From Li clusters to nanocatalysis: a personal tour of 40 years of cluster chemistry

G. Pacchioni,[a]

[a] *Dipartimento di Scienza dei Materiali, Università Milano-Bicocca, via R. Cozzi 55, 20125 Milano*
gianfranco.pacchioni@unimib.it

I will trace the history of 40 years of research in cluster chemistry from my personal point of view recalling experiences and anecdotes in my numerous stays in Berlin, Munich, and at IBM in California. I will describe how my research activity began in the early 1980s with studies on the electronic structure of Li clusters in the gas phase. Since then, research on the chemistry and physics of clusters has made enormous progress, thanks to the development of new experimental techniques, advanced theoretical methods and a continuous growth in computing power. The structure and properties of bare clusters, ligand-stabilized organometallic clusters, and supported nanoparticles were elucidated with the ultimate goal of creating strong links between cluster science, surface chemistry, and heterogeneous catalysis. This has led to a better understanding of catalysis using supported nanoparticles down to individual atoms and the possibility of designing new nanostructured catalysts (including single atom catalysts) with desired properties. The presentation will conclude with some considerations on how the way of doing science has changed from when I started to today.

MD-02

Analytical chemistry in front of the curtain: a personal experience of the last 40 years

A.Roda

Deparment of Chemistry Giacomo Ciamician, Alma Mater Studiorum, University of Bologna

aldo.roda@unibo.it

Analytical chemistry has continuously evolved over the last 40 years, leveraging advancements in related fields such as materials science, instrumentation, nanotechnology, biotechnology, "omics," and molecular biology. This evolution has positioned analytical chemistry as an 'enabling science' for numerous disciplines, including life sciences, medicine, environmental science, and food science. Despite its significant contributions, the general public often perceives the work of analytical chemists as routine service rather than scientific innovation. During this transformative period, my scientific activity has been at the forefront of analytical chemistry's metamorphosis. Beginning in the late 1970s, my research in bioanalytical clinical chemistry benefited from the availability of pure enzymes and the development of enzymatic assays that replaced nonspecific and time-consuming chemical methods. We developed highly sensitive coupled enzymatic reactions with co-immobilized enzymes in continuous flow systems, utilizing bio-chemiluminescence (BL/CL) detection. The groundbreaking work of Nobel laureate R. Yalow on radioimmunoassay (RIA) inspired significant advancements in analytical immunology. This led to the production of antibodies against almost any molecule, revolutionizing medicine by enabling the measurement of biomarkers and steroid hormones at picomolar levels. The substitution of radioisotopes with enzymes and BL/CL substrates expanded the use of immunological methods to veterinary medicine, food, and environmental analysis. The specificity of BL/CL, due to the absence of nonspecific signals, facilitated this expansion. Innovations included the development of various BL/CL microfluidic-driven miniaturized devices, validated for point-of-care testing and LFIA biosensors using 3D printing technology. Light measurement advancements, using CCD and smartphone CMOS detectors, enabled simple, affordable portable devices utilized in the ISS space station by astronaut Paolo Nespoli. Additionally, cell-based biosensors using luciferase from various species, including the cloned Luciola Italica, advanced in vivo imaging for cancer models and motility studies in intact animals. Recent research introduced thermochemiluminescence combined with energy transfer principles, offering reagent-free biosensor advantages over CL. Parallel to this, my research on bile acids (BA) since 1975 involved measuring thermodynamic properties such as pKa, water solubility, Surface tension: critical micellar concentration, and Log P in representative BA series. This work led to a productive collaboration with Roberto Pellicciari, studying over 100 new BAs and developing models to predict pharmacokinetics, activity, and metabolism. Ultimately, this research contributed to the pharmaceutical market entry of Obeticholic acid, a new potent FXR agonist. The fruitful collaboration with physical chemistry, synthetic and medicinal chemistry was the main key of the success.

Reflection on Chemistry Educational Research: the example of the pathway on combustion in elementary school

C. Fiorentini [a]

[a] *CIDI Firenze, Via S. Stefano in Pane 23, 50124 Firenze*

cl.fiorentini@virgilio.it

The didactic research of chemistry should have, in my opinion, as a fundamental task that of building a vertical curriculum from elementary school to upper secondary school capable of achieving meaningful teaching, capable, that is, of guaranteeing to all students, with deep and lasting learning, the knowledge and skills necessary for conscious citizenship: a task, a very demanding one, the realization of which cannot arise except from the coming together of multiple competencies, from epistemological and didactic disciplinary ones, from psychological and pedagogical ones, to those related to a critical reflection on the teaching experience. To use a term much in vogue today, it can be said that curriculum research stands on the terrain of complexity; it excludes any reductionist approach, which can only be meaningless or deleterious in educational outcomes. In the above considerations on the meaningfulness of knowledge there is an inescapable aspect that is implicit, but for the sake of clarity it is good to make it explicit: in order to be meaningful, knowledge, in addition to being fundamental and essential, must be adapted to the cognitive and motivational structures of students. Indeed, we think that it is impossible to make knowledge that is too far removed from the possibility of being understood become meaningful, despite all the attempts made to promote understanding through laboratoriality. In scientific teaching, in fact, experiments, per se, are not conceptually obvious and do not guarantee meaningfulness. As all epistemological reflession has pointed out, experiments are theory-laden. Therefore, to build vertical chemistry curriculum hypotheses based on experiments, an epistemologically and psychologically grounded analysis of scientific concepts is indispensable in order to identify, hypothetically, those concepts and experiments most suitable for various ages. An experiment-based approach might otherwise be a livelier variant of specialized disciplinary notionism.

In this contribution we will consider, with an example, the fundamental role of critical reflection on educational experimentation, an aspect much emphasized on the level of principles, but little analyzed and deepened in its indispensable specific functions. Of course, the previously mentioned multidisciplinary theoretical aspects are no less important and are the ones most developed. To these aspects we have dedicated a book [1] where the key parts are epistemological considerations, psychological and pedagogical considerations, those dedicated to a methodological and curricular proposal for the first cycle and finally those referring to a methodological and curricular proposal for the second cycle.

1988-2024, a 35-years journey across computational life and material sciences

M.C. Menziani
Dipartimento di Scienze Chimiche e Geologiche, Università degli Studi di Modena e Reggio E., Italia
mariacristina.menziani@unimore.it

Over the past 35 years, we have witnessed the emergence and development of computational chemistry tools that have significantly influenced the way chemical research is conducted in academia and industry. In particular, with the advent of colour workstations and computer graphics, a new hybrid field of molecular modelling and computational chemistry called "computer-aided molecular design" has emerged.

In this article, I will review some of the key results of my research aimed at deepening our understanding of the physicochemical processes in proteins, hard materials, and protein-material interactions for the design of better drugs, materials, and devices. New challenges and opportunities will also be discussed.

prato@units.it

How strange it is to completely ignore all the restrictions we experienced during the pandemic! It now feels as though those years never existed! However, if the situation has returned to normal, we owe it to the vaccines that were rapidly developed using highly innovative technologies. In fact, especially over the last few decades, science has accustomed us to the rapid resolution of even complex problems, such as the broad diffusion of COVID-19. Solving particularly difficult problems requires considerable efforts from the scientific community, employing multidisciplinary approaches and modern tools, the result of years of research and development.

However, problems are not always solved, and some are not always solvable by science. Think of wars, world hunger, human rights, and poverty. Yet, certain issues, particularly those concerning health and environment, can and must be addressed and solved by scientific research.

During this talk, we will discuss how Chemistry can play a fundamental role in our society. New classes of materials with tailored properties can be prepared and applied once we have the right vision.

Part of the work described in this talk is financially supported by the AXA Research Funds and the European Commission - Horizon Europe through the EIC Pathfinder OPEN 2022 project: PLANKT-ON / 101099192.

Luminescence-based detection of analytes of clinical and environmental relevance

Luca Prodi

Dipartimento di Chimica "Giacomo Ciamician", Università degli Studi di Bologna, Via Selmi 2, 40126 Bologna (Italy)
luca.prodi@unibo.it

Light serves as a potent tool for various applications, including (i) generating bright contrast agents for *in vivo* imaging, (ii) achieving high analytical performance in vitro diagnostics, and (iii) facilitating real-time and spatial measurements of analytes of biological and environmental relevance. Luminescence-based techniques, encompassing photo-, chemi-, electrochemi-, and thermochemi-luminescence, offer high sensitivity and versatility to cater to diverse analytical needs.

This presentation highlights two applications demonstrating the versatility of luminescence-based techniques. Firstly, it addresses the imperative for developing an accurate, rapid, cost-effective, and portable platform for detecting infectious agents, emphasized by recent pandemics. In this case, the use of electrochemiluminescence as a signal transduction mechanism, coupled with effective signal amplification, can enable the detection of infectious pathogen genomes with analytical performance comparable to, or even surpassing, PCR methods.[1] Secondly, this presentation explores the design of derivatized natural polymers to detect micro- and nano-plastics, which pose a significant global challenge lacking adequate analytical solutions. In this case, fluorescence-based microscopies facilitated the visualization of small plastic particles and, in certain cases, enabled material speciation.[2]

Acknowledgments: The financial support from the European Union's Horizon Europe EIC Pathfinder Open programme under Grant Agreement N. 101046787 (Eclipse project, https://eclipse-project.eu) and from the Italian Ministry of Research together with the support from the European Union – Next Generation EU PNRR (PRIN Project 2020CBEYHC – AStraLI: Amplification Strategies for the Labeling and Detection of Infectious Agents – and 2022WAKTFR – LIAISON: Novel Approaches to Micro- and Nano-plastics detection in water) is gratefully acknowledged.

Wastewater-based epidemiology (WBE) has emerged as a powerful approach for surveying the health and lifestyle of population. In this context, proteins have been proposed as potential biomarkers that complement the information provided by previous studies (small exogenous molecules, metabolites, and genomic material). Proteins can also offer a more comprehensive evaluation of wastewater treatments, typically assessed through parameters such as chemical and biochemical oxygen demand[1,2].

In this work, we studied the protein composition in the influent and effluent waters of 3 wastewater treatment plants (WWTPs) in Catalonia which serve communities of different population and industrial profile. The results indicate that excreta (urine and faeces) from humans, and blood and other residues from livestock were the two main protein sources[2]. Furthermore, our findings enable the proposal of specific bioindicators for wastewater-based environmental monitoring. A list of candidates with different application in environmental and health-related fields is selected and will be quantified. This includes human and animal population monitoring, particularly for rodent pest control (amylases) and livestock processing industry monitoring (albumins). Protein-related WBE enables to detect rodent pests in cities and can be a tool with potential for their population control. Rat feces, like human feces, contain proteins that are secreted in the pancreas so, detection of these enzymes in wastewater indicates the presence of live animals, and relative quantification to rodent amylase could allow us to monitor the increase or decrease of rodent feces in these samples. There is no standardized method to determine the numbers of rodents in a city or to estimate population density although some groups have tried to understand their population dynamics. Our work proposes detecting and quantifying rats according to rat feces located in sewage water using some appropriate protein biomarkers.

Additionally, we identified hundreds of proteins from different species including human, livestock and bacteria that allows us a better understanding of the habits and industrial activity of population server by the WWTPs. Our results have allowed us to select a list of protein biomarkers related to different human pathologies to be monitored.

Moreover, this study offers a complete set of complementary information that enhances the understanding of the processes occurring at water treatment plants at a protein level. Proteins are retained in the WWTP and only some recalcitrant molecules remains. This data will be invaluable for implementing new control methodologies in the WWTPs and investigating the impact of wastewater discharge in environmental buffers. In conclusion, sewage proteomics give us new tools for control rodent pest in cities, understand population characteristics and evaluate wastewater treatments

armida.torreggiani@isof.cnr.it

Chemical culture is seen by youth with less and less interest, probably due to the way science is taught in schools, to the difficulties in the understanding of the real impact on the everyday life and finally, to the shortage of attractive career perspectives. In addition, there is the need to bring the themes proposed by the new European challenges into schools to train in the short term (7-10 years) human resources who have entrepreneurial skills, digital, relational and communication skills, respect for gender and diversity.
In this perspective to trigger the students' interest in chemistry, new materials and solutions for a sustainable society, several learning paths for pupils aged 10–18 years were developed in the framework of two projects, "**Change the Game: playing to be trained for a sustainable future**" (Progettidiricerca@CNR) and "**Raw Matters Ambassadors at Schools**" (RM@Schools - EIT), working at national and European level thanks to two networks involving 15 institutes and 11 cities in Italy, and 29 partners from 18 countries, respectively.[1,2] Different educational approaches are used to foster students' interest in chemistry, circular economy, and RM-related topics, but the core element of the approach is to engage youngsters i.e. by empowering them to communicate with peers and wider society.[3] Serious games and laboratory experiments based on the research works were developed and insert in educational pathways offered to Schools. Thus, students were led to deepening for example the chemistry importance in the development of innovative technologies and the green transition by playing i.e. the RawSeeker board game (Fig. 1) as well as the main strategies of the circular economy by playing EcoCEO-it's your business.[4]
These actions will be of benefit to make youngsters aware of the complexity and interrelation of science, economy with social and sustainability issues.

From Supramolecular Towards Adaptive Chemistry

J.-M. Lehn
ISIS, Université de Strasbourg, France
lehn@unistra.fr

Molecular chemistry has developed a wide range of very powerful procedures for building ever more complicated molecules from atoms linked by covalent bonds.

Supramolecular chemistry aims at generating highly complex chemical systems from molecular components held together by non-covalent intermolecular forces, on the basis of the *molecular information* stored in the covalent framework of the components. A step beyond consists in the design of systems undergoing *self-organization*, i.e. systems capable of spontaneously generating well-defined functional architectures by self-assembly from their components.

Supramolecular chemistry is intrinsically a *dynamic chemistry* in view of the lability of the interactions connecting the molecular components of a supramolecular species and the resulting ability to exchange components. The same holds for molecular chemistry when the molecular entity contains covalent bonds that may form and break reversibly. These features allow for a continuous change in constitution by reorganization and exchange of building blocks and define a *Constitutional Dynamic Chemistry* (CDC) covering both the molecular and supramolecular levels.

CDC introduces a paradigm shift with respect to constitutionally static chemistry. It takes advantage of dynamic diversity to allow variation and selection and operates on dynamic constitutional diversity in response to either internal or external factors to achieve *adaptation*.

CDC generates networks of dynamically interconverting constituents, *constitutional dynamic networks*, that may respond to perturbations by physical stimuli or to chemical effectors. Of special interest is the case where the driving force is an *increase in order*.

The implementation of these concepts points to the emergence of *adaptive* and *evolutive chemistry,* towards *systems of increasing complexity.*

Plenary Lectures

PL-01

A brief philosophical history of the periodic table

Eric R. Scerri
Department of Chemistry & Biochemistry
University of California Los Angeles (UCLA)
scerri@chem.ucla.edu
website: www.ericscerri.com

The lecture will begin with a brief history of the origins of the periodic table, beginning with the contributions of Lavoisier, Dalton, Döbereiner and others. I will proceed to the Karlsruhe conference and the ensuing independent discovery of the periodic table by as many as six individuals, culminating with Mendeleev's table just over 150 years ago. We will move on to the challenges that the periodic table faced, such as the existence of pair reversals and the discovery of the noble gases.

Next came several discoveries in physics, including X-rays, radioactivity and the electron, all of which had a profound effect on the understanding of the periodic table. Research in atomic structure beginning at the turn of the 20th century prompted some physicists such as J.J. Thomson and Niels Bohr to begin to seek a fundamental explanation for the periodic table in terms of electronic structure. The later developed quantum mechanics of Heisenberg, Schrödinger, Pauli and others led to a more rigorous explanation, although some open questions remain up to present times. For example, there is yet no fundamental explanation for the empirical rule that the occupation of atomic orbitals proceeds via the simple n + l rule.

In addition, relativistic effects are being increasingly considered in attempts to understand the heavier elements in particular. Finally, several other remaining open questions will be discussed, such as the membership of group 3 of the periodic table, alternative representations such as the 32-column format, the left-step periodic table and whether there may exist an 'optimal form' of the periodic table [1, 2]

"They do it with mirrors"
Biogenic advanced functional materials engineered to fulfill optical functions

Lia Addadi[1], Dan Oron[b], Leslie Leiserowitz[b], Leeor Kronik[b], Steve Weiner[a]

[a] *Chemical and Structural Biology Dept, Weizmann Institute of Science, Rehovot, Israel*
[b] *Molecular Chemistry and Materials Science Dept, Weizmann Institute of Science, Rehovot, Israel*
lia.addadi@weizmann.ac.il

Organisms construct optical 'devices' based on assemblies of crystals of organic compounds. The constituent molecules are mostly purines and pteridines. All the crystals have unusually high refractive indexes in the directions along which the light penetrates the crystal. The crystals form mirrors and light scattering layers that function to increase light sensitivity in the eyes of some organisms, or endow them with brilliant structural colors[1]. The architecture of the reflecting layers varies from multi-layered mirrors tiled with mosaics of guanine[2] or xanthine[3] crystals, to densely packed assemblies of multilayer core-shell spherulites composed of isoxanthopterin crystals[4], or to assemblies of block-shaped crystals of 7,8-dihydroxanthopterin[5]. In all these examples, the hierarchical organization is controlled from the crystal structure at the nanoscale to the complex 3D super-structure at the millimeter level. The molecule, the crystal structure, the crystal size, the crystal morphology and the super-structural arrangement, all together determine the optical properties of the material. We have thus a vast choice of molecular components, assembled following precise blueprints. What makes these components especially apt to fulfill optical functions in organisms, and how do organisms assemble them? Answers to these questions may allow us to synthesize materials with interesting optical properties[6].

Computational Discovery of Metal-Organic Frameworks for a Changing World

Laura Gagliardi,[a]

[a] *Department of Chemistry, Pritzker School of Molecular Engineering, James Franck Institute, Chicago Center for Theoretical Chemistry*
The University of Chicago, Chicago, USA

lgagliardi@uchicago.edu

Addressing the energy challenges that we face globally requires the coordinated efforts of scientists, engineers, and policy makers. Chemistry has the potential to drive quantum leaps in technology. With theory, computation, and machine intelligence we can accelerate the search for solutions to water scarcity, decarbonization, and clean energy. Metal-organic frameworks (MOFs) are versatile platforms for various applications including catalysis for complex reactions and water harvesting. I will first present our ongoing efforts to understand and design the water-filling mechanism for water-harvesting MOFs.[1]

I will then describe our combined computational and data-driven study of MOF-supported catalysts. Utilization of machine learning algorithms in conjunction with experimental data can not only predict superior catalytic materials, but also under which experimental conditions they are most optimal.[2]

Thermodynamic and kinetic approaches for drug discovery to target protein misfolding and aggregation

Michele Vendruscolo

Centre for Misfolding Diseases, Yusuf Hamied Department of Chemistry, University of Cambridge, UK

Protein misfolding diseases, including Alzheimer's and Parkinson's diseases, are characterised by the aberrant aggregation of proteins. These conditions are still largely untreatable, despite having a major impact on our healthcare systems and societies. To address this problem, I will describe drug discovery strategies to target protein misfolding and aggregation. More specifically, I will compare thermodynamic approaches based on the stabilization of the native states of proteins with kinetic approaches based on the slowing down of the aggregation process. This comparison will be carried out in terms of the current knowledge on the process of protein misfolding and aggregation, the mechanisms of disease and the therapeutic targets.

PL-05

Medicinal Chemistry of Orphan G Protein-coupled Receptors

C.E. Müller

University of Bonn, Pharmaceutical & Medicinal Chemistry, An der Immenburg 4, D-53121 Bonn, Germany
christa.mueller@uni-bonn.de

Integral cell membrane proteins such as membrane receptors, in particular G protein-coupled receptors (GPCRs), represent the most important classes of drug targets. With more than 800 members GPCRs constitute the largest protein family in humans. However, only a small percentage of membrane proteins is targeted by current therapies. For about 100 (non-olfactory) GPCRs the endogenous agonist still remains unknown or has been postulated but could not be confirmed. These so-called *orphan receptors* belong to the most enigmatic members of the GPCR superfamily. In order to study their roles and functions, and to validate them as drug targets, selective agonists and antagonists are required as tool compounds. Many orphan GPCRs belong to the δ-branch of rhodopsin-like (class A) GPCRs, and are related to the purine/pyrimidine nucleotide-activated P2Y receptor family. Examples include the MAS-related G protein-coupled receptors (MRGPRs).[1] The subgroup of MRGPRX receptors comprises four subtypes, MRGPRX1-4, which appear to be involved in pain transmission, inflammation, immune responses, allergies, and cancer. However, these receptors are primate-specific, which makes pharmacological in vivo studies challenging.[1] Moreover, potent and selective tool compounds have been lacking to elucidate their potential as drug targets.

Originally motivated by the fact that some MRGPRs are activated by the nucleobase adenine,[2] and based on our proprietary compound library which is enriched in purine-related small molecules (https://www.pharma.uni-bonn.de/pharmazeutische-und-medizinische-chemie/en/muller-lab/compound-library?set_language=en), we embarked on identifying and subsequently optimizing tool compounds for the various MRGPRX subtypes. We discovered the first highly potent MRGPRX4 agonists.[3] Moreover, we discovered that the orphan chemokine CXCL14 activates MRGPRX2.[4] Moreover, we developed MRGPRX2 antagonists with sub-nanomolar potency, that were demonstrated to efficiently inhibit mast cell degranulation (unpublished results). MRGPRX receptors and related orphan GPCRs have great potential as future drug targets for the treatment of inflammation, immunity, and cancer.

cotte@esrf.fr

Since their discovery in 1895, X-rays have been largely used to analyze historical artefacts. Different X-ray based techniques exist (tomography, fluorescence, diffraction…) which offer complementary information about artistic objects structure and composition. Some chemical analyses intend at determining *a posteriori* chemical and physical reactions at stake in the creation of objects (materials, processes…) while other target reactions which have modified the artworks later on, and the main factors responsible for its degradation. Over the last three decades, a new generation of X-ray based techniques have completed the toolbox of heritage scientists, those based on synchrotron light. Synchrotron facilities offer together a high beam intensity, the possibility to focus the beam to few tens of nanometers, an extended spectral range, and a high coherence. These properties are increasingly used to track the chemical composition of fragments of ancient and artistic materials at the sub-micrometric scale. This presentation will focus on analyses carried out at the European Synchrotron Radiation Facility on major Italian artworks, such as Leonardo da Vinci's *Mona Lisa* and the *Last Supper*[1].

Chemistry Innovation in Small Molecule Drug Discovery

Ingo V. Hartung[a]

[a]*Merck Healthcare KGaA, Darmstadt/Germany*
ingo.hartung@merckgroup.com

Small molecule therapeutics continue to form the backbone of therapies for all types of life-threatening diseases. The last decade has seen significant progress in extending the range of biological targets which can be addressed with small molecules.

This progress is based on an extension of drug modalities beyond the classical reversible inhibitors of enzymatic active sites or receptor ligand binding sites. Covalent inhibitors allow to design inhibitors for proteins which were considered undruggable just one decade ago. In addition, small molecule inducers of protein-protein interactions open completely new approaches for the modulation of activity of disease-causing proteins.

Synthetic chemistry innovations are at the core of many of these drug discovery breakthroughs. I will talk about the importance of synthetic chemistry in medicinal chemistry in order to shape the future of drug discovery.

Elements of Future for Sustainable Energy Storage

A. Manthiram[a]

[a]*Materials Science and Engineering & Texas Materials Institute, University of Texas at Austin, Austin, TX 78712, USA*
Email: rmanth@mail.utexas.edu

Rapid increase in global energy use and growing environmental concerns have prompted the development of clean, sustainable, alternative energy technologies. Renewable energy sources like solar and wind are a promising solution, but they are intermittent. Batteries are the most viable option to efficiently store and utilize electricity produced from them as well as for electrification of transportation sector. However, their widespread adoption requires optimization of cost, cycle life, safety, energy density, power density, and environmental impact, all of which are directly linked to severe materials challenges. Among them, cost, sustainability, and supply chain will be the single dominant hurdle, while maintaining fire safety, as the energy storage market is rapidly expanding.

The appetite for high energy density has driven the lithium-ion battery industry with positive electrodes (cathodes) containing expensive and scarcely available elements like cobalt and nickel;[1] cathode is the most expensive in lithium-ion batteries, comprising 50% of the materials cost. It is critical that the chemistry community embarks on a path toward the development of sustainable, supply-chain-free next-generation battery chemistries and materials. Earth-abundant elements like iron, manganese, sulfur, and sodium need to be the focus to be sustainable.[2] However, battery chemistries based on these elements are met with formidable scientific and technological challenges. A fundamental understanding of the intricacies involved in overcoming the challenges can enhance their widespread viability.

To illustrate a path forward towards the sustainable goal, this presentation will center on strategies and approaches for progressively eliminating expensive and scarcely available cobalt, followed by eliminating nickel, and ultimately any mined metal, including lithium. As an example, the progress on cobalt-free lithium-ion cells,[3] cobalt- and nickel-free lithium-ion cells, sodium-ion cells, lithium-sulfur cells, and sodium-sulfur cells[4] will be presented. The challenges of bulk and surface instability, the complexities of electrode-electrolyte interfaces, and the role of electrolytes on these will be discussed. The power of advanced characterization methodologies to tackle the challenges and develop an in-depth understanding will be presented.

The Periodic Table's Women

M. Venturi

Università di Bologna, Italy

margherita.venturi@unibo.it

The Periodic Table, a single page, apparently simple, which revolutionized science, also has a human face. In fact, in each box of this document there is not only an element with its properties, but there are also the people's names who contributed to its birth and those who made it grow by adding new elements.

It is a story made up of prestigious names that are found in all the sacred texts of Chemistry. Those mentioned are basically male names, but many women also contributed, if not to the birth of the Periodic Table, then to filling new boxes. Surely Marie Curie, who was responsible for the discovery of radium and polonium, is known to everyone, but the list is long and includes scientists of great value, often forgotten. The names of these women can be found in the book "Women in their Element"[1] and some of them will be mentioned in the contribution.

[1] *Women in their Element: Selected Women's Contributions to the Periodic System*, edited by A. Lykknes and B. Van Tiggelen, World Scientific Publishing Co, 2019; https://doi.org/10.1142/11442

Between Materials and Meanings: Research at the Interface of Chemistry and Art.

M. Leona

The Metropolitan Museum of Art, 1000 Fifth Avenue, New York
marco.leona@metmuseum.org

In the Spring of 1882, the citizens of New York received an unprecedented – and to this day unique – invitation. In response to accusations in the media that some of the Ancient Cypriot objects in the collection of the Metropolitan Museum of Art were forgeries, the Museum decided to present two large marble sculptures in the Great Hall, outside of their cases and invited Members of the Public to "make the most careful examination of them". Apparently, the visitors were allowed to "cut, … scrape, …treat with chemicals, and examine microscopically" the statues. The verdict of the public was unanimous: authentic!

In the 1920s and '30s the Museum realized that crowdsourcing chemistry was perhaps not the best idea, and started a collaboration with Columbia University electrochemist Colin Fink, who conducted pioneering work on metal analysis, conservation treatments, and preventive conservation research. More important for todays' conversation, in the same decades a young Medieval art curator who had studied chemistry at Harvard, James Rorimer, began experimenting with ultraviolet light as a tool to highlight restoration, alterations, and in general, to "render the invisible visible".

Today, scientists are involved in every aspect of museum practice at the Met, from evaluation of potential acquisitions to art historical studies, from research in support of conservation treatment to indoor air quality monitoring, from development of new analytical techniques to large scale artists' materials and technique studies.

Raman and surface-enhanced Raman spectroscopy, X-ray fluorescence spectrometry and mapping, mineralogical and petrographic techniques, mass spectrometry, reflectance spectroscopy and reflectance spectroscopy imaging are commonly used in collaboration with art historians and conservators to investigate the complexity of works of art. These tools enable us to read works of art -just as historians read documents- and to explore the intersection of materials and meanings.

Chemistry allows us to tell stories about the art, its context, and the people who make it, highlighting cultural practices, economic and social relationships, technical developments, spiritual insights, or the imminent vulnerability of the objects themselves.

Rapid Evaporative Ionisation Mass Spectrometry for the Real-time Monitoring of Medical Interventions: Towards Single Cell Resolution Autonomous Robotic Surgery

Z.Takats,[a] D. Simon,[a] J. Zhao, R. Battle, Y. Wang, M. Runciman, S Giannarou, G. Mylonas, B. Temelkuran,[a] R. Murray,[b] [b]

[a]*Imperial College London, London, UK*
[b]*University of Regensburg, Regensburg, Germany*
zoltan.takats@ukr.de

Hyperspectral imaging of biological cells and tissues has been in the forefront of biomedical research for the last decade. Nevertheless, these methods were developed for chemical histology-type applications, where histological sections of tissues are analysed for their molecular content. Typical examples include spatial transcriptomics, imaging mass cytometry or spatial metabolomics. While these tools brought a true revolution, their applicability to actual living systems is limited. In-vivo spatial spectroscopic approaches are impeded either by coarse resolution exemplified by magnetic resonance spectroscopy or their targeted nature, as in case of calcium imaging by two-photon microscopy. Mass spectrometry seems to be a strange methodological choice for in-vivo applications due to its highly invasive character, however its ultimate sensitivity and specificity still makes it a feasible contender to become the great unifier of the ex-vivo, in-vitro and in-vivo approaches. We have originally developed Rapid Evaporative Ionisation Mass Spectrometry for the real-time identification of dissected tissues in course of cancer surgery, employing a standard surgical diathermy knife as an ion source. Since then various REIMS-based setups were conceived to perform live cell analysis in the laboratory environment, analyse bacterial metabolism in-situ or image biological tissues at subcellular resolution. Combining the REIMS concept with picosecond resonant infrared laser ablation sources resulted in an ultimately versatile setup capable of mapping cellular metabolism in arbitrary environment and providing identical data type for biomedical research, clinical microbiology, histopathology, clinical chemistry and invasive/diagnostic medical interventions. The paper will discuss some of these applications including the data analysis aspects and describe our vision for the broader embedding of the technology into the 21st century healthcare systems.

Plasmonics and Cancer Diagnostics: Ultrasensitive Optical Biosensing of Circulating Tumor DNA in Blood-based Liquid Biopsies from Cancer Patients

G. Spoto,[a]

[a]*Dipartimento di Scienze Chimiche, Università degli Studi di Catania, V.le A. Doria 6, 95125, Catania*
giuseppe.spoto@unict.it

Standard clinical protocols for cancer diagnostics and tumor profiling primarily rely on tissue biopsy, involving the extraction of human cells via specialized needles or surgery. However, tissue biopsy poses challenges for the frequent monitoring of cancer patients due to its invasive nature and limitations in accounting for tumor cell heterogeneity. Liquid biopsy offers an alternative approach, sampling body fluids to assess cancer biomarker levels, notably in peripheral blood, plasma, and serum.

Detecting nucleic acid biomarkers for cancer diagnosis and monitoring through liquid biopsy presents challenges for conventional biosensing platforms. Many biosensors utilize enzymatic amplification to achieve necessary sensitivity, but this amplification step introduces constraints and drawbacks, such as artefacts from sample contamination and recombination between homologous regions of DNA.

To address these challenges, there is a growing emphasis on developing PCR-free protocols for DNA detection. These protocols often leverage signal amplification strategies involving enzymes or metallic nanostructures, such as gold nanoparticles, for highly sensitive DNA detection.[1,2]

One promising approach involves nanoparticle-enhanced surface plasmon resonance imaging (SPRI), which holds the potential for detecting non-amplified DNA circulating in cancer patients' blood. This technique, combined with innovative plasmonic sensor surface designs, including the use of a novel dual-functional low-fouling poly-L-lysine-based surface layer, offers exciting prospects for advancing cancer diagnosis through liquid biopsy.[3]

When MALDI-MSI meets the clinical need: case experience in nephrology

V. L'Imperio[a]

[a]*Department of Medicine and Surgery, Pathology, University of Milano-Bicocca, IRCCS Fondazione San Gerardo dei Tintori, Monza, Italy*

Renal diseases are progressively representing a rising burden for patients' quality of life and for the National Health System. The evolution of renal damage can potentially lead to end stage kidney disease (ESKD), whose only therapies are dialysis and transplantation. To prevent this progression, the prompt detection and therapy initiation is paramount, currently being achieved through the histological analysis of renal biopsies. Although proteomics has been introduced for detecting biomarkers in mini-invasive samples (e.g. blood/urines), the evaluation of structural modifications directly in situ within the diseased renal tissue is a stimulating and intriguing perspective, with enormous potentialities for routine clinical practice translation. Matrix-assisted laser desorption/ionisation mass spectrometry imaging (MALDI-MSI) is the natural solution to study proteomic changes of the renal parenchyma in different pathological states, as documented by the last 10 years activity of the Renal Pathology and Protoemics Units of UNIMIB, applying MALDI-MSI on both snap-frozen and archived formalin-fixed paraffin-embedded (FFPE) tissues. This already allowed the detection of molecules with pathogenetic roles, biomarkers of progression and response/resistance to therapy in different diseases, lastly helping in the diagnosis/detection/quantification and classification of renal amyloidosis, for which the proteomics is already unanimously considered the gold standard. Moreover, the recent introduction of instruments with higher lateral resolutions, down to the level of a single-cell, and the association of digital pathology tools to the in situ proteomics is unlocking the full potentialities of this technique, approaching the bedside day-by-day in this niche of pathology.

MRI-CEST contrast agents: in vivo sensors for metabolic Imaging

D. Delli Castelli,

Department of Molecular Biotechnology and Health Sciences (www.dbmss.unito.it) University of Torino (www.unito.it)
Molecular & Preclinical Imaging Centers (www.cim.unito.it) Via Nizza 52 10126 Torin, Italy

daniela.dellicastelli@unito.it

Metabolic imaging is a branch of molecular imaging that aims at identifying alterations in metabolic pathways to gain early evidence or insight into a given pathological condition. In clinical and pre-clinical settings, numerous imaging techniques have been successfully used to detect aberrant metabolism-associated diseases with Positron Emission Tomography (PET) in a primary position for its impressive sensitivity. However, the drawbacks associated with PET imaging are i) the poor spatial resolution and ii) the use of radioactive tracers. MRS and MRSI (Magnetic Resonance Spectroscopy and Magnetic Resonance Spectroscopic Imaging) were early recognized as powerful tools to detect physiology not invasively and with high spatial resolution. MRS addresses the direct visualization and quantification of NMR signals belonging to different molecules of biological interest as it can detect in vivo endogenous molecules present down to millimolar concentration looking at either ^{1}H- or ^{23}Na- or ^{31}P-resonances. Moreover, with the advent of efficient hyperpolarization techniques, even metabolites enriched in ^{13}C can be observed and their metabolic fate can be directly assessed in real-time[1]. Interesting results have been reported recently by using deuterium-containing substrates. The main issue in most of the MRS/MRSI studies relies on the limited sensitivity only partially overcome by the increased availability of high-field scanners. In parallel, CEST-MRI has emerged as an efficient tool to image metabolic processes by enhancing the detectability of the NMR signals of endogenous molecules through their indirect effect on the much more intense signal of the bulk water following the selective irradiation of their mobile protons[2]. In this regard, CEST-MRI represents an intriguing approach for detecting tumor metabolites with higher sensitivity compared to MRS. Up to now, the in vivo detection of important metabolic substrates such as glucose, glutamate, choline, creatine, and lactate, as well as pH and enzymatic activity assessment, have been demonstrated to be feasible. Despite the promising potential of MRI-CEST contrast agents, challenges such as sensitivity, specificity, and standardization of imaging protocols persist. In this contribution a concise overview of the current landscape of MRI-CEST contrast agents as in vivo sensors for metabolic imaging will be provide focusing on potential and challenges to be addressed.

Translating spatial biology applications from early drug development to a clinical setting

Lucy Flint[a]

[a]Imaging and Data Analytics, Clinical Pharmacology and Safety Sciences, BioPharmaceuticals R&D, AstraZeneca, The Discovery Centre (DISC), Biomedical Campus, 1 Francis Crick Ave, Trumpington, Cambridge CB2 0AA, United Kingdom;
lucy.flint@astrazeneca.com

Spatial biology technologies have revolutionized our understanding of cellular processes and disease mechanisms in heterogenous tissues. In early drug development, having access to spatial-omics data consisting of transcriptomics, metabolomics and proteomics from a single tissue slice can offer invaluable insights into target identification, biomarker discovery and drug response prediction. Moreso, the integration of these data with gold standard histological methods provides a holistic understanding of disease state and drug action detected by advanced technologies such as mass spectrometry imaging (MSI), imaging mass cytometry (IMC) and spatial transcriptomics (ST). These technologies have been applied to analyse a range of tissue types to support early drug development from complex 3D in vitro models such as patient-derived organoids (PDOs) to pre-clinical animal tissues and patient-derived xenografts (PDXs). In addition to the depth of information retrieved from these samples, spatial data collected from patient biopsies has added a greater level of value in supporting therapeutic development and patient stratification. In this presentation, the applications of spatial biology technologies (including MSI, IMC & ST) established for early drug development will be discussed, alongside how the translation of these applications currently support the clinical setting to advance precision medicine and improve patient outcomes.

Point-Of-Care Ultra-Portable Single-Molecule Bioassays for One-Health

L. Torsi

Università degli Studi di Bari Aldo Moro, Dipartimento di Chimica, Via Orabona 4, 70125 Bari
Accademia Nazionale dei Lincei,
luisa.torsi@uniba.it

Screening individuals, including humans, animals, and plants, who show no symptoms, using point-of-care-testing (POCT) technologies with high diagnostic accuracy, although still considered visionary, holds significant promise. Effective surveillance necessitates user-friendly, cost-efficient, highly portable, yet dependable, in-vitro-diagnostic devices that can be deployed wherever necessary.

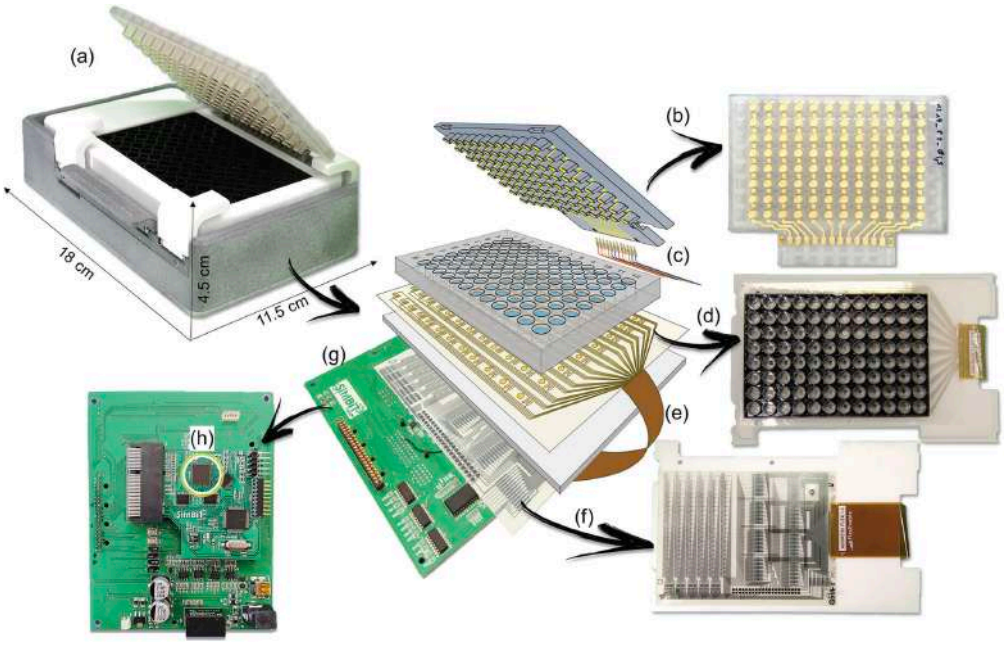

Figure 1: **a)** Picture of the small footprint bioelectronic platform developed in the framework of the SiMBiT project (https://www.simbit-h2020.eu). The disassembled system, shown on the right, comprises, from top to bottom, the following elements: **b)** a 3D-printed array of biofunctionalized sensing gates covering the ELISA plate, **c)** spring-loaded pins connectors, **d)** an array of the EGOFETs on poly(ethylene 2,6-naphthalate) (PEN)-foil glued on a bottomless ELISA-plate, **e)** flat cable connecting the bioelectronics array to the f) multiplexing electronics based on a unipolar OTFT-based technology (*FlexEnable Technology*), **g)** a printed circuit board (PCB), integrating h) a custom Si-IC chip (reproduced with permission from Ref. 1)

Presently, such devices are not available on the market. However, there are two promising technologies in development at readiness level 5: the Clustered-Regularly-Interspaced-Short-Palindromic-Repeats (CRISPR) lateral-flow-strip tests and the Single-Molecule-with-a-large-Transistor (SiMoT) bioelectronic palmar devices. The array version of the SiMoT platform, developed in the framework of the SiMBiT project

Integrative approach by multiscale imaging to monitoring neuron/glia neurochemical communication in healthy and diseased brain networks

Luigia Cristino

Istituto di Chimica Biomolecolare, Dipartimento di Chimica e Scienze dei Materiali del Consiglio Nazionale delle Ricerche (ICB-CNR).Viale Campi Flegrei, 34 – 80078 Pozzuoli, Napoli
luigia.cristino@icb.cnr.it

Although the discovery of novel neuroactive drugs could take advantage of the innovative high-throughput in vitro drug-screening technological development, few novel classes of neuroactive molecules have been discovered in the last few years. This limitation arises mainly because most of the in vitro screening assays fail to capture dynamic properties of neuron/glia neurochemical communication in the brain networks as well as their fast morphological, chemo-physical, and functional adaptation to external stimuli. Moreover, almost all of these studies employ cell homogenates either from tissue or cell culture thus information of spatial distribution is not preserved and contribution from different cell types, each of which could have a very distinct metabolic profile, is lost. To fully understand the role of neurochemical and cell function, it is crucial not only to identify but also to correlate cellular metabolites in the context of tissue anatomy and cell-type composition. In this communication, I will describe an integrative approach to screen small neuroactive molecules by combining advanced in vitro multiple assays at multi-scale levels exploiting the medium-throughput time-lapse sensing and imaging platform Incucyte© coupled with the multiscale morpho-functional imaging obtained by confocal, correlative light and electron microscopy (CLEM), and patch-clamp recording [1-3]. The characterization of neuronal responses to bioactive organic molecules, mostly (endo)cannabinoids and endocannabinoid-like gut microbiota-derived metabolites, will be described at a resolution ranging from nano- to micro-metric scale in different subcellular compartments, neuronal networks, and brain areas. Method that integrates the well-defined cellular classifications obtained by immunochemical staining from selected brain areas with chemical information found within mass spectra recorded by DESI-MS imaging, will also be discussed in ongoing research aimed at identifying new immunoregulatory molecules for pharmacological applications.

Recent advances in portable NMR sensor and its applications

N. Proietti

Istituto di scienze del Patrimonio Culturale (ISPC), Area della Ricerca di Roma 1, CNR,

Via Salaria km 29,300, 00010 Montelibretti (RM).

Nuclear Magnetic Resonance (NMR) is recognized as a powerful tool in many areas of research.

Chemistry is one of the areas where NMR is widely used as structure elucidation in organic chemistry, in pharmaceutical and natural-product sciences, in complex mixture analysis, in structural biology and in materials science.

Recent developments of new NMR methodologies as dynamic nuclear polarization (DNP), that can boost sensitivity in NMR experiments, or developments in probe technologies that allowed to rotate the sample faster spinning frequencies (100 kHz and above) to obtain "solution-like" in NMR spectra of solids, combined with the use of superconducting magnets and sizable electronics, have made NMR technique one of the most potent analytical methods. On the other hand high costs of maintenance made NMR spectrometers less commonly available in many laboratories.

With the advent of the 21st century miniaturization began to play an essential role in everyday life and also involved many spectroscopic techniques, including NMR [1-2], leading to dedicated sensors and portable devices with new applications in different research fields. Thanks to the reductions in size, maintenance needs and price tag, the miniaturized portable NMR sensor assemblies have extended their uses beyond conventional NMR laboratories to a broad range of "field" applications, including polymer products [3], food [4], biological tissue [5], and objects of cultural heritage [6]. A price to pay is the inhomogeneity of the magnetic field, which compromises the sensitivity of these devices. However, recent developments in unilateral magnets design offer larger sensitive volume, higher sensitivity and shorter dead times. By these devices it is possible to measure relevant parameters such as proton density, longitudinal (T_1), and transverse (T_2) relaxation times, and the self-diffusion coefficient, and to collect T_1-T_2 correlation maps.

Here recent advances on portable NMR sensors will be shown as well as the various applications in the different fields of research.

Micro and nanoplastics detection in air and water environments

Pietro G. Gucciardi[a]

[a]*CNR – IPCF, Istituto per i Processi Chimico-Fisici, Viale F. Stagno D'Alcontres 27, I-98158 Messina, Italy*
pietrogiuseppe.gucciardi@cnr.it

Microplastics (fragments < 5 mm, MPs) and nanoplastics (particles < 1 µm, NPs) have been found in air, oceans, rivers, and lakes. Recent studies showed their presence in human blood, placenta, stools and lungs, raising concerns for human health. MPs and NPs are generated either during production processes (e.g. 3D printing) or weathering, due to photo-oxidation and/or friction processes (e.g. car tyres wearing) leading to fragmentation at different scales. Detecting small MPs (< 20 µm) is a technical challenge, especially if they are dispersed in liquid. To fill this technological gap, our group has developed an original technique combining optical trapping with Raman spectroscopy (Optical Raman Tweezers, RT) enabling the chemical identification of individual MP and NPs in liquid environments. RT employ tightly focussed laser beams (Fig.1, a-b) to both optically trap and excite the Raman scattering of MPs and NPs (Fig. 1c), with a sensitivity down to tens of nanometres in size.[1,2] In this talk I will first review methodologies and gaps in the analysis of MNPs. Then I will illustrate the most recent advancements and future challenges regarding the development of portable RT setups interfaced with microfluidics for MPs and NPs analysis. Finally, a new method to analyse particles levitated in air in a contactless and container-less fashion, namely Raman Acoustic Tweezers (Raman-AT), is introduced. Here, by taking advantage of an array of ultrasound transducers coupled with a compact Raman spectrometer (Fig. 1d) we developed a portable setup capable enabling the chemical analysis of millimetric and sub-millimetric MPs, but also dispersions of NPs in µL volumes. These results were obtained within the projects NextGenEU PNRR-SAMOTHRACE (ECS00000022) and PRIN2022-PLASTACTS (202293AX2L).

Smart Biosensors in food analysis: current applications and future trends

G. Marrazza

[a]*Department of Chemistry "Ugo Schiff" (DICUS), University of Florence,*
Via della Lastruccia 3, 50019 Sesto Fiorentino (FI), Italy
e-mail giovanna.marrazza@unifi.it

The issue of food safety is a significant global concern, regardless of a nation's level of economic advancement. To safeguard consumers' well-being, it is imperative to prioritize food safety along the entire supply chain: "from farm to fork''. The implementation of strict quality control protocols and regulatory frameworks can effectively reduce risks and uphold exemplary standards in the food industry. The use of advanced analytical technologies that provide rapid and accurate results plays a key role in monitoring food safety and detecting any undesirable substances, including allergens, toxins, chemicals, or pathogens, that could potentially expose public health if consumed.

As a solution, sensors and biosensors have emerged as essential tools for quantitative detection and screening of various contaminants, ensuring immense potential in food safety and quality control. However, further progress still needs to be made to combine all the necessary features for on-site detection and real-time quantitative assessment.

In this presentation, the potential of integrating (bio)sensors with portable devices for rapid and on-site detection in a cost-effective manner will be discussed[1]. Moreover, the advancements in nanotechnology and new synthetic bioreceptors that can enhance sensitivity, selectivity, and speed of detection, making biosensors ideal for use in various food safety applications, will be presented[2].

Additionally, the future directions and potential applications of advanced electrochemical (bio)sensors will be explored.

Multidimensional separation methods have gained widespread appeal across various fields, offering distinct advantages over traditional single-dimensional approaches. Since their introduction, comprehensive two-dimensional chromatography methods have transitioned from niche tools to commercially available solutions, advancing alongside improvements in hardware (interfaces and modulators) and software (data collection, processing, and analysis).

By focusing on sample complexity and integrating mass spectrometry detection, comprehensive two-dimensional chromatography techniques emerge as exceptionally potent tools to thoroughly characterize both volatile and non-volatile sample constituents.

Beyond their increased dimensionality, the notable benefits of comprehensive two-dimensional chromatography methods include organized chromatograms, where chemical components of the sample are systematically arranged based on their properties and retention mechanisms.

This structured distribution facilitates rapid identification of sample components and the prediction of analyte structures by analyzing their characteristic positions within the two-dimensional space (Figure 1).

[b] *GC Image, PO Box 57403, Lincoln, NE 68505-7403, USA*
Presenter: chiara.cordero@unito.it

Multidimensional chromatography systems, combining physico-chemical discrimination of individual components by orthogonal chromatography principles with the structure-elucidation potential of mass spectrometry, are the ultimate solutions for comprehensive investigations of complex samples in many application areas including the food quality and safety domains. However, the multidimensional data arrays generated by these platforms require non-conventional approaches to fully exploit the encrypted information potential and generate new knowledge on sample properties, going beyond current quality indexes.

In this context, Artificial intelligence (AI) offers tools and concepts to face the many challenges posed by food applications where the compositional complexity of samples (*e.g.*, primary metabolites, secondary/specialized metabolites, processing derivatives, exogenous compounds from microbial communities, presence of xenobiotics and contaminants, etc.) is connected to properties by specific yet unique chemical patterns.

The contribution aims to illustrate how the complex datasets derived from comprehensive two-dimensional gas chromatography (GC×GC) in the application area of food-omic can efficiently be explored AI tools. Thanks to the multidimensional nature of GC×GC data arrays, Computer Vision and Augmented Visualization open new opportunities for decision-making strategies targeted to food quality and sensory features. With these advanced yet peculiar AI tools chromatographic image distortions are efficiently compensated, thereby facilitating comparative visualization and related strategies. Moreover, by actively exploiting mass spectral signatures in the presence of co-elutions and misalignments, *unknown-knowns* can be specifically targeted, and by identifying key food odorants in the presence of interferents, aroma signatures can be predicted by an AI-smelling machine[1,2]. Practical examples showcase the challenges and potentials of the application of AI to GC×GC-MS data obtained in studies related to food volatilomics [3] and sensomics [4].

Generation and modeling of plasmonic nanoparticles for sensing

Giuseppe Compagnini,[a]

[a]*Chemistry Department – University of Catania, Viale A.Doria 6, Catania (Italy)*
giuseppe.compagnini@unict.it

The ability of noble metal nanoparticles to couple with electromagnetic radiation in the near IR and visible regions stimulates research worldwide because of possible applications in several technological fields such as sensing, solar cells, spectroscopy and several biological and medical issues. It is also known that the geometrical features of the nanoparticles, their coupling and the nature of the metal, mostly define the optical properties in terms of scattering, absorption and extinction cross-sections. In this talk I will review some of the most challenging methods to obtain variously shaped metal nanoparticles in the colloidal form. Among them some conventional chemical methods[1], based on a classical nucleation and growth as well as new laser approaches[2] in the liquid phases which can give long-term stability despite the absence of stabilizing agents.

The plasmonic features of these particles are studied with the help of some simulation tools which are of great support to understand any optical properties and field distributions and help experimentation for specific application purposes.

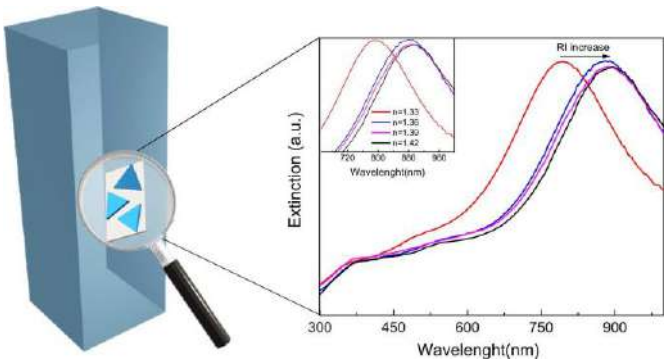

Figure 1: Generated metal nanoplates to pave disposable cuvettes for plasmon sensing devices.

Some strategies for the deposition of plasmonic layers onto solid substrates will be also presented in order either to transfer the plasmonic features on solid surfaces and obtain suitable sensing devices[3]. Applications of the obtained nanostructures for plasmon sensing and surface-enhanced phenomena are used as excellent examples showing the advantages of these tools.

There is a critical unmet need to detect and image two-dimensional (2D) materials within single cells and tissues while surveying a high degree of information from single cells. Here, we propose a versatile multiplexed label-free single-cell detection strategy based on single-cell mass cytometry by time-of-flight (CyTOF) and ion-beam imaging by time-of-flight (MIBI-TOF).[1] This strategy, "Label-free sINgle-cell tracKing of 2D matErials by mass cytometry and MIBI-TOF Design" (LINKED), enables nanomaterial detection and simultaneous measurement of multiple cell and tissue features. As a proof of concept, we selected a set of 2D materials, transition metal carbides, nitrides, and carbonitrides (MXenes), to ensure mass detection within the cytometry range while avoiding overlap with more than 70 currently available tags, each able to survey multiple biological parameters. In addition, MXenes have received substantial attention for their promise as biomedical nanotools.[2-4]

First, we demonstrated their detection and quantification in 15 primary human immune cell subpopulations. Together with the detection, mass cytometry is used to capture several biological aspects of MXenes, such as their biocompatibility and cytokine production after their uptake. In vivo biodistribution experiments using a mixture of MXenes in mice confirmed the versatility of the detection strategy and revealed MXene accumulation in the liver, blood, spleen, lungs, and relative immune cell subtypes. Finally, we applied MIBI-TOF to detect MXenes in different organs revealing their spatial distribution. The label-free detection of 2D materials by mass cytometry at the single-cell level, on multiple cell subpopulations, and in multiple organs simultaneously, is expected to enable exciting new opportunities in biomedicine.

Advanced NMR monitoring of the transport properties in hydrogels and eutectogelst

A. Mele,[a] F. Castiglione,[a] V. Vanoli,[a] M. E. Di Pietro,[a] M. Casalegno,[a] F. Rossi[a]

[a]*Department of Chemistry, Materials and Chemical Engineering "G. Natta", Politecnico di Milano, Piazza L. da Vinci 32, 20133 Milano*
e-mail of submitter: andrea.mele@polimi.it

The investigation of entrapping small molecules within the voids of polymeric porous materials is not only a current research focus but also holds significant practical applications.

A paradigmatic case could involve trapping active pharmaceutical ingredients (APIs) within a polymeric scaffold, typically in the form of hydrogels, to obtain a drug delivery system.

The controlled release of APIs relies significantly on molecular diffusion within the porous structure of hydrogels, thus calling for a thorough understanding of the factors affecting the random displacement such as mesh size, drug dimensions, and intermolecular interactions (drug-polymer and drug-drug interactions).

The majority of hydrogels utilized thus far are derived from natural polymers or oligomers (such as cellulose, chitosan, pectin, and cyclodextrins), either chemically or physically cross-linked. More recently, a captivating category known as eutectogels has emerged, which are formed by physically cross-linking eutectic solvents with appropriate gelators, presenting a novel type of scaffold.

This keynote presentation highlights the strategies at the state-of-the-art based on NMR spectroscopy to attain detailed insights into the diffusion dynamics of small molecules within constrained environments like the pores of hydrogels and eutectogels. The high-resolution magic angle spinning (HR-MAS) NMR approach is described in combination with pulsed field gradient spin-echo (PGSE) sequences to investigate solute diffusion in confined networks. Experimental findings will be interpreted using refined mathematical models, enabling the generalization of motion types to non-Fickian diffusion.[1-3]

Relevance of per- and polyfluoroalkyl substances (PFAS) contamination in Italy

S. Valsecchi

Consiglio Nazionale delle Ricerche, Istituto di Ricerca sulle Acque, Via Mulino 19, Brugherio (MB)
sara.valsecchi@irsa.cnr.it

First environmental measurements of per- and polyfluoroalkyl substances (PFAS) contamination in Italy began in the first decade of the new millennium. Widespread environmental contamination by PFAS in human-inhabited areas is due to the extensive use of these substances in consumer products and subsequent discharge into water bodies through municipal wastewater treatment plants. However, in Italy it soon became evident that beside the baseline environmental contamination there are additional sources of contamination in the environment stemming from industrial production and usage of these compounds, and waste disposal.

This presentation will provide an overview of the PFAS distribution and sources in Italian ecosystems, covering both legacy and newly identified PFAS, along with examples of substitutions of regulated products that were banned or restricted.

Very high concentrations of PFASs have been documented in environmental matrices downstream of fluorochemical and fluoropolymer facilities, leading to both localized and widespread regional pollution. In one case, the manufacturing plant caused contamination of one of the largest aquifers in Europe, and the population have been exposing to contaminated drinking water for decades. However, some specific industrial districts involving mainly surface treatments, such as textile (including the production of technical textiles or upholstery fabrics) or tanneries also appear to be important sources of emissions of these compounds. No less important as a source of environmental contamination in Italy is the waste cycle precisely because of extreme chemical stability and environmental mobility of PFAS. Waste and sludge management has contributed to the PFAS contamination of Italian water bodies even far from the places of production and use.

Since the 2000s alongside the measurement of individual compounds, regulatory requirements have moved toward measuring total PFAS contamination. So, at the conclusion of the presentation, the advantages and disadvantages of nonspecific techniques for measuring total PFAS such as Total Organic fluorine by Combustion Ion Chromatography (TOF-CIC) or Total Oxidisable Precursor Assay (TOP Assay) will be presented and discussed. Of great help in bridging the knowledge of total PFAS that may be present in the environment is the implementation of chromatographic techniques coupled with high-resolution mass spectrometry, for which validation of dedicated workflows for suspect screening and non-targeted analysis particularly dedicated to PFAS identification are on going.

PFAS pollution in the aquifers of central Veneto Region: hydrogeological features and environmental implications

Andrea Sottani

Sinergeo S.r.l.
Contrà del Pozzetto, 4 36100 Vicenza, Italy
asottani@sinergeo.it

Perfluorinated Alkyl Substances (PFAS) pollution of groundwater in Central Veneto represents a significant environmental emergency in northern Italy. It has become a public health concern due to the exposure of at least 300,000 people who ingested contaminated drinking water.

Over several decades, a continuous source of PFAS from a chemical plant steadily contaminated the aquifer. The plume migrated over 40 km, impacting productive geological horizons in both the unconfined shallow aquifer system and the deeper artesian wells, utilized for water supply.

Despite ongoing safety measures and source control efforts, the release of PFAS continues.

The hydrogeological setting of the Agno-Guà valley plays a crucial role in contaminant migration. The highly conductive alluvial formations facilitated the extensive movement of PFAS along the prevailing groundwater flow paths. Additionally, fluctuations in the water table, with periodic rises in the water level closer to the surface, contribute to the transport and diffusion dynamics of PFAS within the aquifer.

The substantial width and complex hydrochemical characteristics of the plume, coupled with the heterogeneity of the geological formations, render widespread environmental remediation measures (plume control) challenging and economically impractical.

This contamination has resulted in a significant loss of a valuable drinking water resource, irreversibly compromising one of the most important regional water supply districts.

The event has had severe consequences for the public water service infrastructure and management: extensive emergency measures, including new infrastructure, operational modifications, and increased energy consumption, have been necessitated to address the contamination.

In the keynote, the case study is presented from the aquifer view-point, focusing attention both on the scientific aspects that emerge from this large-scale "tracer test" and on the social and economic implications of the environmental issue.

"The Remediation in the National System of Environmental Protection: state-of-the-art and perspectives"

M. Fratini[a], F. Araneo [a], E. Bartolucci [a]

[a] *Department for the Geological Survey of Italy, Italian Institute for Environmental Protection and Research, Via V.Brancati 00144, Rome, Italy*
michele.fratini@isprambiente.it

The National System for Environmental Protection (SNPA) is a network made up of ISPRA and the 21 Territorial Environmental Protection Agencies (ARPA/APPA) established by Regional Laws. SNPA represents an example of consolidated federal system, which combines the direct knowledge of the territory and its issues with the national policies for environmental protection, so as to become an institutional and technical-scientific reference point for the whole country. SNPA assures its technical support to the Ministry of Environment and Energy Security (MASE) on contaminated sites of national interest activities and, in order to promote the sustainable management of contaminated sites and to stimulate harmonisation in this respect, develops guidelines and technical documents for the characterization and remediation of contaminated sites.

To comply with specific law provisions and to have a complete and homogeneous framework at national level on the sites subject to remediation procedures ISPRA, within SNPA, has implemented MOSAICO, the national register on contaminated sites in Italy. MOSAICO contains data related to sites interested in more than 33.000 management procedures, whether in progress or concluded, and allows to analyse the progress in the management and the contamination status of ongoing procedures, the closure methods of the concluded ones and their time duration. In 2023, a public online consultation section of the MOSAICO georeferenced spatial data, including information on potentially contaminated and contaminated sites, was made available on a dedicated website.

Experiences gained in supporting MASE activity on contaminated sites of national interest combined with analysis of data recorded in MOSAICO help to evaluate timing of the remediation processes, that is crucial for environmental and health considerations, effectiveness, and cost-effectiveness and can help policymakers to design more efficient and sustainable environmental management strategies.

Emerging technologies for Environmental remediation

Annalisa Vacca, Nicola Melis, Laura Mais, Michele Mascia

Dipartimento di Ingegneria Meccanica, Chimica e dei Materiali, Università degli Studi di Cagliari, Via Marengo 2, 09123, Cagliari, Italy
**michele.mascia@unica.it*

Effective strategies for environmental remediation need green, sustainable, efficient, and low-cost solutions for soil/sediment and water remediation, by integrating traditional remediation strategies with innovative technologies. Moreover, the remediation of a range of organic and inorganic pollutants of high concern, can be often achieved with producing useful end-products, including hydrogen and electricity.

A summary of the existing technologies is here presented, with focus on electrochemical technologies combined with other processes.

Some case studies are then discussed where biological, chemical, and electrochemical technologies are applied to remediation of soils and water at pilot scale.

In the first example, an integrated system for effective groundwater technologies was used to enhance the removal of dyes and potentially toxic metals, with bio-electrochemical systems for TPHs, pesticides, antibiotics, and PAHs removal.

The second case study shows the combination of biological and bio electrochemical technologies for soil remediation.

In both case studies, operation conditions for the scale-up were defined, based on experiments and mathematical modelling.

An example of wastewater treatment is also presented, with the integration of a membraneless electrolysis process into the clean water system of a biomass gasification process. The process combines electrochemical oxidation for the removal of organics and production of Hydrogen. The obtained gas is of low quality, but it can however be added to the syngas from the gasification reactor. Results showed it is possible to obtain a steady sate concentration of organics in the cleaning water maintaining a good purity of the hydrogen.

The experimental results were then used in a simulation of the integrated scrubbing and electrolysis system. The simulations were performed with the commercial software AspenPlus (AspenTech, Bedford, MA, USA). The simulations were used to assess the impact of the integration on energy and mass balances of the biomass gasification plant.

Critical chemical elements for the energy transition

Nicola Armaroli

Istituto per la Sintesi Organica la Fotoreattività, Consiglio Nazionale delle Ricerche
Via Gobetti 101, 40129 Bologna
nicola.armaroli@cnr.it

In 1990 an entire house typically contained about 20 chemical elements. Today there are more than 40 elements in a smartphone only. The use of some elements defined as "critical" is particularly relevant to renewable energy conversion and storage technologies that are critical to the decarbonization of modern civilization: photovoltaic panels, wind turbines, batteries, fuel cells, grid infrastructure, etc. The main material bottlenecks of the energy transition will be discussed, focusing primarily on sustainable mobility and renewable power generation and storage.

The arrow of time in recycling materials from energy storage devices

L. Magagnin

Dip. Chimica, Materiali e Ing. Chimica G. Natta – Politecnico di Milano
Via Mancinelli, 7 - 20131 Milano - Italy
luca.magagnin@polimi.it

Growing demand for green and renewable energy in the EU, combined with the vulnerability of supply chains for key raw materials, is driving the need to recover the materials used in green transition application (e.g. batteries and photovoltaic panels, etc.). This presents an opportunity to reduce the risk of downstream pollution from disposing of or recycling these items.[1]

Developments in recycling technology have largely focused on short-life-cycle products, such as plastic waste from packaging, consumer electronics, and construction debris, while complex, resource-rich, long-life-cycle electronic products, energy-storage, and photovoltaic components have been somewhat overlooked due to their intrinsic property of containing multimaterial in a complex manner. High-value products contain valuable elements, which are intricately incorporated and often lost at end of life.[2]

In light of the arrow of time, taking into account the necessity to supply free energy to let possible a transition from disorder to order, available technologies and processes to transform wastes from energy storage devices in secondary raw materials are presented. The usual representation of the circular economy, which considers only the mass balance, is discussed, illustrating new paradigms needed for the recycling techniques.

The recycling facilities also need to innovate their technologies to effectively recover material from the evolving material design products. Existing challenges and opportunities for recycling energy resources to achieve long-term sustainability will be presented, underlying the intertwining between recycling materials from energy devices and sustainability.

Moving Towards More Sustainable (Post-)Lithium Batteries

Dominic Bresser

Helmholtz Institute Ulm (HIU), Helmholtzstrasse 11, 89081 Ulm, Germany
Karlsruhe Institute of Technology (KIT), P.O. Box 3640, 76021 Karlsruhe, Germany

dominic.bresser@kit.edu

Lithium-ion batteries are today the dominating electrochemical energy storage technology, powering portable electronic devices as well as (hybrid) electric vehicles, and finding application also for the stationary storage of renewables.[1] Since their first commercialization about 30 years ago, the energy density has more than tripled and the cost have decreased almost exponentially.[2,3] This great improvement originates from advances in engineering and materials development; with regard to the latter, this includes especially the transition to graphite and nickel-rich lithium transition metal oxides as active materials for the negative and positive electrode, respectively. Remarkably, despite earlier concerns that their maximum energy density might have been reached, there is still continuous progress thanks to new electrode and cell designs as well as the development of new and better electrode materials and advanced electrolyte systems, and there is still room for further improvement, especially with regard to sustainability, which is key towards a truly greener future. Meanwhile, alternative battery technologies such as sodium-ion batteries promise an intrinsically greater environmental friendliness, as they do not rely – or at least much less – on critical elements and compounds such as cobalt, nickel, copper and graphite.[4,5]

Herein, the current state of the art will be presented with a specific focus on the remaining challenges and approaches to overcome these in the coming years and to enhance the sustainability of next-generation lithium and sodium batteries, while highlighting that the diversification of battery chemistries by itself provides already a pathway towards a more responsible use of (critical) resources.

Sustainability key-challenges across the European battery value chain: an overview from the BATT4EU/Batteries Europe joint Task Force

E. Quartarone[a,b]

[a]*Dept. of Chemistry of the Univerity of Pavia, Via Taramelli 16, 27100 Pavia Italyffiliation 1, Address, City*
[b]*GISEL-INSTM, Via Giusti 9, 50121 Firenze Italy*
eliana.quartarone@unipv.it

Addressing present and emerging battery systems, the new position paper of the *BATT4EU/Batteries Europe joint Sustainability Task Force* [1] aims to take a comprehensive look at the sustainability of batteries and the entire value chain, including the framing conditions. It also explores how this fast-growing sector can foster an innovative environment and develop a more sustainable battery ecosystem, considering the importance of recycling, second use, and the circular economy. Three key dimensions are in focus: economic, social, and environmental sustainability, especially from a life cycle perspective. Furthermore, the paper will reflect on EU regulations and activities such as the "Net-Zero Industry Act," the "Critical Raw Materials Act" (ACRM), and “Safe and Sustainable by Design” (SSbD) as framing conditions.

For present batteries, the new Batteries Directive (including the Battery Passport) with challenging minimum recycling rates and recycling content in batteries in the future are quite important. The ongoing discussion regarding PFAS and the usage of critical raw materials in the case of lithium batteries highlights the challenges and importance of recycling and a circular economy. Additionally, the low economic value of used materials in Post-Lithium batteries (such as Sodium-Batteries) creates foreseeable challenges that need to be addressed today. Therefore, activities regarding "design for recycling" and first attempts towards direct recycling are promising options to overcome these challenges.

Recent Advances in Electrocatalysts for Low Temperature Fuel Cells and Electrolyzers

Alessandra D'Epifanio

Department of Chemical Science and Technologies, University of Rome Tor Vergata, Via della Ricerca Scientifica, 00133 Rome Italy
alessandra.d.epifanio@uniroma.it

Hydrogen has been identified as an essential part of the solution for enabling energy system decarbonization. Water electrolyzers and H_2-fed fuel cells are crucial to achieving H_2 production from renewable sources and using H_2 as a feedstock to generate electricity.

Polymer Electrolyte Membrane Fuel Cells (PEMFCs) and Polymer Electrolyte Membrane Water Electrolyzers (PEMWEs) technologies have reached a level of maturity but still depend heavily on critical raw materials (CRM) in their crucial components. Those devices share the oxygen electrode, substantially affecting their performance and durability due to the intrinsically slow kinetics for oxygen evolution/reduction and poor durability under harsh operating environments. Although CRM-based electrodes are catalytically active toward oxygen electrocatalysis, their use in fuel cells and water electrolyzers is not sustainable. Therefore, the rational design of advanced electrocatalysts for oxygen electrocatalysis is critical for advancing the development of PEMFCs and PEMWEs [1,2].

This work overviews recent advancements in developing transition metal (TM)--based electrocatalysts for applications in PEMFCs and PEMWE electrodes. We present the main strategies and synthetic approaches for tailoring the properties of TM-based electrocatalysts to enhance their activity and durability toward oxygen reduction reaction (ORR) and oxygen evolution reaction (OER).

Emphasis will be given to designing TM-based (TM=Fe, Co, Ni) electrocatalysts derived from metal-organic-frameworks (MOFs) and porous organic polymers (POPs) as self- or soft-template to modulate the materials' micro/meso/macro porosity and enhance metal functionalization. The versatility of the synthetic approaches allows for the development of bifunctional ORR/OER electrocatalysts. Applications in H_2-fed anion exchange membrane fuel cells (AEMFCs), microbial fuel cells (MFC), alkaline direct methanol fuel cells (ADMFCs), and anion exchange membrane water electrolyzers (AEMWEs) will be discussed [3-4].

Based on the achieved results, TM-based electrodes result to be suitable for developing electrodes for low-temperature fuel cells and electrolyzers.

Membranes for Energy

A. Figoli, J.C. Jansen, F. Galiano, E. Esposito, E. Fontananova
[1] *Institute on Membrane Technology, National Research Council of Italy (CNR-ITM), Via P. Bucci 17/C 87036 Rende (CS), Italy*
**Presenter's E-mail: a.figoli@itm.cnr.it*

Energy is one of the key resources determining the overall socioeconomic development: a robust energy supply must be secured for a sustainable growth and an improved living standard. Global energy consumption is increasing at an exponential rate: it is estimated that global energy consumption will rise by 48% between 2012 and 2040 [1]. In this context, the development of alternative energy resources able to alleviate the skyrocketing demand for clean energy and related environmental issues are urgently required [2].
Water has always been crucial to combustion and hydroelectric processes, but it could become the source of power in membrane-based systems that capture energy from water or produce hydrogen as energy vector. In this contest, two innovative based membrane operations will be presented and discussed: *a)* Reverse Electrodialysis (RED) using Salinity gradient energy or Salinity Gradient Power (SGP), also referred to as 'Blue Energy' for sustainable power generation [3], *b)* Membrane-based water electrolysis applied to produce high-purity and sustainable hydrogen for green energy production. In both cases, the conducting membranes are the heart of the investigated processes. Several factors, as the operating parameters, the membrane materials, which influence the performance of the membrane process will be discussed and future prospects will be also highlighted.

