be finely tuned in order to produce nanomedicines with the desired hydrodynamic diameter, high homogeneity, high drug loading, and good storage stability.

Since 2020, the use of MF has been widely and deeply investigated for nanomedicine production, improving the results of research projects and leading to products with a higher TRL; however, not only is the translatability of previously optimized products towards a MF device not linear, but also the MF technology itself is now facing some challenges that need to be addressed.

In this talk, an overview will be given about the use of the MF technique for NMed production, the main types of devices available, and protocol development. Moreover, highlights will be given about the difficulties in protocol translatability from benchtop to MF, and the future steps towards the development of this promising technology.[2,3]

Prolamin-Based Formulations for Drug Delivery Applications

Agnese Gagliardi[a], Silvia Voci[a], Nicola Ambrosio[a] Donato Cosco[a]

[a]*Department of Health Sciences, University "Magna Græcia" of Catanzaro, Campus Universitario "S. Venuta", I-88100, Catanzaro, Italy.*

gagliardi@unicz.it

The proline- and glutamine-rich proteins (*prolamins*) contained in cereal grains have emerged as promising biomaterials with a wide range of applications. Among them, corn zein and wheat gliadin were the natural polymers employed for wound healing and oral delivery purposes, respectively. In detail, a green and biocompatible zein gel (20% w/v of protein) containing rutin (0.5-5% w/w with respect to the polymer) was characterized by means of passive and dynamic rheology, demonstrating the formation of samples with a marked solid-like character and a pseudoplastic behaviour. *In vitro* scratch assay performed on human keratinocytes and *in vivo* wound-healing studies performed on rats, respectively, showed that the entrapment of the drug within the zein gels promoted a faster wound closure as compared to the free form of the compound. Moreover, empty and rutin-loaded zein gels showed healing properties similar to the commercial formulation DuoDERM®; this was followed by a significant decrease of various pro-inflammatory cytokines in the serum of the animals due to the peculiar, intrinsic anti-inflammatory properties of the protein, suggesting a plausible application of the gel formulation as innovative wound dressing.

In another investigation, zein nanoparticles stabilized by sodium-deoxycholate were used as carriers of ovalbumin (OVA), used as a model of antigen, and then embedded within a thermosensitive hydrogel matrix made up of poloxamine-908 (P908), with the aim of obtaining an injectable formulation for the nanovaccination. The addition of OVA (0.2-0.8 mg/mL) did not significantly compromise the physico-chemical features of the carriers, obtaining an almost quantitative retention of the molecule (≥90%) and a sustained release over time. Successively, the nanoformulation prepared with 0.8 mg/mL of OVA was embedded within the hydrogels; the multistage formulation was characterized by a shear-thinning behaviour able to enhance the immune response after injection.

Additional experiments were focused on the characterization of gliadin nanoparticles and on the evaluation of their *in vivo* fate after oral administration. In this regard, the incubation of the nanosystems with *ex vivo* porcine intestinal mucus evidenced their ability to interact with the intestinal mucosa, while the biodistribution performed on rats evidenced that 4h-post oral administration the samples were able to reach the small intestine. Intake studies with *Caenorhabditis elegans*, used as an additional *in vivo* model, confirmed the ingestion of the particles through the oral route and evidenced the decrease of the age-related lipofuscin pigment in the nematodes in a dose-dependent manner. The obtained results provide the rationale of the conceivable use of gliadin nanoparticles as oral drug delivery systems.

Dual function surfactants for pharmaceutical applications: the case of alkyl biguanides

D.R. Perinelli,[a] F. Del Bello,[a] L.A. Vitali,[a] M. Nabissi[a], G. Bonacucina

[a]*School of Pharmacy, University of Camerino, Via Madonna delle Carceri, Camerino*
diego.perinelli@unicam.it

Biguanide is an interesting molecule whose chemical moiety can be found in the structure of several compounds with different therapeutic activities such as antidiabetic, antiviral, antimalarial, antibacterial, antimycotic, and anti-HIV. Biguanide derivatives are currently employed in clinics as orally administered hypoglycemic agents and they have been also proposed for the treatment of several other conditions (e.g. polycystic ovary syndrome, cancer, tuberculosis)[1]. Regarding antimicrobial activity, several biguanide derivatives are known to be active against a wide range of gram-positive and gram-negative bacteria as well as fungi, yeasts, and viruses. Indeed, a cationic bisbiguanide as chlorhexidine (and its salt form chlorhexidine digluconate) is one of the most used topical disinfectants and antiseptic agents for skin and mucosa[2]. Despite the large interest in biguanides derivatives, no detailed studies have been conducted for the development of novel surface-active molecules bearing this chemical moiety. Indeed, only one study can be found in the literature, in which a biguanide was linked to alkyl chains of a different length to produce amphiphilic molecules[3]. According to these premises, the biguanide moiety can be exploited to design new surfactants with a dual function as surface-active molecules and antimicrobial/disinfectant agents. As such, a new series of amphiphilic compounds derived from the alkylation (C3, C6- and C10-) of 1-(orto-tolyl)biguanide was synthesized and characterized in terms of surface tension, aggregation properties, and antibacterial activity.

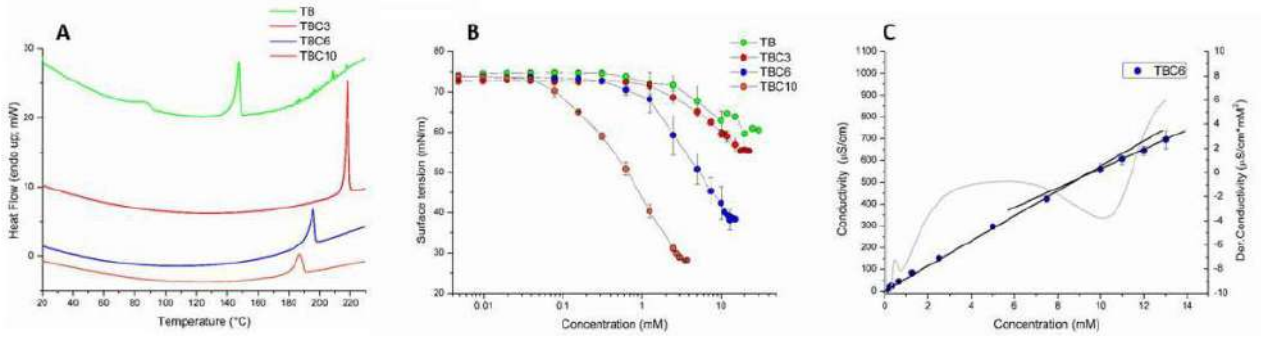

Figure 1: DSC traces (A), surface tension (mN/m) *vs* concentration (mN) (B), and conductivity (µS/cm) *vs* concentration (mM) (C) plots for the synthesized biguanide derivatives (TBC3, TBC6, and TBC10) in comparison to the commercial compounds 1-(o-tolyl)biguanide (TB).