Applications of NMR techniques in the design and development of Polymer Electrolyte Membranes for energy production and storage

C. Simari,[a] I. Nicotera,[a]

[a] *Department of Chemistry and Chemical Technology, University of Calabria, 87036 Rende (CS), Italy;* cataldo.simari@unical.it

Polymer electrolyte membranes (PEMs) hold a critical role in shaping the performance of various energy production and storage technologies, including fuel cells and batteries [1]. Ongoing research efforts focus on enhancing the ion conductivity, durability, and reliability of PEMs through meticulous control over their composition, morphology, and nanostructure. The overarching goal is to overcome key challenges such as efficiency and cost-effectiveness, thereby facilitating widespread commercial adoption across various energy applications [2]. Nevertheless, the pursuit of efficient PEMs demands a deeper understanding of their structure-property relationships. In this context, Nuclear Magnetic Resonance (NMR) techniques have clearly emerged as invaluable tools for elucidating the molecular dynamics, morphology, features of ion solvation, structure of transport channels, and transport phenomena within PEMs [3].

The presentation delves into the myriad applications of NMR spectroscopy in the characterization of PEMs, accentuating its pivotal role in assessing polymer chain mobility, ion conduction mechanisms, water uptake behavior, and interface interactions within the membrane matrix. Notably, NMR techniques, especially pulsed field gradient NMR, offer a distinct competitive advantage since enables the selective measurement of the mobilities and self-diffusion coefficients for all ions and molecules involved in charge transfer, for example, solvents (^{1}H and ^{13}C NMR), protons and hydroxides (^{1}H NMR), lithium cations (^{7}Li NMR), and counterions (^{19}F NMR). Through a comprehensive overview of recent advancements, challenges, and future perspectives, the presentation underscores the indispensable contributions of NMR techniques in paving the way for targeted enhancements and advancements in the design and development of PEMs for enhanced energy conversion and storage applications.

Sustainable and Circular Materials Chemistry

J. Chris Slootweg[a]

[a]*Van 't Hoff Institute for Molecular Sciences (HIMS), University of Amsterdam*
P.O. Box 94157, 1090 GD Amsterdam (The Netherlands)
j.c.slootweg@uva.nl

In addition to the well-known Green Chemistry principles that have revolutionized optimizing and sustaining linear processes, Circular Chemistry[1] moves beyond value extension and aims at making chemical processes and production cycles circular by using waste (or ideally products) as resource.

In this lecture, I will highlight the importance of using waste as resource as well as stress the need to develop Circular Technologies, which use chemistry as enabling tool, to target the conservation of critical raw materials (element scarcity) as well as contribute to solving pressing waste problems.[2,3] Such an endeavour will combine molecular design and synthesis with the environmental fate and impact of current products targeting safe by design (no persistent, bio-accumulative, and toxic compounds; green chemistry) and design for re-use, recovery and recycling (circular chemistry).

I will apply this vision to the key biogenic elements CHNOPS and hydrogen in particular, since H_2 has becoming one of the key energy carriers for the future to deal with the challenge of climate change and achieve the goals of the Paris Agreement. Hydrogen can also can help to compensate for the intermittency of renewable energy resources, while it can be sustainably produced from e.g. solar and wind power through the electrolysis of water. Large-scale usage of H_2, however, will necessitate its storage at massive scales, which will also allow the safe transport of large volumes of hydrogen from cheap production sites to demand centres elsewhere in the world. Multiple H_2 storage options exist, among which through the production and use of $NaBH_4$, associated with the regeneration of the carrier $NaBO_2$. I will highlight our recent advances in the development $NaBH_4$ as circular H_2 storage option and energy vector. In particular the focus is on the electrochemical recycling of the carrier to achieve the circular use of $NaBH_4$. Also a comparison will be made between H_2 usage from $NaBH_4$ and the direct usage of $NaBH_4$ in fuel cells to generate and use electricity, as well as other popular hydrogen storage materials like methanol, ammonia and LOHC.

Discovery of entrectinib: an amazing journey from target biology to innovative therapy

E. Ardini

Nerviano Medical Sciences s.r.l., Nerviano 20014, Milano, Italy
elena.ardini@nervianoms.com

Treatment of lung cancer dramatically changed during the last 20 years due to the identification of genomic alterations resulting in the expression of activated proteins that set the basis for precision medicine approach. In particular, the identification of recurring ROS1 and ALK chromosomal rearrangements in discrete subsets of lung cancer patients emerged as valuable opportunity for the development of highly potent and selective drugs for the treatment of patients harbouring such alterations.

At the time the screening of NMS proprietary kinase targeted library was conducted and led to identify the initial promising hits, the liabilities of the first-generation ALK/ROS1 inhibitor crizotinib in clinical settings were already emerging demonstrating that, despite the good clinical efficacy, relapse due to the acquisition of secondary mutations was common. In addition, the poor brain penetration of crizotinib resulted in lack of efficacy in patients with brain metastases at baseline and evidence of progression in the brain in patients relapsing after initial response. These emerging clinical observations guided the medicinal chemistry efforts in NMS with the aim to identify a second-generation ALK/ROS1 inhibitor able to overcome such liabilities. The focused lead optimization approach led to the identification of entrectinib, a highly potent ALK/ROS1 inhibitor, able to inhibit several acquired resistance mutations and, importantly, able to efficiently cross the blood-brain barrier and achieve efficacious exposure in the brain.

Although these features of entrectinib already opened the possibility for its development and approval as best-in-class drug, the most extraordinary opportunity arose from the discovery that entrectinib, designed to be a ROS1/ALK inhibitor, was also highly potent in inhibiting NTRK, a closely related kinase. However, no evidence of a potential major role of NTRK as target in tumours had been published at that time. The full exploitation of this activity become possible due to the serendipitous detection of a NTRK rearrangement in a colorectal cancer (CRC) cell line that prompted to search for this genomic alteration in patients. The successful identification of NTRK rearrangements in a subset of CRC patients spurred the exploration of other tumour types resulting in the identification of activated forms of NTRK in several different histologies.

Based on preclinical evidence, the clinical development of the drug was conducted in target-selected patients, including ROS1- and ALK-positive lung cancer and NTRK-positive tumours across 19 different tumour types. The excellent clinical efficacy associated with the good safety profile resulted in breakthrough therapy and priority medicine designation granted by FDA and EMA, respectively, and, ultimately, to an accelerated approval for treatment of ROS1-positive lung cancer and agnostic approval for NTRK-positive tumours. The partial response achieved in the first NTRK-positive CRC patient treated with entrectinib represented the first compelling clinical validation of NTRK as a target in this tumour type and paved the way for the treatment of all subsequent patients.

In this work, we present a crosstalk between medicinal chemistry, pharmaceutical technology, and biology to address the challenge of overcoming therapeutic and delivery limitations of existing radiopharmaceuticals. Cholecystokinin type 2 receptor (CCK2-R) represents an ideal target for cancer therapy since it is overexpressed in several tumors and it is associated with poor prognosis. Based on preliminary studies from our group[1], Nastorazepide (Z-360), a selective CCK2-R antagonist, has been selected as CCK2-R ligand for targeted therapy[2]; however, Z-360 high hydrophobicity may represent a limit to cell-selectivity and optimal in vivo biodistribution.[1,2] Here, Z-360 was linked to spacers bearing a mono, a di or a tri-saccharide (x) to sulforhodamine B leading to new derivatives of increasing hydrophilicity (IP-002x-Rho). Through 2D and 3D in vitro studies we evaluated the influence of spacer features on compounds association with and selectivity for CCK2-R overexpressing cells (A431-CCK2-R$^+$) *vs* CCK2-R low expressing cells (A431 WT). 2D in vitro studies highlighted a progressively increase of IP-002x-Rho association with A431-CCK2-R$^+$ cells according to the linker hydrophilicity. Trafficking studies on A431-CCK2-R$^+$ cells incubated with IP-002x-Rho suggested the co-existence of receptor-mediated endocytosis and simple diffusion. On the contrary, a high and selective uptake of the most hydrophilic derivative by A431-CCK2-R$^+$ cells only was observed on 3D scaffolds embedded with cells, underlying the importance of 3D models in in vitro preliminary evaluation. Once selected the best performing molecule, sulforhodamine B has been replaced with a set of chelators and investigated for targeted radiotherapy.

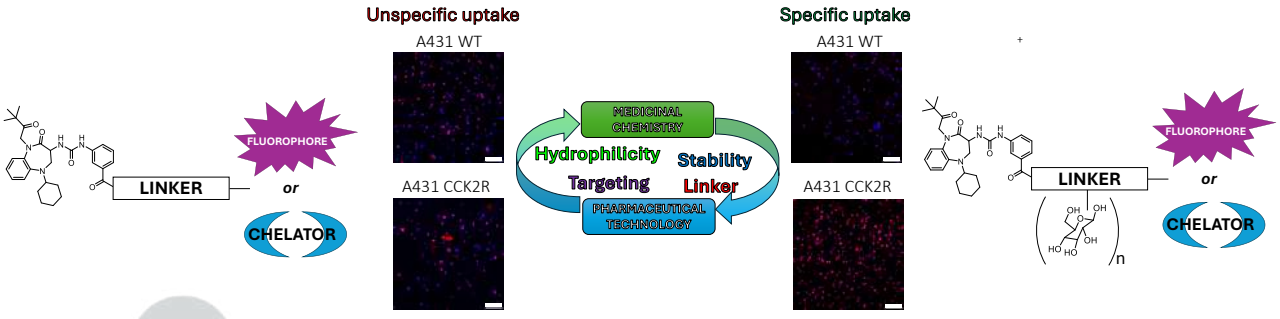

Figure 1: Schematic representation of Z-360 derivatives and specificity for CCK2R$^+$-expressing cells.

Non-canonical nucleic acids arrangements for targeted therapies

C. Sissi[b]

[a]*Dept. of Pharmaceutical and Pharmacological Sciences, v. Marzolo 5, 35131 Padova*
e-mail of submitter: claudia.sissi@unipd.it

Upon the discovery of the DNA double helix, our understanding of the multifaceted structures and functions of nucleic acids has steadily advanced, fostering an ever-increasing interest in these biomolecules within medicinal chemistry. This correlates with the abundance of chemotherapeutics known to target nucleic acids which, despite a frequent lack of selectivity, remain widely used in the clinic. In parallel, we are finally recording a constant increase in the number of approved nucleic-acids-based therapeutics. Besides two aptamers and emerging mRNAs, the majority share a common molecular mode of action based on the pairing of two nucleic acid strands[1]. The good prediction of the energetic associated to the RNA-RNA, DNA-DNA or RNA-DNA double helices formation from the sequence composition remarkably speed-up the design of short oligonucleotides selective for the selected target and made it potentially adaptable to treat many diseases as well as specific variants or mutations that may emerge. This encouraging scenario still faces several limitations, largely related to the stability and distribution of oligonucleotides. An additional frequently underestimate issue is related to the structural features of the target and the drug. For example, RNA chains easily accommodate folded domains where the pairing of a complementary strand is hindered. This structural issue is further complicated by the potential occurrence of so-called “non-canonical nucleic acids arrangements” which depend on both primary sequence and environmental conditions. Unfortunately, the predictive capability for these arrangements remains unsatisfactory[2].

However, we can look at this polymorphism from an alternative perspective and transform it into a novel opportunity for targeted therapies. Indeed, the divergent three-dimensional features of nucleic acids structures, suggest differences in cellular component recognition. Moreover, their formation can be time and space controlled directly by the cellular environment, overall indicating their involvement in specific cellular functions. Last but not least, they occur at a small subset of nucleic acid sites. These evidences envisage their exploitation as sites for targeted therapeutic interventions[3]. Here, we will present how different experimental approaches can provide a comprehensive understanding of the functions of these structural elements at the molecular level, and how this knowledge can be used to develop variegate of strategies to ultimately modulate a single cellular pathway.

Exploring a new dimension in DNA for the future of precision medicine

J. Amato

Department of Pharmacy, University of Naples Federico II, via D. Montesano 49, 80131 Naples
jussara.amato@unina.it

In the ever-evolving landscape of biomedical research, G-quadruplex (G4) nucleic acid structures have emerged as fascinating therapeutic targets for precision medicine and molecular diagnostics. These noncanonical arrangements of DNA or RNA play crucial roles in gene expression regulation and are implicated in the pathogenesis of various diseases, including cancer[1]. Integrative analyses of mutations found in patient-derived tumor cells, combined with assessments of differentially G4-enriched genomic regions, have linked G4s to cell-type specific transcriptional control, tumor heterogeneity, and genome instability[2]. G4-interacting ligands show potential for therapeutic modulation of G4 biology. However, precise targeting of specific G4 structures is essential for clinical translation. Developing ligands with enhanced affinity and specificity is essential to realize the full therapeutic potential of G4-targeting strategies[3,4]. Moreover, G4-ligand interactions offer diagnostic potential, enabling the development of biosensors and imaging tools for early disease detection and personalized treatments, with potential to improve patient outcomes. The latest advances in this research field will be discussed, along with strategies for enhancing the specificity and effectiveness of G4-targeting ligands.

Well known polysaccharides (hyaluronic acid, alginate) we know rather little about

N. Tirelli

Fondazione Istituto Italiano di Tecnologia (IIT), via Morego 30, 16163 Genova
Nicola.tirelli@iit.it

Polysaccharides have a well deserved position in drug delivery (mostly as excipients), in biomaterials (as components of artificial extracellular matrices) and in medical devices (viscosupplementation, dermal fillers); facing this wealth of medical/pharmaceutical applications, it would seem natural that both their physico-chemical behaviour and biological interactions have been long understood, down to a very detailed level.

This is, however, not often the case.

This talk provides two examples:

- The nature of the counterion can dramatically and somehow unexpectedly alter both solution properties and gelation processes of alginate. Here we focus on magnesium, which is the only double-charged cation that does not induce alginate gelation; on the contrary, Mg intramolecularly cross-links polysaccharide chains, reducing their viscosity in solution and changing both kinetics and morphology of the exchange with calcium ions[1]. The latter makes Ca alginate obtained from Mg alginate significantly different from that produced from the Na salt; this provides a very convenient means to fine tune e.g. mechanical properties and therefore enhance the potential of personalization of a delivery vehicle.
- The interactions with cell surfaces, and the mechanism of binding (recognition) and internalization are what we invoke in cell targeting, which is a cornerstone concept in personalized medicine. CD44 is the main receptor for hyaluronic acid, and the tumour cell-targeting properties of this polysaccharide are typically ascribed to their interactions. In cell targeting through receptors such as CD44 we have a basic question: are the receptors those that a) recognize and bind an extracellular object (capture), b) bring it inside the cell through endocytosis (internalization), or c) both? Starting a few years ago[2], with time we have accumulated sufficient evidence that CD44 is essentially a selective internalizer (point b). One or more yet to-be-identified receptors would take case of the initial, and possibly less selective capture of hyaluronic acid. This begs the question whether we may still refer to phenomena of non-selective binding/selective internalization as “cell targeting”, due to the inherent presence of off-target effects (non-selective recognition).

Innovation in Precision Medicines: Antibody-Drug Conjugates

Gianfranco Pasut[a], Barbara Valsasina[b]

[a]*Dept. Pharmaceutical and Pharmacological Sciences, University of Padova, Via F. Marzolo 5, 35131, Padova, Italy*
[b]*Nerviano Medical Sciences, Viale Pateur 10, 20014 Nerviano (MI)*
gianfranco.pasut@unipd.it
barbara.valsasina@nervianoms.com

Antibody–drug conjugates (ADCs) are a successful technology for targeted delivery of cancer therapeutics. Based on the covalently coupling of a drug to a tumour-specific monoclonal antibody, ADCs have demonstrated effectiveness against various cancers with 13 ADCs in clinical use and more than 100 in clinical investigation. An ADC targets a specific tumour antigen, typically a cell surface receptor, and specifically deliver potent drugs (EC50 < 0.01-0.1 nM) to tumor cells. After binding to the antigen, the ADC-antigen complex is internalized into the cancer cell, and addressed to lysosomes where the drug is released through an enzymatic, hydrolytic, or reducing step. Several factors can dramatically affect the success of ADCs, like the rate of endocytosis and lysosomal trafficking or the level of neonatal Fc receptor (FcRn)-mediated cell surface recycling. Other factors influencing the activity include the payload potency and mechanism of action and the type of antibody-payload linkage that determines the mechanism and rate of drug release or the payload itself.

Tubulin binders are the most common payloads in currently approved ADCs but, despite their clinical success, they suffer from some liabilities in terms of sensitivity to multidrug resistance system with reduced activity in chemoresistant tumors and showed some safety concerns, being hematological toxicity and peripheral neuropathy among the most common ones. The recently introduced Topoisomerase I inhibitor dexuxtecan, characterized by a cleavable linker and with a strong bystander effect, interestingly showed activity in context where previously tested ADCs failed. This renewed the interest in novel payloads with diversified mechanism of action to face emerging resistance and to explore new combinations. Nerviano Medical Sciences is developing a platform of cytotoxic and targeted payload linkers, based on its proprietary chemical collection of more than 100.000 compounds and selects tumor antigens, for possible synergism with the payload mechanism of action, to maximize selectivity and further increase the therapeutic window of generated ADCs.

Regarding ADC linkers, these are divided in two categories: cleavable or non-cleavable. The most used releasable linker is the cathepsin-sensitive dipeptide Val-Cit coupled with the self-immolative spacer p-aminobezyl carbamate. In the case of non-cleavable linkers, the drug is released only after the lysosomal proteolysis of the antibody. Recently, Pasut's group reported on the use of a hydrophilic, non-cleavable, PEGylated linker for the preparation of ADCs with high drug loadings, showing increased physical stability and decreased plasma clearance in mice compared to Kadcyla. The linker had been designed with a "pendant" shape having two monodisperse PEG12 arms appended to the linker. Such linkers have been further improved by the insertion of cleavable peptides (Phe-Gly or Val-Ala-Gly), thus allowing the release of the drug.

In conclusion, it is important to highlight the relevance of the drug-linker optimization, specific insights can help the design and development of new antibody-drug linkers.

Extracellular vesicles (EVs), crucial mediators of cell-to-cell communication, hold significant diagnostic potential due to their ability to concentrate protein biomarkers in bodily fluids. However, challenges in isolating EVs from complex biological specimens hinder their widespread use. The preferred strategy involves direct analysis, integrating isolation and analysis solutions, with immunoaffinity methods currently dominating. Yet, the heterogeneous nature of EVs poses challenges, as proposed markers may not be as universally present as thought, raising concerns about biomarker screening reliability. This issue extends to EV-mimics and analogues, where conventional methods may lack applicability. Addressing these challenges, we report on Membrane Sensing Peptides (MSP) as pan-vesicular affinity ligands for both EVs and their non-canonical analogues, streamlining capture and phenotyping through Single Molecule Array (SiMoA). MSP ligands enable direct analysis of circulating EVs, eliminating the need for prior isolation. Demonstrating clinical translation, MSP technology detects an EV-associated epitope signature in serum and plasma, distinguishing myocardial infarction from stable angina. Additionally, MSP allows analysis of tetraspanin-lacking Red Blood Cell-derived EVs, overcoming limitations associated with traditional antibody-based methods. Overall, our work underlines the value of MSP as complementary tools to antibodies, advancing EV analysis for clinical diagnostics and beyond and marking the first-ever peptide-based application in SiMoA technology

Fluorinated nanoparticles as bioimaging tools and delivery agents

F. Baldelli Bombelli[a]

[a] *Department of Chemistry, Materials and Chemical Engineering, Politecnico di Milano, Via Luigi Mancinelli, 7, 20131-Milano, Italia*

francesca.baldelli@polimi.it

This work addresses the current need for novel sensitive, robust, and selective diagnostic tools for non-invasive *in vivo* imaging, which are able to improve the medical practice through earlier diagnosis of disease, implementation of targeted therapies, and localization of diseased tissues. Our approach is based on the development of sustainable fluorinated probes enabling ^{19}F-MRI, as a complementary tool, to be coupled with other diagnostic imaging techniques such as ^{1}H-MRI, Raman and fluorescence imaging, in order to overcome their present shortcomings. This talk reports about a unique fluorinated imaging agent (PERFECTA) bearing 36 equivalent ^{19}F atoms and therefore showing a single, intense ^{19}F-NMR signal. Biocompatible nanoparticles loaded with PERFECTA demonstrated excellent cellular compatibility and spectral properties (relaxation times and sensitivity) adequate for in vivo ^{19}F-MRI use [1-2]. In this presentation PERFECTA ability to work as multiscale and multimodal probe will be shown [3]. Moreover, effects of fluorination on self-assembly of PERFECTA amphiphilic derivatives will be also presented as well as their biological interactions and response also in the perspective to use them in precision medicine.

Printed electrochemical strips to early diagnose diseases, to evaluate vectors' encapsulation, and to monitor therapeutic efficacy: user-friendly diagnostics for personalized treatments

S. Cinti

Department of Pharmacy, University of Naples Federico II, Via Domenico Montesano 49, 80131 Naples, Italy
Stefano.cinti@unina.it

The use of portable diagnostics is always more occurrent in the clinical field, and in particular the application of screen-printed electrochemical strips is capable to provide benefits to all the steps, from prevention to therapy. Focusing in the field of cancer, screen-printed electrodes have been successfully applied towards the determination of various molecules, relevant for managing cancer. In this presentation, the use of portable electrochemical devices will be highlighted in 1) detecting miRNA and exosomes as markers for early diagnosis, 2) evaluating the efficacy of encapsulation of drug in lipid nanovectors to be used for treatment and 3) evaluating the therapeutic efficacy in various type of cancers by monitoring the changes in reactive oxygen species level.

Making the invisible visible: contrast agents for diagnostic imaging

L. Lattuada

Bracco Imaging SpA, via E. Folli 50, Milano
luciano.lattuada@bracco.com

Bracco Imaging, a private-capital Italian company, is a worldwide leader in the production and marketing of contrast agents for *in vivo* diagnostic imaging. The use of a contrast agent in combination with the suitable diagnostic technique allows the visualization of the inside of a human body leading to a fast and accurate diagnosis.

In this presentation the main diagnostic imaging techniques,[1] such as CT,[2] MRI,[3] Ultrasound, Nuclear Medicine and Optical Imaging (Figure 1), and the corresponding contrast agents employed will be disclosed and discussed.

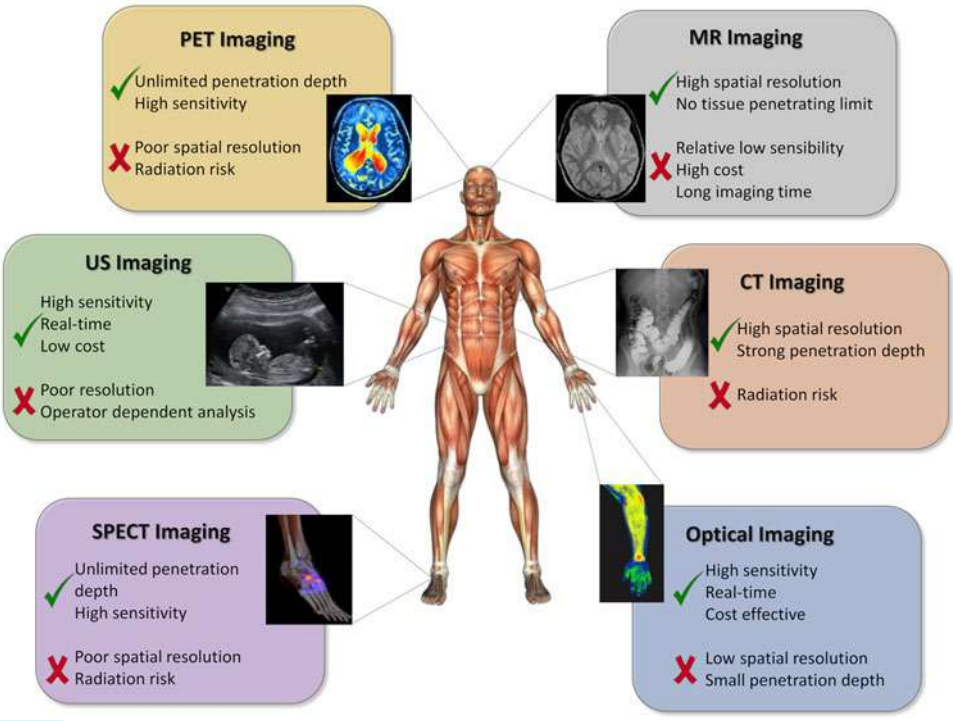

Figure 1: Principal diagnostic imaging techniques.

Non-invasive diagnostic imaging plays a key role in advancing precision medicine, particularly in scenarios where achieving a minimum drug concentration threshold is critical for therapeutic efficacy. Boron Neutron Capture Therapy (BNCT) is a pre-targeting technique that involves the injection of a non-radioactive, non-toxic chemical containing ^{10}B, which is only triggered by neutron irradiation after accumulation at the tumour site. The main advantage of this approach is that by administering ^{10}B and producing alpha radiation selectively in diseased cells, it can kill the pathological cells while sparing the surrounding healthy tissue.[1] However, the expected efficacy has been compromised by the non-specific and non-sufficient biodistribution and rapid metabolism of clinically used BNCT agents. By incorporating a magnetic resonance imaging (MRI) probe into the NCT agent, it is possible to assess the amount of ^{10}B nuclei that have reached the tumour region, thus offering the possibility of personalised therapy thanks to direct observation of biodistribution. In addition, the non-radioactive isotope ^{157}Gd can also react with neutrons to produce high LET Auger electrons, further enhancing the therapeutic power. Therefore, our research is focused on the development of theranostic agents based on closo-carboranes, with high boron content and in vivo stability, acting as a platform linked to a suitable biological vector and an MRI agent. These agents were administered alone or formulated into nanoparticles capable of improving pharmacokinetics and achieving an appropriate tumour-to-blood ratio.[2] To avoid tumour cell relapse and increase the efficacy of the boron agents, a synergistic strategy was also adopted by coupling the enzymatic inhibition of carbonic anhydrase IX to BNCT. (Figure 1) More recently, our group has envisaged the use of BNCT as a powerful and innovative technique for the treatment of Alzheimer's disease as a means of disaggregating β-amyloid plaques.

The Superintendence of the Sea.
Research, protection, enjoyment, and enhancement of underwater cultural heritage in Sicily

Roberto La Rocca

Regione Siciliana - Soprintendenza del Mare

rlarocca@regione.sicilia.it

The “first” Superintendence of the Sea in Italy was established in Sicily in 2004, thanks to the driving force of Sebastiano Tusa [1]. In the framework of the Department of Cultural Heritage and Sicilian Identity, the main tasks are the protection, enjoyment, and enhancement of underwater cultural heritage. Its activities, based on a multidisciplinary approach that combines historical-archaeological aspects with ethno-anthropological and naturalistic ones, have placed it in a position of European prominence since its inception.

The Superintendence of the Sea, equipped with a highly specialized team (composed of archaeologists, art historians, underwater technicians, restorers, architects, biologists, and chemists), has carried out numerous research projects, excavations, and conservation activities on the seabeds throughout Sicily and its smaller islands over the past twenty years. Many missions have also been conducted abroad (Japan, Kenya, Tunisia, Estonia, Denmark, Libya, Turkey), often in collaboration with prestigious universities. Close collaboration has also been established with law enforcement agencies (Carabinieri and Guardia di Finanza), the Armed Forces (Navy, Harbor Masters, and Air Force), and the Italian and foreign academic world. Numerous scientific publications, conferences, thematic meetings, and awareness-raising activities with schools have been organized. Among the most important achievements, it is worth mentioning the reconstruction of the location and dynamics of the "Battle of the Aegates" in 241 B.C., where 27 rams, numerous helmets, weapons, and onboard equipment were recovered from the traces of the clash between the Roman and Carthaginian fleets. The submerged cultural itineraries, currently 26 realized by the Superintendence, represent a real network of distributed museums that offer the opportunity to visit archaeological sites still in their original location. The current itineraries, already accessible through authorized local diving centers, will soon be even more inclusive, thanks to their adaptation for blind and disabled visitors.

For this year, the Superintendence already has plans to complete the restoration and musealization of the Imperial-era wreck named "Marausa II," which was completely recovered in a complex operation never before realized; the excavation and recovery of the Archaic Greek wreck named "Gela II"; instrumental investigations in deep waters on 11 underwater sites (about 700 square kilometers) with the help of AUVs equipped with Side Scan Sonar; and the new research campaign on the site of the Battle of the Aegates.

Finally, while work has already begun that will lead in a couple of years to the opening of the "Museum of the Sea and Navigation of Sicily" in the historic and monumental building of the Arsenal of Palermo, the restoration and adaptation works of the operational headquarters (former Roosevelt Institute, Addaura) are nearing completion, which will provide a center of excellence for the study and research in underwater archaeology.

Underwater Cultural Heritage: knowledge and conservation

Part 1: Physico-chemical approaches for underwater archaeological metals

Maria Luisa Saladino

Department of Biological, Chemical and Pharmaceutical Sciences and Technologies (STEBICEF)-University of Palermo – Palermo, Viale delle Scienze, Bld.17, I-90128, Palermo, Italy and National Research Council of Italy (CNR), Institute for Chemical-Physical Processes (IPCF), V.le F. S. d'Alcontres 37, I-98158, Messina, Italy.
marialuisa.saladino@unipa.it

The investigation of archeological metals recovered in underwater sometimes is a challenge for a chemist because of the reactions involved in the developing of their corrosion and the lack of information about the environmental conditions. Here, some examples of investigation is reported: the Montefortino-type helmets [1] and the metals fragments (nails and lead sheathings) from the Punic Ship [2], the roman and punic rostrum from the Egadi battles, the orichalcum ingots of Gela [3] and a series of metal objects belonging to the ship's cargo, so-called. For each case-study, an appropriate approach was developed to answer to the archaeological questions, and help to reconstruct the history of the objects. The approaches will be presented to describe possible available information and at the same time clearly show the strong impact of the chemical-physical investigations to unveil a kind of degradation processes developed in the underwater archaeological metals.

Part 2: Underwater Cultural Heritage, balancing conservation, exploitation and sustainability

Silvestro Ruffolo

Università della Calabria, Dipartimento di Biologia, Ecologia e Scienze della Terra, via Bucci, Arcavacata di Rende Cosenza Silvestro.ruffolo@unical.it

Underwater cultural heritage (UCH) represents a significant part of human history submerged beneath oceans, seas, rivers, and lakes. Conservation efforts for UCH aim to protect, preserve, and manage submerged cultural sites for present and future generations. Conservation involves various activities, including site documentation, excavation, artifact preservation, and site monitoring. Conservation strategies must prioritize the protection of UCH from natural deterioration, looting, and damage caused by human activities such as fishing, maritime traffic, and industrial development. Additionally, international frameworks such as the UNESCO Convention on the Protection of the Underwater Cultural Heritage (2001) provide guidelines for the preservation and management of UCH at the global level. Since then, several goals have been achieved in the framework of the protection of UCH, particularly concerning the examination of stone materials, degradation processes, and novel methodologies for in-situ consolidation and protection. This contribution centers on scrutinizing the primary findings derived from numerous investigations conducted thus far, offering supplementary guidelines for practitioners in the UCH domain, including restorers, archaeologists, conservation scientists, geologists, among others. These guidelines serve as a pivotal factor in augmenting understanding, management, protection, and promotion of underwater sites. Several case studies, such as Baiae in Naples, demonstrate the diverse approaches to managing UCH and the importance of balancing conservation, exploitation, and sustainability.

The preservation of historical violins between restoration, function and enhancement

Fausto Cacciatori

Museum of Violin, Piazza Marconi, 26100 Cremona
curator@museodelviolino.org

The violin as well as all bowed string instruments require special attention from a conservative point of view, being composed mainly by wood and organic materials.

The focus on microclimatic control is based on the interaction of wood with the environmental thermo-hygrometric parameters and with all aspects related to the biological degradation processes, including the xylophagous attack. It is also important to highlight that the case of musical instruments as a class of historical artifacts often involves their use and therefore the fact that they can be played can represent a potential negative effect on their state of preservation.

The new control procedures developed at the Violin Museum in Cremona, based on maintenance and conservation procedures, also through preventive diagnostic campaigns, is an interesting case of control and evaluation of their conservation status.

Invasive and non-invasive diagnostic techniques for the study of violin historical materials

Marco Malagodi

Department of Musicology and Cultural Heritage, University of Pavia, C.so Garibaldi 178, 26100 Cremona, Italy
marco.malagodi@unipv.it

Scientific and technical studies of ancient musical instruments have seen an important development in recent years with a particular attention to string instruments and especially violin. The study of this extraordinary historical artifact that was born in the first half of 1500 involves some different scientific perspectives that must dialogue with each other and that deal with interdisciplinary and connected issues.

Thus, the study of violins has been in the last ten years an important aim for several scientific and diagnostic researches.

The studies have been performed by new non-invasive analytical protocols that have allowed to shed light on some construction techniques and on different classes of materials historically used by important luthiers such as Stradivari or Guarneri.

The main spectroscopic and imaging techniques, as well as facilities such as synchrotron light, have allowed to characterize the original varnishes, grounds and wood treatments. In addition, micro-invasive analyses[1] performed on cross-section have deepened the studies on the different layers and thickness of the different treatments.

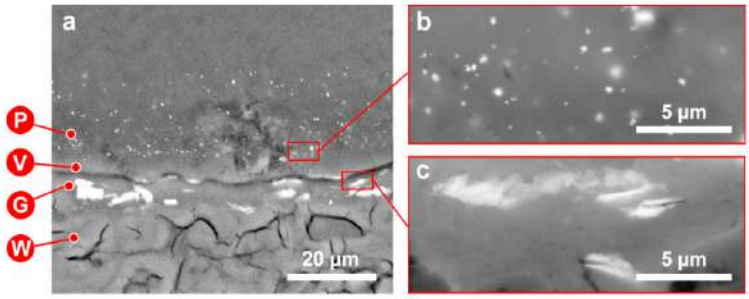

Figure 1: BSE-SEM images of cross section from violin

The role of science between research, protection, and fruition of cultural heritage: a 20-year experience at the CCR "La Venaria Reale"

Federica Pozzi

Centro per la Conservazione ed il Restauro dei Beni Culturali "La Venaria Reale",
Via XX Settembre 18, 10078 Venaria Reale (Turin), Italy
E-mail: federica.pozzi@ccrvenaria.it

Museum galleries and heritage sites worldwide house countless artifacts of enormous historical, artistic, and monetary value, many of which have come down to us from the distant past and each of which requires tailored care in order to be passed on to future generations. Increasingly, over the years, the protection and enjoyment of cultural heritage objects has based its identity on the contributions made by conservation science, a technically complex field at the intersection of chemistry, physics, biology, geology, materials science, and engineering. The scientific investigation of artifacts of archaeological, historical, and artistic significance often constitutes a multifaceted endeavor, combining multiple aspects such as dating of the works, analysis of their material composition, degradation studies, and environmental monitoring. The development of cutting-edge technologies and, more broadly, fundamental research provide conservation scientists with essential tools to meet the needs typically encountered in this field: among them, the need to preserve the physical integrity of particularly delicate artifacts, which cannot be moved outside of museum galleries, storages, or conservation studios, by carrying out investigations in situ and in a non-invasive manner; the availability of highly specialized analytical techniques that are able to deliver an increasingly more detailed characterization of materials of different nature; and the development of innovative instrumentation enabling the continuous monitoring of the works' state of preservation as well as ongoing conservation treatments. Through relevant case studies tackled over the years at the CCR "La Venaria Reale", this talk aims to illustrate the crucial role of science and the challenges currently faced in the field of conservation and cultural heritage research.

KN-044

Cutting-edge investigation methods in the field of non-invasive and micro-invasive analytical approaches for diagnostics applied to heritage studies and conservation

Bruno Brunetti, Consorzio INSTM, Università di Perugia e Associato CNR-SCITEC brunetto.brunetti@unipg.it

Maria Perla Colombini, Dipartimento di Chimica e Chimica Industriale dellUuniversità di Pisa, maria.perla.colombini@unipi.it

Part I, Bruno Brunetti: MOLAB laboratory: from single point analysis to hyperspectral imaging

Non-invasive identification of chemical composition of a polymateric work of art is one of the specific tasks of diagnostics applied to heritage studies and conservation. In this field, characterized by investigations carried out in situ, with no sampling and even no contact with the examined object, single point analytical measurements have led during the last decades to the achievement of powerful results in studies of paintings, sculptures, manuscripts, ceramics, etc.. However, a more complete answer to the questions posed by heritage professionals, today comes from the identification of materials coupled with information on their semi-quantitative spatial distribution on a macroscopic scale (surfaces of thousands cm2).

In recent years, some efforts of heritage science have been addressed to the development and applications of hyperspectral analytical imaging/mapping techniques, which led to significant results thanks to the exploitation of innovative instruments and methodologies. Along this line of development, the MOLAB laboratory, born in the early 2000s with the first projects for the establishment of the E-RIHS infrastructure (E-RIHS-http://www.e-rihs.eu/), has recently strengthened its own analytical potential, open to the access of Italian and European researchers, with the introduction of systems for hyperspectral imaging/mapping, thus ensuring an effective alignment of its services to the most advanced analytical methodologies required by the sector. Recent applications of traditional and established imaging techniques will be described, along with innovative methodologies that, based on multimodal/integrated approaches, probe different chemical properties and unexplored spectral ranges.

Part II, Maria Perla Colombini: Shedding light on the organic materials in artistic and archaeological objects by chromatography-mass spectrometry

A detailed understanding of the organic chemical composition of archaeological objects and paintings is crucial for identifying not only the original materials but also for enabling the detection of materials added during restorations or those induced by time and pollution. Additionally, it aids in comprehending the function of archaeological objects. Chemical characterization integrated with historical and archaeological data, has significantly advanced our understanding of past painting techniques and technologies.

Chemical analysis of organic materials poses challenges for chemists due to their complex compositions, susceptibility to degradation processes from aging, environmental factors, and human activities (e.g., heating processes applied to plant resins). Moreover, these materials are often present in very low quantities compared to inorganic materials.

Currently, techniques based on chromatography and mass spectrometry, including SIFT-MS (selected ion flow tube mass spectrometry), EGA-MS (evolved gas analysis mass spectrometry), Py-GC-MS (pyrolysis gas chromatography-mass spectrometry), GC-MS, and HPLC-MS, play a crucial role in analytical procedures for artistic and archaeological objects. The lecture focuses on current analytical procedures based on chromatography-mass spectrometry techniques that allow the characterization of macromolecules in archaeological objects and paintings, demonstrating their utility in integrating historical and archaeological information. Case studies will be discussed to illustrate the practical application of these techniques in providing valuable insights into the composition and preservation of cultural heritage.

Methodologies and experiences in comparison in the field of paper restoration

L. Montalbano

Opificio delle Pietre Dure, Fortezza da Basso, Firenze

letizia.montalbano@cultura.gov.it

The *Opificio delle Pietre Dure* (OPD) is an autonomous institution within the Ministry of Culture in Italy. Its mission concerns in all aspects fine art conservation, including treatment, research, education and training. OPD is divided into distinct departments of conservation categorized according to the various materials and techniques used in the creation of works of art. The Paper and Parchment Department Conservation deals whit the conservation and restoration of traditional media, including drawings, prints, preparatory cartoons, and a wide range of paper-based decorative objects, as well as the restoration materials and their possible interaction. Research finalized to diagnostics and knowledge of works of art materials and their deterioration is a key activity of OPD. The application of modern nanotechnologies and materials has been intensively investigated in the last decade in cooperation with distinguished partners as CSGI & University of Florence, whose contribution was fundamental for the development of specific intervention protocols carried out at OPD. Among others, many efforts have been addressed to consolidation of graphic media and supports (e.g. modern papers), treatment of photographic materials, removal of stains and aged pressure sensitive tapes (PSTs).
This contribution will report on some illustrative examples which include drawings, printings, and manuscripts.

Nanostructured materials for the conservation of graphic documents

R. Giorgi

[a]*CSGI & University of Florence, Dept. of Chemistry, via della Lastruccia 3, Sesto Fiorentino*
rodorico.giorgi@unifi.it

Graphic documents constitute one of the pillars of our cultural identity and legacy. Unfortunately, they often suffer severe degradation pathways due to both endogenous and exogenous factors, which favoured chemical alteration and a consequent loss of mechanical properties. Sometimes the effects of such processes are also strongly amplified by wrong past interventions. The conservation of these valuable objects is very challenging, requiring a continuous development of innovative solutions, which must meet several constraints: eco-sustainability of the treatment, chemical compatibility of materials, long-term stability, cheapness.

Nanoscience is nowadays providing innovative and effective technological solutions in a wide range of applicative fields. Among others, nanomaterials have hugely enriched the palette available to conservators to rescue and protect works of art. The aim of the present contribution is to provide an up-to-date overview of the main achievements of CSGI, which pioneered the use of nanostructured materials in this field, on the use of advanced colloidal systems tailored to the conservation of graphic documents.

Consolidation of graphic media and removal of undesired detrimental materials represent two of the most serious concerns of conservators. Highly retentive organogels loaded with green solvents are very promising and efficient tools to achieve controlled and complete removal of aged pressure sensitive tapes (PSTs), largely used in the past to repair torn or weakened pages. The main effects of natural aging of PSTs are their colour variations, stains formation, and loss of adhesion. For that, a complete removal of them is usually necessary, but the commonly used procedures are sometimes ineffective. Weakly bound dyes or inks, typically found in graphic art, represent another complicated conservation challenge. Unfortunately, the commonly used practices rely on the use of synthetic or natural adhesives, which are not fully satisfactory, because they may alter the optical properties of surfaces. Nanostructured starch-based systems have been recently obtained and investigated. A bottom-up approach was followed to obtain a gluten-removed *Jin Shofu* wheat starch that was gelatinized and then precipitated in a non-solvent to obtain a stable dispersion to be used by nebulization.

Successful interventions recently performed on valuable objects using these novel solutions will be described.

A Nobel Prize to shape our future. An example of technology transfer

Maurizio Stefano Galimberti
Department of Chemistry, Materials and Chemical Engineering "G. Natta", Politecnico di Milano, Via Mancinelli 7, 20131 Milano, Italy
maurizio.galimberti@polimi.it

Many stereoregular polymers exist in nature, for example cellulose and rubber. Giulio Natta broke the monopoly of nature for the synthesis of stereoregular polymers with a high degree of order, as it was stated on the occasion of the awarding of the Nobel prize to Prof. Ziegler and Prof. Natta. Isotactic polypropylene is the most famous stereoregular polymer and is also the most widely used polymer today. But professor Natta and coworkers prepared more than one hundred new polymers and, among them, a large number of polymers with different stereoregularity. "The results are of extraordinary interest; perhaps one should call them revolutionary in significance" said Paul Flory. Giulio Natta was named as the "father of stereospecific polymerization".

This revolutionary adventure was characterized by interdisciplinarity and by a tight cooperation between University and Industry, i.e. between Politecnico di Milano and Montecatini, which provided sufficient funding to set up an advanced training school and to form an important research group at Politecnico. Many young researchers belonging to Montecatini worked in the labs of Politecnico, interactions were deep and continuous, also on a daily basis, in the academic and industrial sites. The time to market of isotactic polypropylene was of only three years.

The scientific rigour and the originality of Giulio Natta's research throughout his career were often directed at solving industrial problems. The Nobel Prize for the discovery of stereospecific polymerization is the brightest example of how goals for industrial development and collaboration with forward-looking companies can benefit basic research.

The legacy of Giulio Natta is fundamental to shape our future, inspiring the eco-design of sustainable polymers.

Sustainability evaluation to support technological transfer: a case study.

Elza Bontempi [a]

[a] *INSTM and Chemistry for Technologies Laboratory, University of Brescia, via Branze 38 - 25123 Brescia*

Benefits associated with the development of new green markets due to the diffusion of new suitable technologies may be substantial. For example, Meyer [1] evaluated that resource efficiency improvements may allow to obtain 17–24% of raw material savings with a cost savings of more than €600 million in Europe. However, in general, despite continuing dramatic increases in published research about new proposed sustainable technologies, there has been poor exploitation in an industrial context of such results.

The discrepancy between scientific and applicative results may be attributed to several reasons, such as the absence of a suitable legislative framework, the lack of transferability of the research results, and/or the high cost of the stabilized (or synthesized) secondary raw materials. Another reason why new technologies are not widely used in industry may be also attributed to the lack of knowledge about their real convenience. This presentation aims to present a tool (ESCAPE) designed to evaluate the sustainability of new emerging technologies, in terms of involved energies and emissions, in comparison, to a reference one [2]. This approach is expressly designed to support laboratory studies that often need preliminary evaluations, allowing the comparison with already available natural and/or commercial materials/technologies. The use of this tool is extremely promising in increasing the resilience of industries. The presentation will demonstrate the potentialities of using the ESCAPE index in materials design synthesis strategies (Fig. 1), with the possibility to account for the difference in countries' energy mix (that derives from the local mix of fossil and non-fossil fuels). This approach can support the rapid and flexible change of strategies, supporting technological transfer.

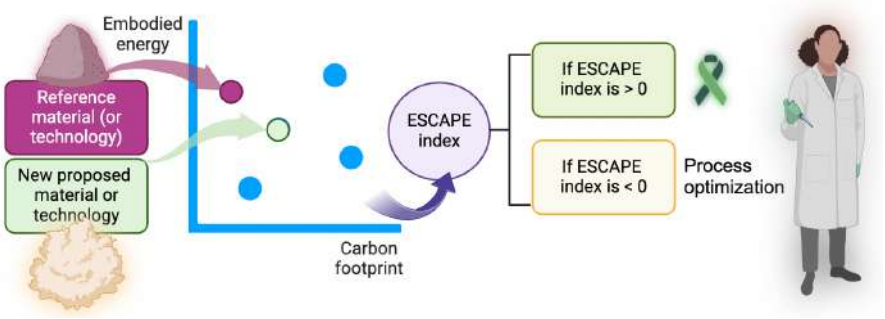

Figure 1: The ESCAPE index evaluation. The figure was realised with Biorender

WembraneX s.r.l. is an Italian start-up founded in September 2023 with the ambition to make a significant contribution to the United Nations Sustainable Development Goal 6: Ensure Access to Clean Water and Sanitation for all by 2030. The Company aims, as its first target, to step-change the performance of municipal wastewater treatment facilities by significantly reducing membrane fouling, which is their largest operating cost challenge. It also aims as a second target to address complex industrial separation processes in Food and Beverage, Textiles, Pharmaceuticals and Chemicals. The operating performance improvements are achieved thanks to a proprietary coating technology developed by WembraneX and applicable on commercially available substrates. The unique coating technology was originally developed by the researchers of the Institute on Membrane Technology (CNR-ITM) in collaboration with the University of Calabria (UNICAL) and the Karlsruhe University of Applied Sciences (HSKA, Germany) within the framework of a EU project (BIONEXGEN, GA n.246039) and later redefined to create a new class of membranes with superior anti-fouling characteristics. The technology was further validated in a second EU project (VICINAQUA, GA n. 689427,) where the newly developed membranes were applied in wastewater treatment processes in the Lake Victoria region (Kenya). In 2021, the technology was selected and funded by Progress Tech Transfer s.r.l. (MITO technology), within the call for Proof of Concept (PoC) with the aim of further validate the coating process on a larger scale. The novel coating has already shown excellent benefits at the lab-scale which are described in papers published in several international journals[1,2,3]. The coating technology is protected by a patent (WO 2015/044335) exclusively licensed to WembraneX[4].

PolyCrystalLine – When a good scientific idea is met with passion and competence a company is born.

Dr. Stefano Luca Giaffreda

PolyCrystalLine Spa, Via della cooperazione 29, Medicina (BO)
slg@polycrystalline.it

A journey between dreams, hopes and a great desire to get involved. PolyCrystalLine represents a good example of how a scientific idea becomes an opportunity and the opportunity becomes a company when it is supported by a lot of passion, competences, tenacity and finally perseverance. PolyCrystalLine represents a message for next generation of scientist and/or graduates in general on how an academic spin-off can become a company if behind there is a good idea and know-how.

Technology Innovation to enable Polymer Circularity: *MoReTec,* from inception to industrialization

Gabriele Mei

Basell Poliolefine Italia, P.le Donegani 12, Ferrara

The chemical industry is going through a transformation towards a sustainable and circular approach. Society, consumers and regulations are driving an increased demand for sustainable solutions and low carbon footprint materials.

To realize this transformation post-industrial and post-consumer plastic waste will be the new feedstocks of the polymer value chain. Realizing true circularity and contributing to addressing climate change by displacing fossil-based raw materials and ultimately ending the plastic waste problem.

Technology development will play a fundamental role in this transformation and Innovation will be instrumental to advance the circularity of plastics through complementary pathways: mechanical recycling, advanced recycling and the use of renewable-based feedstocks.

The development of advanced recycling technologies is complementary to mechanical recycling as it addresses hard-to-recycle post-consumer mixed plastic waste that today end up in incineration and landfills and serve applications requiring high purity such as food packaging and healthcare.

Due to this urgent need, LyondellBasell has accelerated the development of its advanced recycling technology, called *MoReTec*. Starting from break-through research at LYB labs in 2018, a pilot plant was built to test the process technology and develop the scale-up design. The engineering for a commercial scale plant progressed and the investment was approved in 2023: the industrial unit is scheduled to be started up in early 2026.

LyondellBasell's *MoReTec* technology is based on an innovative process, uses proprietary catalysts, it is suitable for large scale plants, it is characterized by low carbon footprint and produces feedstocks that can be utilized in the existing olefins crackers.

Corporate Open Innovation- Barilla case

Claudia Berti- Global Open Innovation & IPR

Barilla G. e R. Fratelli S.p.A.

via Mantova 166- Parma- Italy
claudia.berti@barilla.com

Open Innovation (OI) is a concept invented in 2003 by Henry Chesbourg, an organizational theorist that is based on the central idea that companies cannot afford to rely entirely on their own research for innovation. It encourages collaboration, even with competitors, to enhance efficiency and discover new solutions. The diversity of perspectives in this model fosters innovation.

In the context of the food industry, open innovation is particularly important due to the constant changes in demand and supply, and the escalating competition. The industry has shifted its focus towards customer satisfaction, producing goods that align with customer demands. This requires innovative solutions and technologies, which can be facilitated through open innovation.

However, the application of open innovation can be hindered by multiple barriers, especially cultural factors and to maximize success and reduce frictions it is crucial to establish a clear governance and specific initiatives to broaden access to participants and expertise, enhance quality of innovation outputs and product impact on business.

Source- Internal Barilla

Barilla has started its open innovation journey in 2011, when a dedicated role has been formalized. At that time the main goal was to ensure flowless connections with academia and research centers. Since then the

Technology transfer for sustainable industrial development

P. Vacca

Group Research Labs, SAES Getters S.p.A., viale Italia, 77, Lainate (MI)
paolo_vacca@saes-group.com

Technology transfer can play a key role in boosting companies growth in dynamic and competitive business landscape. The overall process mainly consists of knowledge, technologies and intellectual property sharing from between companies, research laboratories, academic institutions for the purpose of combining together different assets to create value through the development of innovative products, services, or solutions.

Since its establishment, SAES has been continuously engaged in radical research activities to develop new materials and technologies supporting a long-term perspective that continuously puts the company on the edge of innovation. In particular, many efforts have been devoted during last fifteen years to develop new technology platforms able to create new materials [1-4], ranging from functional additives to composite formulations, where sustainability and flexibility are the innovation drivers. In this context, SAES has been adopting different forms of technology transfer including i) inbound technology acquisition from academic Spin-offs to further develop an innovative technology based on nanostructured materials; ii) Joint-venture approach to establish a new entity to develop a new technology for display applications; iii) collaborative R&D involving research centres to work together on the development of a new membrane based process to create a new class of chemical materials; iv) high-tech hub for advanced materials Start-ups to sustain the development of new technologies helping bridge the gap between R&D and industrial applications.

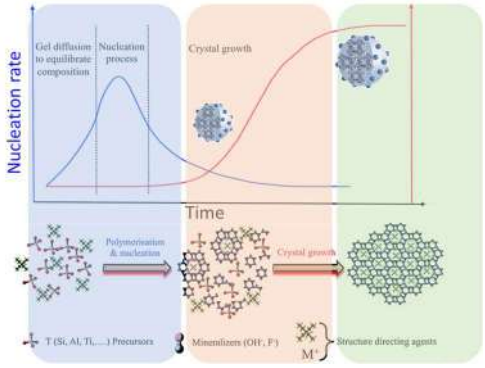

Figure 1: Zeolites technology platform developed through a technology transfer approach

SAES experiences in applying technology transfer approaches will be presented and discussed in terms of materials platform and process characteristics from lab scale to industrial feasibility.

Pharma Innovation & Business in Italy: Nurturing potentials in an underestimated environment thorough EXTEND, a unique structured partnership between Accademia, VC and Pharma

Antonio Felici, PhD

Vice President, Academic Partnership
Evotec S.E.

The pharmaceutical landscape in Italy is undergoing a transformative phase, driven by a convergence of factors such as technological advancements, global health challenges, and changing therapeutic modalities. Amidst this dynamic environment, the concept of innovation has taken center stage. In this context, the collaboration between academia, venture capital (VC), and pharmaceutical companies becomes pivotal.

EXTEND, a translational bridge joint venture, was founded collaboratively by CDP Venture Capital, Evotec and Angelini Ventures in 2022. This unique initiative aims to accelerate the development and commercialization of promising assets originated within Italy's academia and emerges as a catalyst for nurturing untapped potentials within Italy's pharmaceutical ecosystem.

Academic institutions play a crucial role in fostering innovation. By bridging the gap between research and practical application, they provide a fertile ground for novel ideas. EXTEND leverages the expertise of Italian universities and research centers, encouraging collaborative projects that address unmet medical needs.

Venture capital firms bring financial backing and strategic guidance. Their involvement in EXTEND ensures that promising innovations receive the necessary resources to flourish. By connecting accademia and early-stage ventures with established players, VC firms facilitate knowledge exchange and accelerate product development.

Established pharmaceutical companies often face challenges in adapting swiftly to disruptive changes. EXTEND offers a structured platform for these industry giants to collaborate with academia and startups. By sharing insights, resources, and risk, pharma companies can explore novel business models, streamline R&D processes, and enhance market access.

Italy's pharmaceutical ecosystem has immense potential, yet it remains underestimated on the global stage. EXTEND recognizes this discrepancy and aims to unlock latent opportunities. By fostering cross-sector partnerships, it seeks to elevate Italy's position as a hub for innovation, clinical trials, and commercialization.

In conclusion, EXTEND represents a paradigm shift, a departure from siloed approaches toward a holistic ecosystem that thrives on collaboration. As Italy's pharma landscape evolves, this structured partnership holds the promise of unlocking breakthroughs, benefiting patients, investors, and society at large.

Drama Science, Diversity, and Inclusion

T. Cecchi,[a] A. Giuliani,[a]

[a]*ITT "G. e M. Montani", Via E. Bellesi 22, Fermo*
cecchi.teresa@istitutomontani.edu.it

Carolyn Bertozzi, who was awarded the 2022 Nobel Prize in Chemistry for the development of bioorthogonal chemistry, is among the 25 female Nobel laureates in STEM subjects; almost 600 men shared this honour. Carolyn Bertozzi is an extraordinary "role model" for the inclusion of women in STEM subjects. She is also an advocate for diversity as an open lesbian in academia and science.

This contribution reports on a drama science tribute to her research focus on sugars. The theatre piece was designed and prepared during the first curricular course of Outreach in an Italian secondary school (ITT "G. e M. Montani" Fermo) and will be performed on the 5th Nov 2024 in Turin by chemistry students. It follows that it is also an innovative educational experiment. Since 2012 extra-curricular projects have been combining the formal learning of chemistry with informal, exciting and stimulating on-stage spectacular experiences because acting in science festivals, videomaking, photo essays, and experiment mastering increase students' understanding[1]: a positive emotional energy in outreach events[3 4 5 6] stimulates a greater propensity to propose explanations[2].

We will show (live with two students / reels) the spectacular chemistry of sugars whose didactic importance is beyond any dispute. In particular, the well-known oxime/hydrazone formation from aldehydes and ketones, commonly practiced by students, will be shown to be a ligation strategy that fulfils the requirements of bioorthogonality, discussed by Carolyn Bertozzi in the Nobel Prize lecture "The Bioorthogonal Chemistry Journey, from Laboratory to Life" delivered in 2022 at the Stockholm University.

The performance aims at inspiring young girls to be #"STEMerarious" and engage with chemistry, which is a crucial tool for civil commitment.

Contribution of catalysis and process optimization to improve sustainability in thermoset materials

C. Cortelli,[a]

[a]*Polynt SpA, Via E. Fermi 51, 24020 Scanzorosciate, Italy*
e-mail: carlotta.cortelli@polynt.com

Composite thermoset materials play a key role in green transition as they are widely used in the production of renewable energy and in the electrification, production, and transport of hydrogen. There are also many other essential applications in transportation, building and construction, and infrastructure. Therefore, decreasing the carbon footprint of thermoset polymers and composite materials is key in achieving better sustainability and targeting the Green Deal objectives.

Among thermoset polymers, unsaturated polyester resins (UPR) are the most important polymers used in the production of fibre-reinforced articles. Two very important raw materials (building blocks) for UPRs are maleic (MA) and phthalic (PA) anhydrides, industrially produced by catalysed gas phase oxidation reactions of n-butane (MA) and o-xylene (PA).

Even if the industrial processes to produce MA and PA are well consolidated and have been used worldwide for decades, continuous and incremental improvements in catalyst performances are sought to improve process yields and contemporaneously decrease CO_2 emissions, thus decreasing the carbon footprint of the entire production chain of composite materials (Figure 1). In parallel, breakthrough research activities are focused on using renewable raw materials and developing lower energy consumption processes to further improve the sustainability of these monomers.

In developing new solutions, the availability and cost of renewable raw materials, as well as investment costs needed to implement new sustainable processes, must be carefully considered, as they could be barriers to the achievement of sustainability targets.

CO_2: from a Waste to a Resource in the Energy Sector

R. Millini[a]

[a] *Eni S.p.A., Research & Technological Innovation Dept., Via F. Maritano 26, I-20097 San Donato Milanese, Italy*
roberto.millini@eni.com

The progressive accumulation of greenhouse gases of anthropogenic origin, in particular CO_2, in the atmosphere is one of the main problems that mankind must face today and in the near future. In fact, to contrast climate change it is necessary to contain the increase in the average earth temperature within 1.5°C compared to the pre-industrial era, as defined in the COP21 in Paris in 2015. This means eliminating GHG emissions well before the end of this century, preferably by 2050[1]. The *Net Zero Emissions* is a very challenging target, especially when considering that the main source of CO_2 is the energy sector which, in 2022, was responsible for the emissions of 36.8 $Gtonn_{CO2}$, 1% above the pre-COVID level[2].

To achieve this target, it is necessary to implement actions that lead to the progressive reduction of the use of fossil sources: increasing energy efficiency, development of renewable energy sources, electrification of transport and buildings are among the most frequently requested actions, but these require a radical time-consuming and expensive adaptation of the infrastructures. For this reason, the scenarios attribute an important role to Carbon Capture Utilization and Storage (CCUS), i.e. to the ways that envisage limiting CO_2 emissions through its capture, e.g. from flue gas, and permanent sequestration in suitable geological formations (CCS) or its use for the production of goods or services with market value (CCU). In this regard, the reuse of CO_2 as a carbon source is attracting more and more attention and extensive R&D activities are now focusing on its conversion into building materials, polymers and chemicals, sustainable synthetic fuels (e-fuels), the latter having a direct impact on the energy sector. In particular, e-fuel are intended to play a role in the transport sector, in particular, for the so-called *hard-to-abate* segments, aviation and marine for which electrification and the use of H_2 are difficult, at least in the medium-long term. e-fuels have very similar characteristics to the corresponding fossil fuels, and this makes them compatible both with the existing transport, distribution, and storage infrastructures, and with the current engines.

e-fuels, whether gaseous (methane) or liquid (methanol, dimethylether, gasoline, diesel, jet fuel) are produced by direct or indirect reduction of CO_2 captured either from concentrated sources (e.g., flue gas), from the air (Direct Air Capture, DAC) or of biogenic origin (e.g., from biogas). For the CO_2 reduction to fuel, green H_2 from electrolysis of water and renewable electrical energy are also required.

Here, the catalytic production processes of the main e-fuels will be briefly examined together with the limiting factors that may hamper their diffusion and the environmental benefits associated with their use.

Ziegler Natta Catalysts & Polypropylene : 70 years of continuous advancement

Ugo Visentini

Giulio Natta Research Center, LyondellBasell Italy, Piazzale Donegani 12, 44122 Ferrara, Italy

ugo.visentini@lyondellbasell.com

Since the discovery in 1953 in Mulheim by Prof. Karl Ziegler of the polymerization of ethylene catalyzed by transition metals and then the following year by Prof. Giulio Natta (11 march 1954),who demonstrated that the same catalyst could produce isotactic polypropylene, the development of Ziegler Natta catalysts evolved rapidly.

Together with technologies development focused on more efficient processes and driven by market products requirements, the development of catalytic systems used for the industrial production of polypropylene since the discovery of Giulio Natta passed through important milestones from first generation catalysts ($TiCl_3$ based) to more advanced catalytic systems based on $MgCl_2$ combined with different classes of internal donors as Phthalates (IV generation catalyst) and more recently also Diethers and Succinates (V generation catalyst).

These new donors classes contributed significantly to polymerization processes improvements and to introduction into markets of innovative polymeric compounds; and the journey is not over…

Finding Common Ground: A Modest Proposal for Effective Chemistry Communication Beyond Chemophilia and Chemophobia

Massimo Trotta[a] and Riccardo Lucentini[b]

[a]*Consiglio Nazionale delle Ricerche – Istituto per i Processi Chimico Fisici, Via Orabona, 4 Bari,*
[b]*Consiglio Nazionale delle Ricerche – Istituto per la Sintesi Organica e la Fotoreattività, Via Gobetti, 101 Bologna*
massimo.trotta@cnr.it

In modern technological societies, followers of chemtrail conspiracy theories and science enthusiasts coexist, for the most part, peacefully. On one side, an irrational and disproportionate fear or apprehension surrounding chemistry applications in everyday life is a constant presence in society. This at times escalates to the highest levels where political decisions are made, thereby exacerbating misconceptions about chemistry and its implications[1]. Chemophobia stems from a variety of events, some of which trace back to domestic[2] or international[3] industrial disasters rather than inherent aspects of chemistry. These incidents provoked a collapse of trust towards a fundamental science like chemistry within segments of the population. Conversely, many of us have witnessed the enthusiastic engagement of students, educators, and the general public in outreach events such as the European Researchers' Night. These events showcase the breadth of science and its tangible effects on people's everyday lives in engaging and inspiring ways[4], contributing to the gradual rebuilding of trust that has faded over recent decades. Yet, these events or how media are engaged with representation of science can generate bombastic and unwarranted optimism among the public or stakeholders, who may believe that a solution is imminent or that a problem has been effectively resolved[5].

The communication approach frequently contributes to polarization in discussions, creating the perception of two major opposing factions. However, within the spectrum spanning from followers of chemtrail conspiracy theories to fervent science enthusiasts, lies a significant portion of the public encompassing a broad spectrum of individuals. It is within this demographic that our interaction is most crucial. Our aim is to emphasize to our audience that chemistry represents the science of progress, acknowledging both its achievements and the inherent risks and failures like any in all human endeavors. We advocate for an intellectually honest approach that steers clear of pushing people from chemophilia to chemophobia.

Metaversity, a place where Education, Communication, and Outreach are innovative

P. Grieco

Department of Pharmacy, University of Naples 'Federico II', via D. Montesano 49, 80131, Naples

paolo.grieco@unina.it

We are witnessing a new revolution in computing thanks to the virtual technologies of the Metaverse. The idea of developing virtual or augmented reality systems for use in scientific and educational fields is not new as it was born a few years after the introduction of the first computers but was also inaccessible until a few years ago due to the high cost of the technology. The immense power of PCs and all communication systems, including the latest smartphones, combined with recent advances in information technology and the ability to operate in a virtual environment, has made the metaverse widely accessible even on mobile devices. And so, we are witnessing a rapid development of virtual reality (VR) and augmented reality (AR), opening up scenarios and new potential in all sectors. The novelty of virtual reality can engage and motivate students more than current teaching approaches and can therefore have a high motivational impact on learning. Like all new technologies, this approach is also extremely useful in the training field, where it is already enjoying enormous success, especially in the academic field. For this reason, the term "Metaversity" was coined, i.e. an academic world where the transmission of knowledge passes from the teacher to the student using innovative methodologies for learning conveyed by digital platforms. In this communication, various scientific-educational approaches will be presented based on both augmented reality and virtual reality, with the aid of smartphones, pads, and dedicated viewers, to experience the virtual world of Metaversity.

The Virtual Laboratory Framework: Blending Computation, Representation and Visualization from Quantum Chemistry, through Machine-Learning, to Virtual Reality

Federico Lazzari

Scuola Normale Superiore, Piazza dei Cavalieri, 7 – 56126, Pisa
federico.lazzari@sns.it

The field of Computational Chemistry demands care not only for the modeling of chemical systems but also for intricate technical aspects; from creating complex inputs files, through submitting computations, to interpreting numerical results. Amidst this complexity, the chemical insight into phenomena becomes obscured[1]. Notably, this challenge extends beyond researchers; it impacts the access to such computational tools in science education and teaching. In this context, the Virtual Laboratory[2,3] emerges as a transformative framework. It seamlessly combines the three critical steps of a computational workflow: computation, representation, and visualization. The goal is to create a user-friendly experience for both researchers and the general audience, allowing even non-experts to easily perform simple computational chemistry tasks. From the computational point of view, recent advancements in quantum software and processors, including novel ARM architectures[4], have ushered in a new era of computational power. Moreover, the boom in cloud computing and web-technologies[5] facilitates complex quantum simulations, transcending the limitations of traditional workstations. From the representation point of view, the explosive growth of Machine Learning empowers data extraction from raw inputs. This means automating the extraction of critical information, guiding scientists (and even non-experts) toward essential patterns in data that might otherwise remain elusive. From the visualization point of view, the market has witnessed an unprecedented surge in GPU capabilities, enabling intricate molecular representations. Beyond smartphones, new platforms like Meta Quest and Apple Vision Pro have democratized access to augmented and virtual reality. These immersive environments redefine how we perceive and interact with scientific data. The following contribution explores how Web technologies allow the use of Molecular Perception[6] and ML algorithms in Immersive Virtual Reality contexts, both for research and education. The case studies considered are an Interactive Molecular Editor and two computational tools (The BPCS1[7] and the Templating Synthon Approach[8]).

Chemistry and Complexity Science allied together for a better future

Pier Luigi Gentili[a]

[a]*Department of Chemistry, Biology, and Biotechnology,*
Università degli Studi di Perugia, Via Elce di Sotto 8, 06123 Perugia
pierluigi.gentili@unipg.it

In the last forty years, humanity has changed radically. The world population has grown over 8 billion in number. Humans are highly interconnected due to the fast means of transport and the World Wide Web. Individuals and societies, their thoughts and cultures are highly intertwined, as the national politics and economies are. In a nutshell, humanity has become a vast network. A problem in a community or a sector regards directly or indirectly everyone on Earth. Any local accident or issue can have global repercussions. Therefore, we are called to face global challenges. It is compelling to prepare new generations to tackle the global challenges of this new century. A paradigm shift in education is required. It is urgent to propose interdisciplinary courses[1]. In these courses, Complexity Science plays a relevant role.[2] Complexity Science is an "in-fieri" scientific theory that describes Complex Systems' features involved in global challenges[3-5]. Students learning Complexity Science discover that systems as diverse as ecosystems, the macroeconomy, cells, chemical reactions, climate, and societies have many common points. Furthermore, they learn that science faces substantial limitations in predicting the behaviours of complex systems. Students understand the reasons for these limitations and become acquainted with strategies to tackle them.

This contribution demonstrates that chemistry students should learn Complexity Science to achieve an interdisciplinary perspective on Complex Systems and systems thinking and promote sustainability. Such an approach favours the development of the "one-world chemistry" concept[6], according to which chemistry plays a pivotal role in the health of human beings, animals, and the environment.

Communicating Science. A creative and ethical challenge

M. Polidoro

Affiliation 1, Address, City
msmpolidoro@gmail.com

The secret of good communication lies in the ability to ignite a spark capable of stimulating the listener's curiosity. Researchers, however, usually tend to speak to colleagues or students, and rarely have a chance to develop the communication skills necessary to talk to and engage a lay public. This talk will provide participants with a simple toolbox of creative and reasoning tools that are essential in order to improve their ability to express themselves in an ethical and easily understandable way.

Stranger Molecules: chemistry becomes art

R. Lucentini,[a] O.Bettucci[b],R.A. Pucciarelli[c]

[a]*Fondazione Ri.MED, via Bandiera 11, Palermo*
[b]*Università degli Studi di Milano Bicocca, Dipartimento di Scienza dei Materiali, Via Cozzi 55, I, Milano*
[c]*Accademia di Belle Arti, Via Giuseppe Re David, 189, Bari*
ricky_l@hotmail.it

Chemistry's beauty lies in our ability to handle and assemble atoms and molecules, which can take on strange and twisted shapes: since in every molecule there always is a shape-property relationship, as chemists we are obsessed with three-dimensional structures of our creations. Each of us wants to put atoms in the right position to obtain the desired properties. This is an utilitarian mindset, typical of applied research and of technological transfer. There is also an opposite, funnier and stimulating approach: a chemist can think of a design, recreate it at molecular level by joining various atoms together and afterwards investigate the properties of the substance. Chemistry thus becomes a form of art that embraces beauty without worrying about possible applications[1]. We have chosen 3 molecules with a strange structure, inspired by mathematics and engineering: Infinitene[2], Cubane[3], Nano-Cars[4]. We will tell their stories to show how there is no uselessness in scientific research and that even molecules created for fun are a fundamental piece in construction of the jigsaw of knowledge.

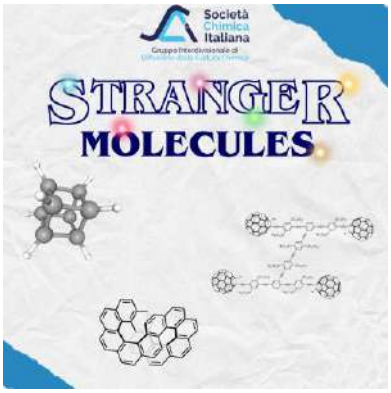

Figure 1: Cubane, Infinitene and Nano-Cars are the main characters of the lecture.

"It's not just a matter of Science!" Tips and clues from the acting world to improve your communication skills

A. Dessì[a]

[a] *National Research Council – Institute of Chemistry of Organometallic Compounds (CNR-ICCOM), Via Madonna del Piano 10, 50019, Sesto Fiorentino (FI), Italy.*
alessio.dessi@iccom.cnr.it

Our first aim as scientists is definitely to carry out meticulous and challenging research, as much as possible. Anyway, even the best research work could not spark interest in the audience of conferences, meetings, and public speeches if the communication is not incisive. Today, communication is everything: while, in the last century, scientists could peacefully work in their labs without any contact with the outside world, today society rightly requires us to be more transparent, social, and engaging. Moreover, the dissemination activity of a scientist is often a matter of judgment by boards and committees for the evaluation of possible work candidates and the funding of projects. For these reasons, delivering a presentation cannot be limited to a mere assembly of slides and graphs, accompanied by an incoherent speech.

During this talk, we will explore the logical process behind the preparation of a presentation and learn how to answer these simple questions:

1. What is the message? Which story would I like to tell?
2. Who is my audience?
3. Which communication skills should I implement in my talk to deliver the message effectively?

Finally, we will dive into some techniques borrowed from the acting world that can help us make our communication engaging and increase awareness and control of our body and voice.

Chemistry, a good choice

Veronica Cremonesi
Federchimica, Via Giovanni da Procida, 11 Milano
v.cremonesi@federchimica.it

There is a very special link between School and Chemistry that must commit the two worlds to a continuous dialogue and common activities.

People are the hearth of the chemical companies; this involves continuous relationships with the education providers in order to have – quantitatively and qualitatively – well-trained young people who are aware of job opportunities.

These activities have always been important in medium-large companies and, in recent years, they have also spread to smaller companies with an increasingly high level of interaction with the territory, and in particular with technical high schools, but there is still a lot of work to do.

For this reason, Federchimica, for over 15 years, has been actively collaborating with the National Plan for Scientific Degrees, with the Italian Chemical Society and, more recently, also with ConChimica, the conference of Coordinators of Degree Courses in Chemistry with the aim of helping young people in orientation and in the implementation of their skills.

Federchimica's activities have four different targets: Primary School, Lower Secondary School, Upper Secondary School, University.

But is chemistry just bad? A journey into the marvelous world of cinema, from Breaking Bad to Railway Men

C. Pettinari

School of Pharmacy, University of Camerino, Via Madonna delle Carceri, Camerino 62032, Italy
ICCOM Sesto Fiorentino Italy

e-mail: Claudio.pettinari@unicam.it

The 20th century is today certainly considered the most important period for the scientific and technological development of the planet, a development that has significantly influenced our lives: it has enriched us with energy, food and new materials, it has made us feel better but also produced major environmental disasters and climate change. Even cinema, born as a scientific invention, has often used science in its stories, even unconsciously, traveling from the science fiction of 2001: A Space Odyssey to Erin Brockovich's chromium pollution, description of pollution, from the search for a cure for 'Lorenzo's oil with Madame Curie's radioactivity (Fig. 1).

Unfortunately, chemistry is often represented as bad and negative; it would seem only useful to produce drugs or generate environmental disasters, it can be used to manufacture nuclear weapons or to poison people. Chemistry professors are often portrayed as crazy or as inventors of impossible things. It is certainly time to change this opinion and present it differently not only to the general TV audience but also on the big screens, showing how chemistry is instead a science that manages to provide us with solutions, to make us feel better, to make us progress.

Unveiling the Dual Genius of Aleksandr Porfir'evič Borodin: Between Chemistry and Music

A. Benedetti,[a] G. De Iudicibus,[a] S. Santangelo[a]

[a]*Conservatorio di Musica "Nino Rota" - Monopoli, P.zza S. Antonio 27, I-70043 Monopoli (BA), Italy.*
a.benedetti@consmonopoli.it

Aleksandr Porfir'evič Borodin (Алекса́ндр Порфи́рьевич Бороди́н, 1833-1887) serves as a remarkable example of interdisciplinary mastery, making seminal contributions to both sciences and music. As a well-known Russian composer and chemist, Borodin's life and work epitomize the synthesis of scientific rigor with artistic expression. The presentation will cover Borodin's dual legacy, illuminating his contributions to organic chemistry and classical music, ultimately enriching his work in both domains[1,2].

In the realm of chemistry, Borodin was a respected scientist, primarily focusing on aldehydes. He became a prominent researcher in the mid-19th century and made notable contributions to the field through his work on the Aldol reaction. His method became crucial for forming carbon-carbon bonds in organic synthesis. Borodin's research provided foundational knowledge that spurred to further developments in organic synthesis and facilitated the advancement of various chemical industries[1,2].

Nowadays, Borodin is better known for his work as a composer. He achieved considerable acclaim as a member of the Russian composer's group named *Moguchaya kuchka*, led by M.A. Balakirev, also known as the *Mighty Handful* or *The Five*[3]. His extensive research on national identity went beyond arranging folklore and liturgical songs and also extended to other aspects of musical language such as harmony, rhythm and texture, as well as drama and genre.

Among his most celebrated works, the opera *Prince Igor* stands out, particularly known for its *Polovtsian Dances,* which vividly embody Borodin's knack for crafting evocative melodies and harmonies. Moreover, his symphonic works, including *Symphony No. 2 in B minor*, reveal his adeptness at large-scale orchestral composition, infused with lush harmonic language and rhythmic vitality[4]. Some other examples of his relevant works are the symphonic poem *In the Steppes of Central Asia* and the *Petite Suite* for piano.

A special focus will be made on Borodin's piano production. A related video-performance by Alessia Benedetti featuring *2 Polovtsian Dances* from *Prince Igor* by Alexander Borodin (F. Blumenfield) will be shown.

Bottom-up machine-learning for chemical modeling

M. Ceriotti[a]

[a]*EPFL, Institute of Materials, 1015 Lausanne, Switzerland*
michele.ceriotti@epfl.ch

Machine-learning techniques are often used in cheminformatics to perform "end-to-end" predictions, making black-box estimates of a property of interest using only a coarse description of the corresponding inputs. In contrast, atomic-scale modeling of matter is most useful when it allows to gather a mechanistic insight into the microscopic processes that underlie the behavior of molecules and materials.

In this talk I will provide an overview of the progress that has been made combining these two philosophies, using data-driven techniques to build surrogate models of the quantum mechanical behavior of atoms, enabling "bottom-up" simulations that reveal the behavior of matter in realistic conditions with uncompromising accuracy [1-2]. I will present several examples demonstrating how the combination of machine-learning and atomistic simulations can offer useful insights on the behavior of complex systems, from molecules [3] to condensed-matter systems [4], and from high-entropy alloy catalysts [5] to matter in astrophysical conditions [6]. I will discuss the challenges and a few solutions to develop an integrated modeling framework in which physics-driven and data-driven steps are combined to improve the accuracy, the computational efficiency and the transferability of predictions, from interatomic potentials to electronic-structure properties.

Enhancing Atomistic Simulations of Oxide Glasses through the Power of Machine Learning

Alfonso Pedone

Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia
Via G. Campi 103, 41125, Modena
alfonso.pedone@unimore.it

Multicomponent oxide glasses, omnipresent in daily life and high-tech applications, conceal intricate structure-property relationships that challenge traditional experimental investigations. Computational simulations, notably Molecular Dynamics (MD), have emerged as powerful tools for deciphering glass structures. Yet, the trade-off between accuracy and computational efficiency remains a hurdle. Quantum mechanics, specifically Density Functional Theory (DFT), offers pinpoint precision but is computationally prohibitive for larger systems.

This keynote explores a transformative approach, leveraging Machine Learning (ML) to revolutionize atomistic simulations of oxide glasses. The talk unveils recent advancements in our research group, demonstrating how ML techniques optimize empirical force-field parameters,[1] develop direct ML potentials,[2] and predict NMR shielding with DFT accuracy.[3] By training ML models on precise DFT data for smaller systems, we transcend computational constraints, enabling accurate simulations of larger, more complex oxide glass structures.

Join this journey through the fusion of quantum mechanics and ML, unlocking the potential to decode the enigmatic world of multicomponent oxide glasses and propel materials science into a new era of discovery.

From molecular modeling to data science: shaping computer-aided drug design for new therapeutic strategies

Maria Cristina De Rosa

Institute of Chemical Sciences and Technologies "Giulio Natta" (SCITEC) CNR,
L.go F. Vito 1, Rome
mariacristina.derosa@cnr.it

Computer-aided drug design (CADD) has emerged as a powerful tool in therapeutic development. CADD methodologies assist the drug discovery pipeline across various stages, significantly reducing both time and costs. With the rapid progress in high-performance computational resources and the introduction of novel *in silico* approaches, the efficiency of CADD has notably improved. Recent advancements in CADD are enriched with different sets of computational methods encompassing physics-based modeling and emerging artificial intelligence and machine learning (AI/ML) technologies[1]. In this presentation I will illustrate how atomic-level simulations have contributed to identification of new drug candidates against diseases with high socio-economic impact, such as cancer, immune system disorders and senescent cell-related pathologies. Combining ligand-based and structure-based virtual screening we discovered new NEK6 kinase inhibitors useful for the treatment of solid tumours[2]. Protein-protein interaction modeling led to the identification of selective inhibitors of the TCR/antigen−MHC complex for the treatment of rheumatoid arthritis[3]. Pharmacophore modeling revealed novel HSP90 inhibitors with senolytic activity[4]. I will also show that ML/AI-powered screens can narrow the chemical space and find applications in drug repositioning for COVID-19[5] and in structural characterization of therapeutic targets[6].

Unravelling the molecular aspects of catalysts under operando conditions combining simulations and machine learning

GiovanniMaria Piccini

Università di Modena e Reggio Emilia
piccini@unimore.it

Catalysis represents one of the most powerful technologies of our time but it is often not completely understood at the molecular level. Molecular simulations offer a potent means to explore these processes. However, simulating catalytic events presents its own set of obstacles: first of all the slow activation kinetics of these processes, subsequently an accurate description of the chemical bond-breaking and formation necessitates the use of computationally expensive ab initio potentials. Furthermore, the structural complexity of catalytic systems under operando conditions can complicate simulation analysis. To address these challenges, a synergistic approach combining enhanced sampling techniques and modern machine learning methodologies emerges as particularly promising. Enhanced sampling with machine learning approximates reaction coordinates for precise catalytic event characterization. Machine learning extends simulation times at costs akin to classical force fields. Tailored data science methods clarify complex simulation results, enhancing catalytic understanding.

Here, we focus on the development and application of such integrated approaches to investigate catalysis within confined environments involving water. Traditionally, such systems present computational challenges, as static ab initio calculations fail to capture the dynamic and statistical properties inherent to operando conditions. Our results center on two seemingly disparate systems— the conversion of aqueous biomass organic compounds within industrial zeolites, and the synthesis of fine organic compounds within hexameric calixarene capsules—revealing underlying similarities and shedding light on their respective catalytic mechanisms. The results demonstrate how leveraging these simulation technologies facilitates a deeper understanding of experimental evidence and promotes the design of materials through computational approaches.

The Hidden Dynamics of Metals: A Deep Dive Fueled by ML

Delle Piane, Massimo; Cioni, Matteo; Perrone, Mattia; Pavan, Giovanni M.
Department of Applied Science and Technology, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129 Torino, Italy
massimo.dellepiane@polito.it

In this contribution, we explore the dynamic nature of metal nanoparticles (NPs) and surfaces through an advanced analysis integrating machine learning (ML) with molecular dynamics simulations, shedding light on the complexities of atomic movements that dictate material properties.

Motivated by the need to understand how atomic dynamics influence the behavior of metals in applications ranging from catalysis, to nanoelectronics and biomedicine, our approach utilizes advanced descriptors, including the Smooth Overlap of Atomic Positions (SOAP), its temporal variant TimeSOAP (τSOAP),[1] and the Local Environments and Neighbors Shuffling (LENS) framework.[2] These methodologies, applied to high-dimensional data from molecular dynamics simulations, enable the precise characterization of atomic environments, identifying dynamic domains and shedding light on the "statistical identities" of metals.

Our findings reveal the inherent dynamics of atoms within gold nanoparticles[3,4] and copper surfaces,[5] challenging traditional perceptions of metals as rigid, unchanging materials. By leveraging ML, we discern the complex interplay of atomic environments, crucial for understanding metal NPs and surfaces' behaviors and even responses to stress-strain scenarios, such as dislocation and fracture. By integrating experimental techniques, such as annular dark-field scanning transmission electron microscopy (ADF-STEM) with advanced computational methods, we overcome the limitations of traditional experimental and simulation methods to provide a novel lens through which the atomic-scale dynamics of metals can be examined.[4]

Ultimately, this exploration into the dynamic atomic landscape of metals not only challenges conventional understanding but also underscores its critical importance for technological applications and material science innovation. Our findings illuminate the fundamental role of atomic dynamics in defining the properties of metals, paving the way for future material science innovations.

Quantum crystallography and quantum computing

P. Macchi[a]

[a]*Department of Chemistry, Materials, and Chemical Engineering; Politecnico di Milano, via Mancinelli 7, 20131 Milano, Italy.*
piero.macchi@polimi.it

Quantum crystallography[1,2] is a discipline that combines experimental information from measurements on crystals (mainly X-ray diffraction) and quantum theory. The two fields have been tightly connected since the very beginning because X-ray scattering has been often considered as the best experimental tool to visualize the distribution of electrons in atoms and molecules. On the other side, the theoretically calculated wavefunctions enable an accurate prediction of atomic and molecular scattering factors to use in modelling of crystal structures and their corresponding electron densities.

In quantum crystallography, the most typical modelling technique is that of the X-ray restrained wavefunction calculation, which enables one to calculate a wavefunction of a system restrained to the measured X-ray diffraction intensities.[3] Similarly, refinements of first order density matrices elements is possible by combining elastic (Bragg) scattering/diffraction with inelastic (Compton) scattering.[4]

The disruptive advent of quantum computing may stimulate significant progresses in this field, especially because of the possibility to determine correlated wavefunctions with the quantum information techniques. The density matrices approach could also benefit from quantum computing. The implications of quantum computing for crystallography may be many others and will be discussed during this perspective lecture.

Role of computational methods in the era of precision medicine

A. Cavalli

CECAM/EPFL, Lausanne, Switzerland
andrea.cavalli@epfl.ch

Computational drug discovery has become an increasingly important tool in the search for new drugs to treat a wide range of diseases. One of the critical challenges in this field is simulating the complex behavior of biomolecules at the atomic level, which can be computationally very expensive and time-consuming. The thermodynamics and kinetics of drug-target binding play a crucial role in understanding and optimizing the interactions between drugs and their target molecules. To address this challenge, molecular dynamics (MD) and related approaches combined with machine learning and artificial intelligence play a crucial role in accelerating the exploration of the conformational space of molecules. These methods also enable researchers to compute the free energy differences between different states of a molecule and estimate thermodynamic and kinetics properties such as binding free energies and residence time. This talk overviews various enhanced sampling methods combined with machine learning in computational drug discovery, as well as their advantages and limitations. The talk focuses on using these methods for free energy and kinetics estimations, reporting on the significant limitations toward accurate estimations for large datasets of compounds. The talk then describes recent applications in drug discovery and discusses the challenges and limitations of these methodologies when applied to biological systems of increasing complexity. In conclusion, the talk illustrates how MD, enhanced sampling methods, and machine learning can improve the efficiency and effectiveness of computational drug discovery and accelerate the development of new therapeutics to treat significant unmet medical needs in the era of precision medicine.

Chemometrics in clinical chemistry: examples of open-source applications for method validation and evaluation of real cases

E. Alladio,[a,b,c] L. Castellino[a], G. Solarino[a], M. Vincenti,[a,b]

[a]*Department of Chemistry, University of Turin, Via P. Giuria 7, 10125, Turin, Italy*
[b]*Anti-doping Center "A. Bertinaria" of Orbassano (Turin), Regione Gonzole 10/1, 10133, Turin, Italy*
[c]*DataBloom Srl, Via P. Giuria 5, 10125, Turin, Italy*
eugenio.alladio@unito.it

In clinical chemistry, the fusion of chemometrics with open-source software is pivotal for ensuring robust and replicable analytical outcomes, particularly in method validation and real-case evaluations. Here, we showcase three compelling instances that underscore the efficacy of open-source applications across diverse clinical and analytical contexts.

(i) We investigated breast cancer detection, where sex hormones in urine are examined as potential biomarkers for early detection. Using supervised data analysis strategies, we conducted a comprehensive study of 250 postmenopausal women, including healthy women and women with breast cancer. Data from the quantified 20 sex hormones were evaluated by a benchmark of machine learning (ML) algorithms, including logistic regression (LR), naive bayes (NB), partial least squares – discriminant analysis (PLS-DA), k-nearest neighbors (kNN), classification and regression trees (CART), support vector machine (SVM), and random forest (RF). Our results demonstrate the superiority of RF in identifying robust biomarkers that achieve a remarkable diagnostic accuracy (i.e., 98% with 5 selected biomarkers).

(ii) Methods Validation App - MVA, an open-source web application crafted in Python, aims to stand as a pinnacle of analytical method validation. It orchestrates an automated workflow tailored for method validation, requiring the preparation of 9 calibration curves derived from triple repetitions across 3 distinct days. Featuring automated and ML tools for assessing the linear dynamic range, limits of detection and quantification (LOD and LOQ), as well as inter-day and intra-day precision and accuracy, sensitivity, specificity, carry-over, matrix effect and uncertainty. MVA ensures meticulous scrutiny of calibration models through *ad hoc* significance tests and streamlines the validation process while upholding the highest standards of precision and reliability.

(iii) SpectrApp is an open-source technology in the field of multivariate data analysis. Designed within the dynamic ecosystem of R Shiny, SpectrApp is meticulously designed for fine-tuning and validating chemometric and ML models. Leveraging its open-source framework, it empowers users to inspect and preprocess the collected data through several techniques and plots, then build exploratory (PCA, cluster analysis, t-SNE, UMAP), class modeling (SIMCA), discrimination (kNN, NB, PLS-DA, SVM), and regression (MLR, PCR, PLS-R) models. The use of user-friendly and open-source interfaces accelerates the analysis and validation process, allowing even non-programming experts to focus on result interpretation.

Food toxicology and food bioactives assessment through in silico methods - is AI the new era of testing?

L. Dellafiora [a] , F. Perugino [a,b], L. Pedroni [a], C. Dall'Asta [a], G. Galaverna [a]

[a] *Department of Food and Drug, University of Parma, Area Parco delle Scienze 27/A, Parma, Italy*
[b] *Department of Biology, University of Naples Federico II, Via Cinthia, Naples, Italy*
luca.dellafiora@unipr.it

The use of computational methods in the field of food science traces its origin back to the late 1970s (e.g. ref. [1]). Since then, food science has broadly benefited from using computer-driven approaches either as integrated methods of analysis or stand-alone analytical frameworks to empower the throughput of analysis and to cope with system dimensions otherwise unmanageable. Germane to the chemical safety and bioactivity assessment of food components, computational methods enabled to investigate the multitude of compounds of food origin quantifying their activity and underpinning mechanisms either as single substances or as a part of complex mixtures. In this respect, the integrated use of in silico methods brought a significant breakthrough expanding at a multidimensional level the space under analysis enabling the combined assessment of food components, rather than estimating the outcome as a sum of single contributions. In a more recent time, a consensus was reached on the importance of the "here and now" chemical context to determine the toxicity and bioactivity of food compounds considering that certain toxicants may vary the potency when combined with certain bioactives, and vice versa. Computational methods were gathered in the so defined New Approach Methodologies (NAMs) and made possible the continuum and unbiased analysis of food components avoiding the prejudicial categorization into toxic and beneficial compounds. This was an important step toward the real needs of current chemical risk assessment. In a few years, the progress in terms of hardware and software, along with the growing availability of high-quality data of all kinds, made possible the development of advanced algorithms giving birth to artificial intelligence (AI). Nowadays, AI systems are capable to accomplish tasks which traditionally required human intelligence, including those related to the assessment of chemicals of food origin and associated regulatory science. With respect to the analysis of food components, AI is renegotiating what's ordinary in the chemical risk assessment and either enables to scale at a human level the interpretation of immense vastitudes of data or expands the horizon of analysis. This upcoming scenario may substantially improve the assessment of risk and the consequent decision making in the matter of food safety [2]. This presentation aims at providing a critical sight on the most important improvements potentially brought by AI analysing also the crucial flaws that should be aware of for a proficient use and subsequent improvement of this technologies in the near future.

DEEP LEARNING TO DESIGN NOVEL AND SELECTIVE NKCC1 INHIBITOR CHEMOTYPES FOR THE TREATMENT OF BRAIN DISORDERS WITH DEFECTIVE NKCC1/KCC2 RATIO

M. J. Ruiz Munevar,[b] M.Borgogno,[a] A. Savardi,[a] L. Mattio,[b] G. Vitali Forconesi,[b] M. Ruggeri,[b] P. Vidossich,[b] A. Garanzini,[c] D. Walu Emakana,[c] L. Cancedda,[a,c] M. De Vivo[a,b]

manuel.ruizmunevar@iit.it

Several clinical and pre-clinical studies have demonstrated that the intracellular Cl^- homeostasis is impaired, and Cl^- transporter cellular expression is dysregulated, in several brain disorders including neurodevelopmental disorders such as Autism Spectrum Disorders (ASD) and Down Syndrome (DS). Interestingly, inhibition of the Cl^- importer NKCC1 by the FDA-approved diuretic bumetanide reverts cognitive deficits in DS mouse models as well as core symptoms (social and repetitive behaviors) in ASD mouse models. However, bumetanide has a strong diuretic effect due to the inhibition of the kidney Cl^- transporter NKCC2, which prevents bumetanide from becoming a sustainable therapy for brain disorders. This evidence opened the way to the development of selective NKCC1 inhibitors as a viable therapeutic strategy for brain disorders characterized by impaired Cl^- homeostasis. In this context, we discovered a novel class of 4-amino-3-sulfamoylbenzoic acids[1,2] that resulted in the development of a drug candidate named IAMA-6, currently in a Phase 1 clinical trial (NCT06300398). On these bases, we have recently discovered novel follow-up compounds with good potency and different chemicophysical properties compared to the current drug candidate IAMA-6. We have employed deep learning-guided enhanced sampling simulations to elucidate the functional cycle of NKCC1 and identify key amino acids responsible for driving ion transport[3]. Subsequently, free energy perturbation calculations were utilized to facilitate the design of new chemical scaffolds. In this way, we experimentally identified new promising hits in a Cl^--influx assay in HEK cells transfected with NKCC1. Iterative medicinal chemistry efforts, guided by computational methods, allowed us to build a robust SAR model and improve the *in vitro* potency, efficacy, and drug-like properties of the initial hits. The chemical expansion of one of the classes of these chemotypes led to compounds with an inhibitory activity *in vitro* comparable to IAMA-6, and a favorable pharmacokinetics (PK) profile *in vivo*. These results further enrich our portfolio of novel and selective NKCC1 drug-like inhibitors, underscoring the efficacy of our computer-aided drug discovery pipeline in advancing new possible treatments for ASD, DS and many other pathologies characterized by defective Cl^- homeostasis.

Sustainability in the chemical industry: a 100-year history

F. Cavani

Dipartimento di Chimica Industriale "Toso Montanari" and Center for Chemical Catalysis-C³, Alma Mater Studiorum Università di Bologna, Viale del Risorgimento 4, 40136 Bologna, Italy

Since the 1980s, the chemical industry has promoted improvements in chemical processes, aimed at obtaining technologies that are more environmentally friendly, as well as economically advantageous. The strategies adopted were different, also starting from the awareness of the damages caused during the period of great post-war economic development; from the modification of the synthetic route, often made possible by the discovery of innovative catalysts, to the use of less dangerous reagents, to the replacement of molecules harmful to health, to process modifications aimed at achieving energy savings. By retracing the history of the chemical industry, both at a national level and in a more international context, and going even further back in time, it is possible to find chemical processes that, even if unconsciously, anticipated the rules of Green and Sustainable Chemistry and Engineering. For example, multi-stage chemo- catalytic processes for the valorization of platform molecules from renewable raw materials; technologies that public research and research in the chemical industry today try to replicate, by virtue of the significant improvements potentially achievable in terms of sustainability. Some examples will therefore be illustrated, to demonstrate on the one hand the considerable progress made in this area by the chemical industry, and on the other how the latter has long since indicated the path to achieving important results in the field of the bioeconomy and clean processes.

The role of catalysis and novel technologies for the definition of modern green chemistry

L. Vaccaro,[a]

[a] *Laboratory of Green S.O.C., Dipartimento di Chimica, Biologia e Biotecnologie, Università di Perugia, Via Elce di Sotto, 8 – Perugia;*
Web: http://greensoc.chm.unipg.it; luigi.vaccaro@unipg.it

Our research group has been contributing to the shaping and development of what is named today green chemistry.

Starting from the Pollution Prevention Act[1] the attention of chemists has been dedicated to the "millions of tons of pollution" and the related cost of "tens of billions of dollars per year".

Accordingly, our approach to modern green chemistry is focused on the general idea that green/efficient processes are those designed to minimize the waste by the rational combination of different technologies and the use of specific metrics needed to quantify the advance in terms of sustainability.

Our research program is mainly committed to the definition of efficient and sustainable synthetic tools by combining the development of several crucial areas of investigation: i) use of safer reaction media, ii) preparation and use of nanostructured heterogeneous and reusable catalytic systems; iii) definition of continuous-flow reactors allowing a minimal waste production and high productivity; iv) applications of metrics and LCA to assess the overall sustainability of the results.[1]

Among the different projects, we are currently dedicated attention to the valorisation of waste for the preparation of recoverable catalytic systems and electrodes to define efficient protocols based on the use of continuous-flow reactors and electrochemistry.

In this contribution it will be presented an overview of our vision and ongoing research in the field.

The intertwined fate of biomass and plastics in the green revolution: from fundamentals to chemical technologies for the circular economy

F. Mauriello,[a]

[a] *Dipartimento DICEAM, Università degli Studi "Mediterranea" di Reggio Calabria, Via Zehender (già via Graziella) - Loc. Feo di Vito, Reggio Calabria, I-89122, Italy*
francesco.mauriello@unirc.it

Green chemistry, as a transformative research field, has made significant strides in developing high-value products through sustainable practices. This field distinctively utilizes renewable resources, such as various lignocellulosic biomasses, and repurposes waste materials, including plastics.[1,2]

The innovative approach of green chemistry lies in identifying underlying similarities between seemingly distinct materials. Indeed, biomass and plastics, although different in origin, share notable structural similarities, especially in their polymer makeup and bond types. Consequently, in recent years, biomass and plastics have developed conversion pathways that have begun to intersect, thereby influencing each other.[3]

This contribution presents a 'unified view' to examine the chemical principles underlying the conversion processes of both biomass and plastics. In areas where biomass valorization has significantly advanced, abundant prospects exist for upcycling waste plastics using analogous methods, and vice versa. Specifically, the chemical mechanisms underlying the cleavage of C-C and C-O bonds in lignocellulosic biomass, and C-C bonds in polyolefins, will be presented. The knowledge gained from lignocellulose conversion, particularly in the cleavage of C_{arom}-C and ether bonds, can be applied to the upcycling of plastics, notably in the production of aromatic compounds. Moreover, even with the inert Caliph-C bond in polyolefins, innovative strategies, such as reductive-assisted depolymerization, have emerged, offering new pathways for biomass transformation. Within these areas of research, the gap between theory and practice will be presented highlighting scientific challenges that have been adequately addressed, and those that are underexplored or yet to be tackled.

Understanding the fundamental chemistry behind these transformations will be crucial in advancing conversion technologies that will align with national and European goals for ecological transitions and the green revolution. Therefore, the ultimate goal of this contribution is to illustrate how fundamental chemical knowledge can drive technological innovations and contribute to a sustainable future.

From research lab to industry embracing circular economy and green chemistry: the real-life case of *ISusChem Srl*

Massimo Melchiorre [a, b]

[a]*Dipartimento di Scienze Chimiche, Università di Napoli Federico II, Complesso Universitario di Monte S. Angelo, via Cintia 21, 80126 Naples Italy*
[b]*ISusChem Srl, piazza Carità 32, 80134 Naples, Italy*
massimo.melchiorre@unina.it

The intensive consumption of raw materials and the resulting environmental impact highlight the urgency to move from a linear to a circular economy. Within this change, the choice of feedstocks is a key point, and biomass exploitation needs to be preferred. Among raw materials, waste and non-food vegetable oils are valuable replacements for aliphatic fossil feedstocks, and are prone to chemical modifications through the reactivity of carboxyl groups and double-bond moieties. Nevertheless, the used process needs to be sustainable and coherent with the green chemistry principles. Starting from the background experience on vegetable oils transformations, Metor+ and Nicle research groups at the University of Naples Federico II first came across unexpected solubility properties of some fatty acid esters suitable to prepare offset printing varnishes,[1] and then developed a fatty acid esterification based on a fully recyclable Zn(II) catalyst.[2] Trying to put out the acquired know-how from university labs into the real industrial world, in 2018 the innovative startup ISusChem Srl was founded. To date, ISusChem Srl is an university spin-off at the University of Naples Federico II, and thanks to the Italian public founding Smart & Start, in 2022 a pilot plant was settled in Marcianise (CA), which started producing esters by September 2023. In this talk, the real case of the start-up ISusChem Srl will be illustrated, from ideas to actions, from obstacles to facilitations, and all the steps that we had to face and still face to keep our ideas real.

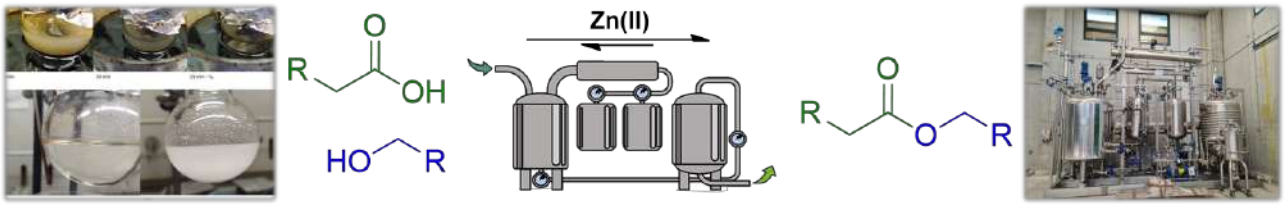

Figure 1: from lab to plant ISusChem esterification process.

Developing complementary technologies and skills for the green transition: from the fundamentals of ecocompatible solvents in liquid chromatography to process intensification in (bio-pharmaceutical) industry

A. Cavazzini,[a,b] M. Catani,[a] C. De Luca,[a] S. Felletti,[c] F.A Franchina,[a] M. Beccaria,[a] L. Pasti,[c]

[a] *Dept of chemical, pharmaceutical and agricultural sciences, University of Ferrara, via L. Borsari 46, Ferrara, Italy*
[b] *Council for agricultural research and economics, CREA, via della Navicella 2-4, Rome, Italy*
[c] *Dept of environmental and prevention sciences, University of Ferrara, via L. Borsari 46, Ferrara, Italy*
cvz@unife.it

Reversed-phase liquid chromatography (RPLC) stands as the predominant analytical technique in the (bio)pharmaceutical industry. It finds extensive application not only for analytical tasks like quality assessment of bulk drugs and formulations but also for preparative purposes in industrial settings, facilitating the extraction of highly pure target (bio)pharmaceutical compounds. Acetonitrile emerges as the most commonly utilized organic modifier in RPLC owing to its chemico-physical attributes, including strong elution power, UV transparency, excellent water miscibility, and low viscosity. Nonetheless, it is important to note that acetonitrile carries a slight toxicity risk upon acute exposure through ingestion, skin contact, or inhalation, and can potentially be metabolized by the body into cyanide.

In the past year, there has been a growing focus on the adoption of environmentally friendly analytical methods in the pharmaceutical sector. This shift aims to minimize the environmental footprint typically linked to manufacturing processes and safeguard the well-being of personnel. Particularly in preparative settings, the extensive use of solvents results in significant waste generation that requires proper disposal. Embracing greener analytical approaches not only addresses these concerns but also promotes sustainability within the industry.

There exist three fundamental strategies to enhance the environmental sustainability of (bio)processes that will be discussed in this presentation:

1. Process Greening. One approach involves process greening, which entails the substitution of conventional chemicals with more environmentally friendly alternatives. This shift towards greener chemicals aims to reduce the ecological impact of industrial activities.

2. Process Intensification. Another method is process intensification, which involves transitioning from traditional discontinuous batch operations to more efficient continuous processes. This change not only enhances productivity but also minimizes resource consumption and waste generation.

3. Process Modeling for Data-Driven Decisions. Furthermore, implementing process modeling techniques allows for the replacement of trial-and-error methods with data-driven decision-making. By leveraging advanced modeling tools, organizations can optimize processes, improve efficiency, and reduce environmental impact through informed and strategic choices.

Circular Economy and material efficiency in Europe: policy failures and strategic autonomy

Roberto Zoboli[a]

[a] *DISEIS, Università Cattolica del Sacro Cuore, Largo Gemelli 1, 20123 Milano, Italy*
roberto.zoboli@unicatt.it

The presentation addresses the evolving strategic framework for the Circular Economy and material efficiency in Europe. Stable trends of international real prices of materials and energy, together with abundant reserves of industrial natural resources, do not provide market incentives for significant increases of material efficiency and innovation. As a consequence, environmental and energy policies took the leading role in driving material efficiency and circularity. In the EU, even before the European Green Deal (EGD), the framework of policies and legislations addressing materials, waste and recycling was already very dense, and the EGD further pushes the transition to a new paradigm for materials through the Circular Economy Action Plan [1]. However, in different key sectors, like plastics, the prevailing policy approach has been insufficient to trigger the development of secondary materials markets that can close the circle. Furthermore, high incentives to renewable energy pushed to a competition between the energy and the material use of bioresources. The insufficiency of policy outcomes brings towards shifting the policy attention to the demand side of secondary raw materials markets and towards a more intensive use of policy approaches like Extended Producer Responsibility that demonstrated to be effective in closing the circles of materials [2]. A parallel need of more intensive research and innovation efforts emerges. European strategies to face the new risks of the international system are bringing to the emergence of 'Open strategic autonomy', also for the procurement of energy and materials [3]. The Green Deal Industrial Plan (GDIP) launched in 2023 through the Net Zero Industrial Act and the Critical Raw Materials Act is a first major step in this direction. However, the GDIP has unexplored implications for the exploitation of domestic natural resources (e.g. mining) in Europe and for a further push towards recycling and circularity, which brings to the challenge of expanding industrial and innovation capacity in these areas..

Safe and sustainable by design chemicals and materials

S. Sala,[a] E. Abbate , I. Garmendia Aguirre, C. Caldeira, G. Bracalente, L. Mancini, D. Tosches, K. Rasmussen, M.J. Bennett, H .Rauscher

[a] *European Commission, Joint Research Centre, via E. Fermi 2749, Ispra (VA) Italy*
serenella.sala@ec.europa.eu

The Chemical Strategy for Sustainability (CSS) establishes a number of actions, including the shift towards chemicals, materials and products that are safe and sustainable by design (SSbD) throughout their life cycles, To support this action, the European Commission's Joint Research Centre (EC-JRC) developed a framework for the definition of SSbD criteria and evaluation procedure for chemicals and materials[1], capitalising on an extensive review of the available approaches and frameworks[2, 3]. The JRC's framework addresses the dimensions, aspects and indicators to be considered, the methods and tools that can be used, and indicate to define criteria in the different steps of the SSbD assessment. It provides a rational and integrative procedure that puts together safety, environmental sustainability and socio-economic dimensions for the first time. It requires that safety and sustainability are considered for the entire life cycle of chemicals, materials and products, and assessed, as far as possible, from the beginning and at all stages of the R&D process. Hence, life cycle thinking and assessment play a pivotal role in the framework. This work underpins the EC Recommendation establishing a European assessment framework for SSbD chemicals and materials[4] that is addressed to Member States, industry, academia and technology organisations. The SSbD framework was tested by EC-JRC, focusing on a case study on alternative plasticizers used in food contact materials[5]. The development of the case studies allowed identifying the challenges in the application of the framework (and on the implementation of the SSbD concept). Those include the integration of the SSbD assessment within the innovation process that normally involves early stage developments for which data is not available and a tiered approach is now under development. Moreover, the EC launched a testing phase for the SSbD framework, which already informed a methodological guidance to foster further scientific research, and the key actions needed to ensure wider applicability of the SSbD[6]. A second testing phase is ongoing and there is a reporting template available to report experiences with the SSbD application.

Why is gender balance important to chemistry?

V.A. Seifert,[a]

[a]*National and Kapodistrian Univeristy of Athens, Panepistimioupoli, Athens*
seifertvan@phs.uoa.gr

It is incontestable that equal professional opportunities should be granted regardless of one's gender. This applies to chemical practice as well. Most often, this reasoning is based on an analysis of fairness and justice: it is morally wrong to exclude women from practicing chemistry or from enjoying the same professional opportunities as men chemists do.

Yet, there are not only moral reasons that justify gender balance in chemistry or science overall. Feminist philosophy of science explores how gender balance contributes to the growth of knowledge and to scientific progress. Specifically, it is argued that women- as other underrepresented groups of people- hold a unique position in how they view the world which in turn allows them to investigate nature and produce scientific knowledge in novel ways.[1] This idea is called situated knowledge. The feminist standpoint theory takes this idea and claims that women's role in science should be promoted as they hold an advantageous position that can lead to further scientific progress.[2]

This theory has been particularly popular with respect to disciplines that study phenomena which in some way involve gender, such as the social sciences or even primatology. In chemistry however, it is not clear how women's standpoint can inform our understanding of chemical phenomena given that the latter do not (at least in any straightforward manner) involve ideas of gender. This prompts the following question: can women's standpoint contribute to understanding chemical phenomena in ways that have not been previously thought? Or, is gender balance better accommodated by promoting a gender-neutral outlook towards chemistry?

In this talk, I explore these questions by presenting the arguments in favour and against the promotion of a standpoint epistemology in chemistry. I track the historical roots of chemistry as a woman's science and present the research questions that may be benefitted by promoting a gendered perspective towards their examination.[3]

Understanding Gender+ Approach in Chemistry Research and Innovation: What, How, Who

M. Bannò[a]
[a]*University of Brescia, Via Branze 38, Brescia (italy)*

Gender+ approach has become a key requirement for accessing research funds granted by the European Union. In particular, increasing female participation in research projects (WHO) and gendered innovations (WHAT and HOW) are included among the objectives of the Gender Equality Strategy 2020-2025.

As concerns the first objective (WHO), facilitating gender parity in research teams aids in bridging the disparities in women's involvement and enhancing their professional careers. In recent decades, two distinct approaches have been employed to facilitate gender equity into research: fix the numbers and fix the institutions. The objective of the first approach is to enhance the inclusion of women in research, such as in the workforce, committees, and events. The objective of the second approach is to modify structures and institutions in order to enhance women's opportunities to attain high-level positions in research domains. Regarding the second objective pertaining to research content (WHAT and HOW), it is imperative to adopt a gender-sensitive approach to research. It necessitates acknowledging the disparities that exist between men and women, whether they arise from biological or gender-related factors. Being aware of the gender dimension in research content improves scientific quality and relevance of results. Gender-sensitive research necessitates the inclusion of gender considerations throughout all stages of the research process, whenever it is deemed suitable. The aforementioned components encompass the development of research inquiries, the assembly of the research team, the arrangement of the study, the determination of the research methodologies employed, the collection and analysis of data, and the presentation and reporting of the obtained results.

In conclusion, addressing the objectives of enhancing gender parity within research teams and adopting a gender-sensitive approach to research are crucial steps towards achieving comprehensive gender equity in scientific domains. By embracing these objectives, we bridge existing disparities and enrich the quality and relevance of research outcomes by harnessing the full spectrum of talent and perspectives within the scientific community.

Diversity & Inclusion: why it matters and how can we make it work? A perspective from the publisher Elsevier.

M. Kolman,[a]

[a]*Elsevier B.V., Radarweg 29, 1043 NX Amsterdam*
m.kolman@elsevier.com

In the presentation, we will present the case for D&I. The moral imperative but also the "business case'': do diverse and inclusive organizations perform better? And if so, how and why exactly?

We will illustrate this by Elsevier's decade-long focus on D&I: a path with successes and setbacks but all in all steady upward progress. Today Elsevier supports inclusive research and inclusive health which we will illustrate with key initiatives.[1]

We will further explore the different dimensions of diversity: gender, race and ethnicity, sexual orientation and gender identity, age, disability, etc. To put this in a broader context we will briefly mention the state of D&I across the publishing world.

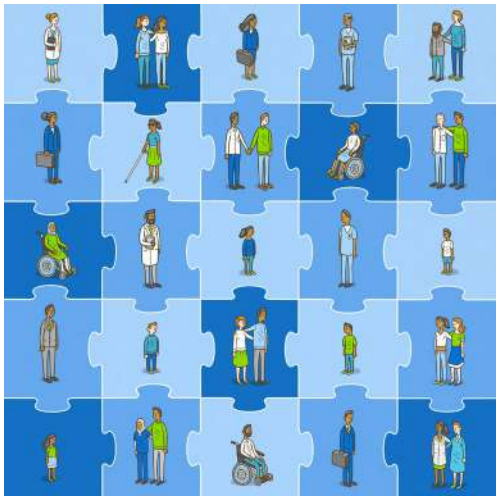

Figure 1: Diversity & Inclusion

Ethical aspects of the chemist profession

(M. Busetto[a], V. Frattini[a] and P.G. Viola[b])

[a]*ARPA Lombardia U.O. Laboratorio, Milano*
[b]*OICFL Presidente, Milano*
maddalena.busetto@pec.chimici.it

Definitions of Ethics: "1. The study of the determination of human conduct and the search for means to actualize it. 2. The set of norms of public and private conduct that, according to one's nature and will, a person or a group of people choose and follow in life or in an activity" (Lo Zanichelli, 1995).Chemistry in Italy has been the main driving force, alongside metallurgy, behind the industrial and economic development of the country after the Great War and especially after the Second World War. During this period, significant discoveries were made in the field of polymers and all their derived materials, in the synthesis of chemical substances, and in the identification of new applications, particularly in pharmaceutical chemistry. Society's perception of the chemist profession became extremely positive, as evidenced by the very high numbers of enrollments in Chemistry and Industrial Chemistry faculties.From the mid-1970s, following the accidents in Seveso, Bhopal in India, society's perception of the profession of chemist completely reversed. Chemistry has been considered dangerous and became unpopular in society. Simultaneously, the chemical community began to reflect on the impact of chemical activities on health and the environment, and consequently on the ethical aspects the profession of chemist entails. The first courses on Environmental Chemistry were born, research focused on the development and study of new products that could replace more polluting ones and the recycling and reuse industry of materials developed.The Code of Ethics highlights that the Chemist must assume social and environmental responsibility in the exercise of his profession. This includes a safe management of chemical products, in order to minimize harmful effects on the environment and public health and promoting sustainable practices. Chemists must carefully consider consequences, both positive and negative, of their discoveries and take informed ethical decisions about the applications and social implications of their research.As citizens, researchers, chemists, are we able to sacrifice, even in part, our professional interests in favor of the broader interests of the social community? A question not easily answered but unavoidable, necessary to change the negative perception that society has about chemistry, in a dialectical relationship.On the other hand, chemists must strive to ensure that the knowledge and research made available by the scientific community do not remain closed within itself but are spread and made available to the whole society obtaining that the use of certain substances (e.g., PPCPs) occurs in the most correct way possible. Not to be ignored is the fact that chemists must follow high ethical standards in their professional practice, that is, "acting with a sense of responsibility and applying chemical and physical knowledge correctly, in accordance with the rules and laws of the State, the Constitution, the European Union's legal system, and within one's own competence with dignity and honorability".Finally, training in a school context has an essential role in promoting ethical and responsible behavior in the chemists of the future. Training shoud help them to understand and face the ethical challenges that may arise in their professional practice.

Molecular architecture and mechanism of RNA-modifying ribozymes

C. Höbartner[a]

[a]*Institute of Organic Chemistry and Center for Nanosystems Chemistry, University of Würzburg, Am Hubland, 97074 Würzburg, Germany*
claudia.hoebartner@uni-wuerzburg.de

RNA modifications such as methylated nucleotides are conserved throughout evolution and expand the structural and functional diversity of RNA. Besides modulating the native RNA modification landscape, synthetic post-transcriptional RNA modifications for labelling and visualization are critical prerequisites for studying RNA localization, folding and structural dynamics. Ribozymes have emerged as powerful tools for modifying RNA in vitro and in cells.

The first methyltransferase ribozyme (MTR1) was discovered by in vitro selection and shown to catalyze the site-specific installation of the natural modified nucleotide 1-methyladenosine (m^1A) in a target RNA.[1] The ribozyme uses O^6-methylguanine (m^6G) as a small-molecule cofactor and shows a broad RNA sequence scope, as exemplified by site-specific adenosine methylation in native tRNAs and synthetic mRNAs. We solved the crystal structure of MTR1, which represents the post-catalytic state of a split ribozyme in complex with the m^1A-containing RNA product and the demethylated cofactor guanine.[2] The structure revealed an active site reminiscent of natural guanine riboswitches and suggested the mechanistic involvement of a protonated cytidine. A synergistic effect of two 2'-*O*-methylated ribose residues in the active site resulted in accelerated catalysis and tolerance of larger alkyl groups. Further research revealed alkyltransferase ribozymes using established benzylguanine substrates for site-specific fluorescent labelling of RNA,[3] as well as the development of additional ribozymes using alternative bioorthogonal cofactors.

Recently we identified an alkyltransferase ribozyme that uses a synthetic, stabilized *S*-adenosylmethionine (SAM) analogue and catalyses the transfer of a propargyl group to a specific adenosine in the target RNA.[4] The trans-propargylation reaction showed nearly quantitative conversion within one hour. The ribozyme was active under a wide range of reaction conditions in vitro, including physiological magnesium ion concentrations. A genetically encoded version of the SAM analogue-utilizing ribozyme (SAMURI) was expressed in eukaroytic cells, and intracellular propargylation of the target adenosine was confirmed. The transferred alkyne group was efficiently conjugated to different azides, including fluorophores and biotin, to enable studies of RNA localization, folding and structural dynamics. We expect that the ribozymes will also become useful tools for tracking or capturing of target RNAs.

A great challenge in cancer therapy is the selective delivery of anticancer agents or radiotherapeutics to tumour cells reducing the side effects on normal cells. To further improve delivery efficiency and cancer specificity, great efforts have been dedicated to the development of effective systems that can actively target tumours through the molecular recognition of unique cancer-specific "markers" that are overexpressed in the cancerous tissues[1].

The use of peptides as targeting tools has been validated in several applications. Examples are radio-labelled peptides used to deliver radio-therapeutic doses to cancer tissues. In this case, a cytotoxic entity, such as a radionuclide or a chemotherapeutic drug, is driven by the peptide to the transformed cells with higher efficacy than to normal cells[1]. Typically such conjugates, at lower doses, have useful applications for diagnostic applications whereby they are used to visualize even small lesions due to the overexpression of tumour genes.

Often, such conjugates can have poor delivery properties, because of intrinsic high hydrophilicity and nanometric vehicles are employed to overcome this issue , Indeed over the past several years, an explosive development of nanovectors (i.e micelles, liposomes) usable in drug delivery and molecular imaging applications has been reported. Nanoscopic therapeutic systems that incorporate therapeutic agents with molecular targeting capabilities are emerging to improve the therapeutic outcome of drug therapy, and even to improve diagnostic outcomes.

In this lecture, we will present our most recent results on a project that aims at the rational design of targeting peptidomimetic ligands to specific tumour receptors. More specifically, the following topic will be discussed: designing new anticancer drugs and/or a new class of non-invasive diagnostic tracers as suitable tools for $\alpha_v\beta_3$-targeted therapy and imaging[2-5].

NADPH oxidases (NOXs) are enzymes responsible for only generating reactive oxygen species (ROS)[1]. The seven NOX isoforms participate in various physiological processes, including cell proliferation[2], and their deregulation has been associated with various cancers, such as colon cancer[3] and leukaemia[4]. To identify *bona-fide* NOXs inhibitors, we firstly explored the structure of the covalent NOX inhibitor **VAS2870**. We observed that replacing of the 2-thiobenzoxazole leaving group with different functional groups abolished NOXs inhibition. By inserting at the *para*-position of the benzyl group of **VAS2870** the pharmacophore moieties able to covalently bind to FAD cofactor, we obtained **MC4762** and **MC4767** that did not provide an adduct with FAD, but **MC4762** selectively inhibited NOX2. Interestingly, **MC4762** was also able to lower ROS levels and to downregulate neuroinflammatory cytokines in BV2 microglia cells. To identify novel *bona-fide* NOXs inhibitors, we also simplified the molecular structure of the lead compound **M41** that we discovered through an *in-silico* screening. We observed that the opening of the central ring (**MC4793**) abolished human NOXs inhibition. Moreover, **MC4876** displayed a significant selectivity towards *h*NOX2, proved in cell target-engagement and proliferation impairment. These results confirmed the feasibility of achieving isoenzyme-specific NOX inhibitors by modifying the **M41**.[5]

Beyond Traditional Paths: Pioneering Drug Discovery at the Chemistry-Biology-Physics Nexus

Maria Letizia Barreca

Department of Pharmaceutical Sciences, University of Perugia, Via Fabretti 48, 06123 Perugia, Italy
maria.barreca@unipg.it

Targeted protein degradation (TPD) has emerged as a revolutionary approach in both drug discovery and chemical biology.[1] This innovative strategy harnesses small molecules (*e.g.,* proteolysis targeting chimeras - PROTACs) to induce the degradation of specific proteins by hijacking the cell's natural protein degradation machinery.[2] While no TPD-based drugs have yet received clinical approval, compounds capable of reducing the levels of disease-causing proteins are advancing in drug discovery pipelines.[3] For chemical biology applications, small molecule degraders can be exploited as chemical probes, allowing to dissect the function and significance of the targeted proteins within living cells.[4]

In this regard, we have recently described a novel paradigm (Pharmacological Protein Inactivation by Folding Intermediate Targeting, PPI-FIT),[5] that leverages the power of chemistry, biology, and physics at the life science interface. PPI-FIT is based on the hypothesis of pharmacologically modulating the expression of a specific protein at the post-translational level by impairing its folding process. The underlying principle is that targeting transient protein conformations - folding intermediates – with a small ligand could promote degradation by the cellular quality control machinery, which recognizes such artificially stabilized intermediates as improperly folded forms. Hence, unlike conventional drug design approaches focusing on native protein structures, PPI-FIT expands the TPD landscape by targeting proteins during the folding process, introducing a new class of small molecule degraders named folding interfering degraders (FIDs). As a result, this breakthrough approach holds great promise for modulating currently undruggable proteins, thereby effectively tackling unmet medical needs.

Some examples of PPI-FIT applications will be presented, specifically showcasing its potential impact in addressing neurodegenerative disorders[5,6] and rare pediatric diseases.

Presently, PPI-FIT is harnessed by Sibylla Biotech S.p.A. (www.sibyllabiotech.it), a preclinical stage company exploiting this pioneering technology in different therapeutic areas.

MICRO4ALL: A MAJOR CHANGE IN DRUG DISCOVERY

Sonia I. Maffioli

NAICONS srl, viale Ortles 22/4, 20139 Milan, ITALY

smaffioli@naicons.com

The world needs sustainable solutions to cope with an increasing and aging human population. Drug R&D programs are time-consuming, costly, and with no guarantee of success. Given the world population increase, fast and efficient development of new drugs is essential. Natural products have found numerous applications to treat and prevent diseases in humans, animals, and plants, and are widely used as research reagents to probe biological processes. They are a proven and sustainable answer to make the R&D process faster and more successful. *micro4all* is a platform that provides access to an extensive online Catalog of Molecules, present in ready-to-screen samples produced by NAICONS proprietary microbes. NAICONS has a collection of 45,000 microorganisms, among the most diversified in the world, and of 50,000 ready-to-screen extracts, a number that is being expanded continuously. Each microorganism produces hundreds of molecules that are present in the extracts and that are identified using a proprietary automated informatic process. The molecules, the extracts and the producing microorganisms are listed in a growing database called Molecules Gateway. *micro4all* provides a search-and-order engine where Users can access information, molecules, extracts, and the producing microorganisms. We will provide an overview of how the Gateway was created, what it contains and demos on the type of searches Users can perform.

Structural insights into G-quadruplex-protein recognition: the case of anti-thrombin aptamers

R. Troisi,[a] F. Sica[a]

[a]*Department of Chemical Sciences, University of Naples Federico II, via Cintia, 80126 Naples, Italy*
romualdo.troisi@unina.it

DNA or RNA sequences rich in guanines have the propensity to fold into four-stranded structures, known as G-quadruplexes (G4s), in which tetrads of guanines, organized in cyclic arrays *via* Hoogsteen hydrogen bonds, stack on top of each other. Naturally occurring G4s appear to play crucial roles in the control of fundamental cellular processes such as transcription, translation, and replication.[1] These structures have also been found in several synthetic oligonucleotides, known as aptamers, that selectively bind to a specific target molecule, exerting interesting biological activities.[2]

A particular case is that of the anticoagulant aptamers able to recognize human α-thrombin, the key enzyme of the coagulation cascade.[3] In the last years, researchers have been particularly interested in a new class of anti-thrombin aptamers, in which the binding affinity and/or anticoagulant activity are modulated by the addition of other domains or appendages to the G4 core.[4] The functionalization of the full-G4 TBA aptamer with a hetero duplex generated by aromatic moieties attached at the 5′ and 3′-ends, leads to a modified aptamer, named TBA-NNp/DDp that, in addition to a considerable improvement of the thermal stability and nuclease resistance, shows a moderate increase in anticoagulant activity with respect to unmodified TBA.[5] Notably, a duplex/quadruplex anti-thrombin aptamer, known as M08s-1,[6] exhibits increased anticoagulant activity in comparison to NU172, the only anti-thrombin aptamer currently evaluated in Phase II of clinical trials.[7]

With the aim to shed light on the molecular basis for the improved properties of these aptamers, spectroscopic, calorimetric, and electrophoretic analyses have been performed in order to investigate the conformational behaviour of these oligonucleotides in the free and bound state. In particular, we solved the X-ray structures of thrombin in complex with TBA-NNp/DDp and a truncated form of M08s-1 (named M08s-1_41mer), which have shown peculiar structural features of the two aptamers.[8,9]

Antimicrobial peptides and their interaction with model membranes: a biophysical approach

R. Oliva,[a]

[a]*Department of Chemical Sciences, University of Naples Federico II, via Cintia, 80126, Naples*
rosario.oliva2@unina.it

The resistance to multiple antimicrobial agents (as antibiotics) in bacteria has become a central problem in our community. Many researchers are focusing their efforts on the development of new anti-infective agents and among these, the most promising are antimicrobial peptides (AMPs). AMPs are small, cationic membrane-active peptides that exhibit broad-spectrum activity against bacteria, viruses, and even fungi. Their primary target is represented by the lipid matrix of the pathogens' membrane. Despite their similar physical properties, AMPs exhibit a limited sequence homology and a wide range of secondary structures upon interaction with membranes whereas they show essentially a disordered structure in solution. The mechanisms by which AMPs can interact with membranes depend on the peptides' molecular properties and, importantly, on the lipid composition of the membrane which in turn modulates the physical state of the bilayer and its microscopic properties. In this talk, a brief introduction to AMPs and biomembranes will be given. Then, it will be shown how the application of biophysical techniques, with a particular emphasis on calorimetry, can be used the disentangle the intricate aspects of AMPs-induced perturbation of biophysical properties of lipid double layer mimicking the bacterial membrane.[1]

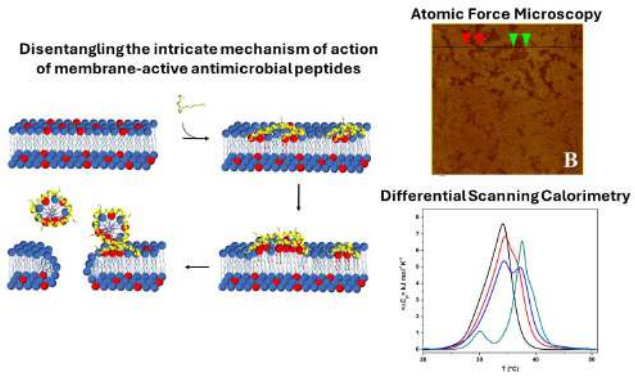

Figure 1: Using a combination of biophysical techniques, including calorimetry, it is possible to reveal the molecular details of peptide-induced perturbation of model biomembranes.

Modulating Biochemical Complexes in Health and Disease: From Glycosylation to Small Molecules

Giorgio Colombo

[a]*Department of Chemistry, University of Pavia, Pavia, Italy*
g.colombo@unipv.it

Protein functions depend on a delicate interplay of structure and dynamics. Ligand binding, post-translational modifications, and interactions with other protein partners provide different levels of control of activities in cells, defining a code that ultimately determines cell life.

Understanding, atomistically, the key physico-chemical elements that rewire the conformational dynamics of proteins, pathologically perturbing functionally-oriented ensembles, is key for development of novel therapeutics. This is particularly relevant for molecular chaperones, hub proteins for the assembly of large multiprotein complexes.

Here, we will present computational studies, integrated with extensive experimental validations, aimed to unveil the links between the perturbation of functionally-oriented dynamics in different biochemical systems and their functional implications. We will discuss how understanding of the effects of *N*-glycosylation of specific residues and ligand-binding can modulate internal dynamics and alters the conformational fitness of regions fundamental for interaction with other partners, and will discuss methods to directly interfere with interactions determined specifically by N-glycosylations. We will also discuss the effects of other modifications in the general framework of conformational selection and long-range functional regulation. Finally, we will discuss how to leverage the knowledge generated to design molecules targeting disease-associated conformational states and assemblies.

A decade of the liposome-protein corona: Lessons learned and future breakthroughs in theranostics

A.L Capriotti,[a] G.Caracciolo[b], D. Pozzi,[b] A. Laganà[a]

[a]*Departmentof Chemistry, Sapienza University of Rome, Piazzale Aldo Moro 5, 00185, Rome, Italy*
[b]*Department of Molecular Medicine, Sapienza University of Rome, Viale Regina Elena 291, 00161 Rome, Italy*
annalaura.capriotti@uniroma1.it

A decade has passed since the concept of the protein corona, as originally termed by Dawson and coworkers in 2007 [1], was extended to liposomes. Although the protein binding to liposomes has been known since the 1970 s, deep knowledge of the factors triggering its formation and interaction with living systems in vitro and in vivo was not fully understood. Over the last 10 years, multidisciplinary efforts from chemistry, physics, materials science, biology, toxicology, and immunology were put together to understand the synthetic-biological duality of the liposome-protein corona. Here we focus on the methods employed for characterizing the liposome-protein corona, the categories of factors shaping its composition, and the most relevant applications in the field of nanomedicine, where liposomes are designed for targeted drug delivery, vaccination against cancer and infectious diseases, imaging, and diagnostics [2]. We conclude the lecture by contemplating future research directions and appealing to researchers, entrepreneurs, and policymakers to recognize the relevance of this field of research.

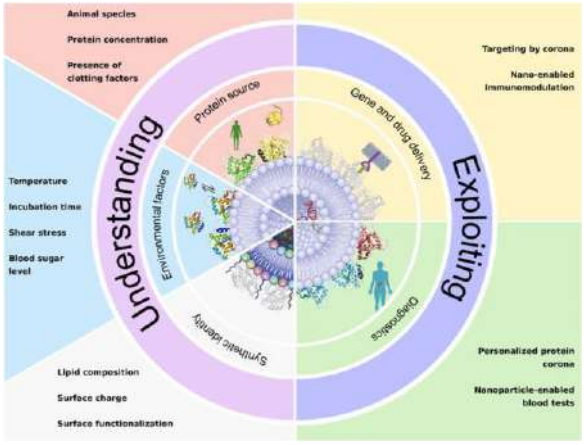

Figure 1: An overview of the main achievements obtained in the field of the liposome protein corona from basic understanding to clinical application.

In recent years, thanks to the recognition of the involvement of the gut microbiota in mental health and cognitive function, interesting opportunities have emerged to produce benefits for brain functions through the manipulation of the microbiota. Diet has emerged as a major factor shaping the composition and functions of the gut microbiota. In 2013, the term "psychobiotic" was first proposed to describe any exogenous intervention that impacts the brain, mediated by bacteria[1]. Initially greeted with distrust, this line of studies has identified probiotics and prebiotics with promising results as psychobiotic agents, both in animal models and in humans. Furthermore, numerous observational studies suggest a link between healthy eating patterns and a reduction in the risk of common mental illnesses, and emerging data from early intervention studies suggest that improving eating habits can improve depressive symptoms. These studies are conducted in different geographical areas, with different cultures. The research is mainly aimed at highlighting the role of individual foods (for example, unprocessed fruit or vegetables), or at developing new food supplements.

Those studies that focus on the overall diet, which investigate the potential synergistic effect that the different components of the diet could have, both on the composition of the microbiota and on health, perhaps deserve greater attention. The study of "integral" dietary approaches represents a path to be followed carefully for the development of new psychobiotic dietary interventions. It is interesting to observe how among the lifestyles studied there is a version of the Mediterranean diet combined with fermented foods. Recently, a short-term psychobiotic dietary intervention based on these assumptions improved perceived stress in a healthy population, while eliciting specific metabolic changes in the gut microbiota[2]. Results that must be interpreted with caution since improvements in stress responses were observed only within the intervention group, while no significant differences were found between groups after the intervention. However, given the fundamental influence of stress on the risk of developing other chronic diseases such as depression, these findings hold promise as potential therapeutic and preventative approaches. It is foreseeable that the use of dietary and lifestyle approaches to address mental health problems will become increasingly important and may be reflected in future nutritional guidelines. To report the opinion of one of the coordinators of the study, prof. John Cryan (University College Cork, Ireland) "What I like about fermented foods is that they democratize science. They don't cost a lot and you don't have to buy them in some fancy shop. You can make them yourself. In this field, we want to provide solutions for mental health to people of all socioeconomic areas." A shared path that science must take to truly impact the well-being of the entire population.

Modular and adaptive self-assembling dendrimers for biomedical applications

L. Peng

Centre Interdisciplinaire de Nanoscience de Marseille, Aix-Marseille Université, CNRS,
163 avenue de Luminy, Marseille, France
ling.peng@univ-amu.fr

Dendrimers are ideal precision materials for elaborating nanomedicine by virtue of their well-defined structure, multivalent cooperativity and nanosize per se. We have pioneered modular and adaptive self-assembling dendrimer nanosystems[1] for the delivery of anticancer drugs[2] and nucleic acid therapeutics[3] as well as imaging agents[4] for cancer detection and treatment. Remarkably, these supramolecular dendrimer nanosystems are able to exploit the in situ tumor-secreted extracellular vesicles for effective delivery and deep penetration in tumor tissue, while overcoming tumor heterogeneity and dynamic evolution.[2] Also, we have recently developed self-assembling dendrimer nanosystems against infectious diseases caused by antimicrobial resistant pathogens.[5] Our findings offer a fresh perspective for exploiting the advantageous features of supramolecular dendrimers to reach the ultimate goal of nanomedicine

Smart multifunctional hybrid materials as key pillars towards innovation and sustainability: advantages and challenges

M. R. Plutino

Institute for the Study of Nanostructured Materials, ISMN–CNR, URT Messina, c/o Department of ChiBioFarAm, University of Messina, Viale F. Stagno d'Alcontres 31, Vill. S. Agata, 98166 Messina, Italy

mariarosaria.plutino@cnr.it

Within the fascinating area of material science, a special place is covered by smart materials, which can respond to external stimuli such as physical parameters (i.e. temperature, humidity, pressure, pH, electrical/magnetic fields) or specific analytes coming from the environmental surroundings. Their production shows several advantages such as increasing the resistance of materials and the product shelf life and reducing the production and maintenance costs.

In this regard, (multi)functional hybrid organic-inorganic materials (HOIM) contribute significantly to this issue, providing unique mixtures of qualities by combining organic-inorganic components at the nanoscale or molecular level to improve strength, conductivity, flexibility, and other final desired properties. The adaptability and innovation of these class of advanced smart materials have gained significant attention due to their potential applications in several industrial sectors, such as buildings, blue-growth, aerospace, healthcare, well-being, optoelectronics, textiles, and renewable energy,[1] also solving complicated issues such as environmental remediation and surface performance implementation. Moreover, the sol-gel method has recently emerged as a sustainable and versatile synthetic approach to obtain smart (multi)functional hybrid materials, thanks to the employed low process temperature, high homogeneity of the final products, absence of cytotoxicity, and high versatility of the silane precursors (also able to stably bind nanofiller/molecules or to anchor to various substrates).[2]

The development and application of smart innovative (multi)functional hybrid materials or nanocomposites, based on an appropriate multicomponent (blended) polymeric matrix featuring functional polymeric precursors/cross-linkers, natural fillers, or molecules, will be described and discussed highlighting the relationship between the designed functionalities and the properties of the obtained systems, also assessing advantages and challenges of a rational "safe and sustainable by design" approach to pave the way to more eco-friendly and innovative products and technologies.[3]

benedetta.carlotti@unipg.it

From biology to optoelectronics, fluorescent materials have long been used as indispensable tools. The phenomenon known as Aggregation-Caused Quenching (ACQ), which occurs when a fluorophore comes into close proximity with other molecules, is a challenge limiting these applications. The opposite phenomenon, the so-called Aggregation-Induced Emission (AIE), offers a straightforward remedy to ACQ. Even though AIE has been observed in several molecular systems, the mechanism underlying this promising effect is still under discussion in the literature. In light of the above, we present an in-depth study of the excited-state dynamics of several donor-acceptor chromophores showing AIE. The investigation employed UV-Vis time-resolved spectroscopies, with nanosecond and femtosecond resolution, allowing for a comprehensive mechanistic insight into the structure-property relationships impacting AIE. The experimental results collected in solution, in water dispersion as well as in the solid-state allow to outline general conclusions upon which to develop new purely organic AIEgens. Interestingly, an increased intramolecular charge transfer character lead to the activation of Room Temperature Phosphorescence (RTP, through spin-orbit charge transfer-induced intersystem crossing) and Thermally-Activated Delayed Fluorescence (TADF, through reduced singlet-to-triplet energy gap). The efficiency of RTP and TADF intriguingly resulted further enhanced upon aggregation. Our findings suggest new opportunities to employ these emitters in the biological field, as photosensitizers for imaging-guided photodynamic therapy, and for the realization of more efficient optoelectronic devices.

Multivalent Interactions in the Detection of DNA and Viruses

Jurriaan Huskens

Molecular Nanofabrication group, Department for Molecules & Materials, Molecules Centre & MESA+ Institute, University of Twente, Enschede, The Netherlands
j.huskens@utwente.nl

Multivalency describes many interactions in Nature, for example, the interaction between viruses and cell membranes.[1] The influenza virus binds through multiple sialyl-terminated carbohydrates (SLNs) non-covalently interacting with hemagglutinin coat proteins of the virus particle. This interaction is weakly multivalent in nature, and therefore it responds very sensitively to the density of carbohydrates. This behavior explains the large differences between virus affinities observed for mutations in the receptor binding domain.

A key aspect of the multivalent interaction of viruses at cell membranes is its strong, non-linear dependence on the receptor density displayed at the surface. We here show the use of surface gradients of receptor-modified supported lipid bilayers (SLBs) to visualize and quantify the receptor density dependence in one microscopic image. This technique is called "Multivalent Affinity Profiling".[2] The fitting of the data by a thermodynamic model allows quantification of the threshold density, comparison of binding selectivities for different virus strains, and thus offers a molecular understanding of the supramolecular binding energy landscape.[3] This supramolecular and nanoscopic picture links fundamental molecular aspects of binding to biological processes of antigenic drift and zoonosis.

The same principles of weak multivalent and superselective binding can be used in the design of a device that selectively captures the cancer biomarker hypermethylated DNA (hmDNA).[4] The selectivity is achieved by careful density control over the surface coverage of the proper receptor for hmDNA, the methyl-binding domaln (MBD) protein.[5] Microfluidic devices coated with monolayers of MBD thus allow purification and up-concentration of hmDNA from solution mixtures with large backgrounds of non-methylated DNA, from cell extracts and from patient samples. This technique promises a faster and cheaper method to employ hmDNA as a biomarker in liquid biopsies, with potential applications as a screening method and for follow-up of treatment.

Smart nanocomposites in tendon tissue engineering

E. Bianchi, M. Ruggeri, B. Vigani, S. Rossi, G. Sandri

University of Pavia, Pavia, Italy
g.sandri@unipv.it

Each year, more than 32 million tendon injuries have been reported mainly caused by sports injuries, and population aging. An innovative approach for the treatment of these injuries is represented by tissue engineered bio-mimetic scaffolds able to support the host cells homing, differentiation, and proliferation. In this context, thermoplastic polymers are of special interest in the tissue engineering field as they allow the production of scaffolds with controlled elastic and mechanical properties, suitable as an effective support during the new tissue formation. However, the polymeric scaffolds alone are insufficient to guarantee a complete healing control, since they lack of adequate hierarchical structure as well as adequate mechanical, chemical, and physical properties to stand the stresses and enhance tissue regeneration. For this purpose, the use of inorganic nanomaterials as doping has gained great interest in tissue engineering applications, due to their wide range of unique properties, such as anti-inflammatory and antibacterial ones.
Given these premises, the design and the development of multifunctional platforms intended for the regeneration of the tendon tissue and doped with inorganics capable of coupling antimicrobial and proliferation enhancement properties will be described.
In particular fibrous scaffolds and highly porous 3D scaffolds have been developed. Thermoplastic polymers as polyurethane and polyhydroxybutyrate have been selected. Natural biomimetic polymers (gelatin or chondroitin sulfate) have been associated to the polymer matrix to enhance bioactive properties. Inorganic doping with cerium, copper and iron oxides gives the scaffolds superior properties of tissue reparation and antimicrobials. The multidisciplinary characterization approach including a physico-chemical characterization (SEM, fibers dimensions, TEM, surface wettability, structural characterization – FTIR, TGA/DSC, SAXS – mechanical properties, degradation properties) and a preclinical characterization (in vitro biocompatibility on tenocytes, release studies, and in vivo safety on murine burn/excisional wound model) allows to pave the way to a translation towards clinics.

Building-up biocompatible functional materials combining inorganic nanoparticles and soft lipid scaffolds

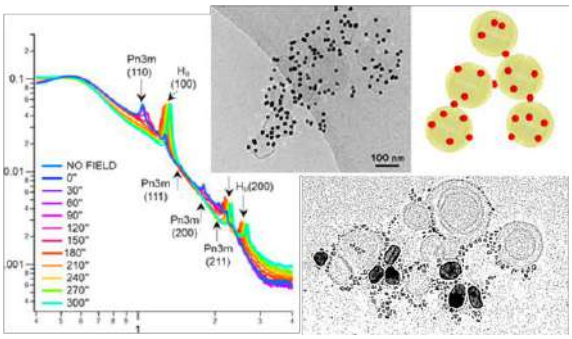
C. Montis[a], J. Cardellini,[a] A. Balestri[a], L. Caselli,[a] D. Berti[a]

[a]Department of Chemistry, University of Florence and CSGI, Florence, Italy

costanza.montis@unifi.it

Associating inorganic nanoparticles with soft lipid scaffolds is an attractive strategy to attain functional materials combining the unique properties of inorganic nanoparticles with the biocompatibility, self-assembly properties, and chemical/structural tunability of lipid systems. Over the years, multiple examples of lipid-nanoparticle hybrids have been proposed, such as magnetoliposomes or, more recently, lipid-camouflaged nanoparticles. However, obtaining controlled hybrid systems of desired characteristics often requires complex synthetic pathways and/or manipulation.