mario.saletti2@unisi.it

Hyaluronic acid (**HA**), a natural polysaccharide belonging to the glycosaminoglycans, represents the main component of the extracellular matrix (ECM). Thanks to its molecular properties, **HA** plays an important role in tissue engineering, wound healing, cancer treatment, ophthalmology, and cosmetics.[1] Ferulic acid (**FA**, 4-hydroxy-3-methoxycinnamic acid), a natural compound largely distributed in the plant cellular wall, possesses many health benefits[2] and represents an interesting biocompatible fluorophore.[3] In this context, aggregation-induced emission (AIE) fluorogenic **FA** residues bearing propargyl (**Pg**) groups were used in the grafting reaction of **HA** macromolecules to afford the resulting hyaluronan derivative **HA-FA-Pg** graft copolymers that could be exploited in Cu(I)-Catalyzed Azide-Alkyne 1,3-dipolar Cycloaddition (CuAAC) conjugation.[4] This synthetic strategy was employed in a biocompatible and biomimetic hyaluronic coating (BBHC) of surfaces of different nanostructures[3-7] to obtain novel materials. Based on the encouraging obtained results, we also evaluated the effects of the covalent coating of **HA**, by using **HA-FA-Pg** graft copolymers, around the spheroidal geometry of poly(propylene imine) (PPI) dendrimers of first, second, and third generation on the architecture and aggregation features of hybrid resulting dendrimeric materials, which represent biocompatible drug carriers endowed with encouraging features in transporting anticancer doxorubicin to tumor cells.[8] Additionally, we further extend the application of **HA-FA-Pg** grafted derivatives, by developing a new crosslinking procedure in which the propargyl groups of **HA-FA-Pg** graft copolymers were exploited in the CuAAC coupling with different oligo(ethylene glycol)-based spacers terminated with azide groups to obtain novel biocompatible crosslinked **HA** materials potentially useful in different biomedical applications.[9-10]

Introduction: Tendon pathologies are medical conditions that include ruptures and overuse injuries accompanied by inflammatory and degenerative alterations, such as tendinopathies and tendinitis. The aim of the present work was the development of fibrous scaffolds based on polyhydroxybutyrate (PHB) doped with magnetic iron oxide nanoparticles (Fe_3O_4 NPs) and coated with gelatin (Gel), able to mimic the hierarchical structure of the tendon and to improve the tissue healing potential [1,2].

Experimental methods: The blends were spun using a centrifugal spinning apparatus obtaining PHB, PHB-Fe_3O_4, and PHB-Fe_3O_4-Gel fibers. The systems morphology and the surface wettability were evaluated. The scaffolds' superparamagnetic behavior, mechanical properties and weight loss in physiological medium were evaluated. Finally, cell adhesion and proliferation in vitro were evaluated with and without the application of static magnetic fields of different extent for 21 days of culture.

Results: The systems were characterized by an aligned structure and Fe_3O_4 NPs were successfully incorporated into the fibrous structure, increasing the scaffolds' rigidity. Moreover, the presence of Gel increased the surface wettability. PHB-Fe_3O_4 and PHB-Fe_3O_4-Gel were characterized by a superparamagnetic behavior, while the PHB scaffold was characterized by a spectrum typical of not-magnetic samples. The scaffolds showed a progressive weight loss in physiological medium, while maintaining the fibers' morphology and alignment for 3 months. Finally, the application of the magnetic fields led to a significant increase in cell proliferation, and alignment onto the systems loaded with magnetite, mimicking the tendon fascicles.

Conclusion: Fibrous scaffolds based on PHB and Gel and doped with magnetite were successfully manufactured, representing an interesting tool to enhance the wound regeneration when combined with the application of external magnetic fields.

Pulmonary administration route has been extensively exploited for the treatment of local lung diseases such as asthma, chronic obstructive pulmonary diseases and respiratory infections and it is one of the most preferred routes for drug delivery, providing a high surface area for a quicker and effective drug absorption[1,2].

The aim of the present work was the development of microparticles (Mps) via spray-drying technique. Insoluble Mps, resulting from the interaction between chitosan (Cs; medium MW, Sigma Chimica, I) and hydrolysed collagen (HC; Kelisema, I), were prepared for the treatment of respiratory tract bacterial infections.

HC aqueous solutions were prepared at different concentrations (1, 2, 4 % w/w) and mixed at 1:1 weight ratio with 2% w/w Cs solution in 0.5M acid acetic. Cs/HC0.5, Cs/HC1 and Cs/HC2 mixtures were spray-dried setting different inlet temperature values ranging from 120 to 200°C (100% aspirator, 0.6 L/h flux). Mps collected were characterized for: i) morphology and size by Scanning Electron Microscope (SEM), ii) physicochemical properties by Fourier-Transform Infrared Spectroscopy (FT-IR) and Thermal Gravimetric Analysis/Differential Scanning Calorimetry (TGA/DSC); iii) aerodynamic performance and particle size distribution by Next Generation Impactor (NGI); iv) in vitro cytotoxicity assay on adenocarcinomic human alveolar basal epithelial cells (A549); v) antibacterial properties and capability to inhibit bacterial adhesion to A549 (*S. aureus BH1CC strain and P. aeruginosa PAO1 strain*).

The main results pointed out that Mps were characterized by a spherical shape and a particle size between 1-10 µm depending on the inlet temperature set and the polymer concentration; in the case of Mps Cs/HC0.5 obtained at 120°C, 95% of Mps had a mean diameter lower than 5 µm, suitable for pulmonary drug delivery. FT-IR and TGA/DSC analysis confirmed the formation of an interaction product (IP) between Cs and HC, responsible for the formation of insoluble and biodegradable Mps. In vitro assay on A549 cells demonstrated the Mps optimal biocompatibility. Mps displayed antimicrobial properties against both Gram + and Gram – bacteria higher than those of the raw materials and their physical mixture. Finally, Mps were also able to inhibit bacterial adhesion to A549.

In conclusion, water insoluble Mps based on CS and HC IP have been successfully achieved by means of spray drying. They were characterized by a size functional to pulmonary administration. The IP was characterized by improved antimicrobial properties and capability to inhibit bacterial adhesion to cells.

bttgdi@unife.it

Chlorogenic acid (CGA) is a natural polyphenol potentially health promoting along the gut-brain axis, even if limited by poor oral bioavailability[1]. As components of therapeutic drugs or functional food, polyphenols can influence each other their absorption from the gut according to circadian rhythms[2].

Therefore, we have evaluated, via HPLC-UV analysis, how the permeability of CGA across IEC-6 cell monolayers, as a model of intestinal barrier, is influenced by the presence of arbutin, gallic, caffeic and ferulic acids and by circadian cycles entrainment by horse serum shock. Moreover, dopaminergic neuronal influence on CGA intestinal permeability was investigated by co-culture with rat pheochromocytoma PC12 cell line mimicking dopaminergic component of enteric nervous system (ENS).

Our results indicate the presence of a circadian-dependent active efflux for CGA permeation across IEC-6 monolayers, suggesting its higher bioavailability in the evening rather than in the morning. Among the natural polyphenols tested, only gallic acid was able to influence the CGA permeation, causing its reduction. Finally, (60 mM KCl)-evoked dopamine release from PC12 cells[3] induced a significant CGA permeation increase across IEC-6 monolayers, probably by downregulation of efflux transporters expression/activity. Dopamine ENS-evoked may therefore enhance the CGA oral bioavailability dependence on circadian rhythms.

Although this is a preliminary study in this field, the results obtained allow us to suggest that the absorption of CGA from an oral administration of a food supplement is not influenced by arbutin, caffeic acid and ferulic acid, whereas it can be enhanced in the absence of gallic acid and by evening intake.

The incidence of melanoma is rapidly increasing worldwide; improvement of both target and immune therapies against melanoma is counterbalanced by a high percentage of severe drug-related toxicity. In fact, tumour microenvironment represents a key obstacle for drug efficacy, being characterized by hypoxia, low blood pressure and acidic pH [1]. To enhance the effectiveness of cancer chemotherapy it is necessary to develop nanocarriers that can be triggered to release the anticancer drug in response to extracellular or intracellular chemical stimuli (e.g., pH, temperature) [2]. Therefore, the use of nanocarriers composed of pH-sensitive substances, like Oleic Acid [3] could exploit the physiological differences between tumour cells and normal cells.