In this contribution, different hybrid systems are presented, where functional (magnetic, plasmonic, or magnetoplasmonic) nanoparticles were associated with lipid and lipid/copolymer assemblies through simple self-assembly steps. By carefully exploiting by design lipid/nanoparticle interfacial interactions, such as ligand exchanges, fine control over the structural, morphological, colloidal, and, ultimately, functional properties of the hybrid was attained.



With this strategy, different hybrid systems have been prepared, such as: (i) lipid vesicles-nanoparticles assemblies with discriminating colloidal properties of potential interest for applications in mixed vesicles dispersions separation; (ii) controlled clusters of gold nanoparticles on lipid vesicles, of enhanced plasmonic properties, of interest for Raman imaging applications, (iii) ternary systems made of magnetite and gold/magnetite core-shell nanoparticles hybridized with lipid vesicles, exhibiting combined magnetic and plasmonic properties; (iv) lipid-copolymer hybrid systems with patched-driven assembly of clustered plasmonic properties.

Overall, these results highlight a facile strategy, based on controlled self-assembly of inorganic nanoparticles and lipid interfaces, to prepare complex biocompatible functional materials of broad applicability.

Advanced Materials requirement for sustainable Food Packaging Equipment design

Gloria Guidetti [a], Silvia Rossi [a]

[a] *Tetra Pak Packaging Solutions Spa, Via Delfini 1, Modena*
gloria.guidetti@tetrapak.com

Food Packaging industries are looking into sustainable solutions not only for packaging material structure development, but also for Equipment components design optimization. The demanding conditions of those parts are translated into material requirements as excellent chemical resistance to aggressive environment, advanced materials for more efficient components, high quality bulk and surface mechanical properties in complex environments. The scouting and the testing of advanced materials and sustainable polymers and coatings available in the Market it has been done, but few candidates were able to satisfy application constraints and technological development. What is then important for industry to develop? Which are the properties/materials that we are looking at?

Highlight of Food industry chemistry of materials needs , and some examples like: research activities toward polymers sustainability for industrial components, green Tribology, self-lubricant materials, functionalization of surfaces, advanced and carbon based materials.

Graphene history – from lab weirdo to breakthrough in industrial innovation

Vincenzo Palermo,[a,b]

[a] *Istituto per la Sintesi Organica e la Fotoreattività (ISOF), Consiglio Nazionale delle Ricerche, Bologna, Italy*
[b] *Chalmers University of Technology, Göteborg, Sweden.*

vincenzo.palermo@isof.cnr.it

Graphene is a robust, flexible sheet of carbon atoms, one-atom thick. At the beginning of its exciting life, graphene was mostly a game for physicists working in fundamental research, enabling them to investigate relativistic quantum phenomena in benchtop experiments, using simple scotch tape. After a while, chemists entered the stage. In 2008, techniques to produce graphene on large scale were invented. In 2012, the first consumer products based on graphene appeared. Since then, the EC decided to launch an ambitious project (The Graphene Flagship), with the visionary goal to translate this scientific breakthrough into innovation for European industries. 2D nanosheets like graphene can be processed, functionalised and then re-assembled together to create new layered 2D composites with useful applications. When two nanosheets are stacked together, the space between them forms a 2D-confined environment which can capture, transport or store small molecules and ions which normally do not intercalate in graphite or in any other material. Here, we will give an overview of novel layered composites with original structure that we produced recently,[1] with useful applications in the sectors of energy storage using lithium and sodium and in gas purification. The materials we describe, besides showing in all cases good performance versus state-of-the-art, demonstrate also the high maturity and versatility reached by the processing of 2D materials into bulk applications, beyond the random mixtures typically used in composites.

Sulfur-rich macromolecular architectures from inverse vulcanization: Novel metamaterials for nanophotonics

P. Stagnaro

CNR, Institute of Chemical Sciences and Technologies "Giulio Natta", Via De Marini 6, 16149 Genova
paola.stagnaro@cnr.it

Low materials costs, ease of fabrication and scale-up are making all-polymer photonic structures increasingly researched for light-control applications. However, in their transparency region, most of processable polymers have relatively low and similar refractive indices, which hinder strong light confinement effects. In this respect, polymers with high content of highly polarizable S-S bonds obtained by inverse vulcanization (IV), named inverse vulcanized polymers (IVPs), revealed to be promising as photonic building blocks endowed with very high refractive index and excellent transparency in the near infrared region (NIR).[1,2]

The simple, solvent-free IV process represents indeed an efficient and green method to up-cycle waste elemental Sulfur, which is an abundant by-product of gas and oil industry, as inexpensive resource to obtain sustainable and innovative polymeric materials with unique functional properties. IV process takes advantage of Sulfur's ring-opening and linear chain-forming tendency at high temperatures by binding vinylic (or analogous) monomers to the Sulfur radicals which form when the S_8 ring opens. This leads to novel amorphous macromolecular architectures exploitable for a variety of applications for light emission control, spanning from free-standing dielectric mirros (Distributed Bragg Reflectors) with very high reflectance and microcavities for NIR emitting lasers, to fabrication of metamaterials for advanced nanophotonics. By varying type and amount of vinylic derivatives, it is possible to tune the refractive index, glass transition temperature and solubility, that is the IVPs properties resulting technologically relevant for the foreseen applications and industrial scale-up.

Molecular Gold Nanoclusters and the Hydrogen/Deuterium Puzzle

F. Maran[a,b]

[a] *Department of Chemistry, University of Padova, Via F. Marzolo 1, Padova, Italy*
[b] *Department of Chemistry, University of Connecticut, 55 North Eagleville Road, Storrs, Connecticut, United States*
flavio.maran@unipd.it

Substituent effects have never been studied by changing a *very large* number of identical substituents. This kind of study obviously requires the use of very special molecules where this kind of substitution is indeed possible. In this context, ultrasmall ligand-protected gold nanoclusters, such as $Au_{25}(SR)_{18}$ where SR is a thiolate, provide the opportunity to test the combined effect of changing 18 identical ligands.[1,2] These systems can be prepared with atomic precision, exhibit truly molecular properties, and their physicochemical, electrochemical, and electron transfer (ET) behaviors can be tuned by acting on both the metal and organic components.[1-9]

We prepared the first *fully deuterated* gold nanocluster, $Au_{25}(SC_4D_9)_{18}$, and compared its electrochemical, ET, solid-state, and photophysical behaviors in comparison with those observed for the corresponding nondeuterated $Au_{25}(SC_4H_9)_{18}$ cluster. We found that the deuterated molecule exhibits several unexpected differences. For example, the rates of heterogeneous ET and, particularly, intercluster ET in films are lower; the rate by which two deuterated clusters react in films to form Au_{38} is significantly lower than for $Au_{25}(SC_4H_9)_{18}$; single crystal X-ray crystallography evidences important differences also between the structures of $Au_{25}(SC_4D_9)_{18}$ and $Au_{25}(SC_4H_9)_{18}$. These and further results indicate that deuterated thiolates are far from being noninnocent ligands. The observed effects may be relevant, *e.g.*, to affect the behavior of nanoclusters when used as building blocks for hierarchical structures.[10]

Defects Activity in Metal Halide Perovskite Semiconductors

A. Petrozza,

Center for Nano Science and Technology, Istituto Italiano di Tecnologia, via Rubattino 81, Milano
e-mail: Annamaria.petrozza@iit.it

Metal halide perovskites (chemical formula ABX3, A = formamidinium (FA^+), methylammonium (MA^+), or Cs^+ , B = Pb^{2+}, Sn^{2+}, X = I^-, Br^-, or Cl^-) have demonstrated a strong potential as a material platform for a new generation of optoelectronic technology. One superior feature of metal halide perovskites is their continuously tunable bandgap from near infrared to ultraviolet by designing the chemical composition of the semiconductor crystalline unit. This enables them to provide top absorbers with matched bandgaps for tandem solar cells and emissive layers for colorful light-emitting diodes (LEDs) just to mention the most common applications.

In this lecture I will assess the most recent advances in elucidating the (photo)chemistry of defects related to the chemical composition of the perovskite crystalline unit. I will show how they define the charge carrier dynamics in the semiconductor. Based on such understanding I will discuss the main electrical and spectroscopic features related to the activity of defects and how to interpret them to improve the figures of merit of optoelectronic devices and their stability.

Mapping metabolism in action by mass spectrometry

Nicola Zamboni[a]

[a]*Institute of Molecular Systems Biology, ETH Zurich, 8093 Zurich, Switzerland*

Over the past three decades, metabolomics has become the leading technique for analyzing complex mixtures, driven by continuous technological advancements that have dramatically improved speed, sensitivity, and detail. The widespread availability of high-end instruments has democratized access to these sophisticated measurements, prompting a critical question: what are the ultimate limits of this field?

In this presentation, I will discuss the fundamental limitations that persist despite decades of development and hinder our ability to further expand our knowledge. Additionally, I will introduce two emerging approaches that are poised to overcome these barriers, namely the use of electron-induced dissociation for fine-grained structural elucidation and the use of isotopic tracers for the quantification of metabolic conversion rates in complex networks.

Proteomics in food research

G. Sagratini, L. Alessandroni

School of Pharmacy, Chemistry Interdisciplinary Project (ChIP), University of Camerino, 62032, Camerino, Italy

gianni.sagratini@unicam.it

The "omics" sciences emerged during the last two decades and have been greatly applied in many research fields. In food science, the application of "omics" techniques to improve quality and safety of food product for consumer's health and well-being, and to increase our knowledge on the underlying pathways and mechanisms behind technological and sensorial qualities of foods, is called "foodomics" [1]. Genomics and transcriptomics were derived from new discoveries in genetics. Consequently, due to the presence of mutations in the coding sequence, variations in the starting site for mRNA translation and post-translational modifications, several million protein species are present in tissues that constitute the proteome. The proteome has been defined the complete set of proteins characterized according to their localization, interactions, post-translational modifications, and turnover at a given time point and for a given condition [2].

Proteomics supplements the other "omics" technologies to expound proteins identity, structure, functions, and interactions with other proteins in the control cellular activity [3]. High throughput and large-scale proteomics approaches are important means to analyze not only food quality but also to understand how food processing is affected by the physiology of the product and through this, to enable the optimization of the overall food production process [4]. The main used methodology to investigate proteome develops in two steps: protein extraction and separation from the cell or tissue to reduce sample complexity, and identification and quantification using mass-spectrometry. Obtained data are then processed through statistical tests to list differential protein, bioinformatics analysis and verification of proteins functions and related molecular mechanisms [5]. On this line, proteomics emerged as a multidisciplinary approach to food analysis.

Analyzing through Scopus search engine, all original and review articles on food proteomics published worldwide, it emerged an increase of more than 160% in research activity on the field from 2013 to 2023. Among the food matrices, meat is the most studied with proteomics approaches. Meat quality, safety, technology and impact of specific farming system, feed or supplements on animal proteomes are crucial topics for industries, also in terms of process sustainability, for example with organic productions [4].

In conclusion, the keynote delves into the state of the art of proteomics in food science and aims to spread awareness on this multidisciplinary high-throughput approach as an applicable tool in food research.

Volatomics and Postharvest Handling of Horticultural Crops

R. Cozzolino

[a]Institute of Food Science, Via Roma 64, 83100 Avellino

rosaria.cozzolino@isa.cnr.it

The postharvest handling is crucial to limit loss of fresh horticultural products as they are highly perishable. It is estimated that 30% of produced horticultural products are lost in processes between harvest and consumption [1]. Reduction of these losses is imperative as they impact the overall volume and sustainability of food produced worldwide. Recently, research has been focused on the development of suitable technologies able to positively affect the postharvest quality and shelf life of fruit and vegetables, also improving consumers' preference [1].

Plants biosynthesize an incredible variety of metabolites through different biosynthetic pathways and emit a multitude of volatile organic compounds (VOCs) that mediate their interaction with the environment. During postharvest storage, horticultural commodities undergo various biotic and abiotic stresses. Biotic stress includes the damage caused by microbial contamination and natural senescence mediated by plant-cell enzymes, while abiotic stress factors typically involve low temperatures, high relative humidity, decrease in oxygen, increase in carbon dioxide concentration. Moreover, postharvest mechanical damage during transport and handling from field to storage site are also considered abiotic stress. Additionally, Ready-to-Eat (RTE) products are subject to further postharvest abiotic stress processes, including washing, peeling, cutting and packaging. Each of these factors induces signature alterations in the metabolic pathways of crops, and their combination ultimately leads to complex changes in the composition of the VOCs profile [3]. Therefore, VOCs changes depending on storage conditions and are biomarkers in postharvest storage management. Volatomics, a subset of metabolomics, concerns with the comprehensive characterization of VOCs to assess the quality of horticulture crops along commercial storage, as the results of a complex interplay of factors also including packaging. Volatomics relies on the targeted or untargeted identification of putative volatile markers of freshness using advanced analytical techniques, firstly gas chromatography coupled with mass spectrometry (GC-MS), also integrated with statistical models, multivariate analysis techniques, and shelf-life prediction by innovative (e-nose) non-destructive strategies [3-5].

Such a structured analytical workflow enables the access to in-depth knowledge of the molecular events that occur in the postharvest phase and contribute to rationally plan the processes aimed at preserving the quality of fruit and vegetables and minimizing losses.

luisa.mannina@uniroma1.it

Foods are complex matrices and it is necessary to combine different skills and methodologies to obtain comprehensive information about their composition. Metabolomics is a non-biased identification and quantification of all metabolites in a biological system. This approach has emerged as an important tool in many different fields including food science. Food metabolomics gives the opportunity to gain deeper insights into, and have a better control of the fundamental biochemical basis of the things we eat. In metabolomics, Nuclear Magnetic Resonance (NMR) is recognized as one of the main analytical methodologies giving a complete view of the foodstuffs metabolites and allowing the identification and quantification of many compounds without chemical separation: NMR can bring ''high-throughput'' spectroscopic/structural information on a wide range of metabolites simultaneously with high analytical precision.
Using this methodology together with a suitable statistical analysis it was possible to obtain relevant results in terms of foodstuffs quality, geographical origin, detection of frauds, processing, raw material safety and so on [1,2].

Here, some relevant results will be discussed underlining the strengths and weaknesses of the methodology and highlighting the complementarity with other methodologies.

Finally, the different activities of the Italian group of Magnetic Resonance in Food Science established in the frame of GIDRM will be shown [3].

The metrological approach for the future of analytical chemistry in food science: issues, sinergies and challenges

M. Careri

Department of Chemistry, Life Sciences and Environmental Sustainability, University of Parma, Parco Area delle Scienze 17/A, Parma
maria.careri@unipr.it

Analytical chemistry has become the "enabling discipline of science" capable of answering interdisciplinary questions for many research areas of chemistry and for other scientific fields such as materials science, life sciences, medicine, or food sciences.

The current role of analytical chemistry in opening up new areas of science is the development of new analytical techniques and methodologies that make it possible to extract reliable (bio)chemical information from objects and systems for decision-making purposes to address increasingly challenging problems[1]. In this context, analytical chemistry has to find a balance between its main aims, namely achieving high metrological quality and analytical problem solving, and its overall objectives, which are to provide reliable chemical information and reduce costs and time[2].

Relating to food science, cutting-edge analytical method approaches are being developed in response to emerging food fraud and safety issues, including also assessment of nanomaterials in food. At the same time, great attention has to be paid to the application of metrological tools in response to the ever-evolving challenges of regulatory demands by delivering results compliant with legislation with the speed and accuracy stakeholders expect, while minimizing the risk of recalls: these needs highlight the importance of metrological traceability in achieving comparable analytical results that are independent of temporal or spatial boundaries[3]. Furthermore, considering the growing interest in real-time analysis and process analytical technology (PAT) systems for process control in the food industry, as well as the trend towards the development of smart devices for point-of-need (PON) food safety screening, metrological traceability and reliability of measurements in real-life conditions has to be demonstrated, a challenge not easily met with the analytical tools of PAT and the analytical methods for PON testing[4].

In this lecture, issues, sinergies and challenges of analytical metrology and nanometrology are addressed.

Agri-food chain legislation: official control in Italy

E. Gregori, P. Stacchini

Department of Food Safety, Nutrition and Veterinary Public Health, Isituto Superioe di Sanità, Viale Regina Elena 299, Rome
emanuela.gregori@iss.it

"Regulation (EU) 2017/625 — official controls along the agri-food chain" has applied since 14 December 2019 to set out common rules for European Union (EU) official controls to ensure that agri-food chain legislation to protect human health, animal health and welfare, and plant health, is correctly applied and enforced. The regulation introduced a more harmonised and coherent system of official controls and enforcement measures along the agri-food chain, and strengthens the principle of risk-based controls. Legislative decree 27/2021" Disposizioni per l'adeguamento della normativa nazionale alle disposizioni del regolamento (UE) 2017/625 ai sensi dell'articolo 12, lettere a), b), c), d) ed e) della legge 4 ottobre 2019, n. 117- GU n.60 del 11-3-2021" was published to adapt national legislation to the Regulation (EU) 2017/625.

The Italian Laws set certain exclusive competences to the State (national coordination, international relations, import controls and international disease protection) and defines the areas where competences are shared between the state and the regions, that have responsibility, within their territories, for planning, coordination, guidance, authorization and verification of official controls.

In Italy most of the competencies for animal health, food and feed safety, animal welfare, risk assessment in the food chain and consultation of producers and consumers are assigned at national level to the Directorate-General for Animal Health and Veterinary Medicine (DGAHVM), Directorate-General for Food Hygiene, Food Safety and Nutrition (DGFHFSN) and Directorate General for Collegial Bodies for Health Protection (DGCBHP) of the Ministry of Health. The operational implementation of controls is handled at local level by 110 ASL. Ministry of Agriculture, Food Sovereignty and Forestry (MASAF) as provided for in Decree-Law No 86 of 12 July 2018, is responsible for plant health and for controls on the quality of food, feed and some aspects in the field of plant protection products and fertilisers to plan, schedule, execute, monitor and reporting on official controls. The National Institute of Health (ISS, Istituto Superiore di Sanità) is the main technical and scientific public body of the Italian National Health Service. The ISS, as a national reference laboratory for many areas of activity, coordinates the laboratories of the Italian National Health Service engaged in food and feed control and, in the event of a dispute, performs the second expert opinion. Its activities include research, control, training and consultation in the interest of public health protection.

Recent trends of allergen analysis in food

R. Galarini[a]

[a]*Istituto Zooprofilattico Sperimentale dell'Umbria e delle Marche "Togo Rosati", Via G. Salvemini, Perugia*
r.galarini@izsum.it

In western countries, about 5 % of adult population and 8 % of children suffers for food allergy. EU Regulation 1169/2011[1] requires the labelling of 14 allergenic ingredients (mainly proteins) when they are included in a foodstuff recipe. Beside immunoenzymatic (ELISA) and bio-molecular assays (PCR) widely used in official controls, in the last fifteen years methods based on liquid-chromatography coupled to mass spectrometry (LC-MS) have been developed, too. By means of a bottom-up approach, LC-MS methods are based on the detection of proteotypic peptides obtained from the enzymatic digestion of allergenic proteins. Despite their high cost, these procedures have two fundamental advantages: high selectivity with the ultimate identification of the allergen then avoiding false positive results and the possibility of the simultaneous determination of more than one peptide also from different allergens enabling multiplexed analysis. Except for gluten[2], there are currently no regulatory limits or action thresholds in Europe to manage the unintentional presence of allergens resulting from potential cross-contamination during food production, despite the fact that objective risk assessment should be based on quantitative evidence. On the one hand, there are several difficulties to compare laboratory results obtained with the various techniques (ELISA, PCR, LC-MS). On the other hand, for LC-MS methods, several quantification approaches based on external and internal standardization have been attempted, including the use of different types of labelled peptides (long and short chain) and concatamers. However, since the initial "analytes" are proteins, when complex foods are analysed, accuracy is not always satisfactory. A review of quantification strategies applied so far is presented here.

How Food Chemistry can support the safety assessment of Novel Foods

C. Dall'Asta

Department of Food and Drug, University of Parma, I-43124 Parma, Italy
chiara.dallasta@unipr.it

The food industry's interest in novel foods is rapidly increasing, driven by sustainability goals, innovation, and the pursuit of new market opportunities. Novel foods offer significant potential for discovering new protein sources, bioactive compounds, and innovative uses of familiar ingredients, while also tapping into the vast chemical biodiversity of plant and marine resources.

Ensuring and properly communicating the safety of these novel foods is paramount not only for obtaining their approval in the EU, but also to increase their acceptance among consumers. Safety evaluation goes beyond traditional assessments of known contaminants or toxins; it must also encompass the identification of potential new compounds with biological or toxicological effects, as well as assessing allergenic risks.

In this context, the molecular approach provided by Food Chemistry serves as a powerful tool for evaluating the safety profile of novel foods. This enables companies in the sector to develop new, innovative, and safe products confidently as well as it offers sound information to risk assessors and regulators.

This presentation will highlight various molecular approaches for assessing toxicity, bioactivity, and allergenic potential, using relevant case studies. Special emphasis will be placed on alternative plant protein sources, such as legumes, and innovative plant-derived products like coffee and hemp, bringing clear evidence of the key role played by Food Chemistry methodologies in their evaluation.

[c]*Department of Biomedical, Dental, Morphological and Functional Imaging Sciences, University of Messina, Via Consolare Valeria, 98125, Messina, Italy*
pdugo@unime.it

Food chemistry studies the chemical processes and interactions of all biological and non-biological components of foods. It is continuously involved in the assessment of food quality and authenticity, the control of technological processes, the determination of nutritional values and the detection of molecules with a possible beneficial effect or a toxic effect on human health.
In this context, analytical methods should be capable to allow the determination of the main components of food samples but also, they should be selective and sensitive enough to determine minor ones.
Surely, chromatography has acquired a central role in food analysis and especially its combination with mass spectrometry provides a unique performance due to the complementarity of the two techniques. Notably, also mass spectrometry itself, due to its high identification power and high sensitivity, might be employed without the support of chromatography.
In recent years, food chemistry, by adopting these methods, helped to solve routine and challenging problems, such as the detailed characterization and quantification of complex natural matrices.
Key aspects of analytical techniques today applied to food chemistry are: miniaturization, automation, reduced environmental impact, speed of analysis, among others. Chromatography and mass spectrometry have for sure moved towards these directions, offering different solution for different laboratories: QA, R&D, industry, academia, advanced research. Nowadays, mass spectrometry enables the obtainment of unique “fingerprints”, with the advantage to be extremely fast ang “greener” since they do not require any sample pre-treatment and analyse the sample as it is (in its native form) without any separation step.
In this lecture, an overview of significant achievements, in the use of different chromatographic and mass spectrometric approaches in food chemistry, useful for the traceability of Italian excellences, are presented.

Coffee chemotaxonomy markers: focus on diterpenes

Elena Guercia,[a] Luciano Navarini[b]
[a] illycaffè S.p.A., Area Science Park, Aromalab, 34149, Trieste, Italy
[b] illycaffè S.p.A., via Flavia 110, 34147, Trieste, Italy
elena.guercia@illy.com

Coffee represents one of the most known traded tropical commodities, however for coffee drinkers it is easy to forget that coffee is, first and foremost, a plant. The coffee plant belongs to the Rubiaceae family, genus *Coffea* which comprises around 130 species distributed through equatorial and sub-equatorial Africa, Madagascar, India, SE Asia and Australasia. The three coffee species with commercial interest are *C. arabica*, *C. canephora* and *C. liberica*, known in the trade as Arabica, Robusta and Liberica, respectively. Coffee taxonomy is undoubtedly a very complex topic, but chemistry can be considered a useful tool to address its complexity. Coffee diterpenes, the major components of the unsaponifiable fraction of coffee oil, have always played an important role for both authenticity and traceability of coffee products. In particular cafestol, kahweol and 16-O-methylcafestol have been the subject of several studies, and their green coffee beans content mainly depends on both botanical species and geographical origin. While chemometric approaches have been widely used to study cultivated coffee species, very little has been done from the perspective of chemotaxonomy of wild species of the genus *Coffea.* We believe that diterpenes, not yet fully exploited from a chemotaxonomic point of view, may also provide useful information on wild coffee species that are currently not of commercial interest or whose taxonomic subdivision is still unclear.

chiara.dilorenzo@unimi.it

In the last decades an increasing attention has been paid to "nutraceutical science", involving different products aimed at enhancing consumers' health: fortified foods, functional foods, some traditional medicine derivatives, and dietary supplements. These products include a spectrum of ingredients ranging from vitamins, minerals, amino acids to botanical preparations. Ensuring the efficacy and safety of nutraceutical products necessitates rigorous quality control measures. Specifically concerning botanicals, particular attention is required for raw materials, including the identification of plant materials, quantification of active molecules responsible for physiological effects as well as adverse effects, the assessment of environmental contaminants or residues from agricultural practices[1]. Another significant challenge in ensuring consumers' safety is related to counterfeits or adulteration with illicit substances such as doping agents or conventional drugs, as documented in scientific literature or in national/international notifications. Quality control procedures require the selection of appropriate analytical methods (according to the objectives), capable to identify/quantify the searched molecules. However, quality aspects are only one of the contributors to the onset of adverse effects.

Consumers' awareness, food-related diseases, specific physiological conditions (pregnancy, lactation, childhood, elderly) and the concomitant drug therapies are considered other important cofactors involved in "safety" concept[2].

The pomegranate fruit: not just a simple food

S. Carradori

Department of Pharmacy, "G. d'Annunzio" University of Chieti-Pescara
simone.carradori@unich.it

Pomegranate (*Punica granatum* L.) is a widely recognized edible food and medicinal plant, containing flavonols, anthocyanins, and tannins, with ellagitannins being the most abundant polyphenols. Its cultivation, consumption and scientific interest are strongly increased, due to multiple beneficial effects as well as the chemical differences found among its cultivars.[1] Its fruit is a balausta surrounded by a thick and coloured peel composed of a hard exocarp and a spongy mesocarp with edible arils inside, whose juice can be released by pressing. The edible portion of pomegranate is known for the nutritional profile, and it provides vitamin C, vitamin K, and folate. Pomegranate seeds are a rich source of dietary fiber which is entirely contained in the peel and seeds. The latter are also used to obtain the oil, rich in fatty acids such as punicic acid. The non-edible peel of the fruit and the split fruit, not suitable for the market, although generally disposed as agricultural waste or transformed into animal feed, compost, or biogas, can be also used to extract bioactive components as dietary supplements and other value-added products, providing new opportunities for the pharmaceutical, cosmetic, and food industries.[2] The limited oral bioavailability can be enhanced using suitable encapsulation methods. Green extraction approaches, including pressurized liquid, ultrasound-assisted, microwave-assisted, and enzyme-assisted techniques, or technological processing of this matrix opened new scenarios. Furthermore, pomegranate peel can be utilized as fertilisers for sustaining soil fertility and enriching soil microbiota and in the food industry, improving the nutritional value, organoleptic characteristics, and shelf life of food products, thus limiting the overall organic waste.[3]

Microplastics in Foods: Origin and Detection Methods

M. Fiorini,[a] N. Lotti,[a] M. Soccio [a], E. Battaglini,[a,b]

[a]*DICAM, Dept. Civil, Chemical, Environmental and Materials Engineering, University of Bologna, Via U. Terracini 28, 40131 Bologna*
[b]*Sherwin-Williams, Via G. Marconi, 40061 Minerbio (Bo)*
maurizio.fiorini@unibo.it

Microplastics (MPs) are defined as plastic particles ranging in size from 5 mm down to 0.1 µm, further classified as primary and secondary MPs. Primary MPs are intentionally added to specific products, such as skincare or cosmetic formulations. Secondary MPs result from the mechanical wear, UV degradation, or oxidation of plastic waste in the environment.[1] MPs were first detected in marine environments in the 1980s[2]; they were later detected in soils and freshwaters. Not surprisingly, seafoods attracted first the attention of scientist looking for MPs presence[3]. More recently, MPs have been detected in other food, such as packed meat, sugar, beer, honey, milk, salt, as well as fruit and vegetables. Additionally, there have been recent reports indicating that plastic packaging could potentially release plastic particles during use and package opening.

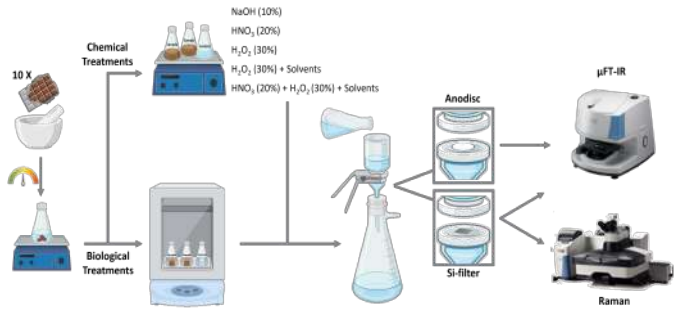

Figure 1: Sample work-up and identification techniques for MPs in chocolate.

In this presentation, the origin of MPs found in food will be addresses, along with the central role taken up by an efficient sample work-up designed to eliminate, or at least reduce, the matrix effects. Examples drawn by the recent literature are discussed, along with some contributions made by the research group at DICAM[4].

Upcycling of fishery unsorted side-streams: a case study

R. Boggia [a], F. Grasso [a], V. Orlandi [a], D. Méndez-Paz [b], Vázquez Sobrado R. [b], Alonso Martínez M.M. [b],Turrini F.[a].

[a] *Department of Pharmacy, University of Genoa, Viale Cembrano 4, 16148 Genova, Italy*

[b] *ANFACO-CECOPESCA, Department of Circular Economy, Colexio Universitario, 36310 Vigo, Spain*

It has been estimated that approximately 35 % of the global fish production is lost or wasted annually, presenting significant economic and environmental challenges. As a result of rising fish consumption, the consequent production of side streams by the fish supply chain (fishing, aquaculture, and the processing sector), namely fishery side streams, is also increasing. Two different types of side streams are commonly generated, the first is made up of whole fishes, coming from unwanted catches, by-catches, and undersized catches. The second type consists of by-products and leftovers from both filleting and/or preservation processes. If in the first case the sorting of different pieces is difficultly feasible, in the second it is feasible, but quite expensive in terms of costs, time and energy. Thus, recovering valuable components before disposal becomes the prime target in the management of solid fishery biomasses and it could be a valid alternative for their upcycling.

Over the years, various conventional techniques have been utilized to exploit these biomasses, including the production of fish meal via wet pressing, fish oil through hydrophobic solvent extraction, and biofuel through esterification. Even if there has been an improvement in fish exploitation, the potential for the generation of fishery side streams remains high due to their highly perishable nature and the presence of inedible fractions. The urgent requirement to shift production systems towards environmentally sustainable alternatives has spurred the EU Commission to formulate and endorse "Blue Growth," a strategic plan designed to promote long-term sustainable growth in the marine and maritime sectors[1]. Many research projects have been funded at the European level, among them EcoeFISHent, which is a project funded under the Horizon 2020 Program - Green Deal (Innovation Action, Grant agreement ID: 101036428)[2]. This project aims at promoting circular economy practices within the fishing sector with the peculiarity to revolve around handling and valorizing of unsorted fishery by-products. In the frame of the EcoeFISHent project, a scalable method represented by a single cascade flowchart for extracting and upcycling proteins from unsorted tuna side streams (both raw and cooked) will be presented as case study[3]. In details, the starting biomasses were made up of a dehydrated mix of canned tuna leftovers stabilised by an innovative industrially patented procedure and the obtained extracts have been addressed to bio-packaging, cosmetic and nutraceutical applications[4].

Use of lamellar solids as a novel approach to food processing

F. Epifano,[a] C. Collevecchio,[a] S. Fiorito,[a] R. Spogli,[b] S. Genovese[a]

[a]*Dipartimento di Farmacia, Università "G. d'Annunzio" Chieti-Pescara, Via dei Vestini 31, Chieti Scalo (CH)*

francesco.epifano@unich.it

Solid phase extraction is nowadays a well validated and powerful technique applicable to chemically complex matrices like edible plant extracts, phytocomplexes, and food preparations in general. This process provides concentration and/or purification of selected chemicals, active principles, and secondary metabolites in general from these matrices for subsequent analysis and isolation, and /or enrichment of food and phytopreparations.

To this concern, during the last five years we developed a novel approach for food processing consisting in the use of solid sorbents belonging to different chemical classes like layered structures (e.g. inorganic and inorganic-organic hydrotalcite and zirconium phosphates), magnesium oxide and hydroxide, and phyllosilicates.

Such techniques have been successfully applied for the selective extraction of anthraquinones from laxative plants[1], of polyphenols and alkaloids from extracts of *Camellia sinensis* (L.) Kuntze (tea plant)[2], of curcumin from *Curcuma longa* L. (turmeric)[3], of bitter principles from leaves and roots of *Gentiana lutea* L. (great yellow gentian)[4,5], of capsaicinoids from different cultivars of *Capsicum annuum* L. (pepper)[6], of oxyprenylated coumarins from *Citrus* fruits[7], of crocetin from *Crocus sativus* L. (saffron)[8], and of polyphenols from *Punica granatum* L. (pomegranate)[9]. In all cases very good extractive yields have been obtained. Finally, the use of the above-mentioned solid sorbents was shown to be useful for the extraction and analysis of some food colorants, like tartrazine (E102) and brilliant blue (E133) from selected food matrices[10]. All solids were recyclable and could be re-used to accomplish additional steps without appreciable loss of adsorption capacity.

Organometallic Catalysis Applied to the Synthesis of High Value Added Compounds: The Contribution of the Research Group of Industrial and Synthetic Organic Chemistry of the University of Calabria

Bartolo Gabriele

Laboratory of Industrial and Synthetic Organic Chemistry, Department of Chemistry and Chemical Technologies, University f Calabria, Via Pietro Bucci 12/C, 87036 Arcavacata di Rende (CS), Italy
bartolo.gabriele@unical.it

In this lecture, I will illustrate some of the most important achievements that have been realized in my lab during the long-lasting experience in the field of homogeneous organometallic catalysis applied to the synthesis of high value added compounds from simple and readily available starting materials.

Particular emphasis will be given on the catalytic activation of carbon oxides (especially, carbon monoxide)[1] for the direct and selective installation of the carbonyl moiety into simple organic substrates (especially, acetylenic derivatives), and on the synthesis of heterocyclic derivatives by metal-catalyzed heterocyclization reactions.[2]

Aluminum Cocatalysts for Olefin Polymerization: Methylaluminoxane and its "Molecular Cousins"

Francesco Zaccaria

Federico II University of Naples, Department of Chemical Sciences, via Cinthia, Napoli.
E-mail: francesco.zaccaria@unina.it

Over the last few decades, molecular olefin polymerization catalysis has rapidly emerged from questions of mere academic interest to applications in large-scale industrial production of high-performing materials. This transformation was sparked in the 1980s by the concomitant discovery of thermally stable group 4 metal catalysts and highly efficient activators/cocatalysts.[1] Nonetheless, the subsequent tremendous progress experienced by this field has been mostly driven by the continuous development of novel catalysts,[2] while advancement in cocatalysts has been limited.

The difficulties in developing innovative cocatalysts derives from the complex cross-reactivity between the various components of the catalytic pool and the many subtleties determining catalytic performance.[1] Even widely used cocatalysts, such as methylaluminoxane (MAO), continue to elude comprehensive understanding.

Some recent advancements in cocatalysts discovery and development will be discussed in this presentation. They include insights on the structure and reactivity of MAO and some of its modifications, as well as the analysis of a novel promising class of molecular Al-cocatalyst. The prototype of this latter class consists of a borate salt of an unusual dinuclear Al-alkyl cation, stabilized by an N-donor and a bridging hydride (**AlHAl**, Figure 1).[3] This species proved to combine the ability of MAO to act as a "complete"/stand-alone cocatalyst with the advantage of having a well-defined structure and working at low concentrations. Despite being an Al-alkyl cation, it is stable at room temperature and easy to synthesize. Furthermore, it is potentially amenable to structural variations for reactivity tuning, which we are currently exploring.

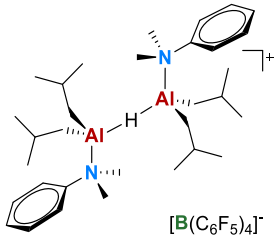

Figure 1: Structure of MAO's "molecular cousin", **AlHAl**.[3]

Novelty in Transfer Hydrogenation and Related Reactions Catalyzed by Ruthenium Catalysts

W. Baratta

Dipartimento DI4A, Università di Udine, Via Cotonificio 108, 33100 Udine, Italy
e-mail: walter.baratta@uniud.it

Transfer hydrogenation (TH) is a straightforward transformation for the reduction of carbonyl compounds to alcohols using suitable hydrogen donors under mild reaction conditions. Conversely, carbonyl compounds can be obtained by alcohols by means of hydrogen acceptors without the use of hazardous oxidants. As a result of the reversibility of the TH, borrowing hydrogen transformations, namely C-C and C-N forming reactions, can be achieved via C-H activation. In order to have access to selective catalytic processes, the development of well-defined homogenous catalysts, obtained through a fine tuning of non-innocent ligands via metal-ligand cooperativity, is a current research target.[1] In addition, high catalyst productivity is a critical factor for applications and relies on the design of robust catalysts.

This presentation deals with the preparation of ruthenium complexes, containing bidentate and pincer ligands, which display high activity in the TH of carbonyl compounds, Oppenauer-type alcohol oxidation, alcohol racemization, hydrogenation, dehydrogenation, amine alkylation and photochemical TH reactions (Figure 1). Mechanistic studies indicates that Ru-hydrides and Ru-alkoxides are key species involved in the catalytic processes.

A multiscale perspective on charge transfer reactions for connecting experiments and simulations

Laura Zanetti-Polzi

Center S3, CNR-Institute of Nanoscience, Via Campi 213/A, 41125 Modena, Italy
Laura.zanettipolzi@nano.cnr.it

The applications of multiscale quantum-classical approaches have experienced a remarkable expansion and diversification in recent times. One of the pivotal objectives of these theoretical modelling approaches is the direct comparison between computed and measured observables, accounting for the intricate interplay between a reaction and the environment in which it takes place. In response to this challenge, we have developed the Perturbed Matrix Method (PMM),[1] a theoretical-computational hybrid quantum/classical methodology to be used in conjunction with molecular dynamics (MD) simulations. This approach has proven its effectiveness as a valuable tool for exploring diverse processes within complex molecular systems. I will highlight two recent applications of the PMM methodology, with a primary focus on charge transfer reactions in biomolecules.

In the first application,[2] we addressed the study of ultrasmall peptide-protected gold nanoclusters (AuNCs), an emerging class of materials with distinct and tunable physicochemical properties that exhibit pH-sensitive photoluminescence (PL). Through the systematic calculation of local environment-dependent deprotonation free energies, we provided insight into how the PL emission intensity of peptide-coated AuNC is related to solution pH, in line with previous experimental observations.

In the second application,[3] we studied the kinetics of the light-induced electron transfer reaction in a flavoenzyme, lactate monooxygenase, that is a good platform for non-natural photoenzymatic catalysis. We investigated the photo-initiated ET at the flavin mononucleotide binding site in the apoenzyme and in the presence of a model substrate. By integrating our computational findings with experimental data obtained from ultrafast spectroscopy, we provided mechanistic insights into the photochemistry of the enzyme.

Advanced supercomputing approaches in chemistry and prebiotic chemistry

G. Cassone

Owing to the impressive growth of the computational power and of the development of novel computational techniques, including data-driven approaches, nowadays it is possible to simulate the behavior of matter under disparate conditions with unprecedented reliability. In this brief introduction, I will show how modern *ab initio* molecular dynamics (AIMD) simulations can shed light on one of the simplest – yet intricate – chemical reactions (*i.e.*, proton transfer) fully including the quantum nature of matter [1]. Besides, I will also show how human-based concepts on which the literature has debated for centuries, like the existence of two different ionic states (*i.e.*, Eigen *vs*. Zundel) responsible for the proton transfer mechanism in liquid water, can be revolutionized by agnostic methods exploiting unsupervised learning [2]. After the presentation of the catalytic properties held by external electric fields in triggering molecular dissociations and proton transfer, I will show how those fields can be tailored to generate either a genuine *chemical* [1] or a *physical* response in H-bonded systems [3,4].

The possibility to explicitly simulate disparate external energy sources with the accuracy afforded by Density Functional Theory and Quantum Mechanics, is particularly useful in prebiotic chemistry, where conditions difficult to be reproduced in laboratory are often encountered. During this talk, I aim to present a series of quantum-based simulations where chemical reactions of interest in prebiotic chemistry were reproduced. After a rapid overview of the potentiality offered by disparate techniques, such as AIMD and metadynamics, in chemistry [5] and in the prebiotic realm [6], I will present the results stemming from a series of advanced simulations based on the multi-scale shock-compression technique (MSST) combined with AIMD approaches. By means of those methods, the shock-wave-driven chemistry of mutually colliding isocyanic acid (HNCO)-containing icy grains has been simulated by first principles [7]. At the highest velocity considered (10 km/s), impacts drive the production of diverse carbon-carbon bonded species. In addition to glycine, the building block of alanine and one of the major components of a plethora of amino acids including, *e.g.*, asparagine, cysteine, and leucine, have been detected after shock compression of samples containing the most widespread molecule in the universe (H_2) and the simplest compound bearing all the primary biogenic elements (HNCO). Finally, if time permits, results on the catalytic properties carried by interstellar ices will be presented [8] in conjunction with very recent computational evidence proving the existence of abiotic chemical pathways capable of producing phosphine in the Venusian atmosphere [9].

From β- to Ω-oxidation: NMR targeted metabolomics sheds light on dual enzymatic functions in mitochondrial long-chain fatty acid metabolism

S. Fabbian,[a] M. Bellanda,[a] E. Schievano,[a] G. Giachin[a*]

[a] *Department of Chemical Sciences (DiSC), University of Padua, Via Marzolo 1, 35131 Padova*
* gabriele.giachin@unipd.it

Fatty acid oxidation (FAO) defects are inherited metabolic diseases caused by deficiency of specific enzyme activities or transport proteins involved in the mitochondrial catabolism of fatty acids. Common disorders of this group include, for instance, very long-chain acyl-CoA dehydrogenase (VLCAD) and acyl-CoA dehydrogenase family member 9 (ACAD9) deficiencies. The clinical features are highly variable, ranging from multi-organ failure in newborns associated with a high mortality rate to late onset milder phenotypes. Understanding the molecular mechanisms governing the oxidation of long-chain fatty acids is essential for effective treatments of FAO defects.

Our investigation unveils a previously unrecognized aspect of mitochondrial long-chain fatty acid metabolism, revealing the coexistence of both β- and Ω-oxidation processes catalysed by two distinct acyl-CoA dehydrogenases. Through the application of ^{13}C NMR metabolomics and MS approaches, we elucidate the intricate interplay between enzymatic functions, providing new insights into the modification of fatty acids. These findings deepen our understanding of lipid metabolism and pave the way for promising biotechnological applications, potentially inspiring the development of novel enzymatic tools for lipid modification and metabolic engineering in various fields.

Late-Stage Functionalizations

Prof. Tobias Ritter, PhD
Max Planck Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1
45470 Mülheim, Germany
ritter@mpi-muelheim.mpg.de

Late-stage functionalization reactions reliably functionalize already complex molecules to quickly access value-added molecular diversity. Late-stage functionalization is desirable in many areas of discovery such as in drug or agrochemical development, and a requirement in other areas such as the synthesis of positron-emission tomography (PET) tracers. I will describe the development of novel, modern highly selective reactions in late-stage functionalization, as well as their application in transition-metal-catalyzed and photoredox reactions, with a focus on the synthesis of ^{18}F and ^{19}F containing complex small molecules. In particular, I will describe the development of broadly useful C-H thianthrenation reactions, as well as the conceptual differences and advances of thianthrenium chemistry when compared to conventional reaction chemistry, with development towards applications in catalysis, drug discovery, and medicine.

The Diamond Anvil Cell (DAC) currently represents the most advanced device to generate static high-pressure conditions ranging from few tenths up to hundreds of GPa, offering unique possibilities to investigate the behavior of matter under high-density conditions and to access unexplored regions of the potential energy surface of the investigated systems. These opportunities are further expanded by combining pressure with temperature and selective photo-excitation, unveiling exotic structures and reactivity compared to ambient pressure and leading to the discovery of new phenomena, to the opening of new reactive paths, and to the synthesis of new compounds. In this talk selected highlights from our high-pressure studies about the structural and reactive properties of group 15 elements will be presented and discussed.[1-5] In particular, the talk will focus on the high-pressure and high-temperature synthesis of pnictogen nitrides by the activation of direct chemical reactions of heavier pnictogens with N_2.[3-5] The discoveries of the first crystalline nitrides of arsenic (AsN)[4] and antimony (Sb_3N_5)[5] represent milestones in pnictogen chemistry and open new perspectives for the high-pressure synthesis of an entire class of new advanced materials of energetic and technological relevance, potentially recoverable at ambient pressure as stable or metastable systems.

New modalities: Chemical synthesis of complex bio-inspired molecules and conjugates

G. Lattanzi[a]

[a] *Aptuit (Verona) Srl, an Evotec company, Via Alessandro Fleming 4, Verona, Italy*
giulia.lattanzi@evotec.com

In recent decades, the drug discovery industry has expanded its common R&D landscape beyond that of small molecules. This innovation is represented by new chemical modalities that include peptides, oligonucleotides, antibodies, and their conjugates.[1]

Consequently, the evolution of techniques and technologies for synthesizing complex bio-inspired molecules has become increasingly crucial, reflecting their growing importance in the modern pharmaceutical landscape.

Peptide synthesis has seen significant improvements over the years, ranging from classical solid-phase peptide synthesis (SPPS) to modern techniques such as microwave-assisted synthesis and automated peptide synthesizers. The incorporation of non-standard amino acids and the synthesis of complex peptides, such as stapled, cyclic, and multimeric constructs, has further expanded their potential for therapeutic applications.

Oligonucleotide-based therapeutics have similarly progressed. Since the advent of deoxynucleoside phosphoramidite chemistry in 1981, solid-phase synthesis has been extensively developed for the preparation of antisense oligonucleotides and siRNA. Moreover, a variety of chemical modification and conjugation strategies have been identified to improve the drug-like properties and RNA-binding affinity of oligonucleotides for therapeutic applications.[2]

Meanwhile, conjugation technologies have evolved to allow the synthesis of hybrid molecules with enhanced properties. In particular, linker chemistry has become more sophisticated, enabling the precise connection of different biomolecules to improve target specificity and therapeutic efficacy.

This presentation will cover some aspects of the continuous expansion of synthetic methodologies for the preparation and conjugation of biomolecules, towards the development of more effective and personalized treatments.

Electron welfare for biological synthesis of hydrogen and CO_2 valorization

Giuliana d'Ippolito and Angelo Fontana

Istituto di Chimica Biomolecolare (ICB), Dipartimento Scienze Chimiche e Tecnologie dei Materiali (DSCTM), Consiglio Nazionale delle Ricerche (CNR).
Via Campi Flegrei, 34 – 80078 Pozzuoli, Napoli
gdippolito@icb.cnr.it

Living cells are powered by energy stored in the chemical bonds of organic molecules released through multiple reactions catalyzed by enzymes. The electrons necessary to sustain the reactions derive from oxidative pathways, such as splitting of water in the photosynthesis or sugar catabolism (i.e. glycolysis) in the fermentation. Cellular "social legislation" prevent overcrowding of the electrons by physiological mechanisms of energy dissipation in order to maintain the redox homeostasis. In a few anaerobic bacteria, the excess of reductants is dissipated by reduction of hydrogen ion to molecular hydrogen by a hydrogenase-dependent catalysis. The reaction generally competes with the formation of other reduced end products of fermentation, such as lactate or ethanol.

In this lecture, as a case study, I will discuss a novel fermentation pathway named Capnophilic Lactic Fermentation (CLF) that has been identified in the anaerobic hyperthermophilic bacterium *Thermotoga neapolitana*.[1] The CO_2-activated mechanism enables a non-competitive synthesis of hydrogen and L-lactic acid (95% e.e.), which is formed by enzymatic reductive carboxylation of acetate.[2,3,4] Chemical studies of the CLF pathway are at the basis for the comprehension of the cellular mechanisms to sustain multiple NADH-dependent reactions, such as hydrogen synthesis or pyruvate reduction to lactate.[5,6] The biotechnological process based on CLF has been patented and can be exploited for the development of sustainable production of green hydrogen and for CO_2 valorization into commodity chemicals starting from sugars, sugar-based waste and renewable feedstocks.[7,8]

Enabling technologies in organic synthesis: the truth about their industrial scalability

Giancarlo Cravotto

Dipartimento di Scienza e Tecnologia del Farmaco, University of Turin, via P. Giuria 9, 10125 Turin
giancarlo.cravotto@unito.it

Currently the sustainability of chemical processes is driving innovation and industrialization in accordance with environmental friendliness, energy efficiency and scalability. Among emerging technologies, continuous-flow chemistry has become mainstream in the development of innovative, highly efficient catalytic syntheses of fine chemicals and active pharmaceutical ingredients (APIs) [1]. Unfortunately, the reproducibility and the claimed scalability reported in several papers are often proven wrong. Conventional conductive heating and mixing in batch reactors is no longer competitive with continuous-flow synthetic methods, and enabling technologies applied in flow-mode can strongly promote reaction kinetics [2]. These advances are leading to faster and simplified downstream processes with easier workup, purification, and scaling-up. In the current Industry 4.0 revolution, new advances based on cyber-physical systems and artificial intelligence will be able to optimize and invigorate synthetic processes by combining cascade reactors with continuous inline monitoring and even predicting solutions in case of unforeseen events. Alternative energy sources such as dielectric [3,4] and ohmic heating [5], ultrasound [6], hydrodynamic cavitation [7], reactive extruders [8] and plasma [9] have revolutionized standard processes. Also worth mentioning are the so-called hybrid or hyphenated techniques, where the combination of two different energy sources often produces synergistic effects. Relevant case studies at pilot and semi-industrial scale of continuous or semi-continuous extraction and synthetic processes under non-conventional techniques will be discussed.

Sample preparation in one click: monolith columns as a case study

C. M. Montone, S. E. Aita, A. Cerrato, C. Cavaliere, A. Laganà, S. Piovesana, E. Taglioni, A. L. Capriotti

University of Roma "La Sapienza", Piazzale Aldo Moro 5, Rome
carmelamaria.montone@uniroma1.it

Miniaturization is a fundamental aspect of the green analytical chemistry approach and should also encompass absorbent preparation, considering factors such as energy consumption, quantities, and types of reagents, especially on an industrial scale. In this context, the use of click reactions remains limited in the development of absorbents for sample preparation despite being a well-established approach in organic chemistry. Within the realm of click reactions, multicomponent click reactions combine the advantages of click reactions with the principles of green chemistry such as equimolarity, large-scale purification, high reaction rates, high yields, stability, modularity, broad applicability, chemoselectivity, and a single reaction pathway. Four-component click reactions without metallic catalysts offer additional advantages such as biocompatibility, atomic economy, and cost-effectiveness. These reactions are achieved by selecting monomers suitable for high reactivity and efficient transformations. Specifically, alkynylcarboxylic acid, primary amine, organic boronic acid, and formaldehyde have been employed; these polymeric products generally exhibited film-forming capacity and high thermal stability. These reactions have been exploited to achieve a reduced and one-pot synthesis of a poly(propargyl amine) polymer within a readily available silica-coated PEEK tube. The resulting monolithic columns have been integrated into an autosampling system for the automatized online extraction and purification of small molecules in complex samples. This approach underscores the versatility, cost-effectiveness, and environmentally friendly nature of multicomponent reactions for generating reverse-phase and mixed-mode adsorbents, facilitating the scaling of the entire analytical procedure from extraction preparation onwards. [1]

In about a decade from the first report by some of us about the outstanding enantiodiscrimination ability of inherently chiral electrodes[1], our research on effective tools and strategies for chiral voltammetry has much grown both in width and depth. A selected casebook will be presented, discussing the following key issues:

(*i*) nature of the stereogenic element(s) (stereocentres, axes, helixes, planes) in selectors and probes[1-8],

(ii) assumptions on selector/probe interactions[9], and possible strategies to enhance them[2,9];

(ii) proposed strategies for effective implementation of chiral selectors at the electrochemical interphase: electrodes modified with inherently chiral oligomer films[1-4], or media of high local order implemented with chirality[5-8] (chiral ionic liquids, ionic liquids with chiral additives, chiral deep eutectic solvents).

Citizen science: An opportunity for innovation in Analytical Chemistry

S. Loiselle,[a] A.Boldrini,[a] A. Polvani,[b] X. Liu[b], G. Tamasi[c]

[a]*Environmental Spectroscopy Group, Department of Biotechnology, Chemistry and Pharmacy, CSGI, University of Siena, Via Aldo Moro, Siena, Italy*
loiselle@unisi.it

Citizen science has the potential to enhance both the impact in scientific research by democratizing access to scientific knowledge and increasing the participation in the process of data collection, analysis, and interpretation. Historically, instruments for experimentation and monitoring, along with the expertise required to design rigorous measurements and analyse results, have been largely confined to academic and regulatory domains. Yet, citizen science initiatives are disrupting this traditional model by empowering the public to engage and support in scientific inquiry.

In this presentation, we will explore the potential impact of citizen science as a catalyst for innovation in Analytical Chemistry by exploring ongoing citizen science projects and where key challenges remain. We will highlight recent developments that have allowed local communities to contribute to data collection efforts, as well as data analysis. These include leveraging new technologies such as portable sensors and low-cost kits to gather robust information on environmental and public health challenges. We will also highlight where new approaches are required to meet challenges, while keeping an eye out for opportunities on the innovation horizon.

We will showcase best practices in methods development and their application to national scale and community scale citizen science programs focused on emerging aquatic pollution challenges in Europe and Africa. Citizen science offers unique opportunities for innovation in analytical chemistry, highlighting the need for new methodologies for data acquisition and analysis[1]. Citizen scientists require novel tools and techniques to address local and global challenges[2], requiring a new approach to experimental design. New processes of validation and calibration are required to ensure consistency, reliability and applicability across diverse environments.

We will also underscore the benefits of citizen science in fostering collaboration between researchers and communities, promoting knowledge exchange and mutual learning. By engaging citizens in the scientific process, scientists can broaden the scope and scale of their research, as well as promoting public engagement with science, enhancing scientific literacy and encouraging environmental stewardship. Through active involvement in the scientific process and support to address local and national challenges with more robust methods and experimental design, analytical chemists can harness the collective power of communities to pave the way for more inclusive and impactful research outcomes[3].

Bioluminescence analytical platforms for One Health: from paper sensors to thread-based analytical devices

E. Michelini, M. M. Calabretta, D. Gregucci, F. Nazir, E. Maiorano

Dept. of Chemistry "Giacomo Ciamician", University of Bologna

elisa.michelini8@unibo.it

Bioluminescence (BL) is a fascinating phenomenon in which photons are emitted as byproduct of a chemical reaction occurring in living organisms, including bacteria, fireflies, and several marine species.

BL systems possess remarkable features, such as high quantum yield and no need for an external light source, that render them highly valuable bioanalytical tools for developing portable biosensors for monitoring molecules, cells, and bioactivities with applications spanning from agro-food to clinical fields. Therefore, bioluminescent biosensors have a great potential to support the "One Health" approach, to guarantee health to humans, pets, wildlife and our environment.

Here we report the development of novel BL tools and strategies which can be used to improve the analytical performance of paper-based smartphone biosensors. BL showed suitable to develop highly sensitive biosensing paper platforms enabling the detection of target analytes down to the ppb levels in complex biological matrices. The stability of these biosensors has been increased by the obtainment of bio-nanocomposites relying on nanomaterials (metal-organic framework, MOF), thus improving the robustness of the analytical platforms.

Moreover, we explored the combination of bioluminescence biosensing with microfluidic thread-based analytical devices (μTADs), which represent a sustainable and low-cost alternative to paper based biosensing, especially to handle very low volumes of samples (less than 5 μl), showing great potential also for multiplex analysis in combination with chemiluminescence. We report a proof-of-principle application of bio-chemiluminescence biosensing on cotton threads and, to prompt future applications in point-of-care and point-of need settings, we exploited smartphone detection enabling easy detection of the bio-chemiluminescent signal.

Artificial intelligence (AI) algorithms were also combined to smartphone-based bioluminescence detection to provide a user-friendly paper-based toxicity smartphone biosensor.

gabriele.lando@unime.it

The rapid growth in demand for lithium-ion batteries (LIBs) is posing challenges in the management of end-of-life (EoL) systems and the supply of critical raw materials (CRMs), especially Li, Ni, Co, and Mn. New greener routes in hydrometallurgy process must be explored to return such critical raw materials into a more sustainable circular economy [1]. The application of organic acids is gaining even more attention due to the combination of good recovery efficiency, low cost, environmental benefit and reduced energy demand [2].

Preliminary screening on systems such as citric, oxalic and formic acid, in combination with reducing agents, demonstrated their suitability as greener alternatives to classical inorganic acids, even at low process temperatures, for the hydrometallurgical recycling of lithium-ion batteries.

The conditions under which these systems are nowadays explored are far away from the typical domain of equilibrium chemistry, but still under those conditions chemistry is going on, despite of our limited capacity to describe and even less of make prevision.

We proposed a very preliminary attempt to give a sort of method to explore the equilibrium chemistry of brines containing one of the mentioned organic acid, namely citric acid (H_3Cit), towards Co(II), and Ni(II). In detail, two sets of potentiometric titrations have been performed, the first in canonical experimental conditions (at millimolar level), and the second mimicking the conditions of the hydrometallurgic process (H_3Cit ~ 1 mol dm^{-3}; Co(II) ~ 0.2 mol dm^{-3}). In both measurement sets, no background salt was added into the measurement cell, this causing a relevant ionic strength variation upon addition of NaOH causing deprotonation of citric acid. Calibration of the electrode system (glass half-cell with double junction reference electrode) was tested both in internal and external fashions. The results of the analysis of potentiometric measurements at low ionic strength were used to check results in comparison with reference literature data [3], and as reference for data analysis at high concentration. Data analysis of the latter measurements resulted very challenging and was done taking advantage of the feature of BSTAC4 software to analyse data also considering variation of activity coefficients during measurements.

XPS study and correlation between surface chemistry and catalytic activity of various oxides

N. Ditaranto

Dipartimento di Chimica and CSGI – Consorzio Interuniversitario per lo sviluppo dei Sistemi a Grande Interfase, Unità di Bari, c/o Dipartimento di Chimica, Università degli Studi Bari Aldo Moro, via Edoardo Orabona 4, 70126 – Bari, IT;
nicoletta.ditaranto@uniba.it

The chemical surface composition of a material is fundamental to determine its properties. Different oxides have been investigated by means of x-ray photoelectron spectroscopy (XPS) to study and correlate the surface chemistry and their performance. The results obtained for oxide and mixed oxide catalysts and paramagnetic iron oxides, will be discussed. XPS results on copper doped-TiO_2 catalysts for H_2 production, in combination with other techniques, revealed the presence of both Cu_2O and CuO deposits on the surface. Notably, the CuO particles reduction to Cu(s) by photogenerated electrons boosting H_2 production rate was assessed, indicating that both Cu_2O and Cu(s) act as co-catalysts for H_2 generation[1]. XPS analyses of MnO_2 and MnO_2/CeO_2 based catalysts were used to correlate their surface properties and catalytic activity in the selective aerobic oxidation of furfural into furoic acid. Also, surface characterization results were used to properly tailor the catalyst surface to obtain the exclusive presence of Mn(IV) species, yielding a mixed oxide with excellent catalytic properties[2]. Various alumina-, silica- and alumino/silicate- supported Ni/Ce catalysts were investigated by XPS to detect the overall nickel loading on the surface, as well as Ni speciation and its interaction with the supports. On the base of $Ni2p_{3/2}$ signal curve fitting and BE values, different abundances of NiO-like and Ni-Aluminate or Ni-Silicate like species were assessed[3], differently interacting with the supports and therefore possessing a diverse reducibility[3]. XPS characterization of magnetite iron oxides was performed through combined information from different Fe spectral regions, namely Fe2p, Fe3p and valence band (VB)[4]. VB region provided useful analytical information like the energy band gap value (Eg) shift for the Cu electrodecorated sample, essential to confirm the occurring of alignment of the Fermi levels at the Cu-Fe material interface[5].

Extractive-Liquid Sampling Electron Ionization-Mass Spectrometry (E-LEI-MS) for real-time targeted and non-targeted analysis of pesticides in light cannabis and drugs

A. Arigò,[a] N. Giovanna,[a] G. Famiglini,[a] P. Palma,[a,b] A. Cappiello [a,b]

[a] *Department of Pure and Applied Sciences, University of Urbino Carlo Bo, Piazza Rinascimento, 6, 61029 – Urbino, Italy*

[b] *Vancouver Island University, 900 Fifth St, BC V9R 5S5, Nanaimo – Canada*

adriana.arigo@uniurb.it

The Extractive-Liquid Electron Ionization-Mass Spectrometry (E-LEI-MS) is the first analytical approach that combines the ambient sampling of not- or minimal pretreated samples with the electron ionization (EI) process, which results in high identification power. The E-LEI-MS setup includes a solvent-release mechanism for the ambient extraction of analytes. The generated solution is sucked into the EI source by the vacuum generated by the mass spectrometer. An open/close valve allows the aspiration or the system isolation during the extraction or stand-by step. The VMC was recently introduced to better vaporize high-boiling point molecules. The analyses were performed using the E-LEI system coupled with a 7010GC/MS triple quadrupole (QqQ) and a 7250GC/Q-ToF quadrupole time of flight (Q-ToF) MS (Agilent Technologies) both equipped with EI sources. The type and amount of solvent, sampling time, VMC, and source temperatures were modified according to the analyte solubility, signal intensity, boiling point, and/or degradation temperature, respectively.

Chlorpyrifos was used as a reference standard for performing test analyses to evaluate improvements in the advanced configurations of the prototype. The pesticide was analyzed after being spotted on a clean surface and in light cannabis. The E-LEI-QqQ-MS system allowed the identification of nine APIs out of fifteen in various formulations by matching with the NIST library spectra. Six samples were also analyzed in high-resolution using E-LEI-Q-ToF-MS to explore and compare the data obtained. The Agilent HR software for unknown identification indicated sildenafil as the API of commercially available illicit tablets sold as supplements. Several old and new-generation BZDs were analyzed using the E-LEI-Q-Tof-MS system. Six BZDs were selected to fortify gin tonic cocktails at concentrations of 20 and 100 mg/L for simulating their illicit use as rape drugs. Spots of cocktails were dried on a glass surface to simulate their residue in glasses collected for forensic tests. All BZDs were correctly identified at both concentration levels.

E-LEI-MS configuration will be improved to analyze pesticides in several samples of light cannabis and other applications. The E-LEI-Q-ToF MS system is a promising tool for environmental, pharmaceutical, and forensic applications in targeted and untargeted analysis.

roccaldo.sardella@unipg.it

The HPLC-UV enantioseparation of the following six synthetic cannabinoid receptor agonists was obtained for the first time with the two chiral stationary phases (CSPs) (*R*,*R*)- and (*S*,*S*)-Whelk-O®1, under reversed phase conditions: the three valinamide indazole-3-carboxamide-based derivatives AB-CHMINACA, 5Cl-AB-PINACA, AB-FUBINACA, the *tert*-leucinamide indazole-3-carboxamide-based ADB-FUBINACA, and the two phenylalaninamide indazole-3-carboxamide-based derivatives APP-FUBINACA and 5F-APP-PINACA.

The analysis of seized samples performed using a water/ACN/FA-55/45/0.1 (v/v/v) mobile phase and the Whelk-O®1 CSPs revealed: (i) the scalemic nature of AB-CHMINACA [in favour of the (*S*)-enantiomer] and 5Cl-AB-PINACA (newer enantioseparated so far); (ii) the presence of enantiopure (*S*)-AB-FUBINACA and (*S*)-ADB-FUBINACA; (iii) the presence of enantiopure (*R*)-APP-FUBINACA and (*R*)-5F-APP-PINACA.

The enantiopurity of the last four samples was established applying the "Inverted Chirality Columns Approach" [1], while information on the absolute configurations were retrieved by coupling electronic circular dichroism analysis to *in silico* Time-Dependent Density-Functional Theory simulations [2].

In a proof-of-concept study, the optimised enantioselective chromatography conditions were also successfully tested, with only marginal modifications, on a HPLC system coupled to a triple quadrupole mass spectrometer for LC-MS/MS evaluations.

The described enantioselective analysis of authentic specimens derived from a selection of seized synthetic cannabinoid receptor agonists containing samples gleans valuable insights into their enantiomeric composition, thereby unlocking potential intelligence information of relevant forensic significance.

carlo.crescenzi@unisa.it

The volatilome, comprising volatile metabolites and other organic and inorganic compounds emanating from living organisms, offers valuable insights into metabolic and phenotypic states. Accessible through non-invasive sampling methods, such as breath, skin, and bodily fluid analysis, the volatilome holds promise for medicinal studies and disease diagnostics. In previous studies the potential of active carbon fibers for thermal desorption (TD) in volatilome analysis was investigated demonstrating superior analyte trapping efficiency, even in challenging conditions Moreover, active carbon fibers exhibit reduced impedance and increased stability compared to conventional sorbent materials. Notably, they eliminate the need for quartz fiber frits, enhancing practicality and reliability. Experimental validation includes successful recovery tests in controlled atmospheres and application in analysing exhaust from a biomass combustion plant, where traditional methods falter. The present study explores the potential application as of non-invasive screening techniques for the detection of gastrointestinal diseases. This innovative approach presents a cost-effective and accurate tool for mass screening and early disease diagnosis.

The interest towards new bioactive components has been ever increasing over the last years. The standard protocol for retrieval of target molecules with promising biological activities includes synthetic procedures, as the preferred route before testing in further studies. As a greener alternative to synthetic procedure, preparative gas chromatography has been exploited over the years, for its capability to isolate target components from natural sources. The rule of thumb is to introduce the greatest sample amount to guarantee the shortest total collection time, while still maintaining a good chromatographic resolution for the target molecule.
The present study details the utilization of multiple gas chromatography techniques alongside nuclear magnetic resonance spectroscopy to characterize the essential oil of *Piper gaudichaudianum* Kunth from Brazil. Seventy-six components were identified using gas chromatography coupled to mass spectrometry (GC-MS), while enantio-selective multidimensional gas chromatography elucidated the enantiomeric distribution of eight chiral components, for the first time in literature. Following GC-MS analysis, an unidentified component, constituting approximately 27% of the total oil, prompted an isolation step through preparative gas chromatography. To this purpose, a Deans switch transfer device was positioned at the exit of the wide-bore column to alternatively divert the target peak to the collection system or a flame ionization detector (FID). Aiming to obtain the fastest collection time, the highest feasible volume (3 μL) of pure oil compatible with the liner internal volume, was injected in each chromatographic run, allowing its collection for structural elucidation techniques. In detail, the combined use of nuclear magnetic resonance (NMR), GC-Fourier transform infrared spectroscopy (FTIR), and mass spectrometry (MS), allowed the unambiguous identification of the compound of interest.

Acknowledgments: The project was funded by the Italian Ministry for the University and Research (MUR) with a "PRIN: Progetti di ricerca di rilevante interesse nazionale Bando 2022" Project n. 2022359CZA "Advanced analytical characterization and synergic evaluation of volatile terpenes of selected β-caryophyllene containing spices for diabetes treatment".

frnfvn@unife.it

Perfluoroalkyl and polyfluoroalkyl substances (PFASs) are a family of manufactured chemicals that are widely employed in consumer goods and industrial applications because of their special qualities. Chemically, these compounds contain a chain of carbon atoms bonded to multiple fluorine atoms, and with different functional groups at the end of the chain.

A portion of these chemicals exhibit a neutral and volatile nature, and are recently gaining more attention from environmental agencies, since they can be released by consumer goods and detected in the air.

Even at molecular weights over 600 Da, the presence of fluorine atoms in PFAS makes them more volatile than non-fluorinated analogues, due to weak van der Waals interaction properties. Therefore, they are suitable for GC-MS analysis.

In the current research, a parallel GC and GC×GC methodology coupled with both low-resolution and high-resolution TOF-MS was developed for the (semi)volatile PFAS analysis. Specifically, the chemical group under study were fluorotelomer alcohols (FTOH), acrylates (FTAc), and alkyl sulfonamide (N-MeFOSA, N-EtFOSA, N-MeFOSE, and N-EtFOSE) derivatives. Regarding the MS ion source, both electron impact, positive chemical ionization, and negative chemical ionization were exploited to study the spectra of the targeted chemical groups.

Dynamic headspace extraction was used for air sampling, using the most appropriate adsorbent material in terms of selectivity and sensitivity. Initially, the extraction method was optimized in terms of sampling volume and adsorbent type using a mix of PFAS standards (MW range 264-571 Da) and different spiked household goods and various environmental samples (air, water, soil).

The goal of the research is to develop a simple method for the analysis of polycyclic aromatic hydrocarbons (PAHs) in extra-virgin olive oils using the "Cryogenic zone compression" approach introduced by Marriott *et al.* in 1996[1] and followed applied for the determination of dioxins in human serum[2]. A liquid nitrogen-free jet-cooled thermal modulator, conventionally dedicated to comprehensive two-dimensional gas chromatography, was located at the end of the GC capillary column upstream of the detector. The column was looped in a single stage around a metal support, and centered between the permanent cryogenic jet (-90°C) employed to trap the eluted compounds, and the intermittent hot jet pulse (300°C, 250 ms) used to release the analytes from the cold spots. A miniaturized sample preparation protocol based on a single liquid-liquid extraction, with reduced consumption of organic solvents (500 µL of ACN per sample), has been employed. The sample preparation was characterized by the absence of both purification and concentration steps. Despite this, considering that the cryogenic zone compression process produced narrower and higher peaks, resulting in an enhancement of the overall method sensitivity, the PAHs limits fixed by European legislation for fats and oils[3] was achieved.

Gas chromatography (GC) is widely used for qualitative and quantitative analysis in numerous fields, such as petroleum, chemical industry, agriculture, environmental protection, medicine, and so on, due to its high versatility, high selectivity, simplicity of use, analysis speed, and low sample consumption. The column is the heart of a GC instrumentation, which allows the analyte separation and their recognition and quantification. Commercial columns do not always allow a complete peak separation when compounds (i.e., isomers) are very similar in molecular weight, polarity, and vapor pressure. The choice of the correct stationary phase, with high selectivity towards target analytes, is the key to obtaining the required chromatographic separation and the subsequent qualitative and quantitative analysis.

Considering the rapid polymer science development and the growing demand for new columns with improved resolution capabilities, in this work novel stationary phases for capillary GC have been designed, synthesized, and characterized in terms of polarity range, resolution, column efficiency, thermal stability, film-forming properties, and support-deactivating capacity[1-5]. The separation features of these novel stationary phases allow high-resolution performances for a wide range of compounds, like aromatic anilines, xylenes, aromatic amines, halogenated benzenes, and aromatic aldehydes, with marked capabilities toward isomer separations.

Search for alternative and innovative analytical methods, capable to provide rapid and informative results for the analysis of plants rich in precious phytochemical is a topic of ongoing interest. In this context, the aim of this research is to provide a method for a rapid characterisation of the main compounds present in Egyptian Calendula essential oil and absolute, known for their beneficial properties and chosen as an example to test the applicability of the technique. For this purpose, direct Ambient Mass Spectrometry (AMS) analysis were applied and the results were compared with those from conventional gas and liquid chromatography (GC-MS and LC-MS) technique applied as support. All samples were analyzed by a shotgun MS approach, *via* direct samples infusion, through a syringe pump, into an innovative ambient ionization source named REIMS (Rapid Evaporative Ionization Mass Spectrometry) coupled to a quadrupole-time of flight (Q-ToF) detector, capable to generate mass accuracy and tandem MS/MS data for structural elucidation. The employment of REIMS-QToF method has led to a rapid untargeted screening of both Egyptian samples in a very short time (3-4 seconds), without the need of clean-up procedures or chromatographic separations. The peculiar fingerprints obtained by means of MS high-resolution analysis have revealed the presence of phytochemicals compounds belonging to different chemical classes such as carotenoids, lipids, phenolic and volatile compounds, by matching the mass accuracy data in commercial and online database. Mass spectra acquired in both positive and negative ionization mode and MS/MS experiments allowed the identification and confirmation of a large number of bioactive compounds.

The technique here applied led to detect and identify hundreds of compounds, confirmed by conventional chromatographic techniques. However, compared to GC and LC methods that require a very long analysis time and a large amount of solvents, REIMS-QTof technology have revealed to be a rapid, greener and reproducible analytical approach that could be used for fingerprinting analysis of poorly characterized natural matrices with potential biological properties.

damiana.spadafora@unife.it

Cannabis (*Cannabis sativa* L.) is one of the most ancient cultivated multipurpose crop plants used for medicinal, industrial and recreational purposes, well known for its therapeutic and psychoactive properties. After harvesting Cannabis plant parts, including inflorescences, undergo drying processes to remove excess of water from the flowers and preserve secondary metabolites including cannabinoids and volatile organic compounds (VOCs) that make the typical cannabis scent. Very often long-term storage in closed containers is also applied. Poor post-harvest handling conditions may cause rapid deterioration of the flowers with consequent changes in precious cannabinoid and VOCs content, thus adversely impacting the quality and potency of the products. From this starting point, we investigated the effects of a novel freeze-drying technology *vs* a conventional tray drying one, and three storage conditions, on the preservation of cannabis secondary metabolites. A multi-trait approach, combining both solid-phase microextraction (SPME) two-dimensional gas chromatography coupled to mass spectrometry (GCxGC-MS) and high-performance liquid chromatography (HPLC), was used for the chemical fingerprint. This approach combined with powerful chemometrics enabled the identification of the best purpose related drying process, with freeze drying resulting useful to preserve cannabinoids preventing their decarboxylation but leading to a substantial loss of VOCs. Among storage conditions, storage in glass bottle seems more beneficial for the retention of the initial VOC profile compared to open to air dry tray and closed high-density polyethylene. However, the glass bottle storage condition causes the formation of neutral cannabinoids at the expense of the highly priced acid forms such as CBGA and CBGA. This is a first step contribution to define and direct producers and stakeholders toward the optimal drying process and storage conditions useful to produce highly valuable and high-quality products for the industry of interest.

martina.catani@unife.it

Reversed-phase liquid chromatography (RPLC) is the most widely employed analytical method in (bio)pharmaceutical industry, not only for quality control of bulk drugs and formulation, but also for preparative scopes. The most widely employed organic modifier in RPLC is acetonitrile (ACN) due to its exceptional characteristics, such as high elution strength, UV transparency, high miscibility with water and low viscosity. However, ACN is slightly toxic by acute exposure through oral intake, skin contact, and inhalation and it can be converted by the body into cyanide.[1]

For this reason, in the last year, there is much interest around all the possibilities that could increase the greenness of analytical methods applied to pharmaceuticals, in order to reduce the environmental impact commonly associated with manufacturing process and to ensure health safety of operators. Indeed, especially in preparative conditions, the large amount of solvents commonly employed leads to the generation of high quantities of waste to be disposed.[2]

Beside alcohols, whose physico-chemical properties are well-known, also less common solvents have recently attracted the attention for this purpose. One of this is dimethyl carbonate (DMC), which is classified among the "recommended" solvents by solvent selection guides. Indeed, DMC is nowadays produced though a clean process, it is biodegradable, and it is not toxic. Although it is widely employed as solvent in novel applications related to supercapacitors, lithium batteries and other emerging devices for energy storage, DMC has been introduced as organic solvent for LC only in a recent paper where the authors demonstrated its applicability in LC hyphenated to inductively coupled plasma mass spectrometry platforms. [3]

In this work, the possibility of using DMC or other less common alternatives as organic modifier in LC with UV-Vis detection will be discussed through a series of case studies including fundamental studies on retention in linear conditions up to applications in preparative conditions for the purification of pharmaceutically relevant peptides. [4,5]

antonella.cavazza@unipr.it

One of the greatest successes of academic research is to become the source of technological progress, providing solutions to global needs. Many studies, rich of potential, are often not exploited, and successful outcomes can be leveraged from the synergy with companies. This can be achieved through technology transfer, offering researchers the opportunity to convey their ideas into effective solutions.

This work shows a real example of synergy between several partners from universities and industries of different countries working together at a common multidisciplinary project. The aim was to find a solution to the request of many companies interested in alternative materials to replace plastic packaging, according to the recent European Regulation. Creating innovative materials within the circular economy, aimed at reducing food waste, represents a great challenge to pursue. The company Greci Industria Alimentare (Parma) supported the finding of useful applications of agro-industrial byproducts usually discarded but rich of bioactive compounds with antioxidant and antibacterial properties[1]. Effective systems of sample extraction, based also on the use of accelerated solvent, were explored at the CIAL Institute of Madrid, and the chemical characterization of active compounds was achieved by LC-MS. The effect of storage on the active properties was also investigated. Innovative formulations to obtain active packaging in form of film, spray or coating were realised, and studies to assess their stability during shelf-life were performed. Velp Scientifica (Usmate, MB), collaborated with the development of a modified Oxitest, an analytical equipment capable to monitor the effects of the formulations on real food samples[2]. Besides, safety assessment experiments based on AMES tests were carried out at the FH Campus of Wien. Finally, a German company concurred in applying the final achievement allowing the production of prototypes of new packaging. All steps of the research have been managed with the cooperation of the interdepartmental centre for Packaging, CIPACK (Technopole of Parma), whose mission is the success of research leading to progress of science and technology.

Crocin-I is a valuable natural compound found in saffron (dried stigmas of *Crocus sativus* L.) showing potential as a new drug lead especially in the field of neurological disorders. To explore its therapeutic value, the development of extraction and purification techniques is required, especially a cost-effective and scalable purification process to isolate considerable amounts of crocin-I from complex natural sources. However, traditional single-column preparative chromatography (batch) poses a yield-purity trade off, meaning that the choice of the collection pool sacrifices either yield in benefit of higher purity, or vice versa[1]. This naturally derives from structural similarities among Crocin-I and other species extracted from the plant.

This study demonstrates how the continuous countercurrent operating mode, namely twin-column MCSGP (Multicolumn Countercurrent Solvent Gradient Purification), resolves this dilemma, by automatically performing an internal recycling of the impure portions to be reprocessed. Saffron stigma was extracted with ethanol, and the extracted feed stability was investigated under varying storage conditions. Concerning the purification, at first the batch process was specifically designed and optimized to separate Crocin-I from impurities having similar structure (e.g., picrocrocin). This step was subsequently followed by the scale-up to the MCSGP process. To ensure a fair comparison, both processes were evaluated under similar conditions (e.g., similar total column volume). The results showed that, at a Crocin-I purity grade of 99.7%, the MCSGP technique led to significant results, namely x3 increase in recovery and productivity and -92% reduction in solvent consumption, with respect to the corresponding batch process[2]. To make the purification process even greener, the only organic solvent employed in all the steps was ethanol. MCSGP proves to be a reliable and eco-friendly technique for purifying Crocin-I from saffron extract, demonstrating for the first time that it can be effectively applied as a powerful approach for process intensification not only for peptides and proteins, as it is well-known from literature, but also for complex natural matrices.

Agrifood residues valorization: chemical profiling of Kombucha beverages by chromatography and mass spectrometry

F. Sabatini,[a,b] V. Termopoli,[a,b] S. Libri,[a,b] H. Lange,[a,b] F. Gosetti,[a,b] E. Maresca,[c,b] M. Aulitto,[c,b] P. Contursi,[c,b] M.E. Orlandi,[a,b]

francesca.sabatini@unimib.it

Food waste valorisation is one of the most relevant topics in the scientific and social context due to its potential to promote more sustainable food production and the recovery of value-added compounds. A smart bio-valorization of agro-industrial wastes would be their possible conversion into fermented foodstuffs and beverages. Kombucha is a traditional Asian beverage which has just recently gained popularity in the North American market for its antioxidant properties and potential health-promoting effects. Kombucha is traditionally obtained by the fermentation of sucrose-rich tea with a Symbiotic COlony of Bacteria and Yeast known as SCOBY.

In this study, three different Kombucha beverages were prepared varying the carbon and nitrogen sources with agri food waste materials produced worldwide by processing industries and consumers. i.e. citrus residues and used coffee pods, respectively. While several other sugar-content raw materials have been used for the fermentation of Kombucha drink, in only few cases biomass wastes were selected. Moreover, citrus residues were never tested for the tea beverage preparation. Thus, the traditional and waste-based Kombucha formulations were processed over 21 days and the kinetics evaluated by monitoring of cell number, pH variation and trace elements. Considering the potential antioxidant content of the starting materials, the total phenolic and radical scavenging capacity was measured by spectrophotometric tests. Several molecular classes of volatile and volatizable compounds were detected by Head Space Solid Phase micro extraction Gas Chromatography coupled with Mass spectrometry (HS-SPME-GC/MS) and GC/MS, allowing to assess the molecular profile of each Kombucha beverage. The application of chemometric tools makes it possible to evidence similarities and differences among samples, and possible interactions between components.

The results of this research highlight the potentialities of employing food waste carbon and nitrogen sources to get Kombucha drinks enriched in bio-active compounds and then improved in antioxidant activity with respect to traditional formulations.

CP-MIMS: a new frontier for the real-time monitoring of hazardous chemical migration from food contact materials

M. Piergiovanni[a], M. Mattarozzi[a], F. Bianchi[a], N. Riboni[a], V. Termopoli[b], V. Consonni[b], D. Ballabio[b], M. Careri[a]

maurizio.piergiovanni@unipr.it

Condensed Phase Membrane Introduction Mass Spectrometry (CP-MIMS) is an innovative technique for direct analysis in absence of sample preparation and chromatographic separation, while providing adequate selectivity for the reliable analysis in complex matrices. This strategy allows for the real-time monitoring of the dynamic processes involving the variation of the concentration of target compounds,[1] making it suitable for monitoring contaminants in food packaging. The migration of hazardous chemicals from food contact materials (FCMs) into food is an issue that analytical chemistry has to face with attention to emerging or re-emerging contaminants.[2] In this context, the recent reduction of the tolerable daily intake of bisphenol A (BPA) by EFSA has renewed interest in evaluating its release from FCMs to verify compliance with the current specific migration limit (50 µg/kg, EU Reg. 2018/213).

In this study, for the first time, a CP-MIMS method was developed and validated for the real-time determination of BPA released from FCMs. A capillary PDMS hollow fiber membrane interface using methanol-heptane as an acceptor phase delivered BPA to an electrospray ionization source and a linear ion trap mass spectrometer operated in the negative MS^2 acquisition mode. A full factorial DoE was applied to optimize four response variables by varying the acceptor phase flow and composition, stirring, temperature, and membrane length. Method validation was performed in drinking water and two simulants, namely ethanol 10% *v/v* and acetic acid 3% *w/v*. Excellent sensitivity and accuracy were achieved, with LOD at low µg/L level, intra- and inter-day precision lower than 18% and 95±6% trueness at the level of interest. Finally, the developed CP-MIMS method allowed the acquisition of the migration profile of BPA over time in the case of plastic FCMs that showed a detectable release. This study provides important insights into the role of CP-MIMS in scientific research across food safety with a focus on migration processes from FCMs.

Electroosmotic Flow in Capillary Zone Electrophoresis: Theoretical and Practical Aspects

D. Corradini

National Research Council, Institute for Biological Systems, Area della Ricerca di Roma 1, 00015 Monterotondo, Rome, Italy
danilo.corradini@cnr.it

Capillary zone electrophoresis (CZE) is performed applying a constant electric field (E field) across the length of a capillary column, filled with a background electrolyte solution (BGE) of uniform composition. A characteristic feature of CZE is the possible occurrence of an electrically driven flow of the BGE across the separation pathway, the electroosmotic flow (EOF), which is generated by the action of the E-field on the electric double layer formed at the interface between the BGE and the charged inner wall of the capillary tube. Charge density and electric potential of the electric double layer at the solid-liquid interface and, consequently, direction and velocity of EOF, depend on both the surface chemistry of the capillary column and the physicochemical properties of BGE, and may either positively or negatively affect migration behavior and electrophoretic performance of the analytes[1].

This communication discusses the results of an investigation carried out to shed light on the factors influencing the formation of the electric double layer at the solid-liquid interphase of bare fused-silica capillaries and the consequent direction and speed of EOF. Several variables, including pH, viscosity and ionic strength of BGE, as well as the immobilization of ionic species in the so called compact or Stern region of the electric double layer are evaluated. The results of the discussed studies include the measurements of EOF carried out in bare fused-silica capillary tubes using BGEs of different composition containing selected adsorbing ionic species at various concentrations and the requested concentration of a neutral salt (NaCl) to maintain their ionic strength at a constant value. The dependence of EOF on the concentration of a variety of ionic species with affinity for the silanol adsorption sites on the inner surface of bare fused-silica capillaries is evaluated and discussed on the basis of mathematical models describing the electric double at the solid-liquid interface. In addition, the communication illustrates and discusses the approach of controlling the electroosmotic flow in order to modulate sample resolution by increasing the virtual migration distance (l_s), which, according to Rathore and Horvath[3], represents the virtual distance that the charged analytes move under the direct influence of the electric field, calculated as the product of the electrophoretic mobility of the analyte (μ) and its migration time (t_m).

Identification and quantification of soybean and mustard allergenic proteins in wheat flour using mass spectrometry-based approaches

M. Bianco[a], G. Ventura[a,b], A. Pagano[a], C.D. Calvano[a,b], I. Losito[a,b], T.R.I. Cataldi [a,b]

mariachiara.bianco@uniba.it

Food allergies represent a significant concern for food safety and public health, as largely acknowledged by the World Health Organization (WHO). To safeguard the well-being of sensitive individuals, European Regulation No. 1169/2011 has listed fourteen allergenic ingredients, including gluten-containing cereals, crustaceans, eggs, peanuts, fish, soy, milk, nuts, celery, mustard, sesame, lupin, sulphites, and molluscs. Manufacturers are required to display these ingredients or their potential presence, for instance from *in-situ* contamination during food production, on food labels, utilizing font sizes, styles, or colours different from other listed ingredients[1].

In recent years, considerable efforts have been dedicated to identifying allergenic ingredients in various food products to safeguard consumer health. While immunological assays have been widely adopted due to their user-friendly nature, relatively high productivity, and low detection limits, they can suffer from false positives[2]. Conversely, mass spectrometry (MS) techniques have emerged as powerful tools, offering both high selectivity and sensitivity for multi-allergen monitoring in food products[3,4]. To address this need for more reliable multi-allergen detection, this study aimed to identify and quantify soy and mustard allergenic proteins in trace amounts in wheat and flour samples using a bottom-up proteomic approach. Different and time-efficient protocols were employed to enhance protein extraction by testing environmentally friendly solvent mixtures. The protein extracts were enzymatically digested and analysed using reversed-phase liquid chromatography coupled with high and low-resolution/accuracy MS. Several data acquisition procedures were exploited, including targeted tandem mass spectra, data-dependent analysis (DDA), and multiple reaction monitoring (MRM). The method was validated to assess linearity, limit of detection, limit of quantification, and matrix effect by recurring to selected marker peptides, qualifiers and quantifiers. Quantification of soy and mustard allergenic proteins in wheat and flour samples was also accomplished.

Organic additives are vital for maintaining the quality of metallic coatings in commercial electroplating baths, but their effectiveness wanes over time due to degradation and drag-out. Constant monitoring and dosing are necessary to maintain optimal concentration levels and preserve both technical integrity and aesthetic appeal. Due to the complex formulation and the synergic effect of various additives traditional chromatographic techniques are impractical for routine industrial analysis. Electrochemical methods, such as the Hull cell test [1] and Cyclic Voltammetric Stripping (CVS) [2] measurements, are typically used to adjust additive concentrations based on their overall effects on the electrodeposition process. The Hull cell test, while widely used, relies on trial and error and operator experience, yielding only qualitative assessments. CVS measures the change in the rate of copper deposition, reflecting additive concentration, but may not be suitable for all types of electroplating baths due to their varying complexities.

Previous Electrochemical Impedance Spectroscopy (EIS) studies on copper plating baths qualitatively correlate changes in impedance with aging [3], our goal was to obtain the quantification of additives through EIS. To achieve that, the experimental data were processed in terms of resistive and capacitive components to calculate the distribution of relaxation times (DRT) using Lasso regression [4], and the results were fed to a multivariate analysis to overcome this challenge.

The positive results obtained [5] make this method of great interest in both industrial and academic settings. Its application in the galvanic field is particularly useful for achieving a detailed understanding of the function of each additive, their interactions, and the aging of plating baths.

Electrochemically powered dissipative hydrogel films for out-of-equilibrium operations

R. Baretta,[a] M. Frasconi,[a]

[a]*Department of Chemical Sciences, University of Padova, Via Marzolo 1, 35131 Padova, Italy*
marco.frasconi@unipd.it

Inspired from the ability of living systems to temporally control their structures and functions, much efforts have been devoted in recent years to the exploration of out-of-equilibrium chemical systems. Despite the progress, it remains challenging to program soft materials with adaptable, time-dependent properties and to leverage these properties to develop out-of-equilibrium operations. Success in this endeavour will lead to a new generation of soft-robotic systems and biomedical devices that can autonomously perform complex operations. Here, we present a new platform that integrates a dynamic hydrogel film onto an electrode surface to enable the temporal modulation of the hydrogel mechanical properties under out-of-equilibrium conditions powered by electricity.

We demonstrate that the lifetime of the transient network of the hydrogel film can be effectively controlled by programming the voltage applied at the electrode directing the transient stiffening or softening of the hydrogel network. In the present study, we also present the application of the developed electrochemically-driven transient process for the release of protein cargos from the hydrogel film. Temporally controlled operations of the hydrogel films are demonstrated for the programmable sequential release of multiple protein payloads from electrode arrays. This application provides an example for the transition from classical switchable materials to more life-like materials capable of adaptive, self-regulated behaviour, thereby providing new opportunities for controlling electrochemically complex out-of-equilibrium operations.

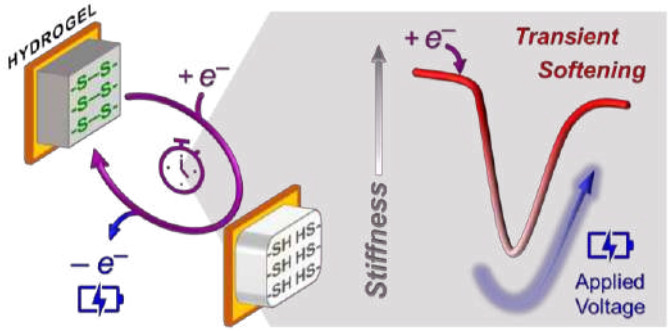

Figure 1: Implementation of electrochemically dissipative cycles enabling the transient modulation of the stiffness properties of hydrogel films.

The development of screen-printed electrochemical biosensors represents a significant advancement in the early detection and diagnosis of Alzheimer's disease (AD), a neurodegenerative disorder characterized by progressive cognitive decline and memory loss.[1] Screen-printed electrodes (SPEs) have emerged as promising platforms for the development of disposable, eco-friendly, and cost-effective electrochemical sensors. Their lightweight and versatile nature allows for the integration into paper-based and wearable devices, making them suitable for point-of-care (POC) applications. The fabrication of SPEs involves the deposition of conductive ink on a substrate, which can be easily customized to detect various biomarkers associated with AD, including proteins, peptides, and neurotransmitter, such as amyloid-beta peptides, tau proteins, and microRNAs, that can be detected with high accuracy and specificity.[2] MicroRNAs (miRNAs), were recently highlighted for their promising role as biomarkers for early diagnosis. In particular, miRNA-29 represents a class of miRNAs known to regulate pathogenesis of AD.[3] Considering this, an electrochemical printed strip for the detection of miRNA-29a at low levels was developed. The architecture was characterized by the presence of gold nanoparticles and anti-miRNA-29a probe labelled with a redox mediator, selecting the most appropriate probe density to detect low target concentration. The present tool was capable to detect miRNA-29a both in standard solution and in serum, respectively, down to 0.15 and 0.2 nM. The platform highlighted a good repeatability of ca. 10% and satisfactory selectivity in presence of interfering species. The results demonstrate the suitability of this approach in terms of easiness to use, time of production, sensitivity, and applicability, reducing the time gap between disease and treatment.

A ligand-based electrochemical magneto-assay for point-of-care determination of BRD4

S. Fortunati,[a] F. Pedrini, [a] G. Donofrio, [b] M. Giannetto, [a] A. Bertucci, [a] M. Careri [a]

[a]Department of Chemistry, Life Sciences and Environmental Sustainability, University of Parma, Parco Area delle Scienze 17/A, Parma
[b] Department of Veterinary Science, University of Parma, Via del Taglio 8, Parma
simone.fortunati@unipr.it

In the context of a research line focused on the development of magneto-electrochemical platforms for the determination of protein biomarkers for Point-of-Care Testing (PoCT) applications,[1,2] a novel electrochemical magneto-assay for the detection of the BRD4 protein was developed. Bromodomain-containing protein 4 (BRD4) is a member of the Bromodomain and Extra-Terminal (BET) protein family, which are well-known epigenetic regulators involved in gene expression mechanisms. BRD4 has been shown to play a significant role in breast and prostate cancer, glioblastoma, and melanoma.[3] Considering that gene downregulation by BRD4 inhibition or degradation has demonstrated significant therapeutic potential for the treatment of several tumour diseases, detection of BRD4 is crucial to assess its overexpression as well as the efficacy of therapeutic protocols based on its inhibition.

Despite the diagnostic relevance of this biomarker in cancer, to the best of our knowledge, there are no literature studies on BRD4 protein biosensors. The proposed method is based on the immobilization of a biotinylated BET-specific ligand on magnetic micro-beads (mMBs) functionalized with streptavidin followed by BRD4 target capture and binding of an HRP-conjugated anti-BRD4 antibody. After enzyme-promoted oxidation of hydroquinone, electrochemical detection was performed by chronoamperometry. This protocol allowed the entire complex to be assembled in a single incubation step in as little as 10 minutes, proving to be extremely fast. The analytical validation was performed in human plasma, with excellent performance in the undiluted matrix, showing no significant differences ($p>0.05$) in the results obtained in PBS buffer, thus proving good sensitivity with a LOD of 1.99 nM. Interestingly, by changing the receptor concentration on mMBs, it is possible to increase the dynamic response range and optimize the analytical performance of the assay.

Finally, the ligand-based magneto-assay was applied to determine BRD4 in untreated cell lysates from HEK cells. The results were consistent with the data obtained using a commercial ELISA kit, demonstrating the potential of the method for developing rapid tests to evaluate the effectiveness of therapeutic treatments and disease progression in PoCT settings.

Real-time updates regarding the health condition of individuals have become a prominent subject in contemporary medical research activities. Undoubtedly, the ultimate objective is to shift from traditional hospitals to a home-based medical care approach with the aim of enhancing the overall healthcare system[1]. Technological advancements are playing a pivotal role in facilitating this significant transition, as they allow for the development of compact sensing devices, which can replace cumbersome instruments, eliminate uncomfortable wire connections, and deliver straightforward data-transferring procedures based on wireless transmission[2]. In this regard, paper-based technology is an obvious choice as a support material, thanks to its wide range of outstanding properties, such as low cost, eco-sustainability, versatility, affordability, and biocompatibility. Indeed, paper can be used to fabricate microfluidic systems integrated into point-of-care devices, conferring to these smart analytical tools several fascinating features. Herein, we present an innovative point-of-care platform for the home-based and self-assessment of hemoglobin and electrolytes in capillary blood, to support oncology patients at home. The point-of-care platform was combined with a four-leaf clover paper-based microfluidic system for the management of the solution, creating a hydrophobic zone to define a hydrophilic working area. The sensing tool encompasses a double printed electrochemical sensor for hemoglobin detection and three ad-hoc modified printed sensors connected with a multi-chip NFC system consisting of multiple boards for wireless simultaneous detection of the target analytes. The electrochemical performance of the hemoglobin sensor has been tested directly in the real matrix, analyzing more than 40 capillary blood samples, and constructing a calibration curve described by the following equations $y = 0.1x + 0.7$, $R^2 = 0.884$. Moreover, the ionophore-based carbon black-potentiometric sensors for Na^+, K^+, and Ca^{2+} have been tested in standard solution obtaining calibration curves described by the following equations: $y = (0.056 \pm 0.002)\ x + (0.300 \pm 0.004)$, $R^2 = 0.993$, $y = (0.057 \pm 0.001)\ x + (0.595 \pm 0.003)$, $R^2 = 0.986$, and $y = (0.034 \pm 0.001)\ x + (0.319 \pm 0.001)$, $R^2 = 0.997$, respectively. The applicability of this sensing platform was evaluated by measuring capillary blood samples of breast cancer patients, obtaining results in agreement with the reference method.

COVID-19, caused by the severe acute respiratory syndrome-coronavirus 2 (SARS-CoV-2), originated a global health crisis, causing over 2 million deaths and affecting human daily life all over the world. This pandemic emergency highlighted how the current diagnostic tests have important limitations.[1] Therefore, it is urgent to develop faster, more precise and sensitive sensors. Graphene field effect transistors (GFET) are analytical platforms that enclose several of these requirements. However, the design of a sensitive and robust GFET is challenging. In this work, we report a GFET-based analytical platform for the detection of SARS-CoV2 spike protein using as a receptor the human membrane protein involved in the virus internalisation: Angiotensin Converting enzyme 2 (ACE2).[2] By finely controlling the graphene functionalisation, tuning the Debye length, we have been able to detect the spike protein with a limit of detection of 2.94 aM.[3] Such limit of detection is comparable with the ones obtained with GFET functionalized with selective antibodies. Furthermore, we deeply characterized the ACE2-spike protein interaction with several technique such as AFM, PSR, QCM an nanomechanical measurements. This work demonstrated that the human membrane proteins responsible for the internalization of viruses can be used as receptor for electrochemical analytical platforms, allowing the detection of a broad variety of pathogens, and being a powerful tool in the fight against future pandemics.

Mulching is a widespread agricultural technique aiming at *e.g.* improving crop quality, curbing weeds proliferation, preserving soil moisture, etc. This practice often involves the use of plastic-based films: these materials contain and release additives (e.g., phthalates, known as endocrine disruptors) that can enter the food webs via soil biota and crop plants, representing a threat for both human health and the terrestrial environment[1].

A smart and rapid sensing of these substances in soil and crops is thus urgently needed. Poly(amino acids) (PAAs) have been employed as novel conducting polymers with a great potential in biosensing; different types of nanomaterials such as metal nanoparticles have been utilized to functionalize PAAs in order to improve their analytical performance[2]. In this study, a nanocomposite biosensing platform, based on poly(amino acids) and gold nanoparticles is first developed and then employed to build an oligonucleotide-based competitive assay for phthalic acid esters (PAEs) detection with enzymatic amplification. Different assay formats are tested to find out the best experimental conditions for achieving a fast and sensitive PAEs determination: specifically, the aptameric DNA sequence is immobilized by exploiting the thiol-gold affinity, and a competition between the analytes and a biotinylated DNA probe, which is complementary to a portion of the immobilized aptamer, is carried out; a similar competition is also established between an immobilized probe and the aptamer in solution. In both cases, the biotinylated hybrids are coupled with a streptavidin-alkaline phosphatase conjugate: this enzyme catalyses the hydrolysis of 1-naphthyl phosphate enzymatic substrate into 1-naphthol electroactive product, detected by means of differential pulse voltammetry (DPV). The developed biosensor will be applied in real samples, as soil and strawberries extracts, to prove its suitability for *in situ* analysis.

In the last decade, cell-based platforms have been studied for many innovative applications comprising advance therapy medicinal products (ATMPs), disease models, and effective drug screening through individual customized in vitro drug testing. The process for the development of well-established ATMPs is challenging. Many issues must be considered from raw material, manufacturing, safety, and pricing to assure the quality of ATMPs and their implementation as innovative therapeutic tools. As for standard drugs, cell-based ATMPs technologies for quality control, and non-invasive isolation and production of cell-based ATMPs are then needed to ensure their rapidly expanding applications and ameliorate safety and standardization of cell production. Stem cells can be found in every tissue, but access is not always easy and cannot be derived in high numbers. Adipose tissue is a very interesting source of mesenchymal stem cells and its use span from aesthetic medicine, for facial and body rejuvenation, to orthopaedic treatments.

In this work we present a new automated instrumentation, Celector® for tag-less cell sorting and quality control, using a micro-camera for cell detection and a specifically designed software for image acquisition, post-processing and data analysis. The output of the instrument is a multiparametric fractogram representing number, size and shape of the eluted cells as a function of fractionation time and it is the fingerprint of the cell sample. In this work, we investigated the ability of the new technology to identify and sort sub-populations of the heterogenous expanded adipose derived stem cells, for improved cell therapies. Celector® was shown able to select the most potent and homogeneous cell components from heterogeneous stem cell populations of different origins and to purify them from senescent and differentiated cells to improve the success rate of ATMP applications. It also provides predictive data for defining successful isolation procedures of primary cells and optimization of cell culture procedures with interesting features for laboratories that isolate and cryopreserve stem cells for clinical applications.

Recombinant proteins are complex molecules expressed by living organisms that present numerous possible conformations, post-translational modifications and microheterogeneity. Chemical and enzymatic modifications can readily occur during production, extraction, purification, formulation and storage[1]. Among these modifications, some of them are particularly critical for the efficacy and safety and are known as Critical Quality Attributes (CQAs), which affect the Quality Target Product Profile (QTPP). Quality Control (QC) is a key factor in biopharmaceutical development since it allows to assess the quality of the final product and thus its safety and efficacy. It involves a series of analytical procedures designed and validated to monitor the product's CQAs. However, the complexity of recombinant proteins makes analytical method development a challenging task. Analytical Quality by Design (AQbD) could represent a structured approach to analytical method development that can help to ensure a robust procedure across its lifecycle. It consists in a systematic approach to procedure development and validation that begins with predefined objectives and emphasizes procedure performance understanding and control, based on sound science and Quality Risk Management[2].

The QC of therapeutic monoclonal antibody Infliximab by using AQbD approach will be presented as guiding example to obtain high performance analytical procedures. Preliminary results of the set-up analytical platform development will be shown. Liquid chromatography, capillary electrophoresis and mass spectrometry were used as analytical techniques to evaluate the QTPP. The adoption of Risk Assessment facilitated the identification and management of risk factors. The application of multivariate tools, at first using a screening phase and then response surface methodology, made it possible to achieve a high degree of analytical procedure understanding.

Despite of the democratic nature of the analyses performed by the Lateral Flow Immunoassays (LFIA), fulfilling all the criteria for point of care testing [1], their development includes different fields and expertise. The material and analytical chemistry must be focused on the development of the device itself. Biotechnology for the generation of monoclonal antibodies, mAbs. Medical and veterinary knowledge to individuate strategical molecular targets. The connections by reference laboratories for collecting the needs of the territory and the samples for the validation and expertise on the regulation and certification. To this aim the collaboration between the authors institutions has been set up for the concerted development of functional LFIA devices for animal infectious diseases diagnosis [2,3]. In this presentation we will report the case of the concerted development of two multiplex LFIA devices (LFD) for the detection and typing of foot-and-mouth disease (FMD) viruses in clinical sample. The FMD is the most important transboundary viral disease of livestock in the international context, because of its extreme contagiousness, widespread diffusion, and severe impact on animal trade and animal productions. The two devices employed capture mAbs, anchored into reactive lines onto the LFIA strip, and detection mAbs (mAb*), labelled with gold nanoparticles. We used experimental design for optimizing the mAbs* and the positioning of the reactive lines [3]. A rapid and simple extraction & test procedure was proposed for ca 0.2 g of epithelial tissue (assay time <20'). The devices were then tested with various lineages of the virus (n=85), to define the reactive spectra for each serotype. Thus, LFD1 and LFD2 underwent to a wide multicentred validation including samples tested at the Pirbright Institute (UK) WRL, in Turkey, Kenya, and Pakistan, (n=317). The LFD1 sensitivity for diagnosing A, O and Asia 1 serotypes was, respectively, 94.3%, 95.8%, and 82.8% compared to reference ELISA, and 87.1%, 93.3%, and 80.0% compared to PCR. A PAN-reactive line diagnosed the 90% of the ELISA+ and 88% of the PCR+ samples. The LFD2 sensitivity for SAT 1 and SAT 2 serotypes was, respectively, 79.2%, and 82.5% compared to reference ELISA, and 74.6%, and 68.6% compared to PCR. The PAN-reactive line diagnosed the 62% of both the ELISA+ and PCR+ samples. These devices are available and employed on-field, mirroring the efficiency of this expertise-combining approach for generating highly functional LFIAs.

We report the development of aqueous-soluble nanotraps that behave as biomimetic receptors, starting from a sustainable source, i.e. silk fibroin, that is biocompatible, nontoxic and already in-use in regenerative medicine. Specific molecular recognition was conveyed to the silk nanotraps by a unique way to exploit molecular imprinting (MIPs), so to entail recognition by a template-assisted synthesis[1]. Herein, the sustainable monomers of silk, were used in the MIP process, instead of conventional acrylamido-based monomers. The synthetic protocol was optimized with the aid of surface response method. The silk-nanotraps, called bioMIPs, were physically and functionally characterized, demonstrating high affinity (nM) for the targets and selectivity.[2] Furthermore, the enzymatic degradation of the bioMIPs was studied. The biocompatibility of the nanotraps was confirmed. The nanotraps were further labelled with fluorescent tags and tested for imaging in cell cultures.[3] The bioMIP's synthesis proved a general route for preparing recognition elements both for proteins and small molecules.[2,4] Applications are in diagnostics, imaging and sensing.

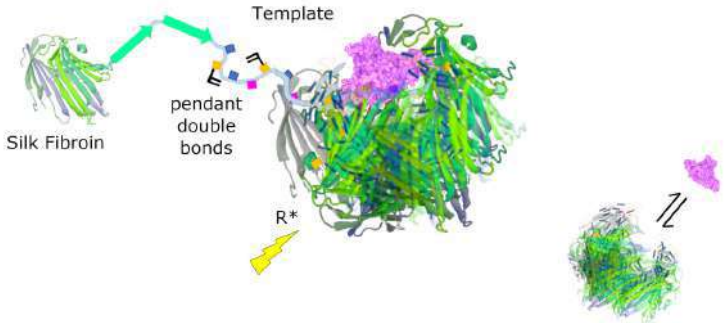

Figure 1: Concept of silk fibroin molecularly imprinted nanotraps.

stefano.giordani7@unibo.it

Polydopamine (PDA) is a melanin like biomimetic material increasingly used in photodynamic therapy, often coupled to recognition systems such as vesicles, due to its excellent biocompatibility, degradability, easy preparation, and photothermal conversion[1]. Despite its various applications understanding the relationship between its properties and its numerous chemical structures remains largely unexplored. Additionally, the simultaneous formation of multiple PDA species during its synthesis protocols is often neglected[2].

To shed light on the topic we exploited a Hollow Fiber Flow Field Flow Fractionation (HF5) platform coupled with UV-Vis, fluorescence and multi angle light scattering detectors. This innovative miniaturized technique allows to study and quantify colloidal content in native conditions, preserve weak supramolecular structures, and separate different colloidal populations providing individual size, morphology, and spectral properties. By monitoring over time a common PDA synthesis, we were able to gather information of the reaction kinetic and detect the presence of two different species, formed independently and at varied rates during dopamine oxidation and self-polymerization. While sharing similar UV absorption spectrum, they displayed differing emissions. The first specie (P), eluting earlier, adopts a coiled polymeric structure with lower molar mass and hydrodynamic radius compared to size standards under similar conditions. The second species consists of monodispersed solid spherical nanoparticles (NP) with a molar mass two orders of magnitude higher than the first, representing a stable supramolecular system with a defined radius, while the first lacks 3D/structural organization.

These results represent an outstanding novelty in the field of elucidating the relationship between different PDA nanoforms since up to now no experimental techniques have been proved to be able to separate the different products of dopamine polymerization in real time. Overall due to its high, fast and unique informativity the presented HF5 platform emerges as extremely powerful tool towards the design and characterization of the most optimal PDA nanoforms for clinical development. Future studies will involve the masking of these materials with vesicular matter to explore their therapeutic potential.

The goal of precision medicine is to tailor treatment precisely to each individual patient. Its achievement would be greatly facilitated by the availability of sensing technologies that enable convenient (one-step) and rapid measurement of drugs and biomarkers directly in undiluted biological fluids. Due to their low cost, ease of use and good analytical performance in complex clinical samples, electrochemical aptamer based (EAB)[1] sensors appear to be a promising means to this end. Therefore, we present here the development of a new EAB sensor for the measurement of therapeutic monoclonal antibodies,[2] which are biological drugs used for the treatment of various diseases such as cancer or infectious diseases.[2] The sensors use a previously reported DNA aptamer capable of recognizing the selected monoclonal antibody. We incorporated these into the EAB platform by truncating them (causing them to undergo a binding-induced conformational change), modifying them with a redox-reporting methylene blue, and covalently attaching them to an interrogation electrode. We then adapted the system to a scaffold approach, using the aptamer as the recognition element attached to a redox-reporting methylene blue double-stranded DNA scaffold. The resulting sensors can measure the monoclonal antibody directly in biological fluids such as blood within minutes. The speed and convenience with which this is achieved suggests that the developed sensors could significantly improve the ease and frequency with which biological drugs can be monitored during the therapeutic treatment.

The value of mass spectrometry in exploring challenging plant lipidome

C.D. Calvano[1], G. Ventura[1], M. Bianco[1], D. Coniglio[1], A. Castellaneta[1], I. Losito[1], T. Cataldi[1]

[1]*Department of Chemistry, University of Bari, via Orabona,4 70126, Bari*
cosimadamiana.calvano@uniba.it

Plant lipids are like hidden treasures within the plant kingdom, holding the key to understanding plant stress responses and paving the way for exciting new plant-based products. Lipidomics allows us to delve deeper into these intricate networks and unlock their potential. To truly advance plant biology and fuel innovation, robust methods for comprehensive lipid analysis are crucial. This communication explores powerful tools based on chromatography-mass spectrometry, specifically designed to tackle the challenges of plant lipidomics. From identifying and quantifying specific lipids to separating complex isomers, these techniques offer unprecedented insights.

We report how the combination of various strategies as hydrophilic interaction liquid chromatography (HILIC) or reversed-phase LC (RPLC), coupled with electrospray ionization (ESI) and mass spectrometry (MS), operated both in high and low-resolution mode, can be a powerful tool to characterize major phospholipids (PL), glycolipids (GL), glucosinolates or minor arsenosugar phospholipids (As-PL)[1] in plant novel foods. Through the acquisition of single (MS) and tandem (MS/MS) mass spectra, or by the all-ion fragmentation (AIF) operation mode in the quadrupole-Orbitrap mass spectrometer[2], a great number of lipid species are recognized in terms of fatty acyl chains and regiochemistry. More, to characterize the carbon-carbon double bond locations of both sn-1 and sn-2 fatty acyl chains, we carried out a simple oxidation by *m-chloroperoxybenzoic acid* followed by collision-induced dissociation of epoxidized species as deprotonated molecules, $[epoM - H]^-$. RPLC separation and a sequential triple-stage MS (i.e., MS^3) analysis of unsaturated and epoxidized lipid species can be very helpful in their identification, starting from a diagnostic product ion pair with 16.0 Da mass difference[3].

Special attention is given to uncommon lipids as signal receptors and signalling molecules that affect plant growth and responses to environmental challenges. In this communication, interesting results in this field will be presented and discussed.

andrea.cerrato@uniroma1.it

In the latest years, lipidomics has become a prominent tool in clinical chemistry due to the proven connections between lipid dysregulations and the insurgence of pathologies. Despite being the foremost technique for lipidomics, high-resolution mass spectrometry (HRMS) is not sufficient for elucidating the lipid structures, especially when it comes to the regiochemistry of carbon-carbon double bonds[1], which play a major role in determining the properties of cell membranes[2]. Over the years, several approaches have been proposed in combination with HRMS for elucidating the regiochemistry of double bonds, including unconventional fragmentation techniques and derivatization prior to MS analysis[1]. Among the latter, photochemical reactions, e.g., the Paternò–Büchi reaction, have shown great potential for their versatility, but have the unavoidable drawback of generating several oxidation by-products and splitting the MS signal due to the inherent asymmetry of the reaction that generates multiple derivatives. Among other possible approaches for derivatizing electron-rich double bonds, the emerging inverse electron-demand Diels–Alder (IEDDA) reaction with tetrazines stands out thanks to its unmatchable kinetics and so far has found several applications in basic biology, protein imaging, and therapeutics[3].

In the present study, we present the first proof of concept of a catalyst-free click IEDDA reaction to pinpoint carbon-carbon double bonds in free and conjugated fatty acids in untargeted MS-based lipidomics. To assess the applicability of the IEDDA reaction, fatty acid and phospholipid regioisomers were analyzed alone and in combination to evaluate (i) the obtention of diagnostic product ions following MS/MS fragmentation, (ii) the optimum reaction conditions to maximize the reaction yields, and (iii) the possibility of performing relative quantitation of lipid regioisomers. The preliminary data showed that the reaction not only confirmed its kinetics even with the scarcely activated alkene groups on fatty acyl chains but also minimized the splitting of the MS signal thanks to the symmetric nature of tetrazine reagents. Finally, the optimized IEDDA protocol was employed in an untargeted lipidomics study on plasma samples of patients suffering from prostate cancer and benign prostatic conditions to confirm the applicability of the proposed reaction with complex matrices of clinical interest.

LipiD7: a Matlab routine for lipids characterization

G. Ventura,[a,b] C.D. Calvano,[a,b] I. Losito, [a,b] T.R.I. Cataldi[a,b]

giovanni.ventura@uniba.it

Lipidomics [1] has experienced significant advancements, primarily due to progress in mass spectrometry (MS) and computational methodologies [2]. These advancements have not only deepened our understanding of biological mechanisms but have also enabled the analysis of a wide array of lipid classes [2], leading to the identification of previously undiscovered lipid species. Such discoveries hold promise for diagnosing stress conditions or understanding how organisms adapt to environmental changes. Addressing the challenge of identifying and characterizing these new lipid species necessitates propper bioinformatic approaches [3].

This study introduces a Matlab-based software designed to characterize lipids through MS and MS/MS analyses, enabling the identification of both the fatty acyl substituents and regiochemistry. Moreover, with information on the derivatization process, the software can infer the position of double bonds [4]. Specifically tailored for handling HILIC-ESI-MS/MS data, wherein class-specific elution times are readily obtained, the software is versatile enough to process direct infusion, MALDI-MS, or RPLC-ESI-MS/MS data. The identification process commences by comparing the experimental retention time (RT), if available, with preset windows. If the RT aligns with the elution window of certain lipid classes, the corresponding lipid precursor mass is searched in a database containing exact masses of selected adducts. Subsequently, the fragmentation pattern is examined to characterize precursor species based on established rules. The software generates an output table summarizing spectrum details and annotated MS/MS spectra. Various functionalities have been developed to handle different lipid types, including glycerophospholipids (alkyl or ether lipids), sphingolipids, glycerolipids, and unconventional natural phospholipids such as GlcA-DAG [5] or As-PL [4]. The software is capable of interpreting spectra from both positive and negative ion modes and is platform-independent, requiring only an Excel file as input. Furthermore, it includes a distinct function to analyse MS/MS spectra related to lipid species not documented in the literature, providing hints on lipid formulas and sum compositions, thereby facilitating the discovery of new lipid species.

The widespread occurrence of plastic waste in aquatic environments and its impact on animals and humans health is a major topic of scientific research worldwide[1,2]. Plastics and bioplastic polymers dispersed in the environment undergo several degradation processes, resulting in significant changes in their morphological properties and in their very small particle sizes. Of greatest concern to the scientific community is the fact that so-called microplastics (MPs), *i.e.* polymeric particles with a diameter below 5 mm, enter in the food chain and can accumulate in the tissues and organs of humans and animals[1,2]. The hazard of MPs is highlighted by its ability to adsorb pollutants from the surrounding aquatic environment, making it a vehicle of toxic substances[2,3]. In this work we report the adsorption of Pb^{2+} ions on MPs of polystyrene (PS), of PS functionalized with carboxylic groups (PS-COOH) and of polylactic acid (PLA). The adsorption capacity of MPs toward Pb^{2+} ions were investigated at different experimental conditions, i.e. in water, in $NaNO_3$ or NaCl 0.1 mol L^{-1} and with small amounts of the surfactant sodium dodecyl sulfate (SDS). Atomic spectroscopy and voltammetry were used to determine the concentration of Pb^{2+} ions. Electrochemical impedance spectroscopy (EIS), scanning electron microscopy with energy dispersive X-ray analysis (SEM-EDX), ξ-potential and FT-IR measurements were performed to evaluate the mechanism of Pb^{2+} ions adsorption onto MPs. The results show that the adsorption capacities of MPs towards Pb^{2+} ions vary from a few hundred μg g^{-1} to a few mg g^{-1} as function of experimental conditions of aqueous suspensions.

Synthetic strategy and application of cellulose acetate microbeads from waste sources for water remediation applications

L. Antonelli[a], M. G. De Cesaris[a], S. Grasso[a], A. Gentili[a]
[a] *Department of Chemistry, Sapienza University, P.le Aldo Moro 5, 00185, Rome, Italy*
E-mail address: lo.antonelli@uniroma1.it

The increasing presence of a wide variety of contaminants in the environment calls for the development of new strategies aimed at removing and minimizing their adverse impact on natural ecosystems. In particular, the environmental sector that requires a prompt action is the hydrosphere. As global population continues increasing, the pressure on water supplies is inevitably intensifying and the development of new technologies is an urgent need. In this study, the main objective was the realization of a nanocomposite sorbent, prepared through the recycling of cellulose acetate (CA) from waste products such as cigarettes' butts. A washing procedure was optimized to regenerate the raw material. Among the wide group of solvents tested for the CA regeneration, tetrahydrofuran (THF) was chosen as the dissolving agent [1]. With the technique of the emulsion precipitation, the organic phase saturated with CA was combined with a water solution, saturated with sodium chloride. As a result of the salting out effect, the organic and aqueous phases were immiscible, and a cloudy solution was formed under magnetic stirring. The addition, drop by drop, of water to the emulsion broke the emulsion and promoted the precipitation of CA in the form of microspheres (50-500 µm). The optimization of the synthetic procedure was performed changing one by one the involved procedural parameters. With the aim of obtaining sorbent material for xenobiotic capture from water, CA microspheres were tested alone and with the addition of active carbon. The secondary component of the composite was added to the organic CA solution in THF. The removal ability was tested in flow through mode, packing the synthetized microbeads in glass cartridges. As regards the treatment parameters, the optimization of the sorbent quantity, the amount of active carbon and the flow of the contaminated aqueous solution was performed building breakthrough curves. To this end, an 2^3 factorial design was conducted. Once optimized the best conditions of microsphere synthesis and treatment parameters, an entire characterization study was conducted via SEM analysis, as well as FTIR spectroscopy for the qualitative confirmation of the obtained material composition.
Performance studies over more than 60 contaminants have shown the broad applicability of the material and its versatility against different classes of xenobiotics. Through competitive removal analysis, differential removal of xenobiotics of different polarity was studied, by returning retention capacity ranging from 0.5 to some dozens of µg per mg.

v.testa@unito.it

During the last few years, the demand for lithium has increased exponentially due to environmental regulation and technological transition, this high rate of demand has included lithium in the critical material list and therefore is considered an element of limited availability. Many methodologies are available for the recovery of lithium from leaching solutions from electronic batteries but most of them present disadvantages related to huge amounts of precipitating agent or the large use of organic solvent for extraction to be used. Moreover, they are inefficient when lithium concentration in the leaching solution is too low[1]. In this way, the ionic imprinting technique could be an innovative approach because it could directly be applied to the leaching solutions.

This work presents an original approach to obtain (ionic imprinted polymer, IIP) selective adsorbent materials for lithium from diluted solutions, exploiting the most traditional bulk polymerization technique. IIPs are obtained from linear bi-functional monomers, as polyethylene glycol diacrylate (PEGDA), that can spontaneously cyclopolymerize and give structures that are mimics of pseudo crown ethers able to stabilize cations thanks to the so-called macrocyclic effect[3]; in this way, the use and functionalization of real crown ethers are avoided.

To assess the validity of this strategy, we studied the effects of different molar ratios of PEGDA: Li (I). For each polymer parameters of affinity and binding capacity are obtained through equilibrium partition adsorption isotherm determined by IC analysis. In addition, the selectivity of the material toward competing ions (Na(I),K(I)) is evaluated and an imprinting factor (IF) is determined related to the presence of Li(I) during the imprinting step. As a result, we obtained at last a capacity of about 0.190 mg/g with the highest selectivity and IF towards lithium. To improve this capacity, different reaction solvents (DMSO and water) and leaching solutions (basic and acidic) are explored and tested. Results show a general increase in binding capacity with the combination of the use of water as a reaction solvent and a basic leaching solution such as Na_2CO_3. This allowed us to obtain an improvement in the capacity of up to 1.70 mg/g of lithium adsorbed, with a good reusability of the material up to 6 cycles after recovery. This improved polymer capability is also compared with the ones obtained by the most innovative Inverse suspension polymerization technique (DMSO/Water in Mineral Oil).

airto@unime.it

Gallic acid (*GA*), whose structure is reported in **Figure 1**, is a naturally occurring polyphenol present in citrus fruit peels, in grapes, hops, oak bark, green tea, displaying antioxidant properties[1].

This contribution reports the preliminary results of a potentiometric study on the acid-base properties of *GA* at $T = 298.15$ K and $0.10 \leq I/\text{mol dm}^{-3} \leq 1.00$ in NaCl, KCl and $(CH_3)_4NCl$ ionic media. The gallic acid binding ability towards two natural systems contaminants such as Cd^{2+} and Pb^{2+} was also investigated at various ionic strengths in $NaCl_{(aq)}$ by means of potentiometry and UV-Vis spectrophotometry, to evaluate the ligand potential as a sequestering agent for the mentioned cationic pollutants in environmental matrices.

The analysis of the acid-base data allowed the determination of the gallic acid protonation constants, which were found to be in good agreement with literature findings[2]. The weak association constants of Na^+/GA and K^+/GA species were determined using the ΔpK method[3]. The dependence of the thermodynamic parameters on ionic strength was modelled using an extended Debye-Hückel type equation. Furthermore, the ligand sequestering ability and the affinity towards the selected cationic contaminants were evaluated by means of the calculation of $pL_{0.5}$[4] and pM[5] parameters at various conditions including pH ~ 8.1 and $I \sim 0.70$ mol dm^{-3}, typical of seawater. Lastly, speciation diagrams on the gallic acid behaviour towards Cd^{2+} and Pb^{2+} were drawn in the presence of the natural components of seawater as well.

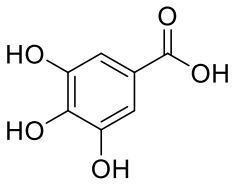

Figure 1. Structure of gallic acid or 3,4,5-trihydroxybenzoic acid.

The misuse/overuse of antibiotics in the last 20 years has caused a dramatic evolution of antimicrobial resistance[1]. To this aim, new strategies to overcome this challenge can by the employ of new rationally designed materials. Among the possible candidates, ZnO-based materials are increasingly studied, given their optimal photocatalytic properties and excellent biocompatibility as reported by the Food and Drug Administration (21CFR182.8991)[2]. The study focuses on the synthesis of ZnO microflowers (MFs) and their incorporation into cellulose foils or powder for the light-triggerable release of ROS (reactive oxygen species). It is demonstrated a synthetic approach of highly photocatalytic active ZnO MFs based on a central composite experimental design in which the synthesis parameters - such as zinc ions and KCl concentrations and synthesis temperature - are all investigated to obtain the optimal photodegradation response of dye pollutants (e.g. methylene blue). The ZnO MFs synthesis is further optimized to induce biologically-inspired dissipative motion for capturing pollutants[3], by ZnO-based microrobots in the form of Ag/ZnO heterojunctions, resulting in promising features. The morphology and the physico-chemical properties of the materials are analysed by instrumental techniques (DRS, SEM, XPS, XRD, UV-Vis and ζ-potential). It is found an optimal ZnO loading to enhance the photocatalytic properties as a result of surface-to-bulk dispersion[4]. In parallel, preliminary antibacterial activity of the ZnO-based systems are studied on gram-positive and gram-negative strains.

Sewage sludge biochar as green d–SPE adsorbent in QuEChERS clean-up process for the multi-residue LC-MS/MS analysis of emerging micropollutants in edible crops

L. Renai[a], G. Bonaccorso[a], M. Fichera[a], L. Rivoira[b], M. C. Bruzzoniti[b], M. Del Bubba[a]

lapo.renai@unifi.it

QuEChERS extraction is a widely used method for the multi-residue analysis of micropollutants in food matrices[1]. Due to the complexity of these matrices, QuEChERS methods usually require a clean-up stage of the extract, which in most cases uses the dispersive solid-phase extraction (d-SPE) technique, exploiting various types of materials (e.g., styrene-divinylbenzene and graphitized carbon black), characterized by significant costs. For this reason, a recycled carbonaceous material derived from the pyrolysis of sewage sludge (BC) was developed as a green alternative to commercial d–SPE adsorbent and applied to the clean-up procedure of high-pigmented edible crop extracts (i.e., rocket, tomato, and strawberry) for the determination of a wide variety of contaminants of emerging concern (CECs), such as pharmaceuticals, sunscreen agents, and PFASs listed in recent European decisions[2]. The use of 50 mg of BC proved to be reliable and cost-effective for the d–SPE clean-up of 23 analytes belonging to the aforementioned classes, being capable of reducing the matrix effect to less than |27%|. Although there were some limitations in recovering a group of CECs, BC allowed for achieving pseudo-quantitative recoveries and insignificant matrix effects for 8 pharmaceuticals, 1 sunscreen agent, and all 8 perfluoroalkyl substances studied. Furthermore, combining 5 mg or 10 mg of BC with 20 mg of styrene-divinylbenzene clean-up performances were improved, achieving quantitative recoveries for most CECs with matrix effects < |29%| (see **Figure 1**). The proposed analytical methodology was applied to the analysis of impacted crop samples, providing method sensitivities comparable to or lower than the limits proposed by the European community.

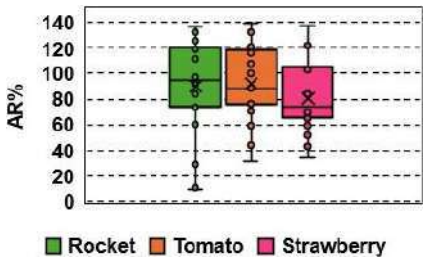

Figure 1: Mean apparent recoveries (AR%) of target CECs in food samples after d-SPE clean-up.

A "white" analytical method for the determination of emerging contaminants in water: optimization of the analytes' extraction by a bio-degradable polymeric film

B. Benedetti, E. Ceccardi, H. MacKeown, M. Di Carro, E. Magi

Department of Chemistry and Industrial Chemistry, University of Genoa, via Dodecaneso 31 – 16146, Genova, Italy.
barbara.benedetti@unige.it

The growing interest in greener approaches in many scientific fields generated the need for a green analytical chemistry. Nevertheless, in many analytical applications, essential method requirements cannot be overlooked, such as performance and time and cost-effectiveness. These aspects are not always easily fulfilled through the greenest strategies. Therefore, Nowak et al recently introduced the concept of "White analytical chemistry"[1](WAC), which highlights the importance of being "greener" without neglecting the value of method performance (accuracy, precision, specificity…) and feasibility. In the environmental analysis of emerging contaminants (ECs), WAC embodies the use of green and sustainable sample preparation, coupled to reliable, accurate and sensitive analytical determinations.

In this framework, the present work deals with the multivariate optimization of an extraction method based on the use of a biodegradable polymeric film (Mater-Bi), coupled to analysis by liquid chromatography-tandem mass spectrometry, for the determination of ECs in treated wastewater.

The interaction among 39 ECs with varying chemico-physical properties and the Mater-Bi film (a patented blend of polybutylene-terephthalate, starch and fatty acids) was investigated by two sequential experimental designs[2], to simultaneously study several factors and optimize extraction efficiency. The results indicated that hydrophobic and weakly acidic analytes were the most prone to interact with the material, resulting in good recovery from water samples. The final method, which basically resembled a fabric phase sorptive extraction, involved pH and ionic strength modification of the sample, 1 h extraction and desorption in ethanol. Satisfactory recoveries from real wastewater were obtained for sixteen analytes (56-116%), as well as excellent precision (inter-day relative standard deviations below 10% for most compounds). Matrix effect was investigated at two dilution factors, with good or acceptable results in both cases. Limits of detection in matrix, from 0.004 to 0.159 μg L^{-1}, were lower than or comparable to those from recent studies employing green extraction procedures. The method demonstrated its applicability to samples from wastewater treatment plants, allowing quantification of pharmaceuticals and UV filters at the μg L^{-1} and ng L^{-1} levels, respectively.

The optimized protocol allows a green, simple and extremely cheap extraction of several ECs from treated wastewater, by using a material so-far unexplored in analytical chemistry. The method guarantees very good analytical performance and demonstrated to comply with WAC principles.

francesca.merlo@unipv.it

The occurrence of organic contaminants, particularly antimicrobials, in aquatic environments is a global threat due to the growing evidence of adverse effects, such as the selection and spread of multidrug resistant bacteria and genes. Sensitive and accurate monitoring studies are a challenge with important but also contradictory aspects, since they help to detect the presence of such pollutants even at very low concentrations, but at the same time they can have an inherent environmental impact due to the resources involved. Recent trends pursue the goal of the sustainability through a simplification of the sample treatments and the use of natural and/or renewable materials[1]. In such a scenario, the focus of this work is the synthesis of efficient, green and biodegradable polymeric membranes for the multiclass thin film microextraction (TF-ME) of antimicrobials, namely fluoroquinolones, sulphonamides, tetracyclines, macrolides, diaminopyrimidines and glycopeptides. With the aim of not only serving the purpose of sample preparation but also avoiding secondary pollution, polycaprolactone has been selected as polymer due to its biodegradability, whereas a wood-derived biochar (Cabot) and a wood-derived activated biochar (Nuchar) have been tested as carbon precursors with the added benefit of extending the life-cycle. The films are home-made prepared, studying different compositions based on the solvent (chloroform or acetic acid) for solubilizing the polymer, the type and amount of char entrapped in the polymeric matrix. The preliminary TF-ME tests allow to evaluate the extraction efficiency (EE%) at different times (5 min ÷ 24 h) for each membrane. The use of acetic acid causes a partial acid hydrolysis of the lactone ring making the membrane less stable and hence less efficient, thus $CHCl_3$ has been selected despite its toxicity which is mitigated by its low consumption (1 mL). The adsorption capacity of the neat polymer was negligible (EE% < 8%) for all analytes, but it increased significantly in presence of Nuchar (15%w/w, EE% ≥ 80% at 8h). This biochar possesses a higher affinity in respect to Cabot (15% w/w, EE% < 15% at 8h) ascribable to the different functional groups and surface area. The results also show that the extraction efficiency is strictly dependent on the amount (15-30% w/w) of Nuchar incorporated in the polymeric matrix, and finally the film with 24% of Nuchar has been chosen as it guarantees quantitative extraction of all compounds in 4h. Different elution conditions, viz. solvent type and volume, type and time of stirring are being studied together with the analytical evaluation of the method in river and wastewater samples.

Controlled Periodic Illumination (CPI) for enhancing the photonic efficiency of a photocatalytic system

V. Maurino, [ab] E. Bianco,[a], F. Sordello, [a] F. Pellegrino [ab]

[a] *Department of Chemistry and NIS Centre, University of Torino, Via Giuria 7, 10125, Torino, Italy*

valter.maurino@unito.it

Semiconductor photocatalysis for water treatment and water photo splitting is plagued by low photonic efficiency and slow mass transfer of intermediate/products from/to the interface, hindering its exploitation[1]. Usually, Photonic efficiency measurements of the photoinduced processes at semiconductor surfaces for pollutant abatement and H_2 evolution (HER) are usually carried out under continuous irradiation of the catalyst. In the last decades Controlled Periodic Illumination (CPI) was proposed to increase the photonic efficiency of irradiated semiconductor systems. CPI consists in the modulation of the incident radiant power, alternating light and dark periods with given duty cycle, intensity, and frequency. The rationale underlying the use of CPI to enhance photonic efficiency is the exploitation of dark periods to allow slow reactions proceed, to induce new reactions or to free up space on the surface of the catalyst. In this work we demonstrated how: i - in the photocatalytic abatement of organic pollutants in aerobic conditions using semiconductor nanoparticles (usually TiO_2) CPI is not able to increase the photonic efficiency at the same average photon flux compared with continuous illumination[2]; ii – conversely, it is effective in the HER using metals like Pt, Pd and Rh alone or in combination with TiO_2.[3] The supposed mechanisms fall under the surface catalytic resonance theory and the differences between active and not-active metals can be explained invoking the Volmer-Tafel or Volmer-Heyrovsky mechanisms.

Oxolinic acid (OA)belongs to the first generation of quinolone antibiotics that are widely used in veterinary medicine and aquaculture. OA can be employed both as a prophylactic to prevent diseases and as a chemotherapy agent, because it is effective against the most common bacterial infections. However, the overuse and misuse of antibiotics have led to increased antibiotic resistance in pathogenic bacteria. The residues of OA and other antibiotics have been found in the environment, waste and urban waters due to incomplete elimination of these compounds in wastewater treatment plants. In this study, we studied the electrochemical degradation of OA in galvanostatic mode simulating real aquaculture effluents. Two boron-doped diamond (BDD) - electrodes with 9 cm² area were used as working electrode (anode) and counter electrode (cathode) along with OA concentration of 10 µM. Supporting electrolytes were chosen to understand the role of the different components of sea water, e.g. NaCl, NaBr, Na_2SO_4, $NaHCO_3$, $NaBO_2$ and their interactions. HPLC-UV results showed that degradation efficiencies were between 50 and 100% within 2 hours depending on the electrolyte tested. OA degradation was almost independent on current density, whereas larger currents generally led to improved mineralization at the expense of energy consumption. Degradations were particularly effective (> 90%) in NaBr-containing electrolytes already at 1 mA cm^{-2} current density with the least amount of energy supplied to the system (1.9 kWh m^{-3}). The addition of supporting electrolyte to Br-containing solutions led to similar degradation and mineralization efficiency but significantly reduced energy input, improving efficiency. While Br^- can improve OA degradation, reactive bromine species can also be responsible for the formation of harmful compounds. In fact, we detected bromate ion through ion chromatography and we hypothesize the formation of a brominated intermediate, but its identity will be investigated in future tests.

Debunking the need (and existence) of "pure" g-C_3N_4 to optimize its photocatalytic properties for environmental applications

I. Sciscenko,[a] A. Actis,[b] E Salvadori,[b] A. Arques[a], C. Minero[b], F. Sordello[b], M. Minella[b]

marco.minella@unito.it

Graphitic carbon nitride (g-CN) is a metal-free semiconductor gaining interest within the scientific community for its simple preparation, low cost, and photo-electrochemical properties.[1] Noteworthy, there is no clear consensus on its optimal synthesis due to the several parameters affecting it, such as, precursor, employed gas on the oven, temperature, or even if the precursor should be compressed or covered to reduce sublimation.[2] In views of standardizing its preparation and optimize its properties for environmental applications, in this work, we have calcinated melamine at different temperatures within the range 350 – 650 °C under anoxic controlled atmosphere and in presence and absence of an aluminium cover to reduce or enhance melamine sublimation, respectively.

Obtained materials were characterised by several techniques, and their photocatalytic performance evaluated as H_2O_2 generation (with methanol as hole scavenger) and phenol oxidative degradation under UVA and visible light, respectively. Results indicated that under UVA light, the best performance was obtained with the g-CN prepared at 425°C with the aluminium cover, leading to 6 mM production of H_2O_2 in 3 h, as well as a 3.4×10^{-2} min^{-1} phenol oxidation rate with an initial concentration of the organic substrate of 100 μM. To correlate the huge amount of data (21 variables analysed for 10 types of g-CN) a Principal Component Analysis was carried out[3], indicating that to maximize the photocatalytic performance under UVA light irradiation, employed temperatures should not exceed the 500 °C, contrarily to what is currently found in literature. On the contrary, for visible light experiments, reduction of band gap by doping the g-CN with nitrogen (employing higher temperatures, thus, observing a higher polymerisation degree and a C:N ratio close to stoichiometric 3/4 value) is required as usually observed in other works.

This work intends to shed light into the basic properties of g-CN and into the correlation between its photocatalytic properties and its physico-chemical features, as well as to promote the use of UVA light in views of saving synthesis costs of this semiconductor.

Exploration of Rare Earth Elements (REE) as potential biogeochemical tracers is constantly gaining attention across various fields of research, thanks to their unique properties. The common method for investigating the data coming from REE quantification by ICP-MS typically involves a visual evaluation of REE distribution, after normalization to a lithological reference. However, this approach has an inherent limitation because the choice of such lithological reference is subjective and therefore the interpretation of the distribution and identification of anomalies may depend on this choice.

In the present study, a new approach for analysing REE concentration profiles is proposed, applying Principal Component Analysis (PCA) for the creation of REE chemometric maps, which allow a simple and direct evaluation of similarities and differences to be performed in the geographical region under study. Moreover, PCA describes the profiles of REE in soils, facilitating the interpretability of results to exploit the chemical information embedded in concentration profiles. Results reveal that loading plots of PC1, PC2, and PC3 distinguish between light and heavy REE while highlighting anomalies of specific elements and REE groups. Data compression allows visualization of REE behaviour using an RGB colour scale (PC1= red channel; PC2= green channel; PC3= blue channel) directly on a geographical map.

Interestingly, similarities in agrochemical conditions were observed among soils belonging to the same lithological family when exhibiting similar REE distribution patterns. This underlines relationships between REE distribution and the diverse array of soil characteristics, supporting traceability studies and environmental monitoring.

Of particular significance is the fact that the application of the proposed methodology to non-normalized data yields results consistent with those derived from normalized datasets. For the first time, it was shown that similarities and differences in distributions can be found starting from raw concentration data, devoid of preconceived normalization biases.

The monitoring of effluent in water treatment plants has a key role in identifying possible pollutants that can be released into the environment. A non-target analysis approach can be used to identify unknown substances and isolate multipollutant signatures related to specific sources using powerful analytical techniques such as high performance liquid chromatography-high resolution mass spectrometry (HPLC-HRMS). However, HPLC-HRMS techniques focused on non-target screening (NTS) produce a huge amount of high-dimensional data, often with noisy and collinear structures; thus, it is necessary to use multi-step workflows involving extensive data processing and multivariate data analysis techniques to handle data sets appropriately and to further obtain interpretable results. Here we present the results from a case study in which urban and industrial wastewater effluent were examined by HPLC-HRMS for NTS[1]. The anomalous infiltration of industrial wastewater into urban wastewater was detected by analysing the information-rich mass spectrometry data of "unknown common" compounds using principal component analysis (PCA) and Self-Organizing Maps (SOMs). SOMs are a rather old type of artificial intelligence (AI) that employs unsupervised learning to convert high-dimensional input data into a lower-dimensional grid composed of nodes or neurons.

SOMs have several advantages over classical chemometrics methods such as PCA, including the ability to capture non-linear relationships and structure in the data, the ability to deal with complex high-dimensional datasets, meaningful visualisation of the outcomes in 2D maps, tolerance and robustness to outliers, the ease with which the latter can be identified, and the simplicity with which the results can be related to the experimental variable importance. In this case study, we compared the outcomes from PCA and SOMs, demonstrating that the PCA model could not fully perceive the differences among the different samples. Moreover, since PCA involves the calculation of new variables based on the original experimental ones, it is not possible to reconstruct a chromatogram that displays the recurring patterns in the urban wastewater samples. This can be easily achieved using the SOM outcomes.

caterina.durante@unimore.it

Food and agriculture account for most of the human demand for water, due to the huge amounts required for crops and livestock. Within the whole agricultural, municipal, industrial and energy sectors, 70% of water is used for cultures and farming. The current available water resources need an aware management to meet the growing global demand for food [1]. Thus, the possible use of reclaimed water for irrigation represents a great opportunity for water conservation and fits in the circular economy approach.

In this study, the optimization of an analytical method based on liquid chromatography-mass spectrometry (LC-MS) was carried out for the determination of 33 polar emerging contaminants in wastewater. The contaminants encompassed various classes including pharmaceuticals, personal care products, and other emerging pollutants.

Due to the high polarity of the analytes under study, hydrophilic interaction liquid chromatography (HILIC) was employed, by testing a zwitterionic stationary phase. To enhance the efficiency of the analysis, response surface methodology (RSM) utilizing a Fractional Factorial Design [2] was employed to optimize the experimental parameters. Indeed, multiple factors influence the chromatographic separation in HILIC, such as initial mobile phase percentage, gradient time, column temperature, type and concentration of salt and flow rate, which were investigated to achieve the best separation and sensitivity for the target analytes. Finally, the optimized method was combined to a suitable sample pre-treatment and applied to different reclaimed water samples. Thus, the method performance could be evaluated in real matrices and the presence of the considered contaminants in treated water was investigated.

Understanding the origins of microplastics and evaluating the consequences of plastic pollution hinges upon precise chemical information. In this regard, a remarkable challenge lies in the chemical changes that microplastics undergo due to photoaging, which could hinder spectroscopic matching and identification.[1] Micro-IR is currently one of the go-to techniques for the screening of microplastics, coupling the possibility of collecting optical images of the particles with the chemical information provided by the IR spectra. The sensitivity of reflectance Micro-IR spectroscopy to the thickness of the particles and to chemical changes induced by photodegradation on one hand hinders the automated recognition by spectral matching, but on the other hand contains layers of information that lie beyond the reaching of conventional data analysis. In this study, we conducted multivariate analysis on four types of microplastics obtained by common objects: two conventional (PE and PS) and two compostable bioplastics (PLA and PBAT). These microplastics underwent artificially accelerated photoaging and were analysed by Micro-IR spectroscopy in the medium infrared range. Principal component analysis (PCA) was able to classify the polymers and show degradation trends, highlighting even subtle changes in the spectra. The issue of reflection "artifacts" in spectra obtained from particles thicker than 100 µm was also addressed.

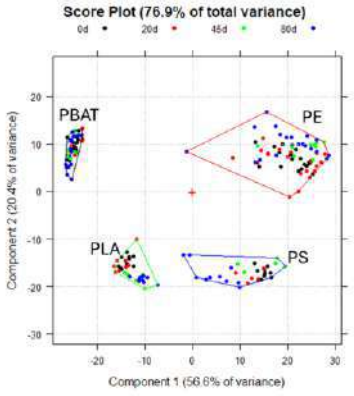

Figure 1: PCA scores plot of the four types of microplastics.