The aim of this study was to develop oil-in-water nanoemulsions (NEs), composed of Oleic Acid, Hepes buffer (pH 7.4 – 10^{-2}M), and Tween 80. NEs were loaded with curcumin, a natural compound useful for enhancing the existing chemotherapy treatments against melanoma [4].

A deep physical chemical characterization of NEs was carried out evaluating size, PDI, ζ-potential, fluidity, microviscosity and polarity. The pH-sensitivity of formulated nanocarrier was demonstrated through fluorometric assays employing different probes, like DPH and Pyrene and by morphological studies utilizing TEM.

Looking to pulmonary administration, NEs were coated by Chitosan, a mucoadhesive agent, to enhance the nanocarrier lung residence time and the selected formulations remained stable even during the nebulization process.

In order to confirm NEs stability and curcumin stability in terms of decomposition/degradation, all samples were analysed by DLS and UV analysis for 90 days at room temperature and 4°C.

Finally, cytotoxicity, cellular uptake and *in vitro* activity were investigated in order to assure the safety and the activity of characterized NEs against B16F10 melanoma cell line.

rita.cortesi@unife.it

In this study ursodeoxycholic acid (U), sodium cholate (C) and sodium taurocholate (T) were selected to prepare bile acids-based vesicles and nanoparticles (i.e. bilosomes and biloparticles) to improve the solubility, the absorption and to preserve the activity of budesonide, used as a model lipophilic drug. It is well known that bile salts are physiologically involved in the digestion of lipids therefore they can affect the absorption of poorly soluble drugs in different ways[1].

Bilosomes and biloparticles were prepared following standard protocols with minor changes[2]. The obtained systems showed good encapsulation efficiency and dimensional stability. Particularly, biloparticles showed an increase in encapsulation efficiency following the order U < C < T.

The in vitro release of budesonide from both bilosystems was performed by means of dialysis using either a nylon membrane or a portion of a Wistar rat small intestine and two receiving solutions simulating gastric or intestinal fluid (i.e. FASSGF and FASSIF). Both in gastric and intestinal fluid, budesonide is released from bilosystems more slowly than the reference solution, while biloparticles showed a significant improvement of budesonide passage into aqueous solution. On the other hand immunofluorescence experiments indicated that budesonide-containing U-bilosomes are able to decrease the inflammatory response induced by glucose oxidase stimuli and to counteract the ox-inflammatory damage within intestinal cells.

In conclusion the obtained bilosystems can efficiently encapsulate budesonide while preserving its properties. However, the influence of different bile acids (i.e. U, C, T) on the performance of the bilosystem needs to be studied in depth to understand their contribution to the specific drug release properties. Future studies will be carried out to delve deeper into the reasons for the different behaviours expressed by the different bile acids used. The encouraging results showing the efficient antioxidant effect by a complete restoring of IL-1β basal level after U-bilosomes treatment, suggest the possibility to further investigate the use of bilosystems to counteract the ox-inflammatory damage within intestinal cells especially for those intestinal pathologies correlated to the development of an oxidative stress status.

Chitosan-associated SLNs promoting mucin binding for ocular drug delivery

M. Ruggeri, M. Pollini, B. Vigani, S. Rossi, G. Sandri

Department of Drug Sciences, University of Pavia, Viale Taramelli 12, 27100 Pavia, Italy
marco.ruggeri@unipv.it

Solid lipid nanoparticles (SLNs) made of biodegradable physiological lipids have been widely suggested as carriers in ophthalmic drug delivery. The synergic combination of natural polymers, such as chitosan, and SLNs could be an effective strategy for increasing nanoparticles retention. This mainly occurs due to the electrostatic interaction between the positively charged chitosan and the negatively charged mucin. At this purpose, in the present study, SLNs were manufactured by means of high shear homogenization and ultrasound method [1]. Three different systems were prepared: naked SLNs, chitosan-associated SLNs (CH-SLN), and SLNs coated with chitosan (CH-c-SLNs). As for naked SLNs, the lipid phase (Compritol 888 ATO and cyclosporin A) was melted and the aqueous phase (water with surfactants – Tween 80 and Pluronic F68) was added to the lipid phase under homogenization (T25, IKA-Werke GmbH, Germany). CH-SLNs were prepared by mixing the lipid to a chitosan hydrochloride solution and then diluted in water, while CH-c-SLNs were produced by adding chitosan solution after hot emulsification of SLNs. All samples were submitted to ultrasound treatment (Elmasonic S80 H) for 10 min to avoid aggregation during particles stabilization.

The morphology and the particle size of SLNs were investigated by means of cryo transmission electron microscope Glacios (Thermo Fisher Scientific) and dynamic light scattering (Litesizer 500), respectively. Overall, the results highlighted circular dark structures related to spherical nanodroplets, and a mean particle size of about 180 nm. In particular, the presence of chitosan led to the production of particles with a higher particle size characterized by a rigid core enclosed by a jelly coating, and to the presence of some free polymer chains without nanoparticles. Moreover, the thermodynamic interaction between SLNs and mucin was investigated by isothermal titration calorimetry at 37°C (MicroCaL PEAQ-ITC, Malvern). After the addition of trehalose as cryoprotectant (solid lipid: cryoprotectant 1:4), SLNs were freeze-dried and dispersed in acetate buffer 20 mM at pH 4.5. The nanoparticle dispersion with a concentration of 1 mg/ml was placed in the syringe and was added into the thermostated cell containing a suspension of mucins in acetate buffer (0.1 mg/ml). A plateau, corresponding to the equilibrium of the system, was reached for CH-SLNs and CH-c-SLNs, meaning that saturation of mucin by the SLNs occurs. In fact, the dissociation constant (Kd) of naked SLNs was higher compared to that obtained for SLNs containing chitosan, indicating a lower binding affinity.

Further studies are ongoing to assess the permeation and penetration of SLNs across the corneal cells, and the cellular uptake.

Polycaprolactone and zein-based fibrous scaffolds for skin tissue engineering

M. Pollini, M. Ruggeri, B. Vigani, S. Rossi, G. Sandri

Department of Drug Sciences, University of Pavia, Viale Taramelli 12, 27100 Pavia, Italy
marta.pollini01@universitadipavia.it

Tissue engineering is a branch of regenerative medicine that focuses on the design and the development of biological substitutes able to repair or replace a damaged tissue[1]. The most promising adavances in this field are the three-dimensional biocompatible scaffolds[2]. In this scenario, centrifugal spinning became a promising method to produce fibrous scaffolds[3].

Given these premises, the aim of the present work was the design and the development of polycaprolactone (PCL) and zein (Z) fibers via centrifugal spinning, for skin tissue engineering.

PCL blends (18%-30% w/w) were prepared in acetic acid 96% v/v and subjected to centrifugal spinning. Z was added to PCL in a concentration ranging from 2% w/w to 10% w/w and the formulations were spun.

The obtained fibers were subjected to physicochemical characterizations. The morphological and dimensional analyses were carried out on both dry and hydrated samples by scanning electron microscopy. The formulation based on PCL 30 % w/w and Z 5 % w/w was the most promising to obtain regular and homogenous fibers with a mean diameter of 5µm. The hydration process, in distilled water overnight, do not show a variation of mean fiber diameter and the overall structure is maintained, indicating that fibers preserved their structural integrity. Since an ideal scaffold for wound healing should be elastic and maintain its shape after mechanical stresses, mechanical properties were evaluated on both dry and hydrated samples. The hydration process does not affect the scaffolds resistance. The degradation of fibers was investigated by keeping each sample in PBS at 37 °C in a water bath for 28 days. Preliminarily results showed that no degradation has occurred. Contact angle was evaluated to assess wettability of the scaffolds. The results reveal that the scaffolds are characterized by a hydrophilic surface that should support cell attachment. Moreover, scaffolds cytotoxicity was evaluated, and the preliminary results demonstrate that the fibers are biocompatible.