Accurate pH monitoring of highly concentrated saline aqueous solutions (Seawater-like) with a pH Colorimetric Sensor Array

A. Pastore[a], D. Badocco[a], L. Cappellin[a], M. Tubiana[a], A. Zanut[a], S. Bogialli[a], M. Roverso[a], P. Pastore[a]

andrea.pastore.1@phd.unipd.it

The increase in the atmospheric CO_2 concentration is causing a decrease in surface ocean pH by ≈ 0.002 pH units per year with a long-term pH decrease from 8.25 to 8.10 in the last two centuries[1]. Caldeira and Wicket predicted further decreases in seawater pH of up to 0.80 pH units by 2300[2]. Monitoring the seawater pH is therefore more and more important to determine negative effects on the environment. In particular, "in situ" real-time pH sensors are more and more necessary[3]. In this context, a pH Colorimetric Sensor Array (CSA) was prepared on a nitrocellulose membrane and used for accurate pH measurement in highly concentrated saline solutions. The CSAs consisted of sensing spots made of a suitable *OrMoSil* polymer prepared from organo-fluorinated-silane precursors and/or organo-silane with tetraethyl orthosilicate hosting an acid-base indicator. Four CSAs were prepared: D, 1F, 2F, and 3F[4]. In D a non-fluorinated organo-silane was present. From 1F to 3F the concentration of the fluorinated organo-silane increased and improved the pH measurement accuracy in highly saline concentrations. No re-calibrations were required and the analytical signal was stable in time[5]. D, 1F, 2F, and 3F were deposited in triplicate and they were prepared to work in the seawater pH interval (7.50-8.50). The use of fluorinated precursors led to a lower pH prediction error and tailored the interval of the CSA at more basic pH values so that the inflection points of the sigmoidal calibrations of D, 1F, 2F, and 3F moved from 6.97 to 7.98. The overall pH prediction error was 0.10 pH units (1F), 0.02 pH units (2F), and 0.04 pH units (3F)[6]. The CSAs were stable, reversible, reusable, and independent of salinity (S) between 20 and 40. The performances of the CSA were compared with those of the glass electrode whose pH_{NIST} values were converted in the pH_{SWS} scale through a conversion equation. Being unaffected by the typical drawback of the glass electrode, the CSAs can be used directly in seawater real samples and it validated the proposed conversion equation[7].

Nano- and microplastic particles are a global and emerging environmental issue. The present work exploits artificial intelligence (AI) to identify nano- and microplastics in water by monitoring the interaction of the sample with a sensitive surface. An Estrogen Receptor (ER) was grafted onto a gold surface[1], realising a plastic optical fiber (POF) platform in order to excite a surface plasmon resonance (SPR) phenomenon.

The ER-SPR-POF interface offers output data useful for exploiting a machine learning-based approach to achieve nano- and microplastic particle sensors. This work developed a proof of concept sensor through a training phase carried out by different particles in terms of materials and size. The experimental results have demonstrated that the proposed "smart" ER-SPR-POF interface combined with AI can be used to identify the kind of particles in terms of materials (polystyrene; polymethylmethacrylate) and size (20 μm; 100 nm) with an accuracy of 90.3%.

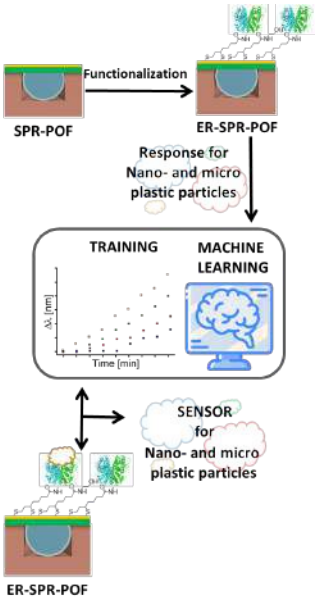

Figure 1: Scheme of sensing strategy.

e-mail: fdellapelle@unite.it

This presentation will be focused on the production of functional surfaces and NMs-films via CO_2-laser plotter and their integration within completely lab-made analytical devices. In particular, an overview of the development of (ii) freestanding laser-induced nanostructured films and their integration in (bio)analytical devices, and (ii) the laser-induced activation/nanodecoration of carbon-based inks for sensors and biosensors development will be given. Particular attention will be paid to nanostructured surface nano-/micro-architectures laser-assisted assembling, and fabrication of disposable devices using low-cost/sustainable substrates (i.e., flexible polymers, nitrocellulose, paper, recycled paper, etc.) via benchtop microfabrication technologies such as stencil-printing, cutter-plotting, CO_2-laser molding, thermal-lamination, etc.

The exploitability of the developed devices will be demonstrated for the analysis of agri-food quality and safety markers, and biological interest compounds in model solutions and real samples. Among others, will be presented the development of (i) laser-activated inks/graphene-based third-generation biosensors for the determination of fructose in food and biological samples, (ii) laser-assembled paper-based analytical devices that integrate and automate analysis steps i.e., (ii) an integrated paper/graphene 3D pop-up device for the quantitative sensing of carbaryl in grains at EU-law limits [2] and (iii) a laser-nanodecorated electrochemical lab-on-strip device for the rapid pretreatment-free evaluation of antioxidant capacity in extra virgin olive oil; moreover, (iv) electrochemical sensors based on laser-induced reduced graphene oxide (rGO) films integrated onto different recycled papers and paper produced from wastes will be also shown.

This presentation aims to prove how CO_2-laser plotter technologies are able to generate nanostructured transferable films and decorate different kinds of conductive surfaces, and how the coupling with benchtop technologies can allow the integration of them within cost-effective, flexible, and sustainable substrates, to give rise to effective everyone reach analytical devices.

Optimization of bioplastic films' properties for colorimetric sensing applications in the food sector

L.R Magnaghi,[a,b] G. Alberti,[a] R. Biesuz[a,b]

[a]*Università degli Studi di Pavia, Dipartimento di Chimica, Viale Taramelli 12, Pavia, 27100, Italy*

lisarita.magnaghi@unipv.it

Plastic materials are worldwide distributed and employed in several fields, thanks to their unique properties, but, unfortunately, they are often wrongly recycled or even just thrown away at the end of their life, resulting in an environmental impact no longer negligible.[1] This latter aspect has paved the way to a wide and miscellaneous group of materials generally referred to as "bioplastics" whose main features are i) renewable starting materials, ii) less energy consuming productive processes, iii) degradability in natural environments and, last but not least, iv) properties comparable to conventional plastic-based materials.[2] While the first features are promptly achieved, developing bioplastics actually showing comparable properties to plastics is not as easy as it seems: indeed, these multicomponent materials can range between extremely different behaviours just minimally modifying either the type of starting compounds or their ratios.[3] Therefore, the usage of multiparameter optimization approaches, such as the Design of Experiments, is mandatory to tune the properties and achieve the goal.[3] Focusing on the development of sensing devices, especially referring to those meant for the food sector, similar issues are emerging since bioplastics are everyday synthesized, generally as recipes found in literature or even in online tutorials describe, and used as they are, thus missing the countless opportunities these multicomponent materials are offering to tune their properties.

Our innovative approach in this scenario relies on the application of Design of Experiments methodology to optimize bioplastics films made of starch, glycerol and carboxymethylcellulose (CMC); we focus on multiple properties in order to produce materials suitable for environmental conditions in food packaging, such as high humidity and low storage temperatures. Then we add pH indicators from sulfonephthaleins class, which have been already reported in literature to monitor the degradation of various perishable foodstuffs efficiently,[4] and we further optimize all the preparation steps to develop sensitive and resistant bioplastic-based colorimetric sensors for freshness detection. As for the target food, we opt for fresh dairy products as case studies that are rarely discussed in literature due to their extremely challenging characteristics like high perishability, high humidity inside the package and low ratio between headspace atmosphere and food amount.

Pancreatic cancer, ranking as the third factor in cancer-related deaths, necessitates enhanced diagnostic measures through early detection. In response, SiMoT-Single-molecule with a large Transistor[1,2,3] multiplexing array, achieving a Technology Readiness Level of 5, is proposed for a timely identification of pancreatic cancer precursor cysts and is benchmarked against the commercially available chemiluminescent immunoassay SIMOA (Single molecule array) SP-X System. A cohort of 39 samples, comprising 33 cyst fluids and 6 blood plasma specimens, undergoes detailed examination with both technologies[4]. The SiMoT array targets oncoproteins MUC1 and CD55, and oncogene KRAS, while the SIMOA SP-X planar technology exclusively focuses on MUC1 and CD55. Employing Principal Component Analysis (PCA) for multivariate data processing, the SiMoT array demonstrates effective discrimination of malignant/pre-invasive high-grade or potentially malignant low-grade pancreatic cysts from benign non-mucinous cysts. Conversely, PCA analysis applied to SIMOA assay reveals less effective differentiation ability among the three cyst classes. Notably, SiMoT unique capability of concurrently analyzing protein and genetic markers with the threshold of one single molecule in 0.1 mL positions it as a comprehensive and reliable diagnostic tool. The electronic response generated by the SiMoT array facilitates direct digital data communication, suggesting potential applications in the development of field-deployable liquid biopsy[5].

simona.ranallo@uniroma2.it

Nucleic acid nanotechnology, which uses synthetic nucleic strands (DNA and RNA) as engineered materials to create functional devices and structures with nanoscale precision, has offered in the last decades new opportunities to handle and regulate biomolecules at the nanoscale level. Synthetic nucleic acids, with their high programmability, low-cost, ease of synthesis, biocompatibility and chemical versatility, have been extensively exploited to develop programmable nanodevices and sensors that can be used as powerful tools for a variety of applications, including sensing and diagnostics.[1] Despite these achievements, several nanotechnological diagnostic tools reported still suffer from a poor trade-off between sensitivity, specificity, simplicity, cost and time for analysis.[2] In response, cell-free transcription/translation systems, which contain the enzymes essential for transcription and translation and are capable of performing the basic processes of the central dogma (DNA➔RNA➔protein) independently of a living cell, are emerging as a new class of analytical tools with excellent sensitivity and specificity, offering exciting approaches for point-of-care diagnostics.[3] Motivated by this, in the last years we have recently developed optical and electrochemical cell-free transcription systems for the multiplexed detection of antibodies and other protein biomarkers in blood serum,[4,5] for controlling the loading and release of molecular ligands from synthetic nucleic acid receptors,[6] and for tuning the amount of transcribed RNA molecules over a large dynamic range in order to coordinate downstream processes of interconnected networks by mimicking strategies used by cellular pathways.[7]

The recognition of biomolecules and pathogens related to severe disease states is one of the most challenging tasks in biomedical practices. Indeed, there is an unprecedented need for advanced detection methods that can achieve early and highly sensitive recognition, given the impact that late interventions have on single human beings, as well as on the population's well-being.

Typically, the biomarkers employed in biosensors are oligonucleotide-based strands (such as DNA, RNA, mRNA) and proteins/antigens. Their detection is achieved through biological recognition elements enclosed with the transducing interface of the sensor.[1] A systematic study of the interface bio-functionalization strategy and the affinity interaction between immobilized recognition elements and analytes is a prerequisite in the development of a new biomedical sensor. Especially, for the assessment of portable devices for virus infection identification, the biofunctionalized surface should guarantee high selectivity along with extreme sensitivity to minimize false negative and false positive responses.

A highly sensitive portable platform for the bioelectronic assay of virus biomarkers will be presented. The device, addressed as SiMoT (Single Molecule with a large Transistor), is based on the electrolyte-gated field-effect transistor structure, encompassing a gate electrode gold surface modified with the bio-recognition elements chosen for the selective detection of a virus capsid protein. Several pathogens have been tested with this technique such as the HIV-1 and SARS-CoV-2 virus, through their capsid protein p24 and spikeS1, respectively.[2,3] We demonstrate the feasibility of the platform for the early detection of those biomarkers at the single-molecule level, in a range of concentrations of $10^{-21}/10^{-18}$M. These performances can ensure the discovery of the infection in an early stage and prevent severe degeneration. Moreover, these results are promising for the development of portable devices for the screening of other high-risk infections such as the HPV-16 and -18 virus types. Indeed, the study is ongoing for the assessment of a highly reliable and cost-effective device for the detection of such a cancer-related virus.

Developing disposable and low-cost electrochemical devices for biomedical applications has significantly increased with the diffusion of remote diagnostics. This is probably due to the need for regeneration of the conventional sensor surfaces and the demand for production processes that allow the manufacture of disposable and portable electrochemical devices promoting the reduction of the volume of samples, *in-situ* detections, and lower cost. [1]

Conductive inks are used for the development of disposable electrochemical sensors. They trigger the possibility of building screen- or stencil-printed electrodes with similar efficiency with respect to solid electrodes. [2] In particular, biocompatible inks are formulated and stencil-printed on a flexible support that could be easily integrated within smart-devices for the continuous and minimally invasive monitoring of lactate and glucose. First, the conductive ink formulation has been optimized based on electrochemical and rheological measurements implemented within a multivariate analysis model. Afterwards, the active carbon electrode was modified with methylene blue (MB) and Hemin to establish an electronic connection with enzymes, since neither alcohol dehydrogenase (ADH) nor alcohol oxidase (AOx) are able to directly transfer electrons. [3,4] Finally, both biosensors have been tested in model solution and sweat to determine the analytical figures of merit (*e.g.,* LOD, LOQ, linear range, sensitivity, selectivity, reproducibility, stability, storability *etc.*).

Single-Stroke laser scribing of optical-active nanostructures on cellulosic substrates for colorimetric and photoluminescent-based sensing strategies

A. Scroccarello,[a] F. Della Pelle,[a] P. Di Battista,[a] D. Compagnone[a]

[a]*Department of Bioscience and Technologies for Food, Agriculture and Environment, University of Teramo, Via R. Balzarini, 1, 64100 Teramo TE, Italy*
ascroccarello@unite.it

The implementation of affordable technologies to manufacture optical and colorimetric paper-based analytical devices (PAD) integrating optical active nanostructures is still a challenge. Therefore, the development of strategies to fabricate colorimetric PAD integrating nanostructured sensing surfaces with a controlled pattern is of great interest.

Recently, our group proposed an innovative and versatile approach to in-situ synthesize optical active gold, silver, platinum, copper, nickel, and aluminum (Al) metal nanoparticles (MNPs) on paper, employing a CO_2-laser plotter[1]. This approach allows laser-induce MNPs well anchored onto paper substrates according to customized designs; these laser-induced MNPs (LIMs) demonstrated captivating and useful features, including (i) localized surface plasmon resonance, (ii) catalytic and (iii) photoluminescent feature-related to the MNPs chemistry and morphology.

In this presentation, completely lab-made PADs integrating LIM coupled with smartphone-based readouts will be discussed. In detail, a photoluminescent Al-based paper-nanostructure employed for the implementation of a fluorometric PAD for the selective detection of o-diphenols will be presented; in this case, the Al-nanostructure fluorescence turn-on, induced by the interaction with the phenolic structures, is exploited for their detection. This peculiar optical behavior was investigated according to the laser-induced nanostructure synthesis, studying the Al-fluorescence turn-on mechanism towards several phenolic structures. Further, a laser approach to induce paper nanostructuration and carbon dots (CDs) formation will be also presented; in particular, the synthesis of laser-induced CDs (LiCDs) doped with different surface functionalizations (i.e., -SH, -COOH, -OH, etc.) will be shown. LiCDs give rise to enhanced fluorescence phenomena according to the surface chemistry; the use of the latter for (bio)sensing purposes will per presented.

Summing up, the proposed CO_2 laser strategy is particularly prone to generate colorimetric and photoluminescent sensing zones in tailored paper-based devices, resulting in a new sustainable nanopatterning technique useful for (bio)sensing and nanochemistry.

The interest in synthetic bioreceptors to develop (bio-)sensing platforms has increased quite rapidly in recent years. Ligand binding assay, which employs a receptor to capture the analyte, relies on the affinity of the receptor toward the binding ligand. In this respect, antibodies (Abs) are still playing a fundamental role. However, they suffer of high production costs to meet the requirements of specificity and selectivity for each analyte of interest. Immunoassays, in fact, rely on a couple of Abs that selectively bind two different epitopes of the same protein cancer biomarker. This aspect is crucial to develop biosensing platforms. Moreover, it is usually very difficult for researchers worldwide to find commercially available Ab couple that meet such requirements. Furthermore, Abs are not particularly useful to detect small molecules, such as chemotherapeutic drugs, as the detection system may imply the use of highly sophisticated equipment. However, there are innovative and valuable solutions represented by aptamers and peptides. In this presentation, we will show few interesting and recent applications of aptamers and of a new class of bicyclic peptides. The former ones have been employed to monitor a chemotherapeutic drug in plasma in an SPR-based sensing platform.[1] Whereas the latter ones have been devised in an electrochemical sensing platform to detect a cancer protein biomarker.[2,3]

Chemiluminescence biosensors for H_2O_2 and oxidases substrates quantification employing DNAzyme-mimicking activity self-assembled guanosine-hydrogel

D. Calabria,[a] A. Pace,[a] E. Lazzarini,[a] M. Zangheri[a], M. Guardigli[a], S. Pieraccini[a], S. Masiero[a], M. Mirasoli[a],

donato.calabria2@unibo.it

Chemiluminescence (CL) is widely used for hydrogen peroxide detection, mainly exploiting the highly sensitive peroxidase-luminol-H_2O_2 system. Hydrogen peroxide plays an important role in several physiological and pathological processes and is produced by oxidases, thus providing a straightforward way to quantify these enzymes and their substrates[1]. Recently, biomolecular self-assembled materials obtained by guanosine and its derivatives and displaying peroxidase enzyme-like catalytic activity have received great interest for hydrogen peroxide biosensing[2]. These soft materials are highly biocompatible and can incorporate foreign substances while preserving a benign environment for biosensing events. In this work, a binary guanosine hydrogel prepared using a mixture of guanosine and guanosine 5′-monophosphate in the presence of K^+ ions are loaded with a CL reagent (luminol) and a catalytic cofactor (hemin), to produce a functional material showing peroxidase-like activity to the CL reaction of luminol with H_2O_2. The hydrogel is then functionalized with a specific oxidase enzyme to enable marker biosensing: the hydrogen peroxide produced by analyte oxidation reacts, in the presence of the self-assembled guanosine/hemin gel mixture, with luminol to produce photon emission. The biosensor takes advantage of both the features of CL detection, offering high detectability and amenability to miniaturization, and of the 3D porous structure of hydrogel, as providing increased stability and catalytic activity even in alkaline and oxidizing conditions of incorporated enzymes. In this work we show the development of four guanosine hydrogel – based biosensors for the detection of glucose, xanthine, uric acid and lactate by simple incorporation of corresponding oxidases: glucose oxidase (GOx)[3], xanthine oxidase (XOD), urate oxidase (UO) and lactate oxidase (LOx). Exploiting 3D printing technology, smartphone-based portable devices for CL biosensors were developed, verifying the applicability to quantify biomarkers of clinical interest at the point-of-care (POC).

Light-up DNA nanostructures as programmable imaging sensors for enzymatic substrates

E. Del Grosso,[a*] S. Gentile,[a] F. Ricci,[a*]

[a] *Department of Chemistry, University of Rome Tor Vergata, Via della Ricerca Scientifica, 00133, Italy, erica.del.grosso@uniroma2.it*

The high programmability of synthetic DNA makes this biomaterial particularly suitable for the development of nanostructures with predefined geometries at the nanoscale. Over the past decades, many efforts have been dedicated to the fabrication of responsive DNA-based nanostructures. Taking advantage of their precise spatial addressability, it is possible to decorate them with various functional elements and develop DNA nanostructures that respond to a variety of different targets, offering potential applications in the fields of sensing, imaging and drug-delivery [1].

Recently, we have re-engineered supramolecular tile-based DNA nanostructures to respond to different chemical and biological inputs. We have also demonstrated several strategies to control their assembly, disassembly and reconfiguration in response to different external inputs [2,3]. Furthermore, we propose here a novel approach to develop light-up DNA-based nanostructures as programmable imaging sensors for enzymatic substrates. To achieve this, we have re-engineered tile-based DNA nanostructures to be decorated with different pH-dependent DNA-based responsive units, and we have initially developed light-up imaging sensors that respond to pH-changes. We have then shown that such decorated DNA nanostructures can be used as imaging sensors for specific enzymatic reactions (and their corresponding substrates) that change the pH of the solution (i.e. urea and glucose). Our approach also offers the possibility to engineer an integrated DNA-based imaging sensor that is functionalized with both, the enzyme (urease) and the responsive unit. This would be crucial for the development of an imaging sensor capable of measuring local concentrations of specific enzymatic substrates.

Liposomes-based Biosensing: innovative electrochemical characterisation strategies for vesicle encapsulation, functionalisation, and sensing mechanisms

R. Cancelliere [a], A. Licheli,[a] E. Paialunga,[a] L. Micheli[a]

[a] *Department of Chemical Sciences and Technologies, University of Rome Tor Vergata, Via della Ricerca 7 Scientifica 1, 00133 Roma, Italy*
rocco.cancelliere@uniroma2.it

Liposomes are artificial microscopic spherical structures composed of lipid bilayers enclosing an aqueous core [1]. These technologies are commonly utilised in a variety of applications due to their biocompatibility, ability to penetrate biological barriers, and capacity to encapsulate hydrophilic and hydrophobic molecules. Liposomes are often employed as carriers in nanodevices, for drug and gene delivery, and as mimics of cell membranes [2,3].

Herein, the production, functionalization, and sensing application of small unilamellar vesicles (SUV, diameter of around 100 nm) made of L-a-Phosphatidylcholine, 1,2-Dipalmitoyl-rac-glycero-3-phosphoethanolamine, and cholesterol in a molar ratio of 1:1:1 is presented. These SUVs, produced by the thin layer hydration (TLH) method, were initially encapsulated with a redox probe (i.e., $[Fe(CN)_6]^{3-/4-}$, L-ascorbic acid). Dynamic light scattering (DLS) is used to evaluate the dimension of vesicles while electrochemical methods like cyclic voltammetry and square wave voltammetry are used to characterize the efficacy of SUV entrapment and breakdown mechanism. After that, SUV functionalization was investigated by leveraging the nucleophilic reactivity inherent in the free amine groups of liposomes. A carbodiimide amide coupling reaction, involving EDC/NHS, was employed to covalently functionalize SUV by linking the free amine groups of liposomes with the free carboxylic groups of antibodies. Labelled and label-free bioreceptors (enzyme-labelled IgG and IgG) were utilised to functionalize SUV, whereas CV, SWV, and absorption spectroscopy were employed to assess method reliability. Finally, interleukin-6 (IL-6) selective Immuno-SUVs were prepared functionalizing SUVs with anti-IL-6 clone-5[4,5]. These liposomes showed promising analytical performances when tested in serum samples, with a low limit of detection (LOD=0.5pg/mL) and good reproducibility (RSD%<12%). Thereby, opening up the possibility of Immune-SUV employment for effective sensing purposes in complex matrices.

patrickseverin.sfragano@unifi.it

Extracellular vesicles (EVs) are biological membrane-enclosed nanometric particles whose classification and role remain unclear. Among them, exosomes are of particular interest. Initially considered simple debris, emerging evidence is now showing important correlations between EV expression and cancer diseases. Over the last few years, multiple methodologies have been applied for the detection and characterisation of EVs, although entailing limitations that include the high costs of the sophisticated instrumentation required, the necessity of high volumes of sample, and the incompatibility with point-of-care approaches. A simpler and cost-effective solution is lately increasingly being found in the field of biosensors.

In this work, a versatile biosensing scheme based on electrochemical readout and superparamagnetic microparticles (magneto-assay) was studied for the capture and determination of EVs. The beads were coated with different biorecognition molecules, testing the flexibility of the assay on a variety of analytes, including DNA. The magneto-assay was further successfully adapted to work in a microfluidic card in a semi-automated approach[1]. The procedure was then adjusted to work in the case of EVs. Indeed, the lack of standardised workflows and the limited literature-reported examples with these analytes, especially involving magnetic beads, required careful optimisation of the procedure[2]. The main challenge was mainly linked to the EVs' sensitivity to stresses during handling procedures. After assessing and optimising critical points of the analysis (*e.g.*, mixing, incubations, and storage conditions), multiple commercially available magnetic particles were preliminarily tested, differing especially in coating and size. Particularly, antibodies and aptamers were considered for use as bioreceptors to capture and immobilise EVs on the beads, exploiting a (hybrid) sandwich-like structure targeting tetraspanins expressed on the surface of the vesicles. The assay was then applied to the detection of EVs extracted from breast cancer, colon cancer, and glioblastoma cell lines. Preliminary results showed limits of detection of sub-nanograms/microliter levels of EVs in buffer, corresponding to ~10^6 EVs/µL.

Quercetin (Que) is one of the most popular and biologically active flavonoids which shows a broad spectrum of physiological activities such as anti- or pro-oxidant, anti-inflammatory, anticancer and antimicrobial effects.[1] The coordination properties of Que were exploited to obtain stable metal complexes with an improved biological action than the free flavonoid. Indeed, the coordination of metal ions changes the redox potential of the ligand thus modifying its antioxidant activity.[2] Moreover, the changes in the flavonoid structure after complexation are responsible for the higher antibacterial activity of the metal complexes which can easily interact with various intracellular components.[3]

Despite the promising broad spectrum of pharmacologically relevant properties, applications are severely confined due to their low *in vivo* bioavailability, poor water solubility, low stability, and short half-life. Various drug carriers were proposed to ameliorate the solubility and stability of Que and, consequently, to increase the biological activity and availability of the flavonoid to produce significant therapeutic effects.[4]

Within this framework, we investigated the capability of a *p*-sulfonate-calix[4]arene derivative,[5] able to form micellar aggregates, to include the flavonoid and its zinc(II)-complex thus enhancing their stability.

The interactions of Que or its Zn(II) complex with the calixarene-based system in the micellar, monomeric or non-amphiphilic forms were investigated by isothermal titration calorimetry (ITC) in aqueous solution at 25 °C and pH 7.4 to determine the binding parameters and driving forces of the molecular recognition equilibria in solution.[5] NMR experiments enabled us to estimate the ability of the micellar system to interact with the flavonoid and its metal complex as well as to unveil the main functional groups involved in the binding process. The micellar aggregates were thoroughly characterized to determine their size and charge. Finally, kinetic stability measurements were performed to assess the ability of the micellar systems to increase the half-life of the flavonoid and the Zn(II) complex.

Overall, these studies provided an in-depth characterization in solution of the drug-carrier assembly which is essential for the development of efficient delivery systems with potential biological applications.

Iron uptake systems can be targeted as strategy to enhance the uptake of antimicrobial cargos. Actually, the pathogenic microbes produce Fe-scavenging molecules that sequester iron from their extracellular environment and transporting proteins.

In this frame, we carried out the solution equilibria studies on Fe(III) and Ga(III) hydroxypyrone complexes.

Gallium(III) is an effective iron(III) mimic but redox inert under physiological conditions.

On the other hand, hydroxypyrone compounds, namely kojic acid derivatives, are a class of chelating agents widely suitable for *hard* metal ions [1,2].

Therefore, the complementary use of potentiometric and spectrophotometric techniques has allowed a solution characterization of the different species involved in the equilibria. Solution equilibria studies of Fe(III) complexes were carried out firstly [ref Toso], and then the corresponding ones with Ga(III) for evaluating the similarity between these two metal ions. The results are clearly consistent with the formation of 2:3 metal:ligand complexes already at high acidic pH, differently protonated with both metal ions. The stability constants calculated for Ga(III) system strictly resemble those calculated for Fe(III).

Moreover, the synthesis in solid state and the characterization by NMR spectroscopy and mass spectrometry gave evidence of the 2:3 stoichiometry.

Lastly, biological test demonstrated that Ga(III)-complexes exhibit promising activity against *A. fumigatus* and gram-negative bacteria.

Among naturally occurring chelating agents, an excellent candidate to be exploited in metal ions removing from water is trans-aconitic acid (H_3L, Scheme 1), a molecule largely present in sugar cane (about 60 % w/w), or that can be isolated from by-products of the sugar industry. It was found that the amount of trans-aconitic acid available in the molasses is between 7.1 and 23.4 g/kg of dry product. The thermodynamics of interaction of trans-aconitate with proton, sodium, potassium, cadmium, manganese, and lead cations has already published[1]. Considering the obtained results and the lack of data in the literature, it was decided to study additional interactions with other metals. The choice of these metals was influenced by the importance of certain cations in natural and biological matrices, as well as their technological significance, such as the La^{3+}. The complexing ability of trans-aconitic acid toward Ca^{2+}, Mg^{2+}, Cu^{2+} , Zn^{2+}, Co^{2+}, La^{3+} and Fe^{3+} was studied by potentiometry, UV-vis spectroscopy and ^1H NMR techniques, in chloride aqueous solutions at different ionic strength values ($0.1 \leq I/\text{mol dm}^{-3} \leq 1.0$) and at $T = 298.15$ K. The ligand sequestering ability and affinity toward M^{2+} and M^{3+} cations were evaluated by determining the $pL_{0.5}$ and pM parameters at different pHs and ionic strengths. The data reported in this study can provide information on the possible employment of a small molecule like trans-aconitic acid, as a chelating and sequestering agent in aqueous solution.

.

An overview of the speciation and antioxidant ability of morin, quercetin and their M^{2+}-, M^{3+}-complexes under physiological conditions

C. Abate,[a] O. Giuffrè,[a,b] C. Foti,[a]

[b] *CNR-IPCF, Viale Ferdinando Stagno d'Alcontres 37, 98158 Messina, Italy*
cabate@unime.it

Morin (Figure 1), a naturally occurring polyphenol, and its metal-complex species have attracted increasing interest from the scientific community for their bioactivity, particularly as antioxidants. Knowing their speciation may help assess their pharmaceutical, nutraceutical and therapeutic potential, which –in turn- could be exploited for the design of advanced antioxidant drugs. The bioactivity of morin, as well as that of its 3'-OH isomer, quercetin, is related to the ionization state of the hydroxyl groups in its chemical structure and metal-chelating abilities.[1] To this end, a speciation study was first performed under physiological conditions of ionic strength and temperature (I=0.15 mol L^{-1} (NaCl) and t=37°C) to determine the protonation constants of morin and quercetin, whose values are controversial in the literature. Therefore, thermodynamic interaction parameters of morin with bivalent (M^{2+}, such as Mg^{2+}, Mn^{2+} and Zn^{2+}) and trivalent (M^{3+}, such as Al^{3+}) metal cations, as well as their antioxidant ability were also studied by the 2,2'-diphenyl-1-benzopyran-4-one (DPPH) method.[2] This investigation sheds light on the different pH-dependent species of morin, quercetin and their M^{2+}-, M^{3+}- complex forms in aqueous solutions, also highlighting the effect of coordination on the resulting antioxidant abilities.

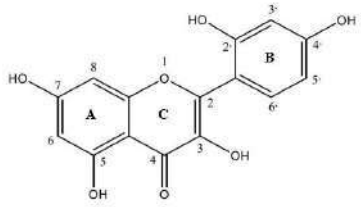

Figure 1: chemical structure of morin.

Beyond the thermodynamics of metal-peptide complexes: new perspectives for antimicrobial agents

D. Bellotti,[a] S. Leveraro,[a] K. Garstka,[b] M. Rowińska-Żyrek,[b] M. Remelli[a]

blldns@unife.it

The importance of antibiotics to fight infectious diseases is undoubtedly well recognised worldwide. However, the antimicrobial resistance of many microorganisms has forced to reevaluate their application. Antimicrobial peptides are promising alternatives to classical antibiotics. Their bioactivity can arise from different mechanisms, one of which is known as nutritional immunity and has metal micronutrients and metal-binding biomolecules as its main players. The human antimicrobial peptide calcitermin is an example. It has been previously studied by our research group aiming to evaluate its metal chelating ability and bioactivity against various pathogens *in vitro*.[1]

A systematic study was further undertaken on calcitermin derivatives. Chemical modifications have been introduced in the native sequence to verify the impact of divalent Cu(II) and Zn(II) ions on the stability, coordination and antimicrobial activity of the formed complexes.[2,3] A deep investigation of complex formation equilibria and coordination chemistry of the formed species has been obtained by means of potentiometric titrations, mass spectrometry, UV-Vis spectrophotometry, circular dichroism and electronic paramagnetic resonance. Antimicrobial assays provided information on the bioactivity of the compounds against a wide panel of microorganisms and highlighted the crucial role of metal ions. Given the obtained results, the characterization of the thermodynamic properties in solution of metal-peptide complexes represents a stepping-stone for the development of new metal-based antimicrobial agents.

Financial support of the National Recovery and Resilience Plan (NRRP), Mission 4 Component 2 Investment 1.1 – NextGenerationEU (PRIN PNRR 2022 - P2022EMY52) is gratefully acknowledged.

The contaminants of emerging concern is a class in constant evolution since new compounds which may present toxicity towards the biota are continuously detected in the environment, especially in water bodies. Among these substances, gadolinium based contrasting agents (GBCAs) are regarded as possible contaminants of relevance due to their widespread use in medicine[1]. Substances containing gadolinium are used as contrasting agents in magnetic resonance imaging (MRI) analyses due to the paramagnetic properties of Gd; since gadolinium ion in its free from, Gd^{3+}, is highly toxic, it is administered before MRI examination as a complex with an organic ligand which ensure a high stability of the compound avoiding the release of free Gd ions into the body fluids[1]. The high stability implicates that GBCAs are persistent also in the environment, and indeed their concentration in the aquatic ecosystems is expected to increase, possibly leading to adverse effects.

In this work, we investigated the presence of two GBCAs, namely gadoterate meglumine (Gd-DOTA) and gadoteridol (Gd-HP-DO3A), in two different aqueous matrices, wastewater both at the entrance and at the exit of a wastewater treatment plant in Trieste, and seawater collected in the gulf of Trieste near the WWTP's pipeline.The wastewater samples were pre-concentrated by evaporation, while the seawater samples, presenting a high salinity, needed a specific treatment consisting in a solid phase extraction to remove the saline components in order to prevent interferences during analysis[2]. The determination of GBCAs was carried out by HPLC-ICP-MS using an anion exchange column and a mixture of 125 mM ammonium nitrate buffer at pH 9 and MilliQ water in a 25:75 ratio as a mobile phase. The isotopes ^{157}Gd and ^{158}Gd were monitored.

The high recoveries obtained for Gd-DOTA and Gd-HP-DO3A proved the validity of the two sample preparation methods. The results showed the presence of both substances in the samples analysed, in the range between 0.1 and 50 ng/L; indeed, higher concentrations were found in the wastewater matrices, while the concentration was lower in the seawater samples, providing information on the environmental pathway of these compounds.

ilangasco@uniss.it

Rice is a staple food for over half of the global population and plays a crucial role in the worldwide economy. To ensure consumers' health, it is essential to continuously monitor the presence of both essential and potentially hazardous elements in food. This is particularly important for rice, which has the tendency to accumulate toxic elements from the soil-water system. Rare earth elements (REEs) are the class of trace elements that are frequently studied in food, due to their emerging contaminant status and their use in geo-referencing purposes[1]. Therefore, researchers are evaluating the toxicity and translocation of these elements from abiotic ecosystems to living organisms[2].

Elements mobility is primarily influenced by soil features and their interactions among microorganisms and rhizosphere, in turn influencing the bioavailability of REEs[3,4]. This study aimed to investigate the translocation of REEs throughout the soil-rice system at varying of irrigation techniques, and a comprehensive analytical procedure was developed for this purpose.

Soil, roots, stems, leaves, panicles, husks, and rice grains from the *Sprint* rice genotype (Indica subspecies) were collected at the Santa Lucia experimental farm of Sassari University, Sardinia, Italy.

The study considered three irrigation methods: continuous flooding, saturation irrigation, and sprinkler irrigation[5]. The matrices underwent mineralization using a microwave-assisted acid/oxidant digestion with an ultraWAVE device from Milestone. The quantification of REEs was performed using an inductively coupled plasma mass spectrometry NexION 300X from Perkin Elmer.

raffaello.nardin2@unisi.it

To fight counterfeits, and to protect the consumer, the interest in certifying the origin of agricultural goods has been growing in the last years. To increase the accuracy of zoning models, a multivariate approach is needed. This has been proven to be better suitable than univariate analysis when it comes to the investigation of geographical origin of agri-food goods[1] especially when trying to move past the state-of-the-art challenge of discriminating products coming from extremely close regions[2] (sometimes in a range of under 20km). By means of ICP-MS, samples coming from the 2022 and 2023 sampling campaign were analysed for their metal content and these levels used in the construction of simple discriminant models that have been proven successful to separate samples coming from the Tuscany countryside. Furthermore, by collecting samples of soil, plant matter and finished product it was possible to investigate the direct link between geographical location and agri-food goods, without the possibility of any interferences from the production chain[3] introduced in the samples masking potential correlations. Lastly, metabolomic profiles, which are known to be modulated by abiotic factors[4,5], were correlated with the chemical composition of the soil, with the aim of further understanding the difference in characteristic of agri-food goods due to geographical locations.

This study was carried out within the Agritech National Research Center (Spoke 9) and supported by the European Union Next-Generation EU (D.D. 1032 17/06/2022, CN00000022).

Growing tea in Europe is a new frontier, offering opportunities for research and development [1]. This study provides an in-depth examination of the elemental compositions found in tea leaves sourced from multiple European gardens (**Figure 1**), focusing on the determination of 21 essential and potentially toxic elements in tea leaves (fresh, dried and processed to produce green and black tea) and soils, in relation to processing methods and garden locations. The findings indicate no accumulation of toxic elements from soil to leaves. No significant variations in elemental content based on tea leaf processing techniques were registered. However, the application of chemometric and machine learning techniques (RDA, PCA, PLS-DA, LDA and SVM analysis) revealed distinct elemental profiles among tea leaves originating from different European regions. This study underscores the potential utility of these elemental profiles in improving the traceability of European tea products.

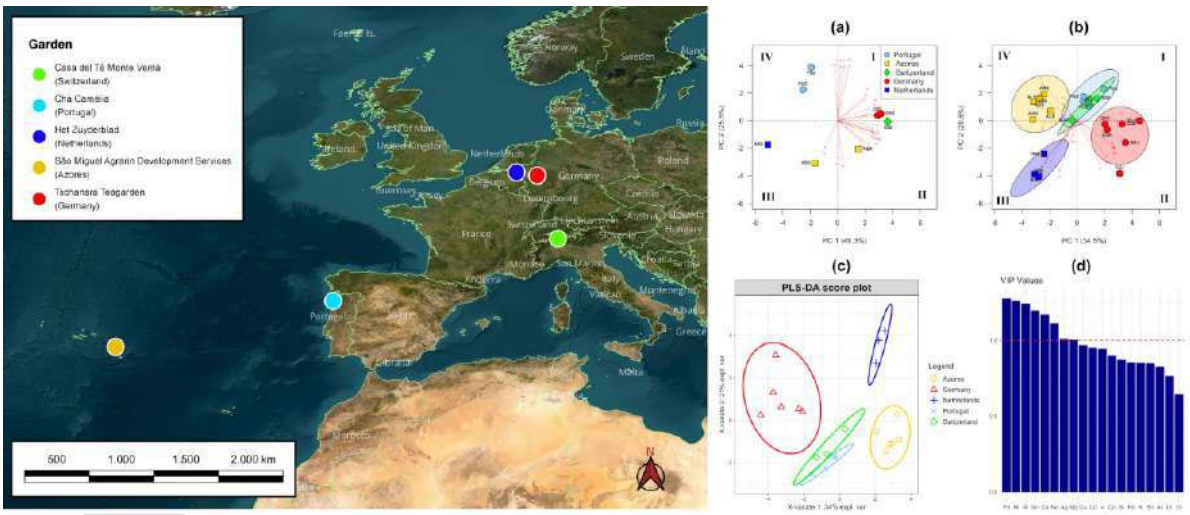

Figure 1: sampling locations across Europe and main results: PCA on soil (**a**) and tea leaves (**b**) samples, PLS-DA (**c**) and VIP values bar plot (**d**) of tea leaves.

elisa.robotti@uniupo.it

In the perspective of the protection and valorisation of typical products, the role played by analytical chemistry appears of primary importance in order to provide consumers and workers in the production chain with useful information on the characterization of the products. The study presented here was developed within the "Pa.N.E." project. – Panem Nostrum Every Day" (PSR 2014-2020, Measure 16 – 16.1.1), aimed at the recovery of a historical variety of soft wheat, the San Pastore variety, widely used in the Piedmont area until the 1960s, then fallen into disuse, and now the almost exclusive prerogative of a few research and conservation centres, the most authoritative of which in Italy is the Morando Bolognini Foundation.

The project involved the valorisation of San Pastore wheat along the entire supply chain, from wheat to flour to bread, rediscovering the modernity of a traditional wheat, with the aim of combining innovation with tradition.

From a characterization point of view, the supply chain was followed from different points of view:

- Characterization of wheat: 4 different varieties of San Pastore (San Pastore and 3 variants) were studied and compared with 4 other varieties, 2 of which were modern and 2 historical, with the aim of characterizing their proteomic, lipidomics and small molecule profiles;
- Flour authentication study: the stone-milled San Pastore wholemeal flour was mixed with increasing contents of flours of two modern soft grains, in order to evaluate the possibility of identifying any adulterations with less valuable products;
- Authentication study on bread: the bread produced from San Pastore flour currently in production was studied to evaluate whether variations to the recipe could be detected (type of oil, yeast, flour, operator), as part of the identification of commercial frauds. The study was approached using experimental design techniques to study the effect of the recipe on the chemical characteristics of the final product.

All phases of the research were followed through a characterization obtained by a multi-omics approach. Wheat, flour and bread samples were pre-treated to extract proteins, lipids and small molecules which were identified and quantified using UHPLC-HRMS (proteomics and lipidomics) and GCxGC-MS (small molecules). The data were processed using chemometric pattern recognition techniques (PCA, cluster analysis, Kohonen autoassociative maps, MFA) and classification methods (PLS-DA, SIMCA, Artificial neural networks), also coupled with variable selection methods.

Metabolomic Profiling of 'Patata di Montese': Authenticity Assessment and Regional Discrimination Using uHPLC-MS and ROI-MCR Method

L. Strani,[a] C. Durante,[a] S. Pellacani,[a] M. Cocchi[a]

[a]*Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Via Giuseppe Campi 103, Modena*
lostrani@unimore.it

European Union prioritizes protecting and promoting mountain products, introducing Mountain Product indication in 2012 to enhance their recognition and indirectly support mountain economies. This indication applies strictly to food items sourced or processed in mountain areas, contributing significantly to Italy's PDO products, particularly in Emilia-Romagna, necessitating research to uphold authenticity and consumer choice. In this context, metabolomic profiling aids in ensuring food authenticity, with applications ranging from targeted quantitative analysis to untargeted pattern acquisition, vital for identifying unique markers on food products. In this study, the research activity focused on analyzing the metabolomic profile of potato cultivar samples labeled as 'Patata di Montese,' an authentic and traditional product of the Emilian Apennines. Ultra-high-performance liquid chromatography coupled with mass spectrometry (uHPLC-MS) was utilized to delineate the molecular fingerprint of the investigated samples. In the first part of this work, influential instrumental parameters affecting chromatographic separation were optimized using experimental design techniques (Face Centered Central Composite Design, FC-CCD) to achieve resolved chromatographic signals in the shortest possible time. In the second part, the optimized analytical method was used to characterize the metabolomic profile of samples from the same potato cultivars grown in mountain (Montese, MO) and plain (Castelfranco, MO) regions. ROI-MCR method[1] was employed in order to reduce the complexity of the chromatographic signals correcting noise or undesirable effects (peak shifts, baseline drift) that could obscure useful information for analysis. The algorithm performs extensive data filtering and compression operations to transform the original structure into a matrix of potential "features" (Region of interest, ROI) and resolve the relative chromatographic profiles of the various components representative of the entire sample. Once these features were extracted, they were compared with data from the literature[2] and specific databases, such as Compound Discoverer, to achieve a preliminary identification of the present compounds/metabolites. Finally, Principal Component Analysis (PCA) was used as an exploratory method directly on the final datasets containing the features to identify the most influential metabolites in differentiating between the two categories in the space defined by the principal components.

valentina.miele@unina.it

Ovatoxins (OVTXs), produced by marine dinoflagellates like *Ostreopsis* cf. *ovata*, are potent marine neurotoxins structurally similar to Palytoxin (PLTX). In recent years, the global expansion of *Ostreopsis* spp correlated to a phenomenon called Harmful Algal Blooms (HABs)[1] has led to an increase of OVTXs, raising concerns about public health and environmental impact. Exposure to OVTX-contaminated seawater can lead to skin and eye irritation, respiratory issues, and muscular pain[2]. Despite their impact, the lack of well-characterized reference materials (RM) for OVTXs complicates their detection and risk assessment. Our research addresses this challenge by focusing on the optimization of the isolation protocol of OVTX-a from *Ostreopsis* cf. *ovata* cell pellets[3] in 4 steps: Extraction, Medium Pressure Liquid Chromatography (MPLC), Semi-preparative High Pressure Liquid Chromatography (HPLC-step 1) and Preparative HPLC (HPLC-step 2). Through meticulous optimization of each step, we achieved a doubling of total recovery yields from 12.5% to 25%. Moreover, refining the latter two steps enabled the chromatographic separation of all OVTXs present in the initial cell pellet, including OVTX-a, OVTX-d/e, and Isobaric PLTX, resulting in a final OVTX-a fraction with a purity exceeding 94%. This accomplishment marks a significant advancement in preparing reference materials for analytical and toxicological purposes, thereby aiding regulatory efforts to safeguard public health.

Precision and personalized medicine advancements allow to tailor clinical approaches, depending on the makeup of patients' DNA and expression issues. Liquid biopsy and the chance to use selected biomarkers from biological fluids, could strongly contribute to the improvement of an increasingly patient-oriented method, avoiding invasive assays and tissue biopsies. Among the most important effectors of cellular interplay, Extracellular Vesicles (EVs), are on the rise for the possibility to be considered as powerful biomarkers, although the severe limitations of standard tools hinder their complete understanding and use. In fact, isolation, enrichment and sorting techniques available are often instrument- and time-heavy, and require a high amount of sample. Moreover, EV characterization needs various steps of sample pre-processing, involving e.g. centrifugation, which can influence stability, size and cargo release. The technological gap in handling this kind of sample, in its complexity and heterogeneity, limits the exploitation of such an information-rich pool, both for diagnostic and medical research applications. We aim to move forward in disentangling EVs heterogeneity going beyond limitations imposed by standard methods of analysis. In particular, using Flow-Field Flow-Fractionation (4F) and on-chip detection for their full characterization, our purpose is to build a benchtop-ready device able to identify arrays of biomarkers associated to the size and to different functions of EVs subclasses, customizable according to clinical needs. A key point is the effort in removing all the highly impacting processing procedures to operate in the most native conditions possible, reducing time and cost, and preserving EV morphology and properties. We present here the first results on combining dynamic cell culturing and on-chip detection of conditioned media[1] with in-flow sorting and selection of EV-rich fractions[2] to reduce processing steps, shorten analysis time, and enhance sensor lifetime by reducing interferences, in a streamlining process towards realistic liquid biopsy.

Copper-chitosan (Cu-CS) films, composed of encapsulated bioactive nanophases within a thin polymer coating[1], are promising antimicrobial films for food packaging applications with excellent bioactivity. In this contribution, we report on Cu-CS thin films obtained by a simple solvent evaporation method accurately tuning the inorganic loading of nano-toxicologically safe Cu sub-microparticles. The procedure is green and straightforward, and exploits water-based solutions and mild conditions. The Cu-CS films were characterized by spectroscopic and scanning probe microscopy techniques with respect to composition and physicochemical properties. Electrothermal atomic absorption spectroscopy (ETAAS) studies were conducted to predict the antimicrobial properties of these composites via the quantification of Cu^{2+} ionic release over time.

Besides, atomic force microscopy (AFM) to image *E. coli* incubated on antimicrobial thin films between 2 and 20 h was used to visualize morphological alterations of bacterial cells when in contact with multicomponent antimicrobial surfaces like Cu-CS. Different antimicrobial mechanisms of action were identified based on the thin film composition and the incubation time. Signs of bacterial stress, like "blebbing", fimbria and flagella growth, clustering and the development of extracellular polymer matrix (EPS) were clearly evident[2]; massive cell lysis for long-time exposure to the antimicrobial surfaces was also observed. As response to harsh external conditions such as nutrients starvation and the presence of antimicrobials, the morphology of bacteria was altered from a rod-like to a smaller and coccoid shape associated with the reduced energy requirements to overcome hostile conditions[3]. These findings indicate a synergistic antimicrobial action exerted by CS and Cu particles when combined into composite thin films. This study investigates bacterial behavior when in contact with antimicrobial surfaces to better understand the mechanisms of action of these materials and the potential development of antimicrobial resistance phenomena.

rosaria.picca@uniba.it

Zn-based materials, such as zinc oxide or zinc phosphate, have different applications including antimicrobial treatments[1,2]. In the last years we have devoted part of our research activity to the development of green electrochemical approaches[3-5] for the synthesis of nano- and microstructures demonstrating its easiness, high yield and ability in controlling size and quality of the produced materials. In particular, the sacrificial anode electrolysis in alkaline media allowed preparing ZnO in several shapes and sizes by adding suitable stabilizers applying low current density. More recently, Calcium zincate was also synthesized and applied as antibacterial agent[5].

In this contribution, some successful examples of Zn-based (nano)material development will be illustrated emphasizing the advantages of electrochemical sol-gel routes. The versatility of this strategy will be further demonstrated, and cases of study will be discussed, including the development of advanced, or multi-component antimicrobials such as zinc phosphate particles and AgCl-nanoparticles @ ZnO-nanorods. The morphological and spectroscopic characterization of the proposed materials will be presented, highlighting the importance of structure, surface composition, and metal ion release. High-resolution TEM analysis, coupled with EDX elemental mapping, was performed to investigate morphology and composition. Moreover, spectroscopic characterization by FTIR and XPS techniques demonstrated that nanostructures composed of zinc phosphate tetrahydrate were obtained. Comparison with zinc phosphate produced by precipitation methods was also carried out, suggesting superior results of the electrochemical method.

Quantitative XPS analysis: the case of NiP alloys.

D. Biggio,[a] B. Elsener,[a] M. Fantauzzi,[a] A. Rossi[a]

[a] *Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari, Cagliari, Italy*

e-mail of submitter: deborah.biggio@unica.it

X-ray photoelectron spectroscopy (XPS) is an acknowledged surface-sensitive technique suitable for qualitative and semi-quantitative analysis.[1] The results obtained on a series of NiP coatings deposited on a copper substrate, previously characterized by EDX, XPS, and by AAS and UV-Vis (for determining Ni and P content respectively)[2], are presented in this investigation, which is focussed on the factors that might influence the quantitative analysis by XPS. A Theta Probe spectrometer (Thermo Fisher, UK) equipped with a monochromatic Alkα source (hν = 1486.6 eV) was used for the XPS analyses of NiP alloys. Prior to introducing the samples in the XP-spectrometer, they were cleaned for 16 h in isopropyl alcohol; then they were ion-etched using Ar^+ at 3kV x 3 μA, 3*3mm^2, for 3 minutes to remove any surface contamination. The high-resolution spectra were processed using CASAXPS software and applying the Shirley-Sherwood background. Peak intensities were corrected by using the calculated relative sensitivity factors[1]. The best linear relationship between the peak areas corrected for the relative sensitivity factors were obtained by considering the Ni 3s to P 2p corrected intensity ratio vs the chemical composition of the alloys, despite the fact that the Ni 2p is the most used signal in XPS quantitative analysis. These results can be explained by considering the influence of the kinetic energy differences within the Ni 2p and the Ni 3s signals that affects the inelastic mean free path (IMFP). The data quality parameters as accuracy, precision, range of linearity will be discussed by considering various concentrations of the NiP alloys together with the effect on the peak areas (peak intensities) of the background subtraction functions; of the correction for the instrumental parameters (asymmetry parameter and intensity energy response function) and of the method used for the calculation of the peak areas.

Dried oregano leaves are commonly subjected to economically motivated adulterations, which consist in adding lower cost plant materials of different botanical origin. Frequent adulterants found in oregano samples include olive, sumac, strawberry tree, and myrtle leaves. To face this issue, the European Spice Association suggests the use of non-targeted fingerprinting techniques coupled with chemometric methods to monitor product authenticity[1].

In the present study, we evaluated Near Infrared Hyperspectral Imaging (NIR-HSI) as a rapid and non-destructive analytical tool to detect adulterated oregano samples. By proper chemometric elaboration of hyperspectral data, NIR-HSI enables a comprehensive chemical characterization of heterogeneous samples like dried oregano leaves thanks to the possibility of acquiring both spatial and spectral information from a sample.

Hyperspectral images of authentic oregano, pure adulterants (i.e., olive, strawberry tree, myrtle, and sumac leaves) and oregano with different percentages of adulterants were acquired in the 980 – 1660 nm spectral range using a line scanning spectral imaging system.

Multivariate classification models were calculated to differentiate authentic oregano from pure adulterants by using two classification strategies: class modelling with Soft Independent Modelling of Class Analogies (SIMCA)[2] and soft discriminant approach with Soft Partial Least Squares Discriminant Analysis (Soft PLS-DA)[3]. Soft PLS-DA achieved the best classification results, since this algorithm combines the advantages of class modelling and discriminant analysis methods.

Finally, based on Soft PLS-DA results the corresponding percentage of pixels predicted as oregano was calculated from each image. This allowed to establish a threshold value of 10% adulteration, serving as a detection limit of NIR-HSI to distinguish authentic oregano from adulterated samples.

riccardo.voccio@edu.unige.it

The chemistry of tyre materials is complex due the presence of several compounds, that are mixture of elastomers and other chemicals, such as curing agents, fillers etc… In more detail, the curing agent is one of the most important constituents, as it promotes the vulcanization process. This process is a chemical reaction in which cross-linking bonds are formed between the polymer chains of the elastomers. The final product properties are strictly dependent on the cross-linking density and, therefore, it is of crucial importance to determine this value. Up to date, one of the most common analytical methods to determine such parameter is the equilibrium-swelling method[1], which requires some days to be performed and a huge amount of solvents.

The development of an analytical method fast and solvent-free can therefore be a huge advantage for the tyre industry. To the aim, Time-Domain Nuclear Magnetic Resonance (TD-NMR) spectroscopy is worthy of being studied, as its decay profile is highly correlated with the chain mobility in rubber-based materials.[2]

In the present study, performed in collaboration with Pirelli Tyre S.p.A., TD-NMR decays (^{1}H 18 MHz- obtained using the Carr-Purcell-Meiboom Gill (CPMG) sequence – developed in collaboration with Prof. Marco Geppi, University of Pisa) of 428 samples of compounds with a cross-linking density in the range 0.44-5.28 x 10^{-5} mol/g have been acquired. 285 of these samples, have been selected as training set (venetian-blind scheme) to build a regression model able to predict the cross-linking density value. The remaining 143 samples have been used to test the model.

Partial Least Square (PLS) regression models changing the signal pre-treatments (Discrete Exponential Fitting (DEF)[3] or Inverse Laplace Transform (ILT)[3]) have been built and compared in cross-validation. Applying the PLS model built on raw data on the test set a value of Root Mean Square Error in Prediction (RMSEP) of 0.65 has been obtained. The results obtained on DEF- and ILT-pretreated data ($RMSEP_{DEF}$ = 0.63; $RMSEP_{ILT}$ = 0.65) are comparable to the ones obtained with the raw data highlighting the robustness of the models.

Finally, an in-depth physico-chemical interpretation of the results allows to understand how variance in cross-linking density is correlated to variance in raw signals and pre-treated profiles.

vcaponigro@unisa.it

A previous study presented at the XXX Congresso della Divisione di Chimica Analitica (2023) in Vasto demonstrated the efficiency of Sequential and Orthogonalized Covariance Selection (SO-CovSel) Linear Discriminant Analysis (LDA)[a,b] in identifying biomarkers for Congenital Heart Disease (CHD) through metabolomic datasets. By integrating metabolomic and lipidomic profiles from *non-pregnant mothers* with CHD-affected offspring, the study achieved a test accuracy of 92% while reducing the variables to only 5 analytes. Furthermore, it reported a classification accuracy of 94.74% in structural CHD (sCHD), showcasing the power of targeted variable reduction in complex biological data analysis.

Building on this foundation, the current study extends the focus to metabolomic and lipidomic profiles from *pregnant mothers* with CHD-affected offspring. It aims to compare the efficacy of common data analysis approaches—including univariate analysis, Support Vector Machines (SVM), Random Forest, and Partial Least Squares Discriminant Analysis (PLS-DA)—with the previously mentioned SO-CovSel-LDA method. Additionally, this research investigates the impact of data augmentation techniques on enhancing the performance of these models across various analytical strategies.

The novelty of this work resides in its comprehensive approach to model comparison and a critical evaluation of data augmentation, a common strategy in data science, as a means to address challenges such as data scarcity and imbalance prevalent in medical research datasets.

Through this research, novel biomarkers may be identified that could initiate hypotheses to potentially uncover the sources of pathology. This offers promising avenues for early intervention and ultimately aims to improve maternal and fetal health outcomes in the face of this widespread congenital anomaly.

Estimation of structural disorder degree from carbon materials' Raman spectra by Multivariate Curve Resolution and Partial Least Squares Regression

S. Cerruti,[a] E. Robotti,[a] L.Cagna,[a] G. Gatti,[b] A. Croce,[a] V. Polliotto,[c] E. Marengo [a]

simone.cerruti@uniupo.it

Raman spectroscopy is the most frequently used technique to evaluate the disorder degree inside the chemical structure of carbon materials: whereas a perfect graphite sample shows only a narrow band at ca. 1580 cm^{-1} (*G* band), other components (*D* bands) become Raman-active in the presence of structural defects[1], the most prominent being at ca. 1350 cm^{-1} (D_1), thus broadening the global profile of the spectrum between 1000 and 1800 cm^{-1}. Usually, the spectra are treated via a curve-fitting process, using a pre-established set of mathematical functions (at least 5, with different shapes[2-3]), and then some specific disorder indices are derived from their properties (height, width, position, etc.). However, there is no general agreement on the number or shape(s) of those components; moreover, the fitting is usually done by hand or by non-automatic methods, thus resulting in a tedious and time-consuming process and leading to a high uncertainty of the results[4].

To overcome some of these problems, two different chemometric procedures based respectively on MCR and PLSR techniques, were applied in order to evaluate the disorder degree directly from the Raman spectra of many different carbon materials: petroleum coke, partially graphitized coke, synthetic and natural graphite (ca. 350 measures in total). The indices were calculated via a semi-automatic software[5] and consist of the ratio between the intensities of *D* and *G* (R_1), the sum of the areas of all the components divided by the intensity of *G* (*Standard Total Area*, *STA*), and the ratio between the average intensity value in 1575 – 1595 cm^{-1} and the average intensity value in 1610 – 1630 cm^{-1} (*G-shape-factor*, *GSF*)[5]. Monte Carlo cross-validation was used to estimate the prediction ability and in the case of PLSR to establish the optimal number of Latent Variables to retain, whereas for MCR a set of 3 pure components represent the best compromise between description completeness and model complexity: in any case, the models show good performances both in description and prediction, always leading to a coefficient of determination $R^2 > 0.99$ in fitting and > 0.98 in cross-validation.

Chemometric Treatment of UV-Visible Spectra of Acetonitrile Extracts: A Novel and Simple Approach for Detecting Plant-Derived Adulterants in Saffron (Crocus sativus L.)

M. Foschi [a], A. Biancolillo [a], M. A. Maggi[b], A. A. D'archivio [a]

[a]*Dipartimento di Scienze Fisiche e Chimiche, Università degli Studi dell'Aquila, Via Vetoio, 67010 Coppito*
[b]*Hortus Novus, Via Campo Sportivo 2, 67050 Canistro, L'Aquila, Italy*
e-mail : martina.foschi@univaq.it

Saffron, derived from the stigmas of Crocus sativus L., is used worldwide as a food colorant and flavor agent and is increasingly employed as a medicinal formulation ingredient. However, its reputation and economic worth are constantly threatened by adulteration practices. The conventional ISO 3632 normative method[1], while effective in grading saffron quality, struggles to detect adulterants at low contamination levels, leaving room for fraudulent activities. We developed a novel UV-visible spectroscopic method inspired by ISO 3632 and specifically designed to identify common adulterants like Calendula officinalis L. petals (calendula), Carthamus tinctorius L. petals (safflower), and Curcuma longa L. powdered rhizomes (turmeric) in saffron. Our research underscores the limitations of traditional spectroscopy-based techniques in detecting plant-derived adulterants in saffron, which derived from their high solubility in water and strong absorption capabilities. After a preliminary screening of different solvents, we selected acetonitrile as the most suitable extraction medium, effectively enhancing detection sensitivity towards adulterants in saffron by amplifying their spectral signatures while minimizing interference from saffron constituents.We analyzed 163 saffron samples, including 40 genuine and 123 counterfeited samples with 5-10% w/w contamination levels, each contaminated with one of the aforementioned adulterants (41 for each kind of adulterant). The UV-visible spectra of these samples were processed using multivariate statistical methods to differentiate genuine saffron from adulterated ones. Initially, we employed Sequential Pre-processing through Orthogonalization (SPORT) algorithm[2], which successfully discriminated between genuine and adulterated saffron samples. The SPORT model, calibrated with 145 samples, exhibited remarkable accuracy in classifying external data samples, regardless of the contaminant type or level. Furthermore, a class model for genuine saffron was generated using Soft Independent Modelling of Class Analogies (SIMCA) on the same dataset, demonstrating excellent efficiency in authenticating genuine saffron (90% sensitivity, 100% specificity against safflower and turmeric and 90% against Calendula officinalis L. petals).

paola.fermo@unimi.it

The aim of the present research is to study different aspects of a selection of some of the Papal Bulls held by the Museum of Santuario della Beata Vergine di Saronno, in the north of Italy. The preservation of documents related to the life of the Sanctuary begins from its foundation (1498). The archive, notified by the "Soprintendenza archivistica e bibliografica della Lombardia" in 1997 as being of considerable historical interest, contains more than 30,000 documents, 385 account books, ledgers, registers of various kinds, and 106 papal bulls. These artifacts have never been studied with archaeometric methods, thus any information on the composition of inks and gathered on their general conservation status will be valuable. In particular, four papal bulls were selected and investigated through different methodologies: a bull of Pope Alexander Borgia dated 1502, a bull of Pope Paul III dated 1540, and two bulls of Pope Pius IV dated 1560 and 1561, respectively. The study of the elemental composition of the inks was conducted by means of Particle Induced X-ray Emission (PIXE) technique, which, due to its high sensitivity and spatial resolution, made it possible to study the parchments with very high detail. The analysis of the chemical composition of inks with PIXE has already been carried out on very precious documents such as Galileo's writings [1], providing information on the realization techniques. Moreover, PIXE mapping could be used to study the migration of some elements around the inscriptions, also allowing the analysis of the state of conservation of the artefact. A series of preliminary and non-invasive analyses were carried out at the archive, by means of Multispectral imaging (MSI) techniques. These included UV-induced fluorescence, UV reflectography, infrared reflectography, and UV and IR false-color imaging to identify possible interesting features and areas to be investigated by PIXE.

Fig.1-PIXE experimental set-up at AGLAE

The PIXE measurements were carried out at the Accélérateur Grand Louvre d'analyse élémentaire (AGLAE) of the C2RMF (Centre de recherche et de restauration des musées de France). The chemical nature of the iron gallic inks used in the different documents was studied in detail by also comparing areas where erasures were identified through MSI analysis. The large amount of data acquired will also allow reconstruction of the history of both these important documents and the sanctuary.

salvatore.barreca@unict.it

Organic/inorganic systems are attracting attention in academic and industrial research as highly efficient p-type materials1. For example, several compounds have been coupled with semi-transparent perovskite solar cells, which are used for building-integrated photovoltaics due to their aesthetic advantages as light-harvesting windows2.

Unfortunately, the environmental fate of these systems in the event of uncorrected disposal represents a major environmental challenge that is still poorly understood.

The ROBERTA project aims to fill this knowledge gap by investigating the main variables responsible for the photo-transformation processes of these compounds under different environmental conditions.

The objective of the ROBERTA project is to develop an innovative Green Total Index (GTI) and label to classify different substances used in hybrid organic/inorganic photovoltaic and optoelectronic devices in order to improve the ecological transition.

In this context, elution and stress tests were carried out on different organic/inorganic devices and chemical characterisation was performed.

From the obtained results, the toxicity was evaluated, a Green Total Index was calculated by a specific algorithm and a classification was assigned considering low, middle and high eco-sustainability.

stefano.radice@syensqo.com

Environmental challenges are increasing worldwide in the field of polymer recycling, circular economy and in general waste treatment. One of the main step to face the plastic recycling process is to set up an efficient and affordable sorting capability. Spectroscopy techniques are already in the field to support sorting; most of the polymer matrix have been tested and automated devices are available in the market. Among all polymer matrixes, halogenated and chlorinated needed to be identified[1]. In this study we present the results obtained in the Vibrational spectroscopy field (IR-Raman and NIR) related to polymeric materials containing PVDC (Polyvinylidene Chloride) film layers. The scope was to analyse, locate fundamental normal modes, combination and overtones bands useful to identify and sort PVDC containing films. We recorded data relative to multilayer films, standard PVDC and PE polymers: both frequency data and intensity parameters have been considered and discussed[2]. The spectroscopic findings revealed that the presence of Chlorine atoms nearby $-CH_2$ moieties clearly influence stretching frequencies and intensities in IR and Raman spectra; comparison with PE spectral data are given[3]. These specific features in the Vibrational spectra generate a correspondence in the NIR region (Figure 1). Moreover, to test in a real situation the sorting capabilities of a NIR commercial setup once the right information are stored and used in the sorting system, a Tomra sorting machine[4] has been used in the analysis of a plastic mixed stream. The results of the sorting test give excellent results with the sorting yield > 80%. This first test shed light to the possibility to put in place in the industrial sector advanced and trained sensors for selecting halogens and in particular PVDC containing materials.

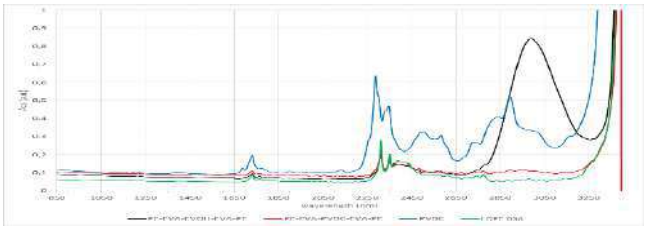

Figure 1: NIR spectra of PE and PVDC based film samples

High-precision Cd isotopic analysis using MC-ICP-MS equipped with 10^{13} Ohm faraday cup amplifiers and application to biological samples from Terra Nova Bay (Antarctica)

M.A. Vecchio,[ab] L. Abou-Zeid,[b] F. Vanhaecke,[b] M. Grotti[a]

mariaalessia.vecchio@edu.unige.it

Cadmium (Cd) is a "heavy metal" of significant concern due to its high toxicity and carcinogenic properties, posing risks to both the environment and human health.[1] Like other toxic elements such as Hg and Pb, Cd can be transported with fine atmospheric particulate matter over long distances, eventually reaching the Antarctic continent.[2] Antarctica serves as a crucial natural laboratory for studying the impacts of human activities on the environment and elucidating biogeochemical processes involving toxic elements such as Cd.

Isotopic analysis of Cd in various Antarctic matrices is a powerful tool to investigate its biogeochemical cycle and trace the sources of anthropogenic Cd pollution. Cd, like other elements with more than 2 isotopes, demonstrates natural variations in its isotopic composition due to mass-dependent fractionation, reflecting the slight difference in behaviour that its isotopes display in physicochemical and biogeochemical reactions.[3]

However, obtaining high-precision Cd isotope ratio data, particularly for samples with low Cd concentrations and complex matrices, remains challenging. Multi-collector inductively coupled plasma mass spectrometry (MC-ICPMS) emerges as the preferred technique for Cd isotopic analysis, providing precise isotope ratio measurements through simultaneous monitoring of the signals for all isotopes.

In this work, a single-stage chromatographic purification method was optimised combined with the use of a vacuum box technology for fast and quantitative isolation of Cd from matrix elements. High-precision Cd isotope ratio measurements at low concentrations were achieved using a high-transmission 'jet' interface and innovative 10^{13} Ω amplifier technology for monitoring ^{110}Cd, ^{111}Cd, ^{112}Cd, and ^{114}Cd isotopes, a novel approach in Cd isotope ratio measurement. External correction for the instrumental mass discrimination was combined with the use of Ag as an internal standard, obtaining good accuracy and precision. An external precision of 0.08‰ (2SD for $\delta^{114/110}$Cd) was obtained at Cd concentrations as low as 10 ng mL^{-1}. This research also introduced $\delta^{114/110}$Cd ratios for specific biological reference materials with low Cd content. Furthermore, various biological and sediment samples from Antarctica were characterized to preliminarily investigate the biogeochemical cycling of Cd isotopes.

Paleoproteomics, the study of ancient proteins, is a dynamic, rapidly growing field at the intersection of molecular biology, palaeontology, archaeology, paleoecology, and history. The analysis of protein residues absorbed in ancient ceramic vessels is used to identify the foodstuff processed, but detailed methodological investigations in this field remain rare[1,2].

The present work aimed at optimizing a protocol for extracting and identifying proteins preserved within food encrustations adhering to archaeological remains (sherds of "pietra ollare" vessels) found inside and around two houses of the medieval settlement of Nogara (Veneto Region), dating to its 9th- 10th centuries. For this purpose, we scraped the encrustations from the inner vessel wall (n=10) with a metal spatula. Protein extraction from ceramic vessels was performed using three different extraction protocols based on (1) 6M guanidine hydrochloride (GuHCl)[1], (2) 7M urea[3] and (3) 4% sodium dodecyl sulphate (SDS)[3]. The GuHCl protocol was adopted and modified by adding ultrasonication (20 kHz) and ultrafiltration (30 kDa cut-off) steps; additionally, extracted proteins were separated on a 12% SDS-PAGE gel and visualized by silver staining. Bands were excised and digested, and peptide mixtures were separated using an Ultimate 3000 nano-UHPLC system connected to an Orbitrap Fusion Lumos Tribrid MS instrument (Thermo Fisher Scientific). Protein identification was done using the Proteome Discoverer software through the Sequest HT search engine. The optimization of the employed protocol, based on the modified GuHCl method, resulted in a more effective extraction of proteins adsorbed to the inner vessel wall, allowing the removal of any potential deposit contamination. The GeLC-MS/MS analysis identified in each sample around 40 proteins (from animal species such as *Bos taurus, Sus scrofa, Gallus gallus,* and *Ovis aries*), with diagenetic modifications typical of ancient proteins, such as backbone cleavages, deamidation of asparagine and glutamine, formation of N-terminus pyroglutamic acid.

Our preliminary results allowed us to identify proteins in archaeological deposits of the Nogara dwelling accurately. This is particularly relevant for contributing to an in-depth study of the dietary practices during the Early Middle Ages in Northern Italy.

In the last 20 years, omics technologies have emerged as multi-disciplinary approaches aimed at comprehensively assessing different classes of biomolecules and genes in complex systems, combining chemical and genetic information[1]. Metabolomics is based on cutting-edge analytical techniques providing a snapshot of all small molecules present in biological samples. Ultra-high-performance liquid chromatography-high-resolution mass spectrometry (UHPLC-HRMS) has emerged as a powerful tool to tackle challenges related to the complexity of the metabolome. In addition to the sensitivity and specificity achieved by HRMS, the coupling with ion mobility spectrometry (IMS) offers an extra-dimension for the separation of co-eluting compounds, increasing confidence in metabolite annotation based on cross collisional section (CCS)[2]. Since thousands of features are generated, chemometrics is required for extracting valuable information.

In this study, the capabilities of UHPLC-IMS-HRMS were exploited for the untargeted metabolomic analysis of cow milk used for the production of DOP cheese. Analyses were carried out in positive and negative electrospray ionization modes by operating in data independent HDMS acquisition. After data filtering, both unsupervised and supervised approaches were applied. Being the dataset affected by high individual variability and presence of multiple factors (i.e. type of production, breeding systems, nutrition, animal conditions, etc…), only supervised approaches based on Partial Least Squares- Discriminant Analysis (PLS-DA) allowed sample clustering with sensitivity, specificity, and non-error rates close to 1. Less than 150 features were required for sample classification according to specific factors, including farm origin, diary production, lactation period. To avoid overfitting, model validation was performed on external test sets and biomarkers were annotated by a multi-dimensional match considering *m/z*, CCS values, isotope similarity and MS/MS spectra.

Novel Psychoactive Substances (NPS) are accumulating in the illicit market and are (un)consciously used in combination with common drugs of abuse, alcohol, and medicinal drugs thus complexing their detection in biological samples. The aim of this pioneer study was to provide effective tools for monitoring the consumption of traditional and new substances of abuse, in particular NPS and synthetic opioids, in different at-risk populations. To assess what type of psychoactive substances are used in Europe and whether people are aware of the intake of NPS or synthetic opioids, two different tools were combined: 1) the laboratory analysis of hair samples to detect the actual molecule taken by the sample donor, and ii) a sociological questionnaire to obtain information on which substances were thought to be consumed. The research took place in 2022 and early 2023 in four different countries: Italy, France, Portugal and Lithuania. In total, 332 samples were collected. When the hair was longer than 6 cm, it was divided in two segments up to 12 cm. From 332 samples, a total of 494 segments was obtained. The analyses were performed with targeted UHPLC-MS/MS for more than 150 substances.

Based on the analysis of keratin matrix samples, in the Italian territory, cocaine (68%), cannabis (50%), MDMA and ketamine (32% each) and heroin (26%) were the most prevalent substances, while synthetic cathinones and synthetic opioids were less frequently identified. Mephedrone, buphedrone and eutylone were detected in people who declared recent use (n=3) and past use (n=9) of MDMA and amphetamines; two people tested positive for recent use of mephedrone even though they did not declare it. Ketamine, MDMA and tramadol were often identified in samples collected from individuals who did not report any exposure to these substances. In Lithuania, the same pattern is repeated with cocaine (27%), MDMA (26%) and cannabis (22%) being the most used while ketamine (12%) and amphetamine (8%) follow. Mephedrone (n=6) was detected mainly in combination with cocaine. 2-FDCK (n=4) was detected in three cases together with cocaine. No heroin use was detected. An interesting aspect is noticed in Portugal: MDMA (60%) is by far the most prevalent substance followed by ketamine (47%) while cocaine and cannabis were detected to a 31% each. Amphetamine (18%) and mephedrone (2%) complete the detection window. Tramadol (n=1), mescaline (n=2) and harmine (n=3) were mainly detected in combination with other drugs.

The identification of substances in biological matrices in diverse populations is essential to obtain an overview of the diffusion of the substances around Europe, to understand the drug prevalence and trade patterns as well as their effects on humans health. While not being representative of the general population, this innovative approach based on two complementary methods provide valuable additional information about variations in use among different groups of people who use drugs.

To gain a deep insight and to obtain a superior understanding about guanosine-based pathway, this paper reports an innovative approach to study this critical subject. Firstly, after an exhaustive analysis of literature with a focus in legal medicine and extracellular vesicles, it was understood that a new method is inevitable to follow, determine, and quantify these analytes (Guanosine monophosphate - GMP, guanosine diphosphate - GDP, guanosine triphosphate - GTP, Guanosine, Neopterin, and tetrahydrobiopterin - BH4.

Starting from a previously method [1], we implemented and validated a new HPLC-DAD method in gradient elution mode with these six target analytes fully resolved in 18 min. The HPLC-DAD method uses a stationary phase XTIMATE C18 and mobile phase's phosphate buffer and Acetonitrile. Good correlation goes from 0.05 to 10 µg/mL with a limit of detection equal to 0.02 µg/mL and a limit of quantification equal to 0.05 µg/mL ($R^2 \geq 0.9824$).

Method was tested on human extracellular vesicles, isolated from different human parts, like urine, saliva and muscle, giving interesting results as different quantification of analytes depending on the sample matrix used. Interesting to underline is that saliva was the poorest source of these analytes, if compared with growth medium and urine.

A dangerous imbalance between antioxidant defense systems and ROS can occur due to the overproduction of reactive oxygen species (ROS) or their missing degradation; in this scenario ROS exert their toxic action, leading to a condition called oxidative stress (OS). OS has been implicated in a variety of pathological condition. Since the lipid oxidative stress biomarkers, isoprostanes (IsoPs), are more chemically stable than other analytes, their study is more advantageous for analytical purposes. They are formed in situ from the oxidation of arachidonic acid esterified to phospholipids by the direct action of ROS in the cellular membrane [1]. Due to the low concentrations in biological fluids, a need to develop highly sensitive methods of analysis, and the use of instrumental analysis such as liquid chromatography coupled to tandem mass spectrometry (HPLC-MS/MS) started to be mandatory [2]. Oral fluid (OF) was used in this work as an alternative matrix being a fast patient-friendly approach and having a simpler composition than blood and urine to develop a new rapid, reproducible, and sensitive method for the quantification of F2-IsoPs in OF by UHPLC-MS/MS. The procedure involved an extraction step which was developed to reduce the volume of organic solvent, using the novel approach based on parallel artificial liquid membrane extraction (PALME). In the PALME setup, target analytes were extracted through a three phases system, exploiting a pH gradient to facilitate the mass transfer of uncharged analytes to an aqueous extracting phase, across an organic solvent immobilized within the pores of a membrane, which led to the low consumption of organic solvents for extraction. Moreover, this technique allows a high enrichment factor (40 fold) without an increasing matrix effect (below 20%). Noteworthy, for the first time, a microextraction technique in the 96-well format was developed for the extraction of IsoPs, to obtain satisfactory extraction levels in the PALME step, it was necessary to pay attention to different parameters: the nature of organic solvent, volumes of biological sample, composition and volume of donator and acceptor solution, pH, ionic strength of donator solution and agitation time.

denisebiagini@dcci.unipi.it

Heart failure (HF) is a complex clinical syndrome that results from any structural or functional impairment of ventricular filling or ejection of blood. Patients are generally stratified with respect to ventricular ejection fraction (LVEF), which could be reduced (<40%, HFrEF) or preserved (>50%, HFpEF). Cardiopulmonary exercise testing (CPET) coupled to exercise stress echocardiography (ESE) is a valuable tool to evaluate metabolic derangements during effort. Additionally, a chemical characterization of metabolites from human biofluids may allow to gain deep insights into disease severity and pathophysiology.

Dysfunction of cardiac mitochondria is a hallmark of HF and a leading cause of oxidative stress, which in turn causes myocardial tissue damage and inflammation thus contributing to HF progression. Oxylipins are important bioactive signalling molecules, which derive from both the enzymatic and non-enzymatic oxidation of polyunsaturated fatty acids (PUFAs), and considerably increase upon inflammatory insult. The analysis of these metabolites in minimally invasive biological specimens, e.g. oral fluid and dried blood spots (DBSs), can be extremely useful in elucidating their biological activity as well as their potential role as biomarkers in the clinical setting.

Here, a very powerful analytical platform, based on micro-extraction by packed sorbent (MEPS) coupled to liquid chromatography-tandem mass spectrometry (UHPLC-ESI-MS/MS), was fully developed and validated for the targeted profiling of fifty-two oxylipins (i.e., isoprostanoids, prostaglandins, epoxy- and hydroxy-fatty acids, specialized pro-resolving mediators) and four PUFAs in DBSs. The protocol was successfully employed in a pilot study on a cohort of HF and control subjects (n=100) during the CPET-ESE.

Using this approach, we identified key changes in PUFA levels characterizing HF population both at rest and during exercise. HF patients showed generally lower levels of antioxidant omega-3 fatty acids than controls, in line with the “malnutrition-inflammation complex syndrome”. Arachidonic acid (AA) significantly ($p < 0.05$) differed between HFpEF and HFrEF at rest, highlighting a different bioavailability of this circulating omega-6 PUFA. AA levels significantly ($p<0.01$) decreased during the CPET-ESE protocol only in HFpEF population, thus suggesting distinctive changes in myocardial uptake and utilization of energy substrates.

These results pave the way for an in-depth molecular understanding of the biological functions of energy substrates and their signalling role, which will be fundamental in the development of novel therapeutic approaches to HF syndrome.

Quantifying N-Acylethanolamines: Unveiling Their Role in Pain and Metabolism with Isotope-Labelled Probes

V. Greco,[a] A. Giuffrida[a]

[a]*Department of Chemical Science, V.le A. Doria 6, Catania*
valentina.greco@unict.it

N-acylethanolamines (NAEs) play a crucial role as lipid mediators affecting pain modulation, inflammation, and metabolism[1]. Precise quantification of NAE levels in mammals, especially utilizing advanced techniques like HPLC-MS/MS[2,3], offers significant insights into their physiological functions. Mouse models are extensively utilized in studies to elucidate the intricate balance and regulation of essential pathways, including the involvement of the endocannabinoid system in pain processing. This quantification primarily serves as a tool to investigate the influence of diets, drugs, and genetic factors on lipid metabolism. Understanding the dynamics of NAEs is instrumental in the development of targeted therapies for conditions such as chronic pain. Using an isotope-labeled PEA (N-palmitoylethanolamine) and/or its derivatives is a valuable method to study the balance of NAEs (N-acylethanolamines) in the body. Additionally, the isotope-labeled drug helps detect changes in endogenous NAE levels, offering crucial information on the regulation of NAEs in response to treatments or specific conditions.

Here, we present a study that assesses the impact of administering PeaOxa (a prodrug of PEA) and PEA itself on NAE metabolism. The study involved administering both molecules, along with their labelled isotopes (Figure 1), to mice. This allowed for the separate investigation of endogenous changes and the exogenous contributions to NAE metabolism. The analytical method, developed using HPLC-MS/MS, unveiled intriguing fluctuations in the metabolic equilibrium of NAEs subsequent to prodrug administration.

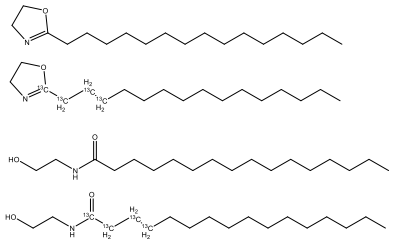

Figure 1: PeaOxa (A), Pea (B) and relate isotope label (C and D) structures.

padonato@unime.it

Supercritical fluid chromatography (SFC) has witnessed a resurge of interest in the last decade, motivated by substantial progress in hardware capabilities and the availability of specifically tailored separation materials. To extend the range of SFC-amenable analytes, an organic co-solvent is often added to carbon dioxide under subcritical conditions (subFC). The mobile phase modifier will also affect the selectivity, as demonstrated by several applications, and TAG separation is achieved based on the partition number and the unsaturation degree.

In the present work, a subFC method was developed for the separation of triacylglycerols (TAGs) in complex lipid matrices, by using photodiode array detection. The TAGs were separated on four columns serially coupled, attaining improved chromatographic performance, in terms of peak capacity and resolution. The method presented in this work is cheaper, faster, and more environmentally friendly than conventional methods used for TAGs analysis, consisting of non-aqueous reversed-phase liquid chromatography (NARP-HPLC), in terms of use of bio-based co-solvent (ethanol from corn), reduced analysis time (30 vs. 110 min), reduced organic solvent consumption and waste (1.5 mL per analysis).

Deep Eutectic Solvents: innovative green strategies to analyze tomato pesticides

S. Della Posta[a], V. Gallo[a], A. Gentili[b], L. De Gara[a], C. Fanali[a]

s.dellaposta@unicampus.it

Deep Eutectic Solvents (DESs) are new green generation solvents, easily obtained starting from two or more components that through hydrogen bonds generate an eutectic mixture, liquid at room temperature[1].
Their low vapour pressure makes them difficult to apply for the determination of trace analytes such as contaminants. In recent years, green strategies involving the use of DESs as extraction solvent or extraction aid for pesticide determination have been presented.
Two innovative DES-based analytical methods for tomato pesticides determination through high performance liquid chromatography coupled with mass spectrometry analysis were developed, optimized and validated.
In the first work a DES was used as extraction solvent in a matrix solid phase dispersion extraction (MSPD) for five triazoles determination in tomato samples. MSPD extraction is based on homogenization phase between a solid sample and a solid dispersant that has the function to break sample improving extraction yield. The developed procedure involved fungicides extraction using a DES composed by ChCl and ethylene glycol (molar ratio 1:2), followed by analytes back-extraction using ethyl acetate. The analytical method optimization was performed through One-Factor-At-Time (OFAT) experiments. The optimized extraction procedure involved the use of Aluminum oxide as dispersant, in a matrix-to-dispersant ratio of 1:5 (w/w), 4.5 mL of DES as extraction solvent and 2 mL of ethyl acetate to perform the back-extraction.
In the second work, a DES composed of ChCl and sesamol, molar ratio 1:3, was tested as possible adjuvant during the homogenization phase of a MSPD extraction for the determination of fourteen tomato pesticides. Aluminum oxide and ethanol were selected through OFAT experiments as dispersant and extraction solvent respectively. The optimized extraction conditions, obtained through a Box Behnken statistical design were: 1:4 matrix-to-dispersant ratio (w/w), 900 µL of EtOH as extraction solvent and 50 µL of ChCl-sesamol.
Both analytical methods were validated and optimal results in terms of accuracy, precision and limit of determination were obtained, comparable with those of previously traditional published work.

Development and application of two LC-MS methods for the determination of several pharmaceutical substances in wastewater and assessment of their sustainability

M. Massano[a], *E. Alladio*[a], *M. Minella*[a], *M. Vincenti*[a,b], *A. Salomone*[a,b]

marta.massano@unito.it

Introduction: In the last few years, the interest in pharmaceutical drugs and their metabolites as environmental pollutants is gaining growing importance and regular monitoring and timely actions are decisive to implement appropriate water resource management strategies. This study aims to present two methods developed for the simultaneous determination of a group of about hundreds of pharmaceuticals from different classes in wastewater. These two procedures are compared, highlighting their advantages and disadvantages and their performance. The two methods will be presented as a procedural evolution and evaluated according to the principles of green chemistry[2] through the use of specific indicators (AGREE, BAGI, etc). The methods were applied to real samples to demonstrate the effective detection of the compounds.

Methods: Wastewater samples (50 mL) were centrifuged at 4000 rpm for 5 min and vacuum-filtered through 0.22 µm filter device. Then, an aliquot of filtered wastewater was added with the mixture of internal standards and, depending on the method, either extracted by SPE[3] or added with a mixture of ammonium formate (2 mmol/L) and formic acid (0.02%). Finally, the samples were vortexed, centrifuged and 7 µL of the supernatant was injected into either UHPLC-HRMS or UHPLC-MS/MS systems. The real samples were collected as 24 h composite samples of the inlet and outlet wastewater from 3 wastewater treatment plants (WWTPs) located in the NW Italy.

Results: Both developed methods proved adequate for the individual detection of the target analytes at concentrations equal or lower than 10 ng/L. Although no universal method is available to detect all drugs reaching the aquatic ecosystem from WWTPs, several multi-analyte detection methods can be found in the literature and the most use solid phase extraction (SPE). However, although well performing, SPE is time-consuming and involves the use of expensive and environmentally-affecting consumables and additional solvents (AGREE score 0.44). In this context, we have developed another analytical procedure using 10 mL sample volume followed by direct-injection (AGREE score 0.61) which was considered more environmentally friendly. Finally, a total of 42 pharmaceutical products out of the one hundred targeted pharmaceutical drugs were detected in almost all sites.

Conclusion: Two sensitive analytical methods for the simultaneous quantitative determination of several pharmaceutical were presented and applied to wastewater samples from 3 WWTPs. The method evolution allowed the creation of a simple, fast and more sustainable procedure. Thanks to these features, the developed procedure can be applied in future in high-performance wastewater monitoring campaigns, thus enabling social and environmental protection actions.

alberto.mazzoleni@unito.it

In the field of forensics, paint analysis is highly significant and encompasses a wide range of areas, from automotive to artistic. The use of non-invasive and/or non-destructive techniques, such as spectroscopy, in the forensic field has always been of paramount importance. Technological advancements in recent years have enabled the development of increasingly smaller, more precise, and faster instruments.

The aim of the present study is to assess the possibility of discriminating spray paints with the same colour code (RAL) but produced by different brands, utilizing various spectroscopic techniques including micro-FTIR spectroscopy, micro-Raman spectroscopy and Vis spectrophotometry.

Each technique has been employed for a specific purpose: the first one focuses on identifying the type of binding medium composing the paint; the second is utilized to study the main organic and inorganic pigments responsible for the characteristic colour tones, while the third enables obtaining a measure of colour in diffuse reflectance.

To exploit the complementary information present in the three spectroscopies, the collected data (33 samples from 3 different brands) were analyzed using multivariate strategies based on PCA (Principal Component Analysis), classification model like PLS-DA (Partial Least Square – Discriminant Analysis) and through a multi-block regression algorithm known as ROSA[1] (Response Oriented Sequential Alternation).

The use of ROSA, and thus the multiblock approach, has proven to be extremely effective in discriminating between paint brands with the same colour, significantly enhancing discrimination capability compared to using algorithms on individual data blocks or in low-level data fusion.

ludovica.gullo@uniroma2.it

Nerve agents, highly toxic substances with severe consequences for human health, are commonly associated with chemical warfare or terrorist activities, posing significant risks to public safety and environmental integrity. Detecting these hazardous compounds, especially in water sources, is paramount to safeguarding human health and mitigating environmental contamination[1]. Utilizing 3D printing technology, which offers cost-effective and portable solutions, presents a promising approach to developing biosensors capable of detecting nerve agents across various applications[2]. This study focuses on the creation of an amperometric biosensor for identifying paraoxon, a nerve agent simulant in water, by inhibiting the butyrylcholinesterase enzyme (BChE).

In constructing electrodes suitable for electroanalytical tasks, thermoplastic polyurethane (TPU) electrodes were 3D printed, with carbon black incorporated as a filler to enhance electrode conductivity. Additionally, the combination of carbon black with Prussian blue nanoparticles (CB-PBNPs) was employed to exploit their electrocatalytic properties, particularly in the oxidation of thiol-containing compounds at low applied potentials[3]. The electrodes' surface characteristics were assessed through electrochemical impedance spectroscopy and cyclic voltammetry, revealing reduced charge transfer resistance, and heightened peak current intensity, attributed to the presence of CB-PBNPs.

The developed biosensor demonstrated a linear response to paraoxon concentrations up to 20 ppb, with a limit of detection (LOD) of 2 ppb. The LOD was determined as the quantity of paraoxon inducing 10% inhibition of the enzyme in drinking water. Such a biosensor holds promise for detecting and addressing the harmful effects of nerve agents in both crisis scenarios and as a preventive measure.

E-mail:alessandro.monari@unimore.it

We have developed screen printed electrodes modified with carbon black (SPE-CBs) for qualitative and quantitative analysis of the main cannabinoids produced by Cannabis sativa L. The electrochemical procedure proposed, together with the good detection performances of SPE-CBs, allow discrimination between different cannabis samples based on their cannabinoid content. Cannabinoids are electroactive, due to the irreversible oxidation of the phenolic group so electrochemical sensors can be used for their fast in situ detection, representing an alternative to other more expensive techniques[1]. Among phytocannabinoids the best known are Δ^9-tetrahydrocannabinol (THC) and cannabidiol (CBD), even if the acidic precursors THCA and CBDA are mainly present in *Cannabis sativa* L. plants. Marijuana, referred to as recreational cannabis, is illegal due to its high THC, which is psychoactive, and THCA content. On the other hand, cannabis plants that contain less than a defined concentration of the psychotropic compound have recently become legal in many countries. These plants, referred as fiber cannabis, and their associated products mostly contain CBD and CBDA, which are not psychoactive. According to the European regulation, vegetal material can be commercialized only when containing a very limited amount of THC, namely <0.3 % w/w[2]. Therefore, accurate controls of the THC and THCA levels to meet specific regulations are fundamental. In this work, we analysed extracts of different types of cannabis characterized by different cannabinoids contents. We verified the possibility to quantify the THCA content in the different extracts using a calibration curve[3]. On the other hand, we investigated the sensor ability to recognize illegal and legal samples by a multivariate approach. Moreover, a prototype of a portable device, capable of performing a rapid in-situ analysis of cannabis samples, has been developed. This device uses micro-pumps and flow sensors to prepare all the solutions, starting from the extraction step, and finishing with the electrochemical analysis performed with a SPE-CB inside a flow cell.

Photolytic and photocatalytic degradation of diclofenac: identification of the transformation products by non-target LC/MS-MS approach

E. Cruz,[a] G. Tseberlidis,[b] S. Binetti,[b] F. Gosetti[c]

e.cruzmunoz@campus.unimib.it

The intensive use of non-steroid anti-inflammatory drugs worldwide leads to environmental problems especially related to the contamination of surface waters by emerging micropollutants (MPs). Therefore, studies focused on mitigating and controlling the occurrence of these MPs in water bodies, among which diclofenac[1], are becoming essential to address derived toxicity issues. Studies carried out in our laboratories have shown that diclofenac in aqueous solution does not degrade when irradiated with visible light alone, whereas it degrades completely in 120 min when subjected to UV-vis irradiation (diclofenac removal of 99%). However, in this case, the UV-vis spectrum of the pale-yellow resulting solution shows the presence of photolysis products that have absorptions in the same wavelength range as diclofenac, probably carbazoles, whose toxicity is greater than their precursor[2]. Therefore, it is planned to try to degrade diclofenac by photocatalysis to test whether the transformation products could be less toxic than the precursor molecule.
This study aims the identification of photolysis and photocatalytic degradation products of diclofenac mediated by kesterite nanoparticles (CZTS). Kesterite is a semiconducting inorganic compound (Cu_2ZnSnS_4) with a band gap of 1.4-1.6 eV and a high absorption coefficient of light radiation. These characteristics make it a potential photocatalyst in the presence of sunlight. Furthermore, this material is insoluble in water and capable of homogeneously dispersing in it, it is non-toxic, and consists of elements that are available in large quantities and at low cost.
An ultra-high-performance liquid chromatography coupled with a high-resolution quadrupole time-of-flight mass spectrometry (UHPLC-QTOF MS/MS) method was developed and fully validated. Following a non-targeted approach, several transformation products, among which 16 already reported in the literature were identified and their formation mechanisms proposed based on the high-resolution MS/MS data. Some common degradation reactions give to carbazole formation via cyclization, radical hydroxylation and oxidation followed by C-N bond scission. In addition, a toxicity and environmental persistence assessment of all the elucidated degradation products was carried out by *in-silico* methods. The results stated that the use of CZTS nanoparticles leads to the elimination of diclofenac (removal of 99% with UV-vis irradiation and 91% with only vis irradiation), and the formation of TP with less toxicity.

Integration of Electrochemical and Photoelectrochemical Modes for Enhanced Nitrate Ion Sensing: A Bimodal Sensor Approach

W. Aidli[a], D. Fumagalli [a], H. Helli[a], L. Falciola[a] ,V. Pifferi[a]
[a]*ELectroANaliytical Chemistry Group, Dipartimento di Chimica, Università degli Studi di Milano, via Golgi 19, 20133 Milano, Italy*
wafa.aidli@unimi.it

Bimodal sensors can provide built-in self-calibration by eliminating interferences and normalizing environmental errors with dual-signal readout mode. This approach piqued the interest of researchers in analytical sensing with the potential to achieve more accurate analyses[1]. In recent years, researchers have succeeded in developing a variety of sensors that incorporate various transduction modes, such as electrochemical-photoelectrochemical (EC-PEC), electrochemical-electrochemiluminescence, electrochemical-colorimetry, electrochemical-fluorescence[2]. Clearly, combining the EC and PEC modes to build a dual mode detecting platform is a promising strategy for accurate, rapid, and sensitive detection, especially when using the same instrumentation. Thus, developing nanomaterials with high electrical conductivity and photoactivity plays a vital role.

Herein, we propose copper doped graphitic carbon nitride (Cu/g-C_3N_4), where nominal copper is dispersed on the nanosheets. In fact, pristine g-C_3N_4 demonstrates poor conductivity and a high electron hole recombination rate, restricting the electron transportation and electro-catalytic activity along with low quantum efficiency which reduces the photocatalytic efficiency[3]. Therefore, nanostructuring and doping g-C_3N_4 with copper assisted in overcoming these flaws and improving its catalytic performance due to the synergetic effect of both Cu and g-C_3N_4. Cu/g-C_3N_4 nanomaterial proved to be an effective photo-electrocatalyst. The sensor was developed by depositing the nano-catalyst on a fluorine-doped tin oxide coated glass and served as an active electrode for the electro/photoelectroreduction of nitrate ions at neutral pH.

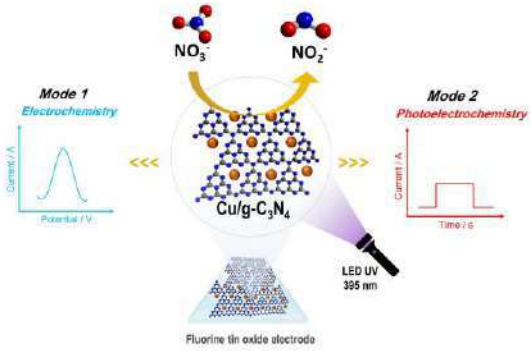

Figure 1: Schematic illustration of bimodal EC-PEC sensor based on Copper modified g-C_3N_4 for Nitrate Detection.

Sustainable Cannabinoids Purification Through Twin-Column Recycling Chromatography and Green Solvents

G. Compagnin[a], S. Felletti[b] , C. De Luca[a] , M. Catani[a] , A. Cavazzini[a]
[a]*Department of Chemical, Pharmaceutical and Agricultural Sciences, University of Ferrara, via Borsari 46, 44212, Ferrara (Italy)*

greta.compagnin@unife.it

Cannabidiol (CBD), a non-psychoactive cannabinoid, has become a focus of research due to its beneficial effect in many areas, i. e. medicine, cosmetic and food industry. The depletion of tetrahydrocannabinol (THC) or purification of other cannabinoids from CBD rich samples is a challenging task due to their similar chemical structure and physical properties. The separation of two substances characterized by close retention times, like several cannabinoids, is one of the largest challenges in HPLC. There are many strategies to overcome the coelution issue, for example changing the flowrate, the solvent gradient and/or the column bed length. When decreasing the flowrate and changing the gradient do not result in separation of the target peaks, a longer column bed length might be the solution. Recycling chromatography could be an interesting alternative strategy to increase the column bed length. This process enables an equivalent separation capacity of a long column using one or two identical short columns and a valve. In the one column system (close loop recycling), the eluted target peaks are re-injected in the same column through the pump. In a twin-column system (alternate pumping recycling), a 2-position valve is placed between the two columns and, by the switch, the eluted target peak from one column is re-injected into the second column without passing through the pump. In both cases a recycling circuit is formed, which can be repeated several times until desired separation is achieved[1,2].

In this work, twin-column recycling chromatography has been employed for the purification of a real Cannabis extract by using a green solvent, ethanol, as the mobile phase. The performance of the method, in terms of purity, recovery, productivity and solvent consumption, was compared to that of traditional batch operations showing the potential of the twin-column recycling approach. The employment of a theoretical model to predict the band profiles of the two compounds during the recycling process has facilitated method development, thus further contributing to process sustainability by avoiding trials and errors or suppressing their numbers significantly.

Food packaging is a well-known practice to primarily safeguard and encase food items. However, with the advancement and increasing complexity of society, there has been a rising demand from various finally users, including food producers, retailers, and consumers, for ensuring food safety and quality within the packaging. This growing emphasis on food safety and quality has led to the emergence of intelligent food packaging as an innovative packaging solution [1].

Intelligent food packaging refers to a packaging system equipped with smart sensors to monitor the condition of packaged food by the detection of several physical and chemical parameters, such as temperature, humidity, and gas concentration.

In this regard, oxygen has the potential to cause food spoilage via the i) oxidation of food components, ii) enzymatic reactions that accelerate ripening and browning, and iii) proliferation of aerobic microorganisms. In this context, it is crucial to monitor oxygen levels within the food packaging to ensure food quality and safety.

In this overall scenario, we are under development of a flexible miniaturized self-powered electrochemical sensor for oxygen monitoring in intelligent food packaging. In detail, the device encompasses i) a cathode layer based on silver ink screen-printed on oriented polypropylene substrate, acting as oxygen diffusion layer, ii) a sustainable deep eutectic solvent gel electrolyte[2] characterized by high ionic conductivity, low-cost, and biodegradability, and iii) an anode based on pure metal. The three layers were pressed giving rise to a solid-state self-powered electrochemical sensor. The whole detection system is based on the oxidation of anodic metal ions by oxygen, allowing it to diffuse through a gas diffusion layer from the air at the cathode. The final quantification of oxygen is carried out by means of open circuit voltage (OCV).

For the development of the self-powered sensor, optimization studies were first conducted on the cathode silver layer deposition, the anodic material layer, and finally on the DES composition. The electrochemical sensor will be applied for oxygen monitoring in simulated packaging for real-time oxygen measurement.

In recent years, the market for foodstuffs and dietary supplements containing cannabinoids has grown steadily.[1] Among the cannabinoids available on the market, the most commons are non-psychotropic cannabidiol (CBD, **1**) and psychotropic Δ^9-tetrahydrocannabinol (Δ^9-THC, **2**), whose effects have been thoroughly investigated over the years and whose sale is legal in some countries, depending on current legislation.[2,3] Recently, hexahydrocannabinol (HHC, **3**), a tricyclic compound that is formerly the hydrogenated counterpart of Δ^9-THC, has emerged, having been neglected by some regulatory authorities. HHC is semi-synthetic Δ^9-THC derivative, prepared via acid catalyzed cyclization of CBD followed by catalytic hydrogenation. There are only few reports on the effects of HHC in humans, although it is supposed to have much the same biological activity of Δ^9-THC. Nevertheless, it has been classified in the Table I of the substances of abuse in Italy in 2023.[4] In order to limit the spread of HHC and its analogues, there is a growing interest in improving the routinely available GC-MS and LC-MS methods for the identification and quantification of newly synthesized cannabinoids.[5] In this work we have developed a liquid extraction method for the analysis of seized HHC-containing gummy sweets. The main cannabinoids present in the samples analyzed were identified and quantified via GC-MS analysis, indicating that along with HHC, significant amounts of unreacted starting materials (i.e., CBD and THCs) were present. The data obtained allowed us to identify the synthetic procedure used to prepare the active principle present in the sample.

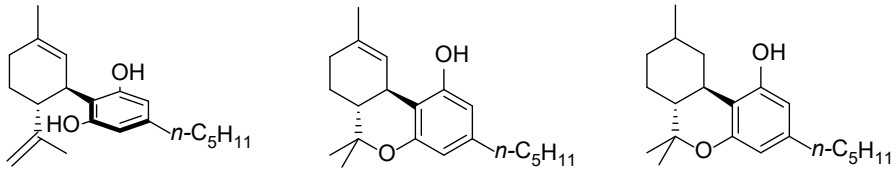

Figure 1: structure of cannabidiol (CBD, **1**), Δ^9-tetrahydrocannabinol (Δ^9-THC, **2**) and hexahydrocannabinol (HHC, **3**).

The widespread use of synthetic polymers has led to a significant environmental crisis caused by plastic pollution, with microplastics being found in various environments and posing risks to both human health and the ecosystems. Moreover, microplastics in the environment undergo continuous mechanical fragmentation due to chemical weathering, photo-oxidation, biological decomposition, and mechanical forces, leading to the formation of smaller plastic debris, more prone to be transported and dispersed by atmospheric agents. The potential for plastic fragments to disperse in the air as particulate and to be accidentally inhaled by humans potentially causes harm to the respiratory and other systems[1]. Therefore, there is a particular necessity to study microplastics as air pollutants. In this study, we tested a combination of analytical pyrolysis, gas chromatography, and mass spectrometry, as well as gas and liquid chromatography-mass spectrometry, to identify and quantify both microplastics and their additives in airborne particulate matter and settled dust from two indoor work environments. By using this combined approach, we were able to accurately quantify ten distinct synthetic polymers (polyethylene, polypropylene, polystyrene, acrylonitrile butadiene styrene copolymer, polymethyl methacrylate, polycarbonate, polyethylene terephthalate, Nylon-6, Nylon-6,6, and polyvinyl chloride) as well as eight classes of polymer additives. The determined additives include phthalate esters, adipates, citrates, sebacates, trimellitates, benzoates, organophosphates, and newly developed brominated flame retardants.

This study received funding from the European Union - Next-Generation EU - National Recovery and Resilience Plan (NRRP) – MISSION 4 COMPONENT 2, INVESTMENT N. 1.1, CALL PRIN 2022 D.D. 104 02-02-2022 – DIORAMA (A deep dive into the study of microplastics in aqueous matrices).

CRISPR-Cas12a Amplification of Transcription Factor DNA-Binding Activity by Using Dynamic DNA Translators

L. Capelli,[a] Sofia Marzari,[a] A. Bertucci[a]

[a] *Department of Chemistry, Life Sciences and Environmental Sustainability, University of Parma, Parco Area Delle Scienze 17/A, 43124, Parma, Italy*

luca.capelli@unipr.it

The field of nucleic acid diagnostics has undergone a transformation with the application of CRISPR-Cas12a-based biosensing technologies, which enhance signals by causing collateral target-induced cleavage of tagged DNA reporters. However, interfacing the CRISPR-Cas machinery with non-nucleic acid targets has been limited due to the intrinsic difficulty of converting non-nucleic acid targets, such as proteins and small molecules, into nucleic acid inputs for CRISPR-Cas activation. Our main goal was to tackle this challenge and look at new ways to integrate CRISPR-Cas12a signal amplification into protein sensing. We specifically focused on transcription factors (TFs), a class of DNA-binding protein that play a central role in biological processes and are significant targets in diagnostic, therapeutic and bioengineering strategies. We leveraged the inherent DNA-binding activity of target TFs to integrate an activity-based approach with DNA nanotechnology, demonstrating that CRISPR-Cas12a nuclease activity can be triggered by a range of different transcription factors in a programmable manner. We have engineered libraries of conformation-switching DNA structures that act as dynamic translators. These rationally designed translators undergo a controllable conformational change when they bind to their cognate transcription factor [1,2], exposing a CRISPR-Cas12a target sequence only upon TF binding. This allowed for converting the DNA-binding activity of transcription factors such as TATA-binding protein (TBP), Myc-Max, EGR1 and EGR4 into a trigger input for the activation of CRISPR-Cas12a, generating an amplified optical signal proportional to the protein concentration. This study paves the way for new modalities of protein-controlled CRISPR-Cas molecular computation and exemplifies how CRISPR-Cas12a signal amplification may be successfully incorporated into protein sensing.

Implementation of rapid diagnostics: nanoMIPs transform the LFA paradigm

T. Serra [a], V. Testa [a], S. Cavalera [a], F. Di Nardo [a], C. Baggiani [a], L. Anfossi [a]

[a] *Department of Chemistry, University of Torino, Via Pietro Giuria, 7 – 10125 Torino*
thea.serra@unito.it

In the realm of immunodiagnostics, antibodies have long been regarded as the gold standard for molecular recognition, playing a pivotal role in various applications[1]. However, the challenges associated with antibody production, high cost, batch-to-batch variability, and ethical concerns, have spurred exploration into alternative molecular recognition systems. Among these alternatives, molecularly imprinted nano polymers (nMIPs) have emerged as promising biomimetic materials. They are synthetic, highly cross-linked materials designed with cavities that exhibit selective molecular recognition[2]. Although the current state-of-the-art applications predominantly employ nMIPs for tasks such as molecular separation, sensing, and controlled release, their adoption as primary recognition elements in diagnostics remains limited. While LFA has become a widespread and user-friendly tool for rapid diagnostics, traditional antibodies continue to dominate as the recognition element. The potential of nMIPs in LFA, with their advantages of stability, reproducibility, and cost-effectiveness, is an area ripe for exploration[3]. This study presents a novel approach to lateral flow immunoassay (LFIA) diagnostics, aiming to reshape point-of-care testing (POCT) by minimizing reliance on biomolecules. The innovation centres around integrating nMIPs with core-shell gold silica nanoparticles (Au@SiO_2), a strategically chosen marker widely utilized in colorimetric LFIA[4]. nMIPs were synthesized to selectively target IgG bovine, establishing a molecularly imprinted framework. Functionality and binding properties of the composite nanomaterial were investigated through batch rebinding to estimate affinity and binding capacity. Characterization studies, including transmission electron microscopy (TEM) and dynamic light scattering (DLS), validated the structural integrity of the material. To enhance their functionality, the nMIPs were conjugated with Au@SiO_2, ensuring a synergistic integration of their selective recognition properties with the optical advantages of gold nanoparticles. Experiments were meticulously designed to evaluate the applicability of the new hybrid material in the LFA. Key objectives included establishing the visual limit of detection, unravelling the dynamic interaction between nMIP and IgG, and conducting selectivity studies were crucial to defining the potential of this innovative detection system. This proof-of-concept challenges conventional LFIA paradigms, showcasing the power of nMIP for the advancement of synthetic receptors in rapid bioanalytical tests. This approach paves the way for a future where LFA becomes more accessible, robust, biomolecule-free, and user-friendly, signalling a significant advancement in rapid screening tests.

Innovative On-line Pressurized Hot Water Extraction with Solvent Recirculation Coupled with Liquid Chromatographic-Tandem Mass Spectrometric Analysis of Pharmaceuticals in Soil

G. Bonaccorso, L.Renai, L. Checchini, M. Del Bubba

Department of Chemistry "Ugo Schiff", University of Florence, Via della Lastruccia 3, 50019 Sesto Fiorentino, Florence, Italy
giulia.bonaccorso@unifi.it

In this study, a new self-assembled apparatus for the extraction of solid samples was built, using suitably modified standard chromatographic equipment, in order to develop a recirculated pressurized hot water extraction directly coupled to liquid chromatography-tandem mass spectrometry. In order to investigate the potential of this new extraction apparatus, the proposed system was applied to the analysis of 34 target pharmaceuticals compounds characterized by heterogeneous physicochemical properties (e.g., -0.05 ≤ log D ≤ 4.31) in three soils with different textural characteristics (i.e., loam, silt-loam and silty-clay-loam). A multivariate strategy based on the design of experiments[1] (DoE) was used to identify the best extraction conditions for the target analytes by studying temperature, pressure and number of extraction cycles. The optimization procedure successfully demonstrated that the number of cycles, in combination with the high temperature, had a favourable impact on the recovery of target analytes. The application of DoE set point to the three reference soils provided average semi-quantitative recoveries (≥ 60% for most target analytes in all soils) and good precision (< 25% in almost all cases), regardless of the textural differences among samples.

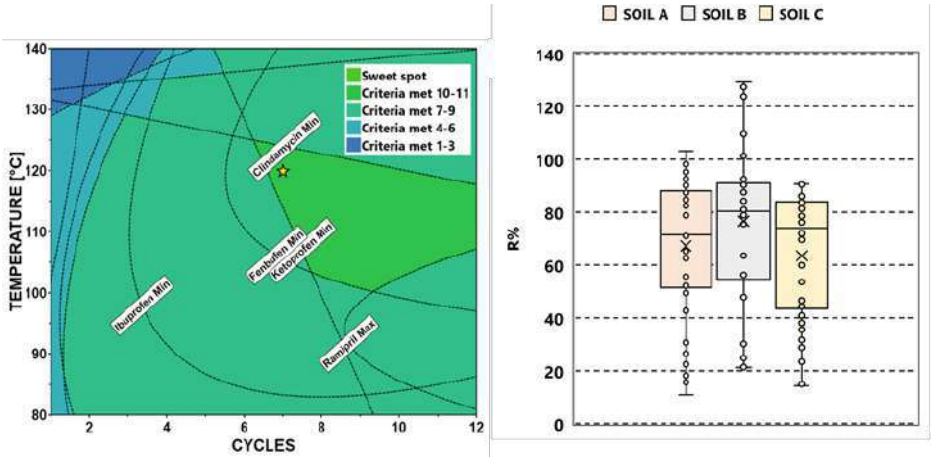

Figure 1: Sweet spot plot for the 12 significant CMAs; the star point refers to the best compromise in terms of R% values and extraction time (120 °C, 110 bar, 7 cycles), (B) box plot of recoveries for the three soils under the optimized conditions.

Photochemical-driven dissipative metal-coordinated gels for transient controlled release and autonomous mechanical actuation

R. Baretta,[a] I. Willner,[b] M. Frasconi[a]

roberto.baretta@phd.unipd.it

Transition-metals, such as Fe^{3+}, can strongly coordinate carboxymethyl cellulose (CMC),[1] leading to the formation of stimuli-responsive Fe^{3+}-CMC hydrogels for a variety of applications.[2] However, the lack of mechanical robustness is a major issue for the implementation of these polymer networks in advanced applications, such as soft robotic. Here we report an innovative strategy to fabricate redox responsive Fe^{3+}-CMC gels, which can retain the high loading capacity of the porous network, while accessing enhanced mechanical properties, for photochemical-driven, transient controlled release and mechanical actuation under aerobic conditions (Figure 1). Cryogels of Fe^{3+}-CMC are obtained by multiple cycles of freezing and defreezing, which induce the formation of a Fe^{3+}-crosslinked cryogel matrix, displaying enhanced stiffness properties.[3] The cryogel matrix is redox responsive and the photosensitized reduction of Fe^{3+}-CMC, mediated by Ru(II)-*tris*-(bipyridine) complex, leads to the lower stiffness $Fe^{3+/2+}$-CMC gel. In the presence of oxygen, the aerobic re-oxidation of Fe^{2+} in the matrix restores the initial high-stiffness Fe^{3+}-CMC gel, leading to the development of a dissipative functional matrix with transient stiffness properties.

The light-induced transient release of a model payload from the cryogel matrix is reported. In addition, the light-triggered, transient mechanical bending of a bilayer construct, made of poly-N-isopropylacrylamide (p-NIPAM)/Fe^{3+}-CMC, is demonstrated (Figure 1), providing the potential use of dissipative metal-coordinated gels for developing the next-generation self-regulative, autonomous materials.

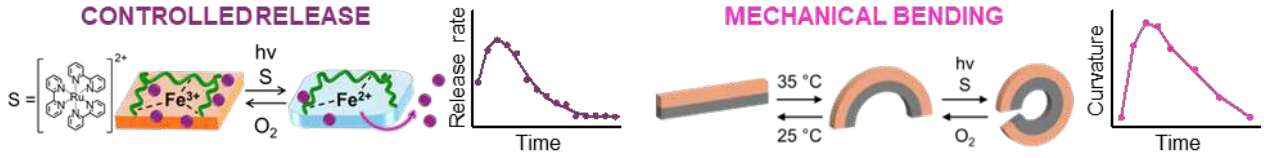

Figure 1: Schematic representations of photochemical-driven, transient controlled release (left) and autonomous mechanical bending (right) of the Fe^{3+}-CMC cryogel matrix.

saraelsa.aita@uniroma1.it

Patulin (PAT) is an α,β-unsaturated γ-lactone mycotoxin generated as a secondary metabolite by at least 60 different species of fungi[1]. *Penicillium expansum* species is the most threatening one for people's health and market security[2]. This species is often associated with a post-harvest disease affecting apples[3], although other fruits can be contaminated, including pears[4], citrus[5], and grapes[6]. A PAT-specific molecularly imprinted polymer was successfully synthesized, utilizing dopamine and melamine as functional monomers, along with formaldehyde as the cross-linker. This resulting material displayed numerous hydrophilic groups, including hydroxyls, imino groups, and ether linkages. For the first time, uric acid was used as a dummy template for its structural similarity to PAT. Comprehensive characterization and analysis of the adsorption process were conducted through adsorption isotherms and kinetics studies. Separation, identification, and quantification of PAT were achieved using ultra-high performance liquid chromatography coupled with both photodiode array detection and tandem mass spectrometry, which was crucial for confirming PAT presence in real samples. The methodology was validated with 20 apple juice samples, demonstrating the polymer's high selectivity and specific adsorption capabilities, with mean recoveries ranging from 85 to 90% and a relative standard deviation below 15%. The developed molecularly imprinted polymer exhibited good linearity within the concentration range of 1–100 ng mL^{-1}, with a coefficient of determination (R^2) > 0.99. Furthermore, the method displayed a low limit of detection (0.5 ng mL^{-1}) and quantification (1 ng g^{-1}). The hydrophilic nature of the developed polymer facilitated efficient purification of apple juices, owing to the polar interactions established with the target analyte.

Comprehensive structural characterization of seaweeds polar lipidome by coupling single-phase extraction and aza-Paternò-Büchi derivatization

E. Taglioni, S. E. Aita, C. Cavaliere, A. Cerrato, C. M. Montone, A. Laganà, A.L. Capriotti

Università Degli Studi di Roma La Sapienza, Italia
enrico.taglioni@uniroma1.it

The valorization of seaweeds has generated unprecedented interest in recent years due to their unique chemical characteristics. The taxonomic differentiation between Chlorophyta, Rhodophyta, and Ochrophyta is often supported by their contrasting chemical characteristics. The lipid contents of seaweeds are generally low and quite variable between and within phylum. Seaweeds are known for their rich content of biologically active polyunsaturated fatty acids (PUFA), such as eicosapentaenoic acid, which are crucial in various physiological processes, including brain development, cardiovascular health, and inflammation regulation. The polar lipidome of seaweeds has gained significant interest in the scientific community since they are the primary deliverers of PUFA. However, despite their importance in determining their biological properties of lipids, little is known on the regiochemistry, i.e., the geometry and position of carbon-carbon double bonds, of free and conjugated fatty acids in seaweeds [1]. In the present work, an analytical platform was developed for the extraction, untargeted HRMS-based analysis, and detailed annotation of the lipid species. First, four one- and two-phase solid-liquid extraction protocols were tested and compared on a seaweed pool sample to select the method that allowed the overall highest efficiency as well as easy coupling with lipid derivatization by photochemical [2 + 2] cycloaddition with 6-azauracil. Underivatized lipids were annotated, employing a data processing workflow on Compound Discoverer software designed explicitly for polar lipidomics. Subsequently, inspection of the MS/MS spectra of the derivatized lipids following the aza-Paternò-Büchi reaction allowed pinpointing the regiochemistry of carbon-carbon double bonds. Once the platform was set up, the lipid extracts from eight seaweed samples from different seaweed species were characterized, with information on the regiochemistry of free and conjugated fatty acids. The overall analytical approach helped to fill a gap in the knowledge of the nutritional composition of seaweeds.

The work was supported by the PRIN2022 PNRR project Prot. P2022PTYWP, entitled “Design of high-pRofit fostEring bioActive coMpounds through integral valorization of seaWEEDs infesting the MEditerranean sea (DreamWEEDme),” provided by the Italian Ministry of Education, Universities, and Research.

nsnchr@unife.it

Therapeutic oligonucleotides represent a recent breakthrough in the pharmaceutical industry since they are emerging due to their ability to regulate gene expression with great specificity [1].
They are short nucleic acid chains and, nowadays, the most established technology to produce them is solid phase synthesis. This technic is a cyclic approach where the progressive addition of nucleotides monomers results in a polymeric chain. However, this leads not only to the main target but also in many structurally similar impurities such as a deletion or addition nucleotide resulting in the so called shortmers (n-1) or longmers (n+1) impurities [2,3].
Therapeutic oligonucleotides require extensive chromatographic purification to ensure that a high-quality Active Pharmaceutical Ingredient (API) is manufactured, and to fulfill the strict purity requirements imposed by the regulatory agencies. In the biopharma industries the purification of oligonucleotides usually is carried out through single column preparative liquid chromatography, in particular the main technique used for this purpose are Anion Exchange Chromatography (AEX) and Ion Pair- Reversed Phase Chromatography (IP-RP) [3].
AEX takes advantage of the negative charge on phosphate linkage on the oligonucleotide, the elution is generally performed with a sodium salt gradient and at the end of the process the product is already in its sodium form. On the other hand, IP-RP purification ensures not only charged based residues but also discriminated neutral lipophilic impurities. However, because of the use of counterion, an additional salt-exchange step is required to yield the oligos in its sodium form [3]. Nevertheless, single column purification techniques suffer from a purity-yield trade off, for this reason the batches are run sequentially to overcome this problem. Therefore, this results in higher production and analysis costs since intermediate analysis steps are necessary between the different purifications [1,2,3].
In this work a multidimensional technique on a preparative scale, the Integrated Batch process, has been applied on a preparative scale for the purification of a single-stranded DNA oligonucleotide. This process can combine two chromatographic steps, where the eluted product from the first column can be diluted in-line and loaded directly in the second column to maximize the throughput of the purification process.

Lipid nanocarriers (LNCs) are powerful and versatile tools in the field of drug delivery for a wide range of medical purposes, from cancer treatment to vaccines[1]. Despite efforts to optimize the efficiency of drug encapsulation and minimize drug loss during the encapsulation process, challenges persist, so during formulation development, techniques such as chromatography, mass spectrometry, and UV-Vis absorption are employed to evaluate the effectiveness of encapsulation[2]. In this paper, we present an innovative and "portable," easy-to-use and inexpensive strategy to rapidly assess LNC quality. This work involves the use of an electrochemical strip using a screen-printed electrode to detect methylene blue (MB) as a representative cargo encapsulated in various liposomes (used as model LNCs), including distearoylphosphatidylcholine, dipalmitoylphosphatidylcholine, and hydrogenated soybean phosphatidylcholine. The experimental setup, including the release of MB content and its electrochemical detection, was fine-tuned through a multivariate design of experiments (DoE), a d-optimal design, which allowed optimization of the 4 variables with only 19 experiments. In addition, using principal component analysis and linear discriminant analysis (PCA-LDA), the lipid bilayer compositions of liposomes were distinguished by analyzing their voltammetric profiles. n this work, therefore, we highlight the synergy between portable electroanalysis and multivariate analysis as a powerful tool for enhancing quality control in the context of pharmaceutical technologies. In addition, this approach also shows promise in the field of diagnostics, especially in its application to naturally occurring lipid nanoparticles, such as exosomes.

dplmrc@unife.it

The floral scent is an important phenotypic characteristic of flowering plants. It plays a critical role in various areas such as attracting pollinators to enable reproduction success, defence and protection from predators or pathogens and species differentiation to reduce competition for pollinators and increase their chances of reproduction.

The floral fragrancy derives from the presence of volatile secondary metabolites, which contains various low molecular weight compounds with a low boiling point. They are mainly synthesized via the terpenoid, benzenoid, and fatty acid biosynthetic pathways[1]. These volatile compounds have been widely used in cosmetics, medicinal products, perfumes, and food flavorings.

Terpenoids are the main responsible for the aroma of many flowering plants, including those belonging to the Cannabaceae family. Furthermore, the synergistic relationship between different chemical compounds in cannabis, including terpenes, appears to enhance biological activity, and this result is commonly referred as the 'Entourage Effects', i.e. the ability of two or more active compounds to work together to produce a greater effect than they could achieve separately[2]. In this regard a more comprehensive chemical characterization is necessary to a better understanding of cannabis volatile composition and variability.

The present contribution aims at exploring, in a detailed manner, the volatile composition of different Cannabis chemovars, using state of the art comprehensive two-dimensional gas chromatography coupled to mass spectrometry (GC×GC-MS) technology[3]. The head-space extraction was dynamic and sorbent-based, specifically using trap tubes, packed with solid sorbent material which were properly selected for their selectivity to terpenoids. After the extraction, they were thermally desorbed online with the GC×GC-MS system using single-stage and dual-stage desorption system to understand pros and cons. Identification of the volatile compounds was carried out using mass spectral similarity and retention indices.

Design and development of a wearable sensing device for monitoring Dopamine in sweat

I. A. Vitale, Giovanna Marrazza, Ilaria Palchetti

Department of Chemistry "Ugo Schiff", University of Florence, Via della Lastruccia 3, Sesto Fiorentino, 50019

ilariaantonia.vitale@unifi.it

Dopamine is a neurotransmitter belonging to the catecholamine family that plays a crucial role in neurotransmission processes, in particular in motor coordination, motivation behavior and regulation of cognitive processes. Impaired dopamine levels in brain lead to the onset of symptoms related to the onset of various and heterogeneous neurological disorders, such as Parkinson and Alzheimer diseases, increasing motorial impairments such as bradykinesia or tremor. Nowadays, the only way to bring relief to patients suffering of Neurological Disorders is the pharmacological administration of drugs with the aim of restoring the adequate levels of neurotransmitter in brain's pathways. Regrettably, the fine-tuning of such pharmacological strategies is strictly dependent on the levels of neurotransmitters in cerebrospinal or blood fluids, therefore a painful and continuous monitoring is strictly required. Taking into account these considerations, several peripheral biofluids, such as saliva, urine and sweat, promote the development of wearable sensitive devices capable to detect neurotransmitters in a painless, continuous, and non-invasive manner. For this purpose, electrochemical-based sensors offer amazing potential for the development of point-of-care-analysis devices. Indeed, due to the miniaturization, sensor can be integrated into comfortable ordinary tools such bracelets or smartwatches. This study introduces a new analytical wearable platform for screening and monitoring dopamine in peripheral biofluids, with the aim of develop a sensitive and painless wearable device. Specifically, graphite screen-printed working electrodes were enhanced with a biocompatible polymeric conductive layer. To this end, different amino acids were studied as biocompatible and biodegradable functional monomers. Then, the polymeric layer was further modified by the enzyme covalent immobilization and by electrodepositing gold nanoparticles for the direct detection of electroactive. The modified platforms were characterized using cyclic voltammetry and electrochemical impedance spectroscopy. The analytical performances were evaluated in both standard solutions and in artificial biological fluids.

In recent years the growing interest on human aging and longevity has promoted the establishment of an international scientific pole for research on aging. The main objective of this research network is to prolong human life and preserve its quality in term also of biological state. Understanding the molecular mechanisms of aging is crucial for developing new therapeutic approaches to improve health and quality of life. Changes associated with aging may involve alterations in protein structure and function, accumulation of harmful or altered proteins, post-translational modifications, and changes in the composition and activity of protein complexes. These alterations can impact various essential biological processes, such as metabolism, cellular homeostasis, stress responses, inflammation, and immune system function.[1]

This study aims to identify such potential blood cell biomarkers conduct a differential proteomic analysis of erythrocytes from cohorts of individuals of different ages. The goal is to characterize the differences and similarities of each group qualitatively and quantitatively at the molecular level.

Extraction protocols and analysis were first carried out on *Mus musculus* as animal model system. Whole blood cells from the blood samples of young (6 months), middle-aged (12 months), and aged (30 months) mice were collected, and the proteinaceous content of membrane was extracted and fractionated. Identification of potential biomarkers related to membrane proteins was performed using untargeted LC-MS/MS Proteomics Analysis. Raw data were processed by using MaxQuant software and output files were subsequently processed using STRING to integrate all known and predicted associations between up- or down-regulated proteins.

Several of the identified proteins differentially expressed play a key role in physio-pathological processes, such as PSMD3 that is involved in maintenance of protein homeostasis by removing misfolded or damaged proteins. Finally, a similar strategy was set up on human blood samples to confirm the accuracy of the model.

Overall, this study reveals potential blood cell-protein biomarkers of aging and explains the possible correlation between the biomarkers and some processes related to immune system or metabolic pathways. The reported data provide a piece to unravel the complex puzzle related to aging processes and to assist basic research that requires multiple, interdisciplinary approaches on the study of human longevity.

Determining time since deposition of bloodstains can be a potent tool for the forensic chemist in resolving legal cases. This topic has been investigated through several analytical techniques, mainly spectroscopies, such as ultraviolet-visible (UV-Vis), Raman, mid and near infrared (MIR and NIR). In this context, the contribution of chemometrics proved to be essential to gain understanding of the subtle spectral changes ongoing during the ageing of this complex biological fluid.

Until now, reduced attention has been devoted to the contribution of environmental conditions and deposition substrate which may have a significant influence on speed and kinetics of blood degradation. Therefore, understanding which factors influence this process (and to what extent) is crucial to avoid over/under estimations of bloodstain age.

To study in depth the impact of such factors, bloodstains were subjected to ageing under controlled temperature (T) and humidity (RH%) in a constant climate chamber (KMF115 – BINDER GmbH, Tuttlingen, Germany), mimicking two environmental conditions with a proper day-night alternance: condition CW – day: T = 25°C, RH% = 75%; night: T = 10°C, RH% = 90%; condition HD – day: T = 35°C, RH% = 60%; night: T = 20°C, RH% = 75%. The effect of direct light exposure was investigated as well, performing the ageing sessions either with or without a window that filters the light going from the lamp to the samples.

Six 20-µl bloodstains (from two different donors) were deposited on each of four different substrates, namely hydrophilic fabric (cotton), hydrophobic fabric (polyblend), metal (knife) and glass, making a total of 96 samples. Their ageing was followed for 12 days with two different analytical techniques: a handheld NIR device (MicroNIR® – Viavi Solutions Inc., Santa Rosa, California, USA), working in the spectral range 900-1700 nm; a confocal Raman microscope (InVia™ – Renishaw plc, Wotton-under-Edge, Gloucestershire, UK), acquiring in the Raman shift range 150-1900 cm^{-1}.

The obtained spectra were pre-processed for minimizing the unwanted systematic effects and subjected to chemometric analysis. Exploratory data analysis by means of principal component analysis (PCA) showed that NIR spectra are more subjected to the effect of the substrate, when compared with Raman spectra. It was observed that absorbing substrates (cotton, polyblend) yield a more efficient time trend model when analysed with NIR spectroscopy, while non-absorbing substrates (glass, metal) gave more consistent results with Raman spectroscopy. PCA also evidenced shifts between sessions carried out at different temperature and humidity, suggesting that environmental conditions may determine not only a faster/slower ageing, but also a different ageing kinetics. Then, ANOVA simultaneous component analysis (ASCA) was applied to quantify the effect of each factor (temperature, humidity, substrate, light exposure) on the ageing of bloodstains, to understand which conditions are most important to be controlled in real case scenarios.

The present study confirmed that determination of time since deposition of bloodstains is strongly related to environmental conditions and deposition substrate and, therefore, that tailoring models to take into account these factors is preferable.

Living cells used as sensing systems have proved to be valuable tools for prediction of the physiological response to drugs, chemicals, and samples in complex matrices, which toxic effects and specific biological activities can be evaluated in a straightforward manner. Thanks to their predictivity, 3D cell models (i.e. spheroids, organoids and microtissues) are replacing conventional 2D cell cultures, enabling to recapitulate the extracellular matrix and cell cell interactions, creating an architecture that reflects native morphology of organs and tumors. Bioluminescent reporter assays represent the gold standard for high throughput screening assays employed in drug discovery and BL proteins showed a formidable tool for elucidating the biological mechanisms underlying morphogenetic and pathogenetic processes and for unravelling molecular pathways involved in the etiopathogenesis of several diseases.

According to the three key pillars of the organ on a chip technology, we developed a bioluminescent tissue on a chip with different cell lines (i.e., human embryonic kidney (HEK293T), human cervical cancer (HeLA)) genetically engineered with newly developed luciferase mutants emitting at different wavelengths and characterized by high stability,[1,2] implemented in a microfluidic system for multiplexed biosensing. Thanks to 3D printing technology a cell cartridge and an adaptor were developed to provide a mini dark box interfaced with portable light detectors for BL signal acquisition.

The proposed biosensing platform could become a useful tool for multiple bioactivity analysis, for on-site screening of toxic substances, prioritizing samples for more accurate chemical analyses.

Synthetic caramel is one of the most widely used colourants in the food industry. The use of caramel in Balsamic Vinegar of Modena PGI is regulated by the protocol of the Consortium of Balsamic Vinegar of Modena[1]. However, recent years have witnessed an alarming increase in food fraud, with synthetic caramel being a significant contributor to adulteration in Balsamic Vinegar of Modena. The challenge has therefore arisen to develop an analytical approach capable of determining synthetic caramel in balsamic vinegar. An approach based on two analytical techniques was thus investigated: fluorescence spectroscopy and solid-phase headspace microextraction coupled with gas chromatography-mass spectrometry (SPME-GC-MS). With both techniques, not only vinegar samples were analysed, but also the raw materials from which balsamic vinegar is produced (wine vinegar, cooked must and concentrated must) to study their effect on the instrumental response. Both techniques result in three-dimensional datasets (i.e. samples x emission wavelengths x excitation wavelengths for fluorescence spectroscopy; samples x retention time x mass spectra for GC-MS) that require the application of appropriate data analysis techniques. In the case of fluorescence, PARAFAC[2] was applied to resolve and quantify fluorophores related to the presence of caramel. For the GC-MS analysis, PARADISe software[3] was used for the resolution, integration and identification of analytes characterising the aroma of vinegar samples. A model was then built to determine the presence of synthetic caramel in balsamic vinegar samples from Modena.

Per- and poly- fluoroalkyl substances (PFAS) are a class of anthropogenic chemicals that have been in use since the 1950s and have received increased public attention in recent years. These environmental contaminants contain an aliphatic fluorinated carbon chain of variable length and a hydrophilic end group which, together with the extremely strong C–F bond, confer unique properties such as thermal and chemical stability, resistance to hydrolysis and microbial degradation but also make them non-degradable resulting in their accumulation in the environment.[1]

Rice husk (RH) is a non-food waste biomass containing approximately 40% cellulose, 30% lignin, 20% silica in amorphous form, pigments, pectins and proteins.[2] The main byproduct from RH combustion is RH Ash (RHA), with highly porous structure that can be used, opportunely treated, as Solid-Phase Extraction (SPE) sorbent for many emerging organic pollutants[3], and in this work for the preconcentration of 12 PFAS in environmental waters. In the framework of Green Chemistry and Green Sample Preparation, the original synthesis[3] of this sorbent, which involved 8-hour ultrasound-assisted oxidation in sulfonitric mixture followed by 10-hour heating at 200° C, has been greatly improved moving on a very short microwave-assisted oxidation (10 min) with a few millilitres HNO_3. The final thermal treatment was optimized by an experimental design evaluating two temperatures (150° C and 250° C) and two times (2 hours and 10 hours). Each one of the four materials obtained was tested for the sorption capacity in SPE cartridges (250 mg) in tap water samples (50 mL, native pH) enriched with 1 µg L^{-1} of each fluorinated analyte. The most performing material (250° C, 2h) showed quantitative adsorption and elution (by 2 mL MeOH 0.1% v/v NH_3) of the 12 PFAS examined (recovery from 82% to 115%, RSD% < 10%, $n = 3$), analysed by UPLC-ESI-MS/MS with marked internal standards quantification.

The procedure was then successfully tested in tap water samples fortified at lower environmentally significant concentration (100, 50 and 10 ng L^{-1}) with recoveries between 70 and 111% (RSD% < 15%, n = 3). Tests in river waters and wastewater treatment plants effluents at the same concentration levels are ongoing.

The widespread use of Rare earth elements (**REE**) in cutting-edge technologies has led to a surge in their consumption and the urgency of finding sustainable solutions for their recovery.[1] The European Community included REE in the list of critical raw materials, i.e. the list of materials whose recovery is considered of strategic interest.[2] Among the different REE recovery methods, adsorption is one of the most attracting, in particular when the employed adsorbents come from waste platforms.[3] This contribution presents the results achieved using three biochars coming from the pyrolysis of dead *Posidonia oceanica*, a marine plant whose leaves accumulate in abundance on the sicilian cost, as adsorbents of REE from aqueous solutions. To this end, thermodynamic and kinetic experiments were carried out to study the recovery of La, Nd and Dy ions onto the biochar of *Posidonia oceanica* as it was (**BC**) and after two types of chemical activations, i.e., an acid activation with phosphoric acid (**BCA**) and a basic activation with potassium hydroxide (**BCB**) in aqueous solution at pH = 5 and t = 25°C. The adsorption of REE ions onto BCA, the best adsorbent among those investigated, was also studied, at the same pH, in $NaNO_3$ 0.1 mol L^{-1} to evaluate the effect of ionic strength. Single batch adsorption experiments were also carried out at pH = 3 and 6 to evaluate the effect of pH. Chemical and morphological characterization of adsorbents were carried out by SEM-EDX, FT-IR, elemental analysis, nitrogen adsorption/desorption and pH of point zero charge measurements. The REE adsorption were well described by Langmuir isotherm and, among the adsorbents investigated, the BCA showed the highest q_m value. The q_m of BCA decreases with the decreasing of pH and in presence of $NaNO_3$. The adsorption equilibrium was reached within 8 hours and the kinetic of adsorption was well described by the double exponential equation. Recycling experiments were also carried out to test the reusability of the BCA.

Evaluation of the relative response factor among different gas chromatographic systems

M. Romagnoli,[a] D. Zanella,[b] A. Cavazzini,[a] F.A. Franchina[a]

[a]*Department of Chemical, Pharmaceutical, and Agricultural Sciences, University of Ferrara, via L. Borsari 46, 44121 Ferrara, Italy*
[b]*Giulio Natta Research Center, LyondellBasell Italy, Piazzale Donegani 12, 44122 Ferrara, Italy*
monica.romagnoli@unife.it

When it comes to gas chromatographic analysis, we usually tend to consider MS as the reference detector to identify the analytes, while FID for their quantification. This is because the molecules do not respond in the same way to different detectors, and due to the analogue response of FID, the analytical signal is more linear to the concentration and the dynamic range maintains the linearity over a range of higher concentration.

If the analysis goal is the chemical elucidation of a given sample, the response normalization of the single analytes on the total detected signal (area %), is an effective and common way to express the chemical distribution of within a given sample.

This is reasonable and accurate with a detector as FID, whose response is fairly consistent between different compounds or at least predictable through the calculation of relative response factors (RRFs). Different approaches have been developed for their calculations, among which the effective carbon number (ECN)[1].

Applying total response normalization when using an MS detector is generating an error, especially if different chemical classes are considered: this is due to the different responses of molecules in relation to their different structure. In addition, predicting the RRFs is not yet demonstrated.

In this contribution the relative response factors of 35 compounds with different chemical structure (*n*-paraffins, *i*-paraffins, olefins, naphthenes, aromatics, and N/O-containing compounds) were calculated for GC coupled to different detectors: FID, qMS, TOFMS, and VUV. Using on-column injection, it was possible to understand the different responses of the various detectors for each class of compounds.

In addition, it was studied the inlet splitting influence on RRFs, through the comparison of on-column and split injection analyses.

The electrodeposition of nanostructured materials on silicon substrates provides a means to combine the desirable properties of metals with the exceptional electronic properties of silicon, enabling the development of integrated circuits, electrodes in batteries, supercapacitors, fuel cells, sensors, and photovoltaic cells[1]. This deposition technique was chosen because is an inexpensive, easily scalable, and quick synthesis route, is carried out at room temperature and atmospheric pressure, in aqueous solution, and with adjustable properties.

In this work, the possibility of obtaining electrodeposited nanoparticles, ultra-thin films, and Under Potential Deposition (UPD) on n-doped silicon was evaluated[2]. The first selection of metals to be electroplated was made through the evaluation of Density Functional Theory (DFT) calculations, considering the Schottky barrier, the metal-silicon, and the metal-metal formation energy. Voltammetric studies were then carried out using solutions containing Ni, Ru, Pd, Rh, Pt, Ag, Mn, and Co. Charge-controlled depositions were performed, and tests on electroless deposition were made. Ideal deposition conditions were sought for the most promising metals. The deposits thus obtained were characterized morphologically and compositionally using Secondary Electrons (SE), Backscattered Electrons (BSE) Scanning Electron Microscope (SEM) techniques, and extensively by analytical spectroscopy point of view, by the means of Energy Dispersive X-ray Spectroscopy Analysis (EDS) and X-ray Photoelectron Spectroscopy (XPS) technique. The focus of the study was the electrochemical deposition of rhodium on silicon which is surprisingly not much covered in the literature. For this reason, multi-step charge-controlled deposition studies were carried out, and the surface coverage, the average thickness, and the variation in deposited particle size distribution were then evaluated accordingly. The knowledge gained was used to obtain ultrathin silicon nanowires (NWs) by a wet etching process assisted by an electrochemically deposited metal thin film, a procedure not widely used in the literature at the state of the art. These results could create new opportunities for smaller-sized and better-performing sensors[3].

The authors acknowledge the support offered by Fondazione CR Firenze, Fondazione per la Ricerca e l'Innovazione of the University of Florence and Confindustria Florence within the FABER4 project.

The ongoing COVID-19 pandemic is undeniably one of the most significant global threats in modern history, which has resulted in severe social and economic consequences.[1] Several detection approaches and genome sequencing methods have been utilized for SARS-CoV-2, as indicated by the extensive number of available data [2]. Currently, the SARS-CoV-2 diagnosis is based on Reverse Transcription-quantitative Polymerase Chain Reaction (RT-qPCR) method, which is considered the gold standard [3]. However, the RT-qPCR major limitation is the non-specificity in the detection of genomic, subgenomic, or degradation product of the viral RNA. Indeed, different studies prove that subgenomic mRNAs (sgmRNAs) could be used as a significant epidemiological marker for detecting different SARS-CoV-2 strains [4,5]. Furthermore, these mRNAs are related with the active replication of the virus[5]. In this study, we evaluated the application of the Single Molecule with a Large Transistor (SiMoT) technology [6] to perform a proof of concept for the early detection of nucleocapsid protein coding SARS-CoV-2 sgmRNAs. The core of the SiMoT device, based on an electrolyte-gated field-effect transistor, is a gold gate electrode biofunctionalized with a self-assembled monolayer [7], densely packed of the sgmRNAs . The proposed label-free, fast electronic assay paves the way to ultra-high performing immunometric point-of-care devices for large-scale screening of the active replication of the virus.

PAM-Engineered Toehold Switches as Input-Responsive Activators of CRISPR-Cas12a for Sensing Applications

N. Bagheri, A. Chamorro, A. Idili, A. Porchetta

Department of Sciences and Chemical Technologies, University of Rome, Tor Vergata, Via della Ricerca Scientifica 1, 00133 Rome, Italy
neda.bagheri@uniroma2.it

The RNA-programmed CRISPR effector protein Cas12a has emerged as a powerful tool for gene editing and molecular diagnostics. Nonetheless, additional bio-engineering strategies are required to achieve precise control over Cas12a activity.[1] Here, we introduce a novel class of Cas12a regulators termed PAM-engineered Toehold Switch DNA, featuring re-engineered locked protospacer adjacent motif (PAM) within the loop.[2] This design enables precise control of Cas12a activities in response to specific molecular targets via structure switching and PAM complementation. Reconfiguring the Toehold Switch DNA from a hairpin to a duplex conformation through a strand displacement reaction provides an effective means to modulate the accessibility of the PAM, thereby controlling the binding and cleavage activities of Cas12a. This approach demonstrates the potential to initiate downstream Cas12a activity by exploiting proximity-based strand displacement reactions upon target binding (Figure 1). By utilizing Cas12a *trans*-cleavage activity as a signal transduction mechanism, our approach shows versatility in sensing applications. Our system facilitates rapid, one-pot detection of IgG antibodies and small molecules with high sensitivity and specificity, even within complex matrices. Beyond its bioanalytical utility, the switchable PAM-engineered Toehold Switches serve as programmable tools, allowing precise regulation of Cas12a-based targeting and DNA processing in response to molecular inputs, thus holding promise for diverse biotechnological applications.