In conclusion, PCL-Z fibers have been successfully developed and have shown promising features for tissue engineering application. Further investigations are ongoing in order to deeply assess the biocompatibility and cell adhesion on the scaffolds.

Ozonized oil-based NLCs for wound healing and infection control

Amedeo Ungolo, Marco Ruggeri, Barbara Vigani, Silvia Rossi, Giuseppina Sandri
Department of Drug Sciences, University of Pavia, Pavia, Italy

Chronic wounds, characterized by impaired healing processes and prolonged inflammation, pose a significant healthcare challenge. Persistent open wounds can also provide a favourable environment for bacterial colonization and proliferation, which can lead to localized or systemic infections (1). Antimicrobials-based nanomedicine can prevent infection and wound chronicity, promoting and accelerating the healing process. In this context, ozonized oils are characterized by considerable antibacterial properties without developing bacterial resistance, due to their capability to disrupt cell membrane and interact with DNA (2). In addition, they can improve the oxygenation of the site and stimulate the release of growth factors (3). At this purpose, the aim of this work was the development of nanostructured lipid carriers (NLC), loaded with ozonized oils, as medical devices, to enhance healing and prevent infections of chronic wounds.
Cocoa Butter (Aboca S.p.A., Sansepolcro, Italy) was used as solid lipid and sunflower ozonized oil (Innovares srl, Sant'Ilario d'Enza (RE), Italy) as liquid lipid. In the aqueous phase Tween80 was added as surfactant. NLC were manufactured using microfluidics (ANP Automated nanoparticle system) at 40°C. Several processes parameters (total flow rate and ratios) were tested, and their impact on size and PDI was evaluated. NLC were characterized using a multidisciplinary approach including morphology, particle size, zeta potential and *in vitro* cytotoxicity towards Normal Human Dermal Fibroblast (NHDF)
Pre-formulative studies on NLCs production show that the processes parameters variation had a significant impact on the particles size and smaller particles were obtained increasing the ratio aqueous/organic phase. In particular, the ratio 8:1 between aqueous and organic phase was the best ratio to obtain nanoparticles with a dimension around 165 nm and a polydispersity index lower than 0.25. In addition, nanoparticles were characterized by negative zeta potentials (-30 mV) at all aqueous to organic ratio. Subsequently, to study the influence of the total flow rate (TFR) on the physical-chemical properties of the nanoparticles, the ratio aqueous/organic was kept constant and nanoparticles were produced at different TFR (5000 ul/min – 10000 ul/min). Hence, nanoparticles dimensions were assessed, and results showed that dimensions and zeta potential were slightly affected by the variation of the total flow rate. Moreover, in vitro assays towards NHDF showed that NLCs were biocompatible and enhance cell proliferations.
NLCs were successfully manufactured using microfluidics and characterized in terms of physical chemical properties. Moreover, they showed good biocompatibility and proliferation properties towards normal human fibroblasts. Further studies are ongoing to assess the antimicrobial properties of the nanoparticles.
This work was funded by project PNRR ON FOODS - research and innovation network on food and nutrition sustainability, safety and security working on foods - PE0000003 - F13C22001210007.

Electrospun nanofibers coated with a pH-responsive film to be used as vaginal delivery systems for the prevention of sexually transmitted infections.

G. Zucca,[a] B. Vigani,[a] C. Valentino,[a] M. Ruggeri[a], G. Sandri,[a] S. Rossi.[a]

[a] *University of Pavia, Department of Drug Sciences, V.le Taramelli 12, 27100, Pavia, Italy*
gaia.zucca01@universitadipavia.it

The present work aims to develop electrospun nanofibers coated with a pH-responsive film to be used as vaginal delivery systems for the prevention of sexually transmitted infections. The film coating should remain intact at vaginal pH, protecting the inner nanofibers. The increase in the environmental pH due to the presence of the seminal fluid should cause film solubilization, resulting in nanofibers exposure, and their subsequent hydration and adhesion to the vaginal mucosa. For the fibers preparation, polyvinyl alcohol (PVA; Sigma-Aldrich, I) and carrageenans (κ-CAR and ι-CAR; Sigma-Aldrich, I) were prepared in MilliQ water (2h at 85°C). Different concentrations of PVA (10-20 % w/v) and CARs (1-2% w/v) were considered. PVA and CARs solutions were mixed at 9:1 weight ratio at 95°C for 1 h^{1}. Mixtures viscosity (shear rates 10-1000 s^{-1}, 30°C) was assessed by means of a rotational rheometer (MCR 102, Anton Paar, I). Polymer solutions were electrospun (STIKIT-40; Linari Engineering, I) at a constant temperature (28-30°C) and relative humidity (30%-40%). The nanofibers obtained were characterized for morphology (SEM; PhenomTM Pure Desktop, Thermoscientific, I) and mucoadhesive properties (TA.XT plus; Stable Micro Systems, UK), using commercial mucin suspensions in simulated vaginal fluid[2] (SVF) as biological substrate. An *in vitro* degradation assay was performed in SVF and simulated seminal fluid (SSF)[3] at 37°C. 8% w/v Eudragit L100 (EL100, Evonik, I) solution in absolute ethanol and glycerol (Gly, Sigma-Aldrich, UK) at 8% and 16% w/v were used for film preparation by casting[3]. Films mechanical properties (tensile strength and elongation at break %) were investigated by means of TA.XT plus. Films were subjected to *in vitro* degradation assays in both SVF and SSF at 37°C. Viscosity values in a range of 2-3 Pa.s at 1,000 s^{-1} were evaluated as ideal to obtain bead-free homogeneous PVA/CAR nanofibers with a mean diameter of about 500 nm. They are characterized by good mucoadhesive properties and a small weight loss after 24 h of immersion in SVF/SSF. EL100/Gly films possess adequate mechanical properties, able to allow their administration avoiding ruptures, a proper stability in SVF and a quick dissolution in SFF, to permit the exposure of PVA/CAR nanofibers after the contact with a potentially infected seminal fluid. In conclusion, promising nanofibers characterized by suitable mucoadhesive and degradation properties, and polymeric films to be used as a protective coating were successfully developed. Ongoing studies are focused on nanofibers loading with a model drug.

Inorganic Nanoparticles-doped nanofibrous scaffold for skin regeneration

S. Marsani[a], M. Ruggeri[a], B. Vigani[a], S. Rossi[a], G. Sandri[a]

[a] *Pavia University, Department of Drug Sciences, Pavia, Italy, Via Taramelli 12*
simone.marsani01@universitadipavia.it

Introduction: Natural polymers are considered promising biomaterials in regenerative medicine since they can provide a suitable microenvironment for wound healing, mimicking the structural and biochemical cues of native tissues [1]. Scaffolds produced by animal proteins, such as gelatin, could sustain cell adhesion and proliferation due to the presence of tripeptide Arg-Gly-Asp (RGD) motifs, while scaffolds based on plant-based proteins, such as zein, have less immunogenic response than animal-derived proteins. In addition, inorganic nanoparticles, such as selenium nanoparticles (SeNPs), can improve the wound healing process, thank to their antimicrobial activity against *Pseudomonas aeruginosa*, a pathogen involved in life-threating wound infections [2]. In light of these considerations, gelatin or gliadin-based nanofibers doped SeNPs were designed and developed.

Materials and Methods: The polymeric blends were based on pullulan, an electrospinnable polymer, and proteins, gliadin or gelatine. Citric acid was added as crosslinking agent and SeNPs as antimicrobials. Nanofibrous scaffolds were obtained using horizontal electrospinning apparatus keeping the same variables for each formulation. the systems were made insoluble by heating and imaged using electron microscopy (SEM and TEM). Physico-chemical properties, including the mechanical ones, were also assessed.

Results: SEM images revealed smooth surface and uniform nano-dimension fibers independently of scaffold compositions. In addition, after crosslinking and subsequent hydration, each scaffold retained a nanofibrous structure. TEM images confirmed fiber doping with SeNPs. Moreover, the mechanical analysis showed that the presence SeNPs led to increased elastic properties and Young modulus in the case of gelatine-based nanofibers.

Conclusion: Nanofibers based on proteins, doped with SeNPs, have been successfully developed. Current studies are ongoing to evaluate the effect of SeNPs on the preclinical properties of the fibers, in particular biocompatibility and antioxidant properties in vitro on fibroblasts.

Composite biomaterial-based microneedles for pathological scars treatment

D. Ianev,[a] B. Vigani,[a] M. Mori,[b] C. Valentino,[a] M. Ruggeri,[a] G. Sandri,[a] S. Rossi,[a]

[a]*Department of Drug Sciences, University of Pavia, Via T. Taramelli 12, 27100, Pavia, Italy*
[b]*1MED SA, Via Campagna 13, CH-6982, Agno, Switzerland*
daiana.ianev01@universitadipavia.it

Abnormal scars, also known as pathological scars, refer to a variety of skin formations that deviate from the typical healing process after injury. These scars may include keloids, hypertrophic scars, or scars resulting from conditions like acne or burns[1]. Recent research has highlighted the potential of drug-free microneedles (MN) in reducing scar growth by inhibiting skin fibroblast proliferation[2]. This effect, known as the contact inhibition effect, is achieved by disrupting the mechanical communication between fibroblasts and the extracellular matrix[3]. The objectives of the present work are i) the development of a novel composite biomaterials consisting of whey protein isolate (WPI, Milei GmbH, DE), and chitosan (CS, Sigma Aldrich, I) or trimethyl chitosan (TMC, ChitoLytic, CAN) and ii) the design and production of composite biomaterial-based MN that employ a mechanotherapeutic approach to treat abnormal scars.

For the development of the composite biomaterials different complexes were prepared by mixing WPI 4% w/w aqueous solution with 4% w/w CS solution in 0.5M acetic acid or 4% w/w TMC aqueous solution at 1:1 weight ratio. The influence of WPI denaturation (70°C for 20 min) on complexes formation was investigated. Rheological, turbidimetric, dynamic and electrophoretic light scattering, SEM analyses were performed to characterize the complexes. Moreover, *in vitro* biocompatibility on NHDF cells and antioxidant activity were also evaluated.

MN patches consisting of the complexes were fabricated via a two-step centrifugation casting method, using two different polydimethylsiloxane molds containing pyramidal cavities. The MN patches were characterized for morphology and mechanical strength. Insertion studies were also performed on model membranes. For the *in vitro* performance studies, a fibroblast-populated collagen lattice system (FPCL) model was used to investigate if MN were able to reduce collagen matrix contraction, modifying its viscoelastic properties.

The formation of CS-TMC:WPI complexes was significantly affected by WPI denaturation. All complexes were characterized by *in vitro* biocompatibility and antioxidant properties. MN showed a well-defined structure with a pyramidal morphology, evidenced by SEM analysis. The fracture force for all the MN prepared exceeded 0.058 N, that is the minimum average penetration force for normal skin. Preliminary results pointed out that MN inhibited FPCL contraction with a significant change in its viscoelastic properties. *In vivo* studies are on-going to evaluate the biocompatibility of the obtained composite biomaterial-based MN.

mariasofia.perucchini01@universitadipavia.it

The present work aims to develop a thermo-gelling and mucoadhesive system intended to be administered as nasal spray for the prevention of viral infectious diseases. The addition of cyclodextrins (CDs), hydroxypropyl-β-CD (HPβ-CD; Sigma-Aldrich, I) and randomly methylated-β-CD (rβ-CD; CycloLab, HU), to hydrophobically-modified hydroxypropyl-methyl cellulose (Sangelose (SG)) aqueous solutions is proposed to obtain thermo-gelling systems. At room temperature, SG/CDs aqueous solutions are characterized by a low viscosity due to SG/CDs complexation. As the temperature increases to physiological values, SG/CDs complex dissociates: SG hydrophobic chains interact with each other, causing the system sol-gel transition[1].

SG/CD solutions, based on 0.5% w/w SG and different HPβ-CD or rβ-CD concentrations (0.1-0.5% w/v and 0.025-0.2% w/v respectively), were characterized in terms of rheological behavior; viscosity and viscoelastic measurements were performed at room (25°C) and body temperature (37°C) and gelation temperature (T_{gel}) and time (t_{gel}) were determined. The mucoadhesive properties were tested by means of a Texture Analyzer using 8% w/v mucin suspension in simulated nasal fluid as biological substrate. Sprayability and spreadability were investigated for the most promising thermo-gelling and mucoadhesive systems. The spray coverage area using a conventional nasal device, tension surface and contact angle on gelatin/mucins substrates were investigated. Spray deposition in a nasal cast model will be also studied. SG/CD systems stability was evaluated in terms of viscosity at room temperature. Finally, *in vitro* experiments will be performed to assess system cytocompatibility on different cell lines (HeLa, MRC-5, A549, or HEp-2 cells).

The addition of both HPβ-CD and rβ-CD to SG solution was responsible for a sol-gel transition within a physiological temperature range (29-34°C) in about 1 minute. SG/CD systems were characterized by a prevalence of the elastic properties on the viscous ones at 37°C; this behavior is functional to the formation of a protective gel barrier on the mucosa. SG/CD systems were characterized by optimal mucoadhesive properties. The most promising formulations showed sprayability and spreadability suitable for nasal administration. *In vitro* test demonstrated that the systems do not alter the viability of any of the cell lines used.

The thermo-gelling and mucoadhesive systems obtained are proved to be easily sprayed through an appropriate device into the nasal cavity and to form a gel at physiological conditions that should act as a physical barrier to the entry of pathogens into the respiratory tract.

Skin chronic wounds are characterized by a disrupted healing process[1]. Therefore, 3D structures are used as scaffolds to stimulate skin reparation[2]. Layered double hydroxides (LDH) are anionic clay minerals which should contribute to boost the cellular processes thanks to their peculiar structure and chemical composition[3]. The aim of this work was the development of polymeric spray-dried microparticles doped with ZnAl LDH to enhance the skin tissue regeneration. The production method was designed in view of a continuous manufacturing process involving the LDH synthesis and the development of the microparticles.

LDH containing Zn^{2+} and Al^{3+} were synthesized via co-precipitation using ammonia as an alkaline agent. The LDH were then isolated and dispersed in water, without further washing. Alginate and chondroitin sulfate were added to the dispersion, which was then spray dried. The microparticles were then crosslinked using $CaCl_2$. Physico-chemical characterizations, together with *in vitro* proliferation assays on normal human dermal fibroblasts (NHDF), were carried out. The efficacy of the systems was assessed through preclinical *in vivo* testing on a murine model.

Microparticles with a spheroidal shape and a mean diameter of 10-15 μm were produced. The crosslinking step with $CaCl_2$ allowed to obtain water insoluble microparticles without changes in morphology. The presence of LDH in the microparticles was confirmed and corresponded to the theoretical value. The amount of Zn released from the microparticles was evaluated to assess its role in the regeneration process. Cell proliferation assays showed that the scaffolds improved cell growth up to 6 days and the presence of the LDH seemed to increase cell viability. *In vivo* testing confirmed the efficacy of the systems and proved the crucial support of LDH in the skin regeneration phases.

To conclude, microparticles made of alginate and chondroitin sulfate doped with synthetic LDH, based on Zn^{2+} and Al^{3+}, were successfully manufactured. These scaffolds proved to support cell proliferation over 6 days and confirmed their efficacy on the skin regeneration process on a murine model.

saliha.moutaharrik@unimi.it

Inflammatory bowel disease (IBD), including Crohn's disease and ulcerative colitis, affects over 6 million people globally[1]. The composition of gut microbiota in IBD patients has been reported to be significantly different from that of healthy individuals. Therefore, the treatment of dysbiosis could have a positive impact on IBD. This may be achieved by various approaches ranging from simple dietary changes to replenishment of the bacteria. Probiotics are commonly administered in the form of capsules or sachets. Their incorporation into tablets, more convenient from the industrial and treatment compliance perspectives, is challenging because of the compaction forces involved[2]. To overcome such limitations, bioprinting, which consists in 3D printing of biomaterials (bio-inks), was here proposed for the manufacturing of a solid probiotic dosage form for colon delivery[3,4]. Particularly, the aim of the present work was to set up an immediate-release core formulation, where the bacteria would be incorporated, intended for subsequent embedding in a functional polymer shell. For fabrication of the disintegrating core, extrudable pastes, including a large amount of solids, were prepared, and printing by a 3D Discovery™ Gen. 5 bioprinter (RegenHU, CH) was attempted. The pastes, also containing paracetamol as an analytical tracer, were based on either insoluble (Kollidon® SR) or soluble (Mannogem® XL) fillers, which were expected to impart the desired mass and density of the final product while maintaining proper viscosity of the formulations to be extruded. In the former case, a superdisintegrant was added to accelerate interaction with aqueous fluids. By adjusting the composition and the process parameters, it was possible to print selected pastes into monolithic units of desired shape and size. These were allowed to dry at room temperature before being characterized in terms of mass, dimensions, mechanical resistance, disintegration time and dissolution rate. Using a soluble filler led to faster disintegration than combining an insoluble one with a superdisintegrant. The best-performing pastes were then loaded with *Lacticaseibacillus paracasei* as a model probiotic, pointing out compatibility issues only in the case of that containing Kollidon® SR, as highlighted through viable cell count. Even though extensive studies need to be performed to assess the impact of formulation and printing as well as drying conditions on cell viability, the present work would pave the way for the use of bioprinting technique in manufacturing solid dosage forms intended for oral administration of probiotics.

Design of microneedles for dermal delivery of cationic liposomes

E. Vettorato,[a] S. Franzè,[a] A. Casiraghi,[a] P. Minghetti,[a] F. Cilurzo,[a]

[a]*Department of Pharmaceutical Sciences, University of Milan, Via G. Colombo, 71 – 20133 Milan (IT)*
elisa.vettorato@unimi.it

Skin delivery of drugs has been investigated for decades to achieve local or systemic effects. However, the strong barrier given by the tightly packed skin corneocytes prevents the passive diffusion of most compounds into the deepest strata. Among the approaches studied to breach the skin barrier, using microneedles (MNs) or very fluid and deformable liposomes seems to be the most effective; therefore, several studies recently proposed a combination of the two methods[1]. However, most of the research tracked the skin permeation of the drugs delivered with this approach, whereas the effect of MNs on the skin penetration of liposomes *per se* has been scantly investigated.

In this work we designed microneedle arrays (MNA) with different geometrical properties to verify how the MNA pre-treatment on the skin could affect the diffusion of cationic liposomes, either conventional rigid liposomes (RL) or fluid liposomes (FL). Squared arrays of 6.4 mm^2 composed of 7x7 pyramidal MNs were produced with a 3D printer at different base diameters (150 or 200 μm) and needle heights (600 or 1000 μm). After UV curing (60°C, λ=405 nm), MNA were characterized for their morphology, mechanical strength (tensile testing machine) and skin depth (Parafilm model[2]). RL and FL liposomes were prepared by thin film hydration method. RL composition was DPPC/DOTAP/Cholesterol/Rho-PE 45/45/9/1 mol/mol/mol/mol whereas FL bilayers were composed of DOPE/DOTAP/Rho-PE 24/75/1 mol/mol/mol and Tween 80 was added as edge activator in 85:15 w/w ratio with respect to the lipid component. The particle size distribution and ζ potential were measured by dynamic light scattering (DLS). Low density MNA of 200x1000 μm showed the best mechanical properties, thus were selected to evaluate the diffusion of RL and FL formulations into full-thickness porcine ear skin. Skin samples were poked with the MNA (30 N, 60 s), then treated with 50 μL liposomes dispersion on Franz diffusion cells under non-occlusive conditions for 15 min before tape-stripping, PFA fixation, cryosectioning, and observation under a fluorescence microscope.

All the MNA reached at least 2 Parafilm layers; MNA 200 μm base and 1000 μm height reached 5 parafilm layers (approx. 600 μm depth). A reduction in base diameter increased the fragility of 1.0 mm height MN and reduced the reached skin depth. Liposomes showed homogeneous nanometric size (121 ± 3 nm RL; 112 ± 2 nm FL) and positive ζ potential (49 ± 10 mV RL, 28 ± 4 mV FL). Fluorescence imaging indicated that after 15 min FL could efficiently reach the epidermis/dermis interface (EDI) either with or without MN skin pretreatment, while the 200x1000 MN improved the diffusion of RL to the EDI (ImageJ elaboration, $p<0.05$, Two-way ANOVA). Thus, MNs treatment may be required to enhance RL diffusion into the skin, albeit less impacting on FL diffusion.

Cytotoxicity of curcumin decorated silver nanoparticles on human fibroblasts

L. Galassi,[a] A. Brigliadori,[b] K.K. Maina,[c] I. Zanoni,[b] A.L. Costa,[b] S. Delbue,[c] Blosi M.,[b] Blasi P.[a]

Silver nanoparticles (AgNPs) have been long known for their antimicrobial activity and are currently commercialized in different consumer products, medicinal products and medical devices. However, their safety has been questioned and, even though many studies on teir toxicity have been performed, the results reported in literature are often unexhaustive and contradictory.[1]

Here we report the results of AgNP cytotoxicity on WS1 human fibroblasts taking advantage of ptychography, a label free, high-contrast imaging technique for live cells using quantitative phase information. Ptychographic quantitative phase imaging (QPI) technology gives consistent information on cell morphology (e.g., sphericity) proliferation and growth (e.g., dry mass content, cell number), cell motility (e.g., displacement, track speed) providing much more complete information on nanomaterial cytotoxicity than conventional assays.[2]

AgNPs were synthesized employing a safe-by-design approach and using hydroxyethyl cellulose as reducing/capping agent (AgHEC)[3] and curcumin (AgCUR) as natural occurring adjuvant, to take advantage of the potential synergistic antimicrobial and/or antiviral effect of Ag and curcumin.

The selected AgHEC and AgCUR formulations had selectivity index (SI) of 22 and 47, displaying effective antiviral concentration 50 (EC_{50}) at concentration of 12 and 8 ppm, respectively.

On human fibroblasts, AgCUR demonstrated a reduced cytotoxicity with respect to AgHEC, probably due to the intrinsic curcumin antioxidant properties resulting in a cell protective effect. AgCUR had no significant effects on cell morphology and at 49 ppm the dry mass content and the cell number were similar to the untreated control. Cell motility was affected significatively only at the highest concentrations (e.g., 195 ppm) with no effect at concentrations lower than 97 ppm.

Taken together, these results demonstrate the potential value of AgCUR as antiviral tool with a favourable cytotoxicity profile.

Lemon derived exosome-like nanovesicles as drug delivery system

M.D. Langellotto,[a] G. Rassu,[b] E. Gavini,[b]

[a]*University of Sassari, Department of Biomedical Sciences, Sassari*
[b]*University of Sassari, Department of Medicine, Surgery and Pharmacy, Sassari*

m.langellotto@phd.uniss.it

Exosomes are extracellular nanovesicles secreted by all cell types and they are involved in various physio-pathological processes, through intercellular communication and substance exchange. The simplicity of large-scale production, low toxicity, low immunogenicity, and high biocompatibility are just some of the aspects that make these nanovesicles attractive as drug delivery systems[1]. The goal is to extract and characterise exosome-like nanovesicles from lemon (ELNVs), load them with a promising drug against Multiple Sclerosis and evaluate the system's effect on an oligodendrocyte progenitor cell line (OPCs)[2]. We successfully extracted ELNVs sustainably without the use of solvents. These particles were characterised in terms of size and stability under different conditions. We were able to load ELNVs with 80% efficiency with an antihistamine drug, Clemastine, achieving a post-loading size of 342.0±107.0 nm in Milli-Q water. The pharmacological activity of the system was assessed in an OPCs model (Fig. 1). ELNVs appear to be a promising drug-loading platform. The outlook is to broaden this technique to more plant sources and include different classes of drugs.

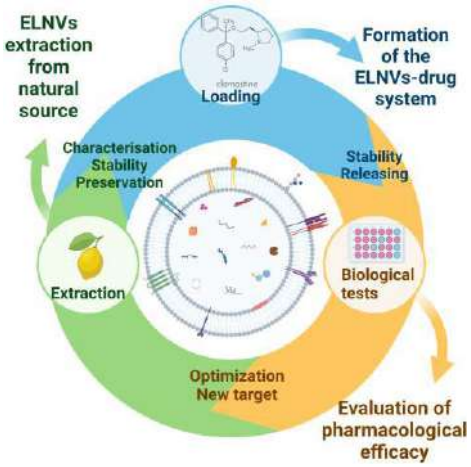

Figure 1: Schematic representation of ELNVs extraction, loading and biological assessment.

Poloxamine-908-based hydrogels containing zein nanoparticles as hierarchical injectable formulations

S. Voci, N. Ambrosio, A. Gagliardi, E. Giuliano, D. Cosco

Department of Health Sciences, University "Magna Græcia" of Catanzaro, Campus Universitario "S Venuta", 88100 Catanzaro, Italy
donatocosco@unicz.it

The excellent flexibility, biocompatibility and soft nature of hydrogels promoted their use in various pharmaceutical and biomedical applications. In particular, the design of thermo-sensitive formulations represent a feasible strategy for the sustained drug release in the required body compartment with reduced side effects. Among the molecules characterized by thermo-responsive features, poloxamines, pharmaceutical excipients belonging to the family of amphiphilic block copolymers, have attracted a certain degree of attention. In this context, this work aims at evaluating the feasibility of poloxamine 908 (P908), a hydrophilic, X-shaped tetrablock copolymer consisting of an ethylenediamine central moiety linked to four chains of poly(propylene) and poly(ethylene) oxide blocks, for the development of *in situ*-forming hydrogels[1]. Various amounts of P908 (15-35 % w/w) were solubilized in cold water under magnetic stirring until a clear solution was formed; then, the samples were characterized by means of passive and dynamic rheology with the aim of investigating the influence of the copolymer concentration and temperature against their mechanical properties. The obtained data showed that the use of concentrations ≥25% w/w P908 favored the formation of systems with a gelation within a suitable temperature range (27-33 °C) and a viscoelastic behavior at 37 °C. Moreover, it was shown that P908 hydrogels can be easily prepared in different physiological relevant media (0.9% saline solution, 5% w/v glucose solution or 0.01 M phosphate buffered saline) and can withstand the autoclave sterilization procedure without any variations of their rheological features[1]. The entrapment of rhodamine B (0.10 and 0.25% w/w) and ovalbumin (1% and 2% w/w), used as models of hydrophilic compound and protein, respectively, demonstrated the ability of the hydrogel matrix to ensure a prolonged and sustained leakage of the entrapped compounds. Additional investigations have been performed in order to develop a hierarchical injectable formulation; in detail, various colloidal carriers, such as zein nanoparticles, have been embedded within the P908 hydrogels with the aim of modulating the biological activity and leakage of the encapsulated compound(s) demonstrating the physico-chemical properties of the nanosystems influence the rheological features of P908-hydrogels.

These results confirm the potential use of P908-based thermo-sensitive hydrogels for the prolonged release of active compounds and the development of multistage systems.

Lipopolyplexes for DNA delivery: the effect of cationic polymer on cytotoxicity and transfection

Camilla Pozza, Viola Bertolotti, Giulia Anderluzzi, Silvia Franzè
Department of Pharmaceutical Science via Colombo 71 Milano

Lipopolyplexes (LPP), namely ternary complexes of biocompatible cationic polymers, nucleic acid and liposomes, represent an attractive though poorly investigated alternative to lipoplexes for gene delivery. Poly-L-lysine (PLL), polyethyleneimine (PEI), spermidine, spermine and protamine sulfate are the most used polymers for LPP preparation[1]. Nevertheless, a systematic study of the polymer nature on nucleic acid complexation and transfection efficiency is missing. Here, we prepared LPP using three cationic polymers (Chitosan, PLL and PEI) and 1,2-dipalmitoyl-sn-glycero-3-phosphocholine (DPPC) based liposomes to complex a pDNA encoding the green florescence protein (EGFP). Briefly, pDNA encoding EGFP was complexed with chitosan, PLL or PEI in PBS 50mM pH 4.5 at different polymer/DNA mass ratios. Selected polyplexes were further complexed with DPPC:DOPE:Chol liposomes (55:35:10 mol%, in PBS 50 mM pH 7.4) at at different molar ratios. All formulations were characterized in terms of hydrodynamic size, polydispersity index (PDI) and zeta potential by dynamic light scattering (Malvern, UK). Cytotoxicity, assessed by an MTT assay, and transfection efficiency were determined HeLa human epithelial cells by GFP detection. A pDNA/DOTAP based lipoplex was used as positive control.

We found that optimal polymer/DNA mass ratios were 10 for chitosan and PLL polyplexes and 6 for PEI polyplexes. These polyplexes were around 100 nm in size, PDI<0.2 and positively charged, while final LPP had a mean diameter of about 180 nm, PDI<0.2 and they were slightly positive/neutral. The formation of the ternary complexes were confirmed by Fluorescence resonance energy transfer (FRET) and crioEM. In vitro, generally LPP were significantly less toxic than corresponding PP, with chitosan LPP being the most biocompatible. LPP showed higher transfection efficiency than corresponding PP and control lipofectamine like formulations. In particular, PEI LPP induced the highest GFP expression, both as percentage of positive cells and mean fluorescence intensity also in comparison with the lipoplex. In conclusion, that the choice of polymer influenced the mode of gene expression mediated by these LPP in vitro; generally, PEI is the most promising polymer for the design of LPP, offering a valid alternative for the delivery of pDNA platform.

IUPAC CrystEng 2024
4th IUPAC Workshop on Crystal Engineering

Lunedì, 26.08.2024: 10:00 - 12:00
Sala: Red2 (level +1)

Chair di sessione: Pierangelo Metrangolo, Politecnico di Milano; pierangelo.metrangolo@polimi.it
Chair di sessione: Gabriella Cavallo, Politecnico di Milano; gabriella.cavallo@polimi.it
Chair di sessione: Giancarlo Terraneo, Politecnico di Milano; giancarlo.terraneo@polimi.it

Satellite meeting to SCI2024 and ECM34 - Padova, in relation with the IUPAC Project 2012-044-1-100 "Basic Terminology of Crystal Engineering"[1]

Abstract della sessione

Crystal engineering is a highly interdisciplinary field, dealing with the design of predictable and controllable solid-state materials by exploiting different intermolecular interactions. Crystal engineering has expanded rapidly in the last decades producing many structurally precise functional materials with advanced properties. The subject goes beyond the traditional division of organic, inorganic, and physical chemistry. It has strong overlap with supramolecular chemistry, X-ray crystallography, material science, and solid-state chemistry and this makes for a very eclectic blend of ideas, techniques and strategies.

This SCI2024-ECM34 satellite meeting aims to provide a forum to discuss the current state of the art of this rapidly evolving field. Through invited talks by leading scientists from institutions and organizations worldwide, we intend to create open relaxed discussions between researchers focused on the latest developments in the field.

We are pleased to invite you to be a part of this exceptional event. It will offer networking opportunities among peers, recognized leaders, young scientists and students and permit the exchange of the latest scientific knowledge regarding the field of crystal engineering.

We look forward to meeting you at the IUPAC CrystEng 2024 workshop in Milan!

Basic Terminology of Crystal Engineering

Metrangolo, Pierangelo
Politecnico di Milano, Italia; pierangelo.metrangolo@polimi.it

Crystal engineering is the design and synthesis of functional crystalline structures, based on a bottom-up approach from smaller building blocks. Crystal engineering is a fascinating and relatively young subject that has expanded rapidly the last 20 years, and is also attracting the interest of the chemical and pharmaceutical industry. It has strong overlap with supramolecular chemistry, X-ray crystallography, materials science, and solid-state chemistry, and, yet, it is a distinct discipline in itself. The subject goes beyond the traditional divisions of organic, inorganic, and physical chemistry, and this makes for a very eclectic blend of ideas, techniques and strategies.

The diversity in both focus and scientific basis of the researchers involved in the field has led to numerous terminology practices that are not consistent among research groups, causing much confusion and unnecessary conflicts.

The purpose and scope of this IUPAC project (no. 2012-044-1-100, https://iupac.org/project/2012-044-1-100) is to provide a basic glossary of terms for this rapidly evolving, highly interdisciplinary field of crystal engineering, to identify and debate open questions, and to point out new directions.

This project brings together a task force of eminent scientists in the field with the objectives to:

• Document, analyze, and evaluate existing practices.

• Make preliminary suggestions for a limited number of terms (basic glossary of terms).

• Organize discussions of these recommendations with a large group of researchers in the area.

• Adjust and optimize preliminary findings in order to have highest possible acceptance from the research community.

• Publish the final recommendations in PAC.

• Approach journal editors and publishers to have the recommendations included, or cited, in their guidelines for authors.

Crystals that Can Self-Heal

Naumov, Pance
NYU Abu Dhabi, Emirati Arabi Uniti; pance.naumov@nyu.edu

Self-healing is an intrinsically exciting concept as it applies to the process of recovery, an almost commonplace effect found in living organisms, and extends to inanimate objects. Self-healing of artificial materials is as beneficial as it is to living creatures, as the effect significantly prolongs the lifetime of both. Self-healing polymers, cementitious materials, and coatings have already found commercial applications. Self-healing of crystals was first discovered in sodium chloride in 1980. However, the field has recently entered a renaissance when it was observed for the first time in the emerging material class of molecular crystals in 2016. The reinvigoration of interest in self-healing molecular crystals stems from their prospects as durable, lightweight, and flexible emissive or electronic materials. As ideally defectless and ordered media, organic crystals have unique optical, mechanical, and electrical properties, and the possibility of self-healing substantially increases their viability for durable, lightweight smart devices.

CV dell'autore: Tenured professor at New York University Abu Dhabi, with a cross-appointment at NYU's Molecular Design Institute, and a director of the Center for Smart Engineering Materials. He is a native of Macedonia, where he

got a BSc degree from Ss. Cyril and Methodius University. After acquiring his PhD in chemistry and materials science from the Tokyo Institute of Technology in 2004, Dr. Naumov continued his research at the National Institute for Material Science, Osaka University and Kyoto University. The research in his group is related to materials science, focusing on smart materials, crystallography, bioluminescence, and petrolomics

Experimental Data Mining of C/N-I···O-N Halogen Bonds

Rissanen, Kari

University of Jyväskylä, Finlandia; kari.t.rissanen@jyu.fi

Data mining is the process in which certain specific information is extracted from existing large data sets to discover systematic patterns or parameter modulations. In crystallography data mining1 normally means the use of large crystallographic databases, such as the Cambridge Structural Database2 (CSD) and Inorganic Crystal Structure Database3 (ICSD) for extraction of geometrical parameters, viz. bond distances, angles, interaction distances (e.g. hydrogen and halogen bonds) etc. Our research interest has been focused on the studies of weak non-covalent intermolecular, viz. supramolecular interactions as the driving force in complex formation, self-assembly and molecular recognition, especially in the solid state by single crystal X-ray diffraction. The lecture will highlight some of our recent studies on N-I···O-N and C-I···O-N halogen-bonded systems, using unusually large set of in-house single crystal X-ray structures.4-7

CV dell'autore: Professor of Chemistry at the University of Jyväskylä, Finland. The research of Rissanen group focuses on the design, synthesis and structures of supramolecular and nano-sized assemblies and the weak intermolecular interaction they manifest. Single crystal X-ray crystallography is an integral part and is heavily involved in all areas of the research group. Projects lie at the interface between synthetic chemistry, structural chemistry and nano-related materials science and aim to the understanding of the weak intermolecular interactions. One major area is the synthesis of receptors for cations, anions and ion-pairs and their recognition properties, e.g. for early detection of cancer

Crystal Engineering: Then, Now and Next

Zaworotko, Michael J.

University of Limerick, Irlanda; xtal@ul.ie

That composition and structure can so profoundly impact the properties of crystalline solids has provided impetus for exponential growth in the field of crystal engineering1 over the past 30 years. This contribution will address how crystal engineering has evolved from its initial focus upon design (form) to its current emphasis on properties (function) was exemplified by three classes of sorbent materials:

• Ultramicroporous materials offer exceptional control over pore chemistry, pore size and pore shape. New benchmarks for CO2 (see Figure), C2H2 and C6H6 have been observed2 thanks to tight binding sites and strong electrostatics associated with these coordination networks, which remain underexplored when compared to materials such as large pore MOFs. Studies that address water harvesting will be presented.

• Flexible metal-organic materials, FMOMs, were once seen as a curiosity but it is now recognized that they can offer solutions to important gas storage and separation applications, especially when they reversibly switch from closed (non-porous) to open (porous) phases.3 New examples of switching FMOMs will be discussed.

• Non-porous solids. Non-porous solids that undergo pressure-induced switching between closed and open phases are of interest for storage and separations applications.4 New examples of such “switching adsorbent materials” covering 0D, 1D and 2D materials will be covered.5

The overall goal of this presentation is to convey how and why crystal engineering can teach us to custom design the right crystalline material for the right application, including what this means for global challenges such as carbon capture and water purification.

CV dell'autore: Bernal Chair of Crystal Engineering, Science Foundation of Ireland Research Professor and codirector of the Synthesis and Solid-State Pharmaceutical Centre, www.sspc.ie. His research activities have focused upon fundamental and applied aspects of crystal engineering since 1990. Currently, metal-organic materials (MOMs), especially microporous and ultramicroporous sorbents, and multicomponent pharmaceutical materials (MPMs) such as cocrystals, hydrates and ionic cocrystals are of particular interest. These new materials are aimed at addressing global challenges such as carbon capture, water purification and better medicines. He is a Fellow of the Royal Society of Chemistry, the Learned Society of Wales and the Institute of Chemistry of Ireland. He is also a Member of the Royal Irish Academy.