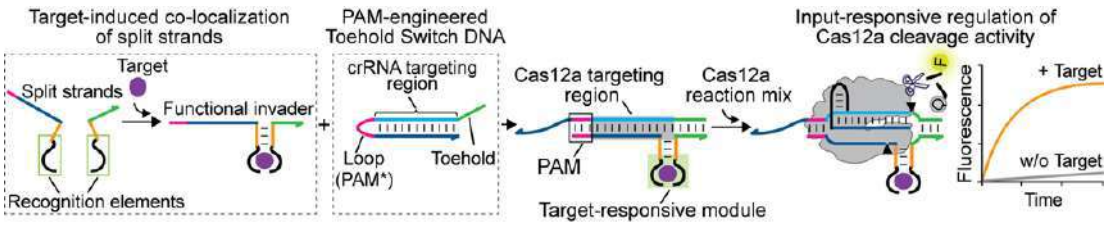

Figure 1: PAM-engineered Toehold Switch DNA reconfiguration enables precise control of Cas12a activities in response to specific molecular targets via structure switching and PAM complementation within a proximity-based reaction network.[2]

The early detection of pathogens is essential for timely diagnosis and implementing preventive measures and treatments. One particularly concerning pathogen is the bacterium Xylella fastidiosa, known for its detrimental effects on various crops and plants crucial for both ecosystems and agriculture. Responsible for diseases such as Pierce's disease of grapevine, phony peach disease, plum leaf scald, citrus variegated chlorosis disease, and olive scorch disease, *X. fastidiosa* is among the most harmful plant bacteria globally. In this study, we employed the Single Molecule with a Large Transistor (SiMoT) technology, utilizing an Electrolyte gated Organic Field-effect transistor (EG-OFET), to detect *Xylella fastidiosa* with high sensitivity. Achieving a limit-of-quantification (LOQ) of 2±1 bacteria in 0.1 mL (20 colony-forming units/mL), the assay utilized a bio-functionalized millimeter-wide gate with Xylella-capturing antibodies. Importantly, this detection was performed directly on saps obtained from naturally infected plants. Furthermore, we demonstrated the selectivity of the SiMoT system against a non-target bacterium, *Paraburkholderia phytofirmans*. To assess the biofunctionalization protocol and antibody capture efficiency, Surface Plasmon Resonance (SPR) technique was employed. SPR offers label-free detection and real-time monitoring of bio-affinity reactions, providing valuable insights into the assay's performance. Additionally, we compared our bio-electronic platform with the established qPCR gold-standard method. Remarkably, our label-free electronic assay proved to be faster (30 minutes) and more precise (with false-negatives and false-positives below 1%) than state-of-the-art technologies, obtaining a limit of quantification two orders of magnitude lower than rt-PCR. This suggests the potential of our platform for large-scale screening of asymptomatic plants, paving the way for efficient plant pathogen detection at the point of care.

Biosensors performance can be affected by many factors, such as stability, temperature, or fluid matrix interferences. The validation of the biosensor performance is the process of verifying and demonstrating that the biosensor meets the predefined specifications and requirements for its intended use. This is essential for ensuring the reliability, reproducibility, and quality of the biosensor results. In this study, we developed a multivariate *Quality Control* (QC) based on *Principal Component Analysis* (PCA) method[1,2] to improve the reliability of SiMoT platform[3]. Due to the complexity of the device and the use of different human fluids, the biosensor performances can be affected by nonspecific interactions due to matrix effects, characteristic of complex biological samples. To this end, it was necessary to define a statistical model to identify and evaluate all experiments that exhibit abnormal biosensor performance and therefore cannot be considered acceptable. Current changes registered with reference gates and with 7 negative control experiments, have been used as variables for QC. Initially, a dataset called '*Normal Operating Conditions'* was defined, including samples in which all sensors operate according to the electronic specifications established. The reliability of the NOC dataset as a reference dataset was evaluated by performing the PCA and verifying the absence of outliers. All other samples were used as test datasets. The latter were compared with the NOC dataset to assess the possible presence of *faulty* samples. Q residuals and Hotelling's T^2 statistics have been analyzed to spot the presence of outliers. To demonstrate the reliability of this QC model, an automatic classification model was built with the same training and test datasets. It emerged that all samples with abnormal biosensor behaviors identified in the test dataset of the QC analysis, were misclassified by the classification model. This underlines the importance of using real-time process monitoring when using biosensors to improve the reliability of such devices.

lorenzo.quadrini@unifi.it

As urea is a common fertilizer and additive for cow feed, it pollutes the environment by causing soil runoff, which in turn leads to eutrophication and algal blooms[1]. This makes it crucial to keep an eye on wastewater's urea levels. Because wastewater often contains significant quantities of urea, quantifying urea is helpful in determining when it might be worthwhile to try recovering it or converting it in a valuable material for many applications, including for energy issues. This will give a contribution in achieving circular economy and to valorize materials that would otherwise be treated merely as waste[2]. Catalytic and biocatalytic methods can be employed in wastewater treatment plants to monitor, treat, and recover urea. In fact, the urea oxidation process (UOR) is now thought to be a promising alternative energy source. Catalytic and biocatalytic technologies can be used to monitor, treat, and recycle urea in wastewater treatment facilities. Indeed, because of its low cost, ecologically favourable features, and green processing, urea oxidation reaction (UOR) is currently considered an attractive alternative energy conversion, environmental remediation, and electroanalysis topic. In contrast, the high selectivity that may be achieved is the driving force behind biocatalytic-based methods[3].

In this work, we developed a novel combination of flow injection analysis (FIA) and bio-cartridges for a real-time urea monitoring process. For continuous monitoring and automated sample processing, FIA-based bio-cartridges are very helpful. Enzymes were immobilized onto spherical particles inside the cartridge, to improve the surface to volume ratio and mimic homogeneous reactions. For the electrochemical readout, the bio-cartridges are then connected to small solid-state ammonium sensors. To generate the greatest signal in the shortest length of time, various parameters were tuned, including the amount of immobilized enzyme, flow rate, and reagent concentrations. After that, the bio-cartridge results were compared with an electrochemical method based on UOR. In order to do this, many Ni-based electrode surfaces for the amperometric detection of urea were examined and characterized. For online detection, various analytical parameters were tuned.

Preliminary results on wastewater samples were reported.

The coordination in solution of first-row transition metal ions naturally occurs in the body or can be induced to enhance the transportation, increase the activity, or reduce the toxicity of the ions[1]. The speciation of metal-ligand systems in solution is useful to investigate the behaviour and the implications of the components in physiological conditions. Quinoline and coumarin derived ligands were studied in combination with some bio-relevant first-row transition metal ions. In particular, 8-hydroxyquinolines (8-HQs) and n-hydroxycoumarins (HCs) represent two families of naturally occurring compounds showing interesting biological properties, including the ability to chelate metal ions[2,3].

Metal ions as $V^{IV/V}$, Cr^{III}, Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II} and Zn^{II} were considered and studied in combination with 8-HQs and HCs derived ligands. These ions are naturally involved in biological mechanisms and their chelation can dramatically change their activity and distribution in the body. The combination of these metals with biologically interesting ligands nowadays represents a strategy in drugs discovery[4]. The considered metal ions and ligands were combined and their interaction was investigated aqueous solution. Several metal-ligands systems were studied adopting a multi-technique approach. Potentiometric, spectrophotometric and NMR titrations were performed, in $KCl_{(aq)}$ 0.2 mol·L^{-1} and T = 298.15 K. The characterization of the systems was further expanded exploiting other electrochemical and spectroscopic techniques as voltammetry, fluorimetry, and EPR spectroscopy. Combining the information obtained from different techniques, it was possible to achieve a good grade of knowledge about the chemistry of the investigated systems. Stoichiometry of the formed metal complexes were identified, and coordination modes were hypothesized. The stability constants of the complexes were estimated, and the speciation diagrams were obtained defining the main species formed in solution over the biologically relevant pH range.

federica.alchera@unito.it

The processing of agricultural products inevitably leads to large amounts of waste, which is a serious disposal problem. In particular, the fruit and vegetable supply chain results in approximately 90 million tonnes of residues per year in Europe, a volume that is expected to increase in the coming years[1]. For example, a large part of the total berry production is processed for juice production, of which approximately 20–30% ends up as waste[2]. Additionally, a large amount of fruit is wasted in the field due to unforeseen weather conditions exacerbated by climate change.

In a circular economy approach, also considering the high value due to the presence of active compounds, it is crucial to recover fruit wastes, rich in phenols and active substances[3]. Taking into account the principles of "green chemistry," the development of a polyphenol valorization process requires the identification of environmentally friendly solvents[4]. From this perspective, polyphenolic extracts obtained by green approach can be used as active agents (antimicrobial and antioxidant) in cosmetics and packaging.

Polyphenols known for their antimicrobial and antioxidant properties can be used as functionalizing agents in active packaging: ‘materials and articles designed to deliberately incorporate components that release substances into or absorb them from the packaged foodstuff or its environment' (EC Regulation 450/2009).

Small fruit sector (e.g. raspberries, blueberries) is one of the Italian markets with high product losses caused by the early onset of senescence phenomena related to microbial contamination. Reason why the active packaging systems currently used for the marketing of fresh fruit and vegetables are based on the control of microbiological contamination.

The aim of this work is to recover bioactive compounds from food waste using green extraction solvents and techniques. The extracted polyphenol will be used as functionalized agent in active packaging produced from bio-based and/or biodegradable polymer. The interaction of phenol compounds and different polymers matrices and the mechanical properties of final products will be evaluated. Finally, the release of bioactive compounds using food simulant will be verified and the antimicrobial properties of active packaging will be tested on fruit samples (i.e. raspberries).

Propofol is widely recognized as the preferred intravenous anaesthetic for short-term sedation due to its rapid onset and elimination, gentle recovery from anaesthesia, and minimal side effects.[1] Improper administration, either excessive or insufficient, may result in propofol infusion syndrome (PRIS) or intraoperative awareness, leading to physiological and psychological harm to patients. Notably, there is considerable variability in individual responses to propofol anaesthesia. Additionally, there is a growing global concern about addiction and fatalities associated with propofol abuse in recent years. Therefore, the assessment of plasma propofol levels is crucial in drug metabolism and pharmacokinetics (DMPK) as well as forensic toxicology research.[2,3]
In this work, an innovative enzyme-based amperometric biosensor was developed by using horseradish peroxidase (HRP) immobilized onto graphene based screen-printed electrodes. In particular, HRP was operated in mediated electron transfer (MET) using $[Os(4,4'\text{-dimethyl-}2,2'\text{-bipyridine})_2(\text{poly-vinylimidazole})_{10}Cl]^{2+/+}$ as immobilized mediator, monitoring the inhibition of H_2O_2 catalytic activity of HRP induced by propofol.[4] Moreover, enzymatic layers applied on the electrode surface have been used to eliminated or decrease the signal of interference molecules that may be present in actual blood samples.
The modified electrodes were characterized by using cyclic voltammetry and amperometry to extract the biosensor analytical figures of merit (e.g., dynamic linear range, limit of detection (LOD), sensitivity and stability). The electrodes were finally tested in blood samples using a smartphone-integrated system in order to develop a blood-prick propofol screening test.

As per the World Health Organization, approximately 422 million individuals, around 5% of the global population, have diabetes, making it a significant health concern.[1,2] Predicted to become the seventh leading cause of death, diabetes is a serious threat due to its associated complications, including cardiovascular disease, blindness, amputation risk, and kidney failure. Managing blood glucose levels is crucial for delaying these complications, but it's a challenge due to significant variability, especially in severe cases. This need for precise monitoring has led to a thriving market for glucose biosensors valued at over 15 billion EUR annually. However, challenges persist, primarily in scaling up biosensor production with multiple costly biological elements. To address this challenge, the scientific community is working on developing reusable biosensing platforms with long-term stability.[3]

Although implantable and minimally invasive sensors offer the advantage of continuous monitoring, their chemical compositions pose significant regulatory challenges for routine usage. As a result, there is a growing emphasis on developing diagnostic devices that are biodegradable, bioresorbable, or ingestible to overcome this limitation. In this regard, we have addressed the very important challenge of tailoring and designing novel conductive smart carbon-based inks completely biocompatible and edible to develop biocatalytic biosensors able to monitor the intestinal absorption of glucose in type 2 diabetic (T2D) patients. We employed a Design of Experiments (DoE) approach like Face Centered Design to optimize processing variables and enhance ink performance, providing a unique model for formulating edible carbon-based inks.[4]

DNA-based dynamic combinatorial library as a multi-analyte sensing tool

S. Brannetti,[a] S. Gentile,[b] E. Del Grosso, [a] F. Ricci [a]

[a]*University of Rome Tor Vergata 1, Via della Ricerca Scientifica 1, Rome*

Complex intracellular networks that dynamically respond to different biological and chemical cues play a fundamental role in regulating signalling transduction pathways. Researchers have recently explored the possibility of developing artificial systems that, mimicking such dynamic networks, allow to build synthetic systems that respond to different targets with high sensitivity and specificity.

Dynamic combinatorial libraries can be promising tools to engineer artificial networks. In these systems, a set (Pool) of building blocks forms reversible bond and are allowed to reach thermodynamic equilibrium in the presence of external inputs, resulting in a variety of output libraries.[1]

Synthetic DNA has emerged as a versatile biomaterial to engineer nanodevices with potential applications in different fields, like sensing, imaging, and drug-delivery. Taking advantage of the high programmability and predictability of DNA-DNA interactions, several strategies used to design synthetic receptors for a wide range of different targets (Antibody, protein and small molecule) have been reported.[2]

Motivated by the above considerations, here we propose to develop a DNA-based dynamic combinatorial library (DNA-DCL) as a sensing tool able to respond to the presence of multiple targets. To achieve this, we have designed a DCL composed of short reactive DNA strands (Pool) that can interact with each other leading to the generation of a library of products (Output). The presence of specific external inputs (Target) can sequester reactive DNA strands from the pool, inducing the upregulated formation of only a specific product.

To prove the versatility of our approach, we have also designed a DNA-DCL to orthogonally control the assembly and disassembly process of DNA-based nanostructures.

The circular economy model promotes the use of sustainable materials and wastes/by-products. In the analytical field, this led to new approaches in which 'recycled materials' are employed as building blocks for analytical devices manufacturing; these sustainable 'materials' often are also sources of compounds with economic/biological added value that deserve to be analyzed, closing the circularity of the process.

In this work, paper-based electrochemical sensors based on films composed exclusively of nanofibrillar biochar (BH) were manufactured and used for the determination of bioactive compounds in food by-products and derivates; the BH was produced from paper-industry waste, while paper from 100% recycled fibers was used as substrate for the sensors. Nanofibrillar BH was dispersed in water via ultrasound-assisted liquid phase exfoliation, conductive BH films were formed onto paper and defined using a laser plotter; eventually, the complete paper sensors were assembled via stencil printing. The biochar-based paper sensors (BH-PS) were employed for the analysis of phenolic compounds (i.e., caffeic acid, catechin, chlorogenic acid, and oleuropein) in exhausted coffee, coffee and cocoa bean husk, and artichoke and olive leaf based supplements. Linear dose-response curves ($R^2 \geq 0.995$) and micromolar limits of detection enclosed between 0.03 and 0.6 µM were obtained. Moreover, analysis of samples returned quantitative and reproducible recoveries (97-114%, RSD≤13%, n=3), allowing sorting samples in agreement with conventional more complex, and time-spending methods. Eventually, White Analytical Chemistry principles were used to evaluate the sustainability of the BH-PS-based approach toward traditional analytical methods[1] highlighting economic and environmental advantages; on the other hand, the analytical performance obtained ensures an efficient analysis of phenols in food by-products and derivatives, allowing to valorize the residual bioactive components.

Figure 1: Representation of the circularity of the biochar-based paper sensors

Bisphenol A (BPA) has become a pervasive environmental contaminant, posing a significant threat to aqueous ecosystems and human health. In this work, for the first time, paper derived from seaweed biomasses (Algae) has been used for manufacturing lab-made electrochemical sensors, that were employed as monitoring tools during eco-toxicological studies performed with Zebrafish embryos (Z-EBs, *Dario rerio*) exposed to different BPA levels. Firstly, the potentiality of Algae paper to assist the stencil-printing was investigated, employing different graphitic inks as conductive elements; Algae-paper sensors were compared with transducers fabricated onto other types of paper (recycled and office-grade) and polyethylene terephthalate (PET), showing superior performances for BPA electro-sensing. The electrochemical properties of the sensors have been improved by employing two kinds of biochars (BH) with fibrillar (F) and amorphous (A) morphology, both deriving from industrial by-products and nano-dispersed through an aqueous-based and solvent-free sonochemical method. The most performing Algae-paper sensor has been challenged towards the direct BPA sensing in Z-EBs culture medium, achieving robust analytical performance devoid of any matrix effects, returning satisfactory limit of detection (LOD = 48 nM) and linear range (0.25 – 6 µM), together with quantitative recoveries (95-113%, RSD≤9.1% n=3). Afterward, the BPA bioaccumulation in Z-EBs during ecotoxicological studies was determined using the Algae-paper sensor; despite the inherent complexity of embryos, in matrix calibrations returned useful linearity (0.25 – 8 µM) and a LOD of 57 nM, allowing the estimation of the BPA bioaccumulated within Z-EBs (recoveries: 98-114%, RSD≤5.4% n=3).
Herein, the marriage between Algae-paper and BH gave rise to an effective analytical tool for monitoring BPA in Z-EBs, employed as an environmental (culture medium) and toxicological (embryos) model. This study proves how by-products can become active and functional parts of analytical devices, creating a virtuous circle able to offer sustainable solutions for environmental monitoring.

To reduce waste and reduce costs, the current trend is to find alternative solutions aimed at combating environmental pollution, e.g. by replacing classic plastics with biodegradable and sustainable materials. Therefore, the use of plant biopolymers could be a valid alternative. In this communication, self-standing zein films, of potential application as food packaging layers, were prepared by co-dispersion with sodium caseinate to improve the mechanical and barrier properties[1]. Zein is a highly hydrophobic corn protein with excellent film-forming properties, which could be extracted by corn gluten meal (byproduct of corn milling process)[2]. Moreover, the embedding of silver nanoparticles (AgNPs) was considered to confer antimicrobial properties[3] to the proposed materials. AgNPs were first prepared according to a green reduction process limiting the amount of silver precursor ($AgNO_3$) and using low-toxic chemicals (ascorbic acid as a reducing agent and zein as a stabilizer). NPs were then added to the zein/caseinate dispersion to obtain antimicrobial films. AgNPs and composite films were characterized by a multi-analytical approach in terms of NP morphology and size (DLS, TEM) and chemical composition (UV-Vis, XPS, FTIR). AgNPs have typically a spheroidal shape with a mean diameter of about 20 nm. FTIR analysis, as reported in the literature[1], confirmed the high compatibility and strong interactions between casein and zein. Mechanical and water absorption tests were performed showing good results. Moreover, preliminary antifungal *in vitro* tests and silver ion release (ETAAS) are presently under study to evaluate film properties.

alessandra.olarini@unimore.it

Tensor-based decomposition methods have long been established as robust methodologies in chemometrics, providing effective tools to analyse complex data structures[1]. In the context of hyperspectral images, where simultaneous exploration of spatial and spectral domains is crucial, Canonical Polyadic Decomposition (CPD) and Tucker decomposition[2] are useful techniques. However, CPD's imposition of rank 1 on each factor can be overly restrictive, while Tucker decomposition offers greater flexibility but suffers from rotational ambiguity. An intermediate method, Block Term Decomposition (BTD)[3], facilitate a compromise. By imposing rank = 1 on one factor and allowing rank ≠ 1 for the other two factors (LL1-BTD), it preserves the uniqueness property of CPD while accommodating more complex spatial structures related to a single spectral signature. Therefore, BTD is well-suited for analysing hyperspectral images where the spatial structures of various spectral components require distinct factorization. This includes scenarios such as the presence of minor components or components with similar spatial distributions but different spectral signatures, and vice versa. In this study, we explore the adoption of LL1-BTD for analysing benchmark hyperspectral imaging datasets of chemical mixtures, biological fluids, leaves, a mineral sample, and remote sensing images. These datasets were acquired using different spectroscopic techniques such as UV-Vis, NIR, Raman, LIBS. LL1-BTD performances are compared with CPD and spectral unmixing methods applied to unfolded hyperspectral data cubes. Results indicate that LL1-BTD shows promise for hyperspectral image analysis, offering insights into the efficacy of tensor-based decomposition methods for addressing the challenges posed by such data.

This contribution presents the preliminary results obtained using waste biomasses from the industrial food chain for the preparation of multifunctional materials possibly able to detect, bind and extract, efficiently and selectively, rare earth metal ions from aqueous solutions simulating real matrices. These metals belong to the list of "Critical Raw Materials", *i.e*. the group of materials whose recovery is considered strategic by the European Community[1]. The use of food-processing industry wastes as secondary raw materials offers a sustainable and environmentally friendly approach, that could also be useful for the rare earth metals recovery. In particular, the adsorption of neodymium and dysprosium ions in aqueous solution was studied at pH ~ 5 and t = 25°C using different waste biomasses, namely Bergamot Pomace (BP), Olive Pomace (OP) and Grape Pomace (GP), chemically pretreated at t = 30°C with H_2O and HNO_3 0.10 mol dm^{-3} [2,3]. The materials were characterized employing different analytical techniques; through the FT-IR ATR spectroscopy [2], it was possible to confirm the presence of functional groups capable of interacting with the above mentioned metals. To evaluate their adsorption capacity, batch experiments were carried out on different solutions containing the metal ions (M^{3+} = Nd^{3+}, Dy^{3+}). The concentration of each M^{3+} was determined by ICP-OES [4]. The results obtained from adsorption experiments show that Langmuir equation was the best isotherm fitting model for BP, OP and GP for the rare earth metals adsorption. The adsorption equilibrium was reached within 24 hours and the kinetic of adsorption was well described by the pseudo-second order model. Then the recovery of the metals adsorbed on the biomasses was carried out using HNO_3, but the reused materials show lower performance than the starting ones, exception done for BP, which showed great reutilization capacities [4].

margherita.izzi@uniba.it

Due to the rise of antimicrobial resistance, new formulations and more efficient materials are being investigated for the control of the microbe spread and the fight against harmful pathogens. This is the case of inorganic antimicrobials, which have become popular in different applications. However, it is nowadays essential to estimate correctly and deeply the nature of bioactivity mechanisms and material surface properties with the ultimate goal of developing safer and greener (nano)antimicrobials. For example, we have recently demonstrated the importance of applying a thorough analytical characterization to predict possible toxicity mechanisms[1], thus suggesting specific dose-effect correlations in the case of Cu nanoparticles. In this communication, we present our recent results about ZnO-based materials. Zinc oxide is a widely used antimicrobial whose action mechanism involves multiple processes[2]. In fact, ZnO bioactivity can be ascribed both to the action of reactive oxygen species (ROS) formed by a photocatalytic process and to Zn^{2+} release from the material surface[3]. In this work, scanning electrochemical microscopy (SECM) is used *in situ,* to evaluate if the ROS generation is caused by the Zn^{2+} ions or by the intrinsic ZnO photoactivity[3]. Specifically, the real-time spatially resolved (photo)reactivity of ZnO-based coatings was investigated, monitoring the local oxidation current of hydrogen peroxide, which is the most stable ROS. First, the detailed analytical characterization of the sub-micrometric ZnO-based materials by microscopic (TEM) and spectroscopic (UV-Vis, ATR-FTIR, XPS) investigation will be presented, offering an overview of the material morphology, chemical composition and surface reactivity. Then, the SECM results will be discussed, allowing a point-to-point correlation between the mapping of H_2O_2 electrochemical evolution, and the antimicrobial surface features. Specifically, higher oxidation currents were produced in specific micrometric regions even at dark conditions, hence without the photoactivation of ZnO. The local release of Zn^{2+} ions occurs in proximity of the ZnO structures that are homogenously distributed into the polymeric coatings, and can be associated to the generation of a significant amount of ROS, even under dark, that could be enhanced under UV-illumination.

eoliva@unite.it

Phytosterols (PSs) are bioactive compounds structurally and functionally similar to cholesterol. They contain an extra methyl, ethyl group, or double bond, and most of their side chains contain 9-10 carbon atoms. PSs have been classified as 4-desmethyl sterols of the cholestan series, which all have double bonds at the C_5 position of the B-ring[1]. These molecules are particularly known for widely range of properties including reduced intestinal cholesterol absorption and potential contributions to the prevention of cardiovascular diseases[2]. PSs are generally classified into three groups based on the number of methyl groups on carbon-4, two (4-dimethyl), one (4-monomethyl), or none (4-desmethyl). Moreover, 4-dimethyl esters and 4-monomethylsterols are metabolic intermediates in the biosynthetic pathway leading to the final product, 4-desmethyl phytosterols, but are usually present at low levels in most plant tissues. These compounds are present in plants, such as seeds, grains and legumes, both in free and conjugated form and they can be found in the form of fatty acyl esters, glycosides and fatty acyl glycosides. The selectivity issue in plant matrices is a challenging task, and classic approach such as solvent or solid phase extraction (SPE) are expensive and not always give the needed selectivity. In this scenario a low cost molecularly imprinted polymers (MIPs) approach for the selective of extraction these compounds was not fully explored. In this work, a fast chemical MIPs synthesis approach for selective extraction of PSs was performed, using cholesterol as a dummy template. The MIPs were used as an adsorbent phase for SPE and combined with a targeted approach using liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) with atmospheric pressure chemical ionization (APCI). The results showed high selectivity with significant extraction performances and low matrix effect, a principal goal in complex plant matrices. The proposed strategy can be consider as fast and effective method to produced MIPs as extraction tool for the determination of these target compounds.

Single Particle Inductively Coupled Plasma Mass Spectrometry (SP-ICP-MS): an innovative approach for inorganic nanoparticles analysis

M. Mataloni,[a] M. Grotti,[a] F.Ardini,[a] E. Cerri,[a] F. Locardi,[a] M. Resano,[b] E. Bolea-Fernandez[b]

[a] *Department of Chemistry and Industrial Chemistry, University of Genoa, Via Dodecaneso 31, I-16146 Genoa, Italy*

matilde.mataloni@edu.unige.it

During the last two decades, the use of engineered nanoparticles (ENPs) in a wide range of applications has been growing exponentially due to their unique chemical and physical properties. The increasing presence of these materials in consumer products has inevitably led to their release into the environment and, consequently, to their incorporation into the human body[1]. Together with their spread, the need for an in-depth risk assessment and the introduction of global regulations for a safe and sustainable employment of ENPs became evident.

In this context, single particle – inductively coupled plasma – mass spectrometry (SP-ICP-MS) represents a powerful and emerging technique for routine analyses of NPs. In SP mode, the conventional ICP-MS unit operates in time-resolved analysis mode by using higher data acquisition frequencies to detect every signal pulse corresponding to each individual NP reaching the ICP[2]. Through a single analysis, SP-ICP-MS can provide a wide range of information, such as chemical composition, size distribution and particle number and mass concentrations, overcoming many of the limitations specific to techniques traditionally used for nanomaterials characterization[3].

In this work, the development of analytical methods for the analysis of different kinds of inorganic NPs (e.g. Au, SiO_2, Ni) will be described. Besides illustrating all the fundamental aspects concerning the analysis, the main challenges in rendering SP-ICP-MS a routine approach, especially for environmental studies, will be underlined.

The presence of plastic waste is recognized as a significant worldwide environmental hazard, with inadequate handling and disposal practices resulting in escalating levels in natural surroundings. Of recent interest is the breakdown of plastics into particles ranging from macroscopic to microscopic, and even to nano-sized particles measuring less than 1µm. At the nano level, plastics pose detection challenges and can be dispersed through air, soil, and water environments. Thus, studying the degradation patterns of plastics is necessary for accurate evaluation of their fate in the environment[1]. Among plastics, expandable plastics offer numerous advantages, including excellent energy absorption, impressive shock and fire resistance, exceptional thermal insulation properties, resistance to water and chemicals etc. These properties make them ideal for use in protective packaging solutions, where they help minimize damage during transportation and provide thermal insulation, among other benefits[2]. In this study, we have acquired engineered expandable acrylonitrile based microplastics to study its UV induced degradation and (photo)-oxidation, using mass spectrometry and microscopy (scanning acoustic microscope, SAM). We observed that microplastics release organic compounds in liquid phase upon degradation and most of them are byproducts of the polymerization process. SEM analysis has been carried out to acquire the morphological information of the polymers and it has been observed that these spherical microplastics ruptured when subjected to degradation. In this presentation we will discuss the degradation of these microplastics upon irradiation using UV light and H_2O_2, and we present the procedures used to study microplastic degradation under environmental-like conditions.

FFF multidetection for direct, real-time, size-resolved measurements of drug release from conjugates of biocompatible gold nanoparticles

J. Wang [a], S. Giordani [a], V. Marassi [a, b], B. Roda [a, b], P. Reschiglian [a, b], A. Zattoni [a, b]
[a]*Department of Chemistry G. Ciamician, University of Bologna, Via selmi 2, Bologna*
[b]*byFlow SRL, Via dell'arcoveggio, 74, Bologna*
Junjie.wang2@unibo.it

The conjugates of gold nanoparticles (AuNPs) and protein are promising systems for drug delivery. Because of its bioaccumulation, targeting, biocompatibility, and surface properties, albumin can transport diverse therapeutic systems in a localized way, which is denoted "spatially controlled release". The interesting optical properties of AuNPs allow them to be monitored using imaging tools, and the photothermal effect can release adsorbed molecules on the AuNP surface, thereby temporally controlling drug release[1].

Curcumin (Cur) is a polyphenolic compound extracted from the rhizomes of Curcuma longa. It is particularly attractive for its antioxidant, antimicrobial, anti-inflammatory, and anticancer effects. This study presents the first application of Asymmetric flow field-flow fractionation (AF4) with on-line detectors like UV/vis and multi-angle light scattering to quantify release profiles of curcumin from Au-BSA conjugates nanoparticles. The main drug carrier, Au-BSA conjugates for improving the bioavailability of curcumin, have been studied in detail in previous work[2].

In contrast to conventional measurements requiring separation of the NPs and dissolved drugs (typically by dialysis) prior to quantification, AF4 provides in situ removal of unincorporated drugs, while the combination of online UV detection selectively provides the entrapped drug concentrations, and hence the drug release information. In the synthesis stage, with the 3D UV-vis spectrum, we can further detect the changes of different species in the incubation solution, especially the independent binding between the drug and excess BSA provides a further basis for the quantification of drug loading. Further coupling with online multi-angle light scattering (MALS) and offline dynamic light scattering (DLS) allows us to monitor the size changing of Au-BSA-Cur carrier at the drug burst release stage. In addition, The factor I 401 nm/ I 530 nm (signal intensity of nanocarriers at 401 nm and 530 nm) as an index to judge the drug loading and release greatly avoids errors caused by stability and environmental changes, while the factor at no-load is 0.54 ±0.01 (n>3).

Overall, with the support of the dialysis models and AF4 technique, we are able to evaluate the Au-BSA-Cur drug carrier from the synthesis to the release stage completely, and the assistance of multi-detectors enables us to accurately monitor the changes in each stage.

Plant sterols (PSs) are secondary metabolites originating from isoprene, occurring in plants in various forms, including free sterols (FSs), esters of fatty acids, steryl glycosides and acyl steryl glycosides[1]. Particularly, PSs are principal components of raft-domains of plasma membrane, in which they exhibit self-association properties with sphingolipids; through these interactions, they can regulate membrane fluidity and permeability[2]. PSs are considered bioactive substances due to their ability to lower blood cholesterol levels and to exert anti-obesity, anti-diabetic and anti-inflammatory activities[3]. In the last decade, with the increasing attention to healthy eating and lifestyle, the interest in fresh, ready to eat innovative vegetables, such as microgreens and baby leaves, including compounds with a nutraceutical potential, like PSs, has been on the rise. The characterization of FSs using reversed-phase liquid chromatography coupled to high-resolution Fourier-transform mass spectrometry with atmospheric pressure chemical ionization (RPLC-APCI-FTMS) has thus been recently undertaken in our laboratories. The attention has been focused on microgreens and baby leaves of *Brassicaceae* species such as broccoli raab and kale, already known as sources of bioactive compounds[4], including PSs, recently identified in these products using GC-MS[5]. In the present work, the ability of RPLC to enhance the separation of PSs and of APCI to efficiently ionize these compounds will be demonstrated. The developed RPLC-APCI-FTMS method enabled the detection of major FS, such as campesterol, β-sitosterol and stigmasterol, its isomers isofucosterol and Δ7-avenasterol, brassicasterol and cholesterol, in the extracts of broccoli raab and kale microgreens and baby leaves. Moreover, the RPLC-APCI-FTMS method was validated to quantify FSs in these innovative vegetables and, for comparison, in corresponding adult forms. The obtained results show that β-sitosterol and campesterol are the most abundant FSs in the examined vegetables; other FSs are principally present in microgreens while their concentration levels are below the method detection limits in adult forms, thus corroborating the nutraceutical potential of innovative vegetable products.

stefano.bertinetti@unito.it

The interest on high mountain sites as observatory for the study of atmosphere composition is growing in the last years. In fact, the use of these sites has many advantages, among which to get insight about the background atmospheric composition, highlight the influences of surround anthropized regions on remote areas, to study the long-range transport of substances in the free troposphere (e.g., Saharan dust events)[1].

In this work we present the inorganic elemental composition of aerosol PM2.5 collected in 2022 at two different sites of Aosta Valley. The first site was near the village of La Thuile (1637 m a.s.l.) and can be classified as medium-mountain rural site; the sampling activity were performed in May and July. The second site was the CNR laboratory Testa Grigia on the Plateau Rosà (3480 m a.s.l.), that can be considered a glacier site of high mountain, and the sampling activity was performed in the month of August. In our knowledge this is the first attempt to study the elemental composition of PM at this site. The prospective of this work would be to extend the monitoring network of PM in high mountain supporting the other national observatories (e.g., Monte Cimone, Col Margherita, Monte Martano).

The sampling of PM2.5 was performed by a low volume aerosol sampler on quartz filters with a daily resolution. The filters have been mineralized according to UNI EN 14902:2005 by microwaves acid digestion. The elements (Ca, K, Mg, Al e Sc, Ti, V, Mn, Fe, Co, As, Sr, Ba, Cr, Ni, Zn, Mo, Cd, Pb, and rare Earth elements) were analysed by ICP-AES or SF-ICP-MS according to their concentration. Crustal enrichment factors have been calculated respect Al revealing that Cu, Ni, Mo, Cr, Pb, Cd, Zn, and Sc are affected by sources different from the crustal one, most probably linked to anthropogenic emission. Multivariate analysis (PCA, cluster analysis) has been performed to extract information from the whole dataset about correlation among the elements' behaviour and differences and similarities between the samples[2]. Events of incoming air masses with higher amounts of aerosol than background level have been recorded at both the sites. Back trajectory analysis will be performed to infer about the provenience of these air masses[3].

Keywords: Electroanalysis, Sensors-BioSensors, Spectroscopy, Aptamers, Polymers.

The biosensors field has become quite a hot topic, especially from an electrochemical point of view, with interests ranging from the biomedical and health-care to biological and engineering fields. In the recent years, a peculiar class of biological species, the aptamers, received high attentions: these bioreceptors which demonstrated pretty good characteristics as sensing platforms, such as high stability and reproducibility, easy chemical modification, enhanced target affinity and ease / cost-effectiveness[1]: these features grant good performances and a large amount of applications[2]. Different aptamers were tested, focusing on *Listeria monocytogenes* specific aptamers. In order to anchor the aptamers to the electrode surfaces, different polymer were used, such as polydopamine and its derivatives (i.e L-DOPA): such polymers were electrochemically deposited onto the electrode surface, with different concentrations. To fully studies the sensors surface functionalization, step-by-step, Cyclic Voltammetry, EIS, FT-IR, ATR, Raman and XPS techniques were used.

Aknowledgments: The authors thank the project IZSPB 02/21 RC “Sviluppo di un sensore innovativo per la ricerca quali – quantitativa di microrganismi patogeni in matrici alimentari” - BIMPA.

alice.marinangeli@univr.it

Molecularly imprinted nanoparticles (nanoMIPs) are synthetic receptors with tailor-made recognition sites prepared by a template-assisted synthesis. NanoMIP-based optical sensors are currently attracting significant interest as they rely on combining the MIP's selective capability with optical techniques that offer exquisite sensitivity, low detection limit and real-time response.[1] In the present work, an optical nanosensor based on MIP was designed for the detection of human serum albumin (HSA) through time-resolved fluorescence spectroscopy (Fig. 1).[2] Fluo-nanoMIPs were physically characterized by dynamic light scattering, showing a hydrodynamic size of about 120 nm. Scanning electron microscopy and atomic force microscopy confirmed the size of the nanoparticles. Steady-state fluorescence spectroscopy was used as a classical method to study the ability of Fluo-nanoMIPs to bind HSA, showing an apparent dissociation constant (Kapp) of 30 pM. Moreover, the cross-reactivity of Fluo-nanoMIPs were tested against different proteins, demonstrating high selectivity for the analyte. Then, a Fluo-nanoMIP-based sensor, challenged with increasing concentrations of HSA, was tested in solution through time-resolved fluorescence spectroscopy. A decrease in fluorescence lifetime decay was detected, and characteristic saturation binding isotherm was observed with a Kapp of 18 pM, a linear dynamic range of 3.0 – 83.5 pM and a limit of detection of 1.26 pM. As a proof of concept, nanosensor was shown to detect HSA spiked in wine, presenting a new potential method for monitoring beverage allergens. Finally, with the idea of knowledge transfer, we attempted to immobilize Fluo-nanoMIP onto a surface to develop a portable, compact and easy-to-use device.

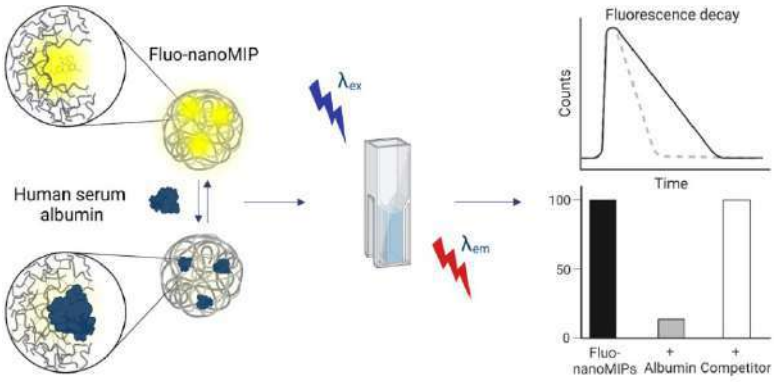

Figure 1: Fluo-nanoMIP-based sensor operation.

aferracane@unime.it

According to the Food and Agriculture Organisation of the United Nations, the extra virgin olive oil world production reached 2.4 million tonnes per year in 2021. This high production is linked to its unique health claim, included in the European Union (EU) Regulation 432/2012. Pest and disease control through the application of pesticides helps to maintain the high production yields. To ensure compliance with maximum pesticide residue levels and to assess consumer exposure to pesticide residues in and on food, multi-annual pesticide residue monitoring programmes (MACPs) are in place within the EU.

The following research involved the development of an easy, rapid, and high sample throughput workflow based on an ultrasound assisted liquid-liquid extraction followed by low-pressure gas chromatography (LPGC) and high-performance liquid chromatography (HPLC) coupled to a triple quadrupole mass spectrometry detection (QqQ MS). 290 pesticide residues were determined in extra virgin olive oil. Separation was achieved in less than 10 min using the LPGC approach, while 15 minutes were necessary for the HPLC analysis. The use of QqQ MS detection guaranteed both the sensitivity and selectivity of the method.

The developed method was validated according to the SANTE/10704/2021 guidelines, showing good recovery, intra-day and inter-day precision, and accuracy results, proving to be a valid and rugged method for the analysis of pesticide residues in extra virgin olive oil. In this regard, the proposed method was applied for the analysis of 50 commercial extra virgin olive oil samples.

emanuele.zanda@unime.it

Since the discovery of Carbon Quantum Dots (CQDs) in 2004,[1] interest in these materials has increased over the last two decades. Moreover, the synthesis of CQDs from green sources offers a valuable alternative for waste management and has received great attention thanks to the biocompatibility and affordability of the starting materials.[2] Among the various preparation strategies, the most common is the green hydrothermal method. However, the literature varies widely on the chosen synthesis conditions. For the hydrothermal treatment using water as solvent, temperature, time, and initial concentration of precursors seem to be the main parameters affecting the properties of the obtained products in terms of particle size and surface functionalization, which in turn reflect on the photoluminescence properties and stability of the CQDs.[3]

This work exploits the chemometric tool of experimental design[4] to optimize the synthesis of biomass-based CQDs. Citrus waste lyophilized bergamot pomace was used as a precursor. An initial hydrothermal synthesis was performed using 250 mg of pomace in 25 mL of water, heated in an autoclave at 180 °C for 6 hours.[5] The experimental design was then conducted according to a 2^k full factorial design while varying the initial amount of precursor (200 and 300 mg of pomace), the temperature (150 and 210 °C), and the reaction time (3 and 6 hours). After purification, the quantum yield was evaluated using quinine sulfate as a reference, and the particle size was evaluated through Transmission Electron Microscopy. The results were used to construct the experimental surface, allowing to determine the optimal conditions for the synthesis of CQDs from bergamot pomace and to clarify which parameter mostly influences the properties of the obtained product.

claudia.granata@studenti.unime.it

Gallium is widely employed in plenty of fields, being crucial in many industrial and technological, as well as medical, applications[1,2]. This widespread use, together with its limited availability, concurred to include Ga(III) in the list of the Technologically Critical Elements (TCEs)[1]. As such, its recovery is important for the reutilization in all these applications. Many Ga properties and applications, as well as some recovery processes, take place in aqueous solutions, in which it is present as trivalent Ga species. Being Ga^{3+} a hard Lewis acid, it undergoes strong hydrolysis in aqueous solution, which deeply affects its chemico-physical parameters and reactivity. Consequently, its speciation is dominated by the formation of several hydrolytic species, both mononuclear and polynuclear, with different stability. The most common species in literature are the mononuclear $Ga(OH)^{2+}$, $Ga(OH)_2^+$, $Ga(OH)_{3(aq)}$ and $Ga(OH)_4^-$, while few other polynuclear species are reported by single authors. Collected literature values were critically analyzed in this work, evidencing that hydrolysis constants and solubility products are determined in a wide range of temperature, medium and ionic strength conditions. However, significant discrepancies were found concerning both the nature and the stability of hydrolytic species of Ga^{3+}. In addition, reported data at different temperatures are usually obtained in single media and ionic strengths, and *vice versa*, highlighting the necessity to perform further dedicated experiments, in order to define a correct speciation model as a function of different conditions[3-7]. However, considering the wide number of aqueous solution studies involving this cation, an attempt of rationalization of available data is necessary. For this reason, being most of literature hydrolysis constants of Ga^{3+} reported at T = 298.15 K in various media (e.g., ClO_4^-, NO_3^-, Cl^-, Br^-) and ionic strengths ($0 < I$ / mol dm^{-3} ≤ 1.5), these data were used for the modeling of the dependence on medium and ionic strength, and results are reported in this contribution.

Retention behavior of Porous Graphitic Carbon stationary phases under High Temperature Supercritical Fluid Chromatography conditions

R. La Tella[a], F. Rigano[a], P. Donato [a], P. Dugo[a,b], L. Mondello[a,b],

[a]*Messina Institute of Technology c/o Department of Chemical, Biological, Pharmaceutical and Environmental Sciences, former Veterinary School, University of Messina, Viale G. Palatucci snc 98168 – Messina, Italy*

roblatella@unime.it

Porous Graphitic Carbon has been known as an HPLC stationary phase since the 1980s; the most significant benefits of PGC materials are their stability at very high temperatures (250 °C) and a wide pH range (1-14), as well as the absence of free silanol groups, which could influence analyte retention properties.

The planar graphite-like sheet functionality of PGC affords unique retention mechanism of polar compounds and separation of structurally related analytes, and extreme chemical stability. Chromatographic behaviour of PGCs may be summarised as follows: i) polar retention effect (PREG), whereby solutes of increasing polarity showed a high affinity towards the graphite surface compared to conventional alkyl-bonded silicas, ii) increased retention of non-polar compounds (based on dispersive interactions), iii) increased selectivity towards structurally related compounds due to the flat and highly adsorptive surface of the graphite. The strength of interaction further depends on both the molecular area of an analyte in contact with the graphite surface and upon the nature and type of functional groups at the point of interaction with the flat graphite surface.

Following a previous work in which PGC columns were explored under high temperature LC conditions [1], the present research focuses on the investigation of the same column under High Temperature Supercritical Fluid Chromatography.

A new instrument configuration has been developed in this study: an SFC system was used. This instrument was interfaced to a GC oven, to heat the PGC column up to 200° C. In this prototype instrumentation, in order to achieve a fast and efficient heating of the eluent coming from the autosampler prior to enter into the column, a pre-heating tube was interposed between the autosampler outlet and the column inlet.

Homologue series of parabens, nitroalkanes and pairs of cis-trans isomers were used as *probes*. The performance of the analytical method was evaluated in terms of retention factor, number of theoretical plates per meter, resolution, peak width, and tailing factor.

Moreover, the greenness was quantitatively estimated to demonstrate the further advantage arising from the use of SFC under high temperature conditions to enhance selectivity and method rapidity, minimizing the use of organic modifier.

lcucinotta@unime.it

Diabetes prevalence is steadily increasing worldwide, estimated to reach over 300 million cases by 2030. Despite the significant progress made using oral anti-diabetic agents, current treatments are far from perfect, requiring to find novel viable alternatives. In this regard, recent studies have shown that some spices and herbs are active in reducing high blood glucose, thanks to the biological activities of the volatile fraction[1]. In this respect, the anti-hyperglycemic effects of sesquiterpenes received attention, since they intervene on biochemical pathways deranged in diabetes mellitus[1]. Among this class of compounds, *β*-caryophyllene (BCP), a volatile sesquiterpene component, has gained interest because of its abundant occurrence, non-psychoactive nature, and dietary availability through consumption of edible plants, including spices.

In this study, an advanced analytical characterization was carried out to define the chemical composition of spices' essential oils, such as black pepper, prior to biological assays. While the quali-quantitative profiling was defined by means of gas chromatography coupled to mass spectrometry (GC-MS) and to flame ionization detection (GC-FID), a deeper investigation about the chiral components was carried out through multidimensional gas chromatography. Moreover, in order to clarify the presence of target components responsible for the therapeutic effect, a preparative GC method was developed. In order to collect the highest amount of target fractions per analysis, wide bore capillary columns were exploited, allowing a consistent reduction in terms of total time analysis. In a first step, this system allowed the efficient isolation of essential oils' sub-fractions, e.g monoterpenes and sesquiterpenes, to be tested with antidiabetic assays. Secondarily, according to the biological results, target components of each sub-fraction have been isolated by means of preparative multidimensional gas chromatography, in heart-cut mode, aiming to demonstrate synergic biological effects.

Acknowledgments: The project was funded by the Italian Ministry for the University and Research (MUR) with a "PRIN: Progetti di ricerca di rilevante interesse nazionale Bando 2022" Project n. 2022359CZA "Advanced analytical characterization and synergic evaluation of volatile terpenes of selected β-caryophyllene containing spices for diabetes treatment".

Multi-analyte method for biomonitoring studies: legacy and emerging pollutants in human serum

R. Comito[a], E. Porru[a], J. Fiori[b], F. S. Violante[a]

[a]*Department of Medical and Surgical Science, Alma Mater Studiorum, University of Bologna, via P. Pelagi 9, 40138-Bologna, Italy*
[b]*Department of Chemistry "G. Ciamician", Alma Mater Studiorum, University of Bologna, via Selmi 2, 40126-Bologna, Italy*
rossana.comito2@unibo.it

Environmental research and public health in the 21st century face numerous challenges including the widespread use of substances potentially harmful to humans. Among the various anthropogenic pollutants present in the environment, persistent organic pollutants (POPs) such as polychlorinated biphenyls (PCBs), are particularly concerning due to their adverse effects on human health and wildlife[1]. However, restrictions have led to the emergence of new chemicals now referred to as "emerging contaminants" (ECs), such as novel brominated flame retardants (nBFRs).

The urgent need to gain a comprehensive understanding of everyone's exposome intersects with the necessity to assess how and how much chemicals are absorbed from the environment into the organism itself, along with the practical question of the methodology applied to measure the exposome. In this context, human biomonitoring (HBM) plays a crucial role in establishing exposure and risk assessment[2].

To contribute to the full characterization of the exposome, a new gas chromatography-mass spectrometry (GC-MS) method was developed to analyze target compounds in serum samples. A broad spectrum of legacy and emerging contaminants, such us PCBs and nBFR, were included.

The Design of Experiments (DoE) concept was utilized to optimize the MS assay, as well as critical methodological aspects such as chromatography separation, method sensitivity, and the extraction procedure of the contaminants. A validated model allowing the estimation of conditions for optimal chromatographic analysis was constructed through chemometric evaluation of the data. The proposed method was validated to achieve high analytical performance in terms of selectivity, linearity (R2 >0.995), accuracy (bias%≤ 10%), precision (CV%≤ 10%), robustness, ruggedness, limit of detection, limit of quantitation, recovery, matrix effect, and repeatability according to the international guidelines.

The developed method represents a powerful tool that can be used in HBM to investigate the impact of pollutants on human health and to expand the still limited knowledge on ECs. This method will be useful in future applications in the field of HBM, for example, involving subjects at high risk of exposure, to assess potential correlations between pollutant levels and disease development.

Extracellular vesicles (EVs) are key players in cell communication and immune regulation and impact tumor growth and therapy resistance: investigating their composition is essential for unraveling the mechanisms behind malignancy regulation. Characterization of EVs from plasma, a complex biological fluid, needs EV isolation, a challenging process due to their small size, high heterogeneity and low concentration. Common isolation techniques including ultracentrifugation, Size-Exclusion Chromatography (SEC), and ultrafiltration demand significant sample volumes (hundreds of µl) and can compromise the structural and biological activity of EVs by potentially causing damage.

Here we present a bivalent approach exploiting a Hollow-Fiber Flow Field-Flow Fractionation (HF5) system to isolate EVs from plasma and as a tool for performance separation control of commonly used EV isolation techniques, such as SEC. The latter is justified by HF5 ability to provide soft and native separation not achievable by other techniques. Assessing EVs content and size was possible thanks to the spectroscopic, light scattering and fluorescent detectors coupled with the separative system. We previously presented a methodology able to select EV-enriched fractions from human serum for online microfluidic biosensing[1], that in this work we transferred to collect vesicles from the plasma of healthy donors. EVs were both collected from plasma via a standard SEC protocol and through the optimized HF5 separation system, then both samples were re-analyzed with the HF5-multidetection platform to obtain a direct comparison of the profile, relative size and abundance, and aggregation state of the isolated EVs.

SEC- and HF5-derived EVs showed differences in population size and vesicles and protein amount; except for the presence of aggregates in SEC-EVs compared with HF5-EVs, no generalized differences between the two isolation methods were measured, while it emerged a high biological variability from donor to donor.

Isolated EVs were also characterized via Western blot and were positive for markers including ALIX, confirming the presence of specific EV markers. In addition, Flow Cytometry demonstrated the expression of EV marker (CD9, CD81) and platelet-associated markers (CD41a, CD42b) in EVs from both techniques.

irene.coralli2@unibo.it

Microplastic (MP) contamination has been extensively studied, while smaller particles known as nanoplastics (NPs, 1 nm – 1 µm) have been less investigated due to analytical challenges. NPs are generating more concern than MPs because of their potential to interact with organisms at cellular level. Furthermore, they are characterised by a high surface area and strong binding affinity, which enable the absorption of substances. This process can alter the particle's identity within the exposure media trough the formation of the so called eco/bio-corona (EC), a matrix-dependent layer strongly bound to the particle's surface, which may amplify their affinity with organisms. To date, the nature, formation and consequence of the EC on particle's identity remain largely unexplored. However, the investigation of these aspects is of outmost importance to trace M/NP's biodistribution. The present study aims to advance the understanding of the interaction between NPs and pollen. Recent findings indicated the presence of MPs on honeybees, suggesting that M/NPs may be transported by bees along with pollen. To the best of our knowledge, a limited number of studies involve NPs analysis in complex matrices and no studies have been conducted on pollen. To fill this gap, we propose a multi-technical approach. Asymmetrical Flow Field-Flow Fractionation (AF4) allowed hydrodynamic size-based fractionation of species, enabling the separation of fractions of NPs, pollen and their mixture. On-line multi-detection using Diode Array, differential Refractive Index and Multi Angle Light Scattering (MALS DAD-dRI-MALS) provided a size, morphological, and spectroscopical characterization of the fractions. Pyrolysis coupled with Gas-Chromatography and Mass Spectrometry (Py-GC-MS) provided the off-line chemical characterisation at molecular level of NP/pollen media. The development of appropriate pre-treatments of AF4 fractions to obtain samples amenable for quali-quantitative Py-GC-MS was the most challenging aspect. The on-line approach has allowed us to characterize the size modification that NPs undergo in the presence of the water-soluble macromolecular pollen species, as well as to assess the formation of EC around the particles. The off-line coupling with Py-GC-MS enabled the chemical characterization of pollen species and NPs, showing the potential to provide insight of the EC composition. Overall, this work represents the first effort in studying how NPs change in a complex matrix, such as an aqueous pollen environment, rather than their mere identification. Increasing and deepening the information in this field can help in elucidating the impact of the EC and NP/matrix interactions on the behavior of NPs in the environment.

alberto.cerchiai@phd.unipi.it

Chemoresistive sensors utilizing metal oxide semiconductors represent one of the most prevalent technologies for gas detection. These sensors are simple and low-cost devices but at the same time capable of rapidly detecting extremely low gas concentrations; on the other hand, they lack sensitivity and need to operate at high temperatures[1]. They are widely employed in various fields such as environmental monitoring, industry safety, and medical diagnostics[2]. In this study, we conducted a comparative analysis of the response exhibited by chemoresistive sensors based on pristine and doped CeO_2 prepared following two distinct fabrication methodologies. The first approach utilized Flame Spray Pyrolysis (FSP), enabling the synthesis and direct deposition of CeO_2 nanoparticles onto interdigitated electrodes (IDEs) through the combustion of liquid precursors in a flame. Additionally, CeO_2 nanoparticles were also synthesised via conventional wet-chemistry and sol-gel processes and deposited onto IDEs via drop-coating and spin-coating. CeO_2 nanoparticles were chemo-physically characterised using XRD, IR, DLS, BET, TGA, UV-Vis and ICP techniques to investigate their composition, dimensions, surface area, thermal stability, and band gap. Subsequently, the sensors were subjected to various gaseous analytes, and their performance was evaluated by comparing the outcomes of the different synthesis and deposition approaches. The most promising sensors showed selectivity to methanol over ethanol and to xylene over toluene and benzene; furthermore, Pd-doped CeO_2 sensors were found to be able to detect down to 150 ppb of hydrogen at room temperature.

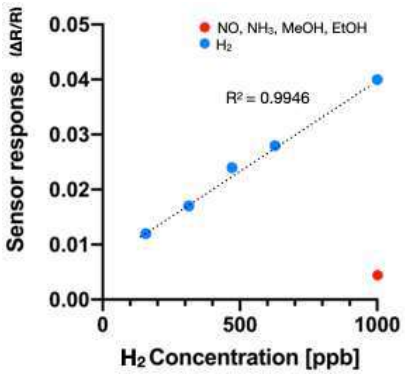

Figure1: Pd-doped CeO_2 sensors prepared with FSP, showing sensitivity to H_2 and absence of any interferences.

Point-of-care sensing devices are crucial tools in assisting clinicians with fast analyses, easy management, and painless monitoring of patient diseases. Indeed, these sensing tools closely align with the ASSURED criteria set by the World Health Organization, where ASSURED stands for affordable, sensitive, specific, user-friendly, rapid, equipment-free, and deliverable to end-users. This concept was further updated to REASSURED, highlighting the real-time connectivity and ease of specimen collection.
In the last decade, the fabrication of innovative point-of-care sensors has extensively exploited the multifarious functionalities of paper, mainly based on its intrinsic properties such as porosity, capillary forces, and easy modification. Indeed, the paper has attracted considerable attention from the scientific community for electrochemical sensor development due to its numerous advantages, including the absence of external equipment for solution flow, the fabrication of reagent-free devices, and the easiness of multistep analyses using an origami approach. A crucial point of paper usage is its loading capability, enabling the storing of the reagents needed for the analysis. Thanks to this capability, it is possible to expose the paper-based sensor to aerosols, including breath, allowing for the wetting of the paper, with the consequent dissolution of the stored reagents. This allows for the use of exhaled breath aerosol as an analysis matrix, having the advantage of the easiness of its sampling by simply incorporating collecting paper into a face mask worn for some time.
In this overall context, we are developing a whole-paper-based analytical tool for hydrogen peroxide detection in exhaled breath, taking into account the high level of H_2O_2 in lung-associated diseases. In this work, we leverage the use of an office-paper electrochemical screen-printed electrode and a flower-like paper collector integrated into a face mask. In detail, the use of the paper-based collector enables the non-invasive sampling and the further treatment-free analysis of the biological sample carried out by the screen-printed electrode. This electrochemical sensor is ad-hoc modified with carbon black-Prussian Blue nanocomposite, enabling the reliable detection of hydrogen peroxide in the collected condensed aerosol breath. The applicability of the flower-like paper collector is under investigation, considering important features comprising the size, the thickness, and the shape, while the screen-printed sensor is under optimization, taking into account parameters such as linearity range, limit of detection, selectivity, and accuracy.
In conclusion, the proposed analytical platform has the potential to open up new possibilities for the design of face masks as active devices for breath analysis, aiming to facilitate health management and improve the quality of patient life.

Chronic wounds, defined as those persisting beyond three months without healing, pose a significant challenge to the healthcare system, exerting a substantial toll on patients' quality of life and necessitating considerable treatment resources. Parameters such as pH and temperature serve as valuable indicators of wound status and its progression towards healing, as these parameters usually decrease as the wound progresses towards healing [1]. In this work, a potentiometric pH sensor with integrated thermistors was devised to monitor both pH and temperature of a wound (Figure 1). The sensor fabrication involved electropolymerization of polyaniline onto a carbon screen printed electrode, which served as the pH-sensitive material. Furthermore, modification of the Ag/AgCl reference electrode with a poly-acrylic acid hydrogel was implemented to enhance both its electrical stability and adhesion to the skin. The sensor exhibited a linear response across the pH range of 3 to 10 in both liquid solutions and on pH-controlled semi-solid agar plates, effectively encompassing the potential pH variations in real wound scenarios. Finally, this sensor was able to measure pH of a real sample of wound exudate with an error within ±0.2 points of pH when compared with the results obtained with a reference glass electrode.

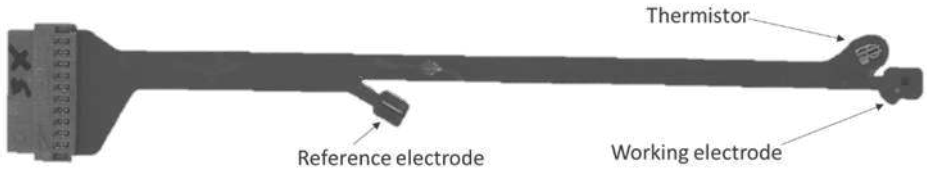

Figure 1: A picture of the potentiometric sensor.

Novel low-cost sensor for water pollution monitoring based on Raspberry Pi

A. Boldrini[a], A. Polvani[a], R. Cirrone[a], S. Loiselle[a].

[a]*Environmental Spectroscopy Group, Department of Biotechnology, Chemistry and Pharmacy, University of Siena, Via Aldo Moro, Siena, Italy*

Dissolved organic matter refers to a large pool of molecules present in freshwater environments, a major fraction of which are optically active, allowing them to be used as proxies for the analysis of changes in water quality[1]. Monitoring typically involves in-situ sampling and laboratory analysis (using spectrophotometer and fluorometer) or calibrated sondes, both of which present a number of analytical (scattering, transport) and practical (cost, calibration) challenges for large scale studies. Although different low-cost sensors working in the UV-Vis range have been recently developed, their performance have not been sufficiently validated and the results of the analysis still require additional equipment for data sharing[2]. Herein, we present a Raspberry Pi based low-cost sensor with a light emitting diode (LED) as RGB light source and light dependent resistors (LDR) for the visible light while for the ultraviolet region a modular UV-light sensor. The single-board computer (Raspberry Pi Zero W) performs calibration, data processing and datasharing, allowing for real-time in-situ measurements of chromophoric and fluorescent dissolved organic matter for water quality assessment. Data acquired from the sensor were compared with a laboratory spectrophotometer, showing high accuracy and precision. The low cost organic matter sensor is currently at a technology readiness level 4.

serena.reale@phd.unipi.it

Background: The introduction of Trikafta therapy has significantly improved the quality of life for individuals affected by cystic fibrosis (FDA approved in late 2019).[1] We investigated the possible effects of Trikafta therapy on exhaled breath chemical composition which may allow to obtain clinically relevant information about disease and treatment progression directly from the breath samples.

Methods: Mixed breath samples were collected at the University Children's Hospital Zurich from 19 patients (12-18 years) in 2L handmade Nalophan bags. An aliquot (250 mL) of breath was transferred at 50 mL/min into sorbent tubes (packed with 250 mg of Tenax GR 60/80 mesh)[2] and then analysed with thermal desorption unit (TD) coupled with a comprehensive two-dimensional gas chromatography (GCxGC) connected to a quadrupole time-of-flight mass spectrometer (Q-TOF).[3]

Results: We could tentatively identify 166 molecules which were significantly increased for the breath vs. room samples. We investigated the differences in breath chemical composition during Trikafta therapy (ANOVA with post-hoc t-test with p-value < 0.01) which resulted in 25 significantly different compounds (12 endogenous, 3 unknowns, 10 anthropogenic). The endogenous breath volatiles were mainly related to energy metabolism and often lipid peroxidation (Figure 1).

Conclusion: We can report significant differences in exhaled breath molecules after Trikafta therapy.

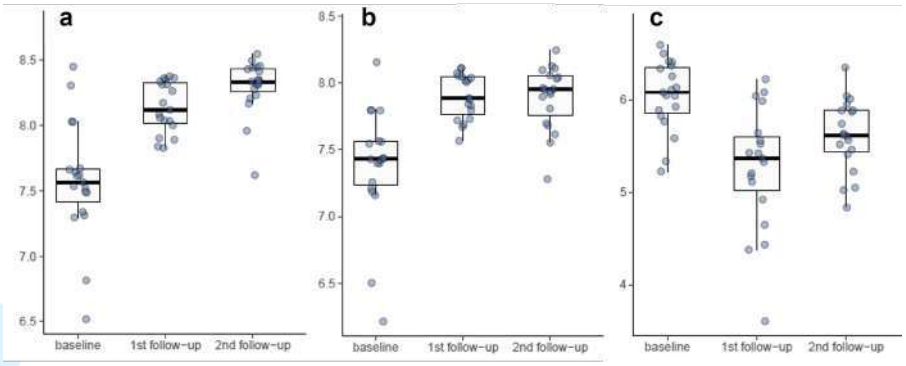

Figure 1: Box plots for three endogenous compounds with: a) acetone, b) pentane, and c) methyl octanoate.

The presence of emerging microcontaminants, including organic UV filters (OUVAs), has been detected worldwide in the aquatic ecosystems. These pollutants, originated from various anthropogenic sources, can persist and transform within wastewater treatment plants (WWTPs)[1], posing a potential environmental hazard.

In this framework, this research presents an innovative electrochemical sensor based on molecularly imprinted polymers (MIPs) for the selective detection of Benzophenone-3 (BP-3), one of the OUVA most spread in the aquatic environment[2], to overcome the analytical challenges related to the quantification of this class of contaminants in wastewater samples.

Different monomers, gold screen-printed electrodes and cyclic voltammetry conditions were tested to select the best parameters for the electropolymerization of the MIP layer. The template washing step, polymer surface blocking and analyte rebinding conditions were also optimized to maximize the selectivity and sensitivity. Electrochemical detection was performed using electrochemical impedance spectroscopy (EIS) supported by an electrochemical probe. In addition, cross-reactivity tests were carried out in the presence of possible interferents, selected on the basis of their size, chemical structure and occurrence in wastewater samples. All the tests were conducted in parallel, using both MIP electrodes and non-imprinted polymer (NIP) electrodes. The sensor demonstrated a significant selectivity for the target analyte, showing an imprinting factor of 55, a linear range between 0.01 and 1 µM and a limit of detection of 5 nM.

The sensor has also been tested with real WWTP effluent samples previously spiked with a known concentration of BP-3, demonstrating no compromised analytical performance despite the complexity of the matrix.

In conclusion, the study showed interesting results that may lead to a specific and cost-effective approach, allowing widespread monitoring and supporting early detection of the target compound in wastewater samples.

Detecting and identifying pathogenic microorganisms is a matter of critical importance, due to the significant impact of them on both healthcare systems and economies. Laser-Induced Graphene (LIG) is a novel promising material that stands out and attracts interest due to its many properties, including mechanical resistance, high surface area, and easy and streamlined production processes[1]. These attributes have opened possibilities to develop low-cost and portable devices that can fulfill the needs of point-of-care applications. In this work, a LIG electrode (Fig. 1A) covalently functionalized with two different aptamers (P12-55 and P12-31[2]) was used for the development of an aptasensor for detecting E. coli. Using electrochemical impedance spectroscopy, the change in the charge transfer resistance (R_{CT}) of the aptasensor was monitored upon interaction with bacteria. The aptasensor showed a linear response in the presence of E. coli within 10^0 – 10^2 CFU/mL when tested in phosphate buffer saline (PBS) solution. Notably, the biosensor displayed minimal response in presence of Staphylococcus aureus and Pseudomonas aeruginosa, proving to be selective for E. coli. Furthermore, the sensor was calibrated using urine samples spiked with a known concentration of E. coli cells (Fig. 1B).

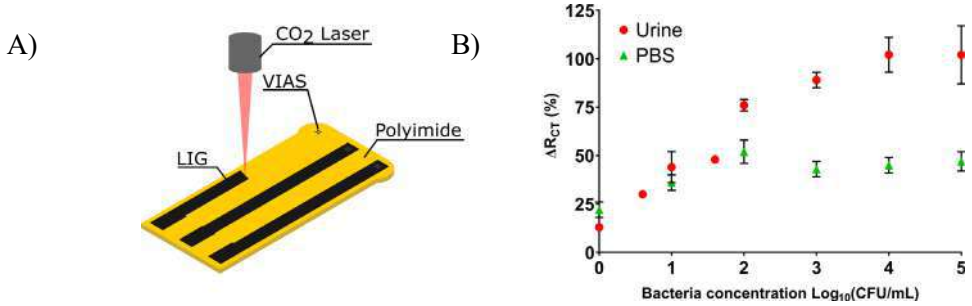

Figure 1: A) LIG electrodes scribed on polyimide. B) Calibration curves at increasing concentration of E. coli in phosphate buffer saline and in urine.

greta.peruzzi@uniroma1.it

In the last decades, several colorimetric sensor arrays have emerged as low-cost optoelectronic devices for the detection of various compounds. Among these, a class of sensors based on noble metal nanoparticles (NPs) has recently gained great interest. Gold and silver NPs, functionalized with specific receptors, have demonstrated to be powerful tools for trace detection of analytes of interest in various fields, including the food industry, environmental chemistry, and cultural heritage conservation.[1] These sensors exploit Localised Surface Plasmon Resonance (LSPR), offering remarkable advantages for analyte detection at exceptionally low concentrations. The mechanism behind these sensors relies on variations in the LSPR through NPs aggregation occurring upon the presence of the analyte, resulting in a shift of the plasmonic absorption and the corresponding colour change.

Another application of NPs, still based on LSPR and well-developed for trace-detection, is Surface Enhanced Raman Scattering (SERS) spectroscopy, consisting of the great amplification of the Raman signal of analytes in proximity to the metal NP. SERS is a powerful analytical technique that provides detailed information about the chemical composition of materials. It has applications in the conservation of cultural heritage objects, and has been already employed for the identification of molecule-specific fingerprint signals in a wide range of applications. The need for sustainable, uniform and flexible SERS platforms [2] has led to introducing metal NPs into polymeric brushes, opening new perspectives for composite nanostructured materials featuring unique mechanical, electrical and optoelectrical properties. Additionally, the gel-brush network has demonstrated to stabilise the NPs and induce their uniform spatial distribution.[3]

We report here on the synthesis and characterization of a new sustainable sensor made of properly functionalized silver nanoparticles (AgNPs) fixed on a polymeric substrate, to be used both as a sampling device and detection system. Different synthetic pathways were experimented, while the substrates were characterised through microscopic and spectroscopic techniques. The SERS performances were tested for probe molecules, which showed a potential for low concentration detection, potentially applicable on analytes of interest for different matrices.

laura.sforzi@unifi.it

The increasing amount of microplastics (MPs) in the environment has raised serious concern about human exposure to MPs in food. Several methods have been developed to extract and detect MPs in food matrices[1]. However, complex matrices, such as those rich in lipids, often require multiple pretreatment steps that, while not affecting the detection of other organic compounds, can lead to sample contamination and reduce recovery rates for MPs analysis. In addition, the presence of lipid material often inhibits filtration processes and compromises the potential chemical characterization of polymers by forming a lipid layer that can absorb radiation.

Here, several multi-step analytical protocols were optimized and validated to extract and purify MPs from different lipid-rich matrices from species suitable for human consumption, such as eggs and fish. First, the lipid content of each matrix was evaluated by gravimetric analysis. Then the most suitable digestion method was evaluated, from basic oxidative digestion to more elaborate enzymatic processes. Recoveries and precision (RSD) were calculated using standards. In addition, the efficiency of the digestion treatment to remove lipid matter was estimated through the compatibility of using μFTIR spectroscopy to chemically characterize the spiked standards. Spectroscopic analysis also allowed the integrity of the polymers to be assessed after the digestion treatment. Quality assurance and quality control were assessed through the entire processes. With the ability to remove all interfering materials, it will be possible to characterize MPs and thus provide an accurate ecological risk assessment on edible species[2].

The presence of MPs in food can pose a risk to human health and animal because of their potential bioaccumulation in organisms and their ability to act as a carrier for other toxic chemicals. Therefore, the validation of methods that accurately detect the presence of MPs in complex matrices such as food is crucial.

Microfluidic thread-based analytical devices (µTADs) are emerging as a new attractive platform for analytical assays due to their advantages in point-of-care (POC) settings such as their large availability, their light weight as well as their low cost. In particular, thread substrate is seen as a valid alternative to microfluidic paper-based analytical device (µPAD) that instead require hydrophobic barriers for the formation of microchannels and show lower mechanical strength, limiting their practical applications in POC assays[1]. Moreover, the µTADs flexible design achieved by sewing, knitting, weaving or twisting them and their small scale offers the possibility to work with reduced sample volumes[1]. All these features make thread-based devices sustainable analytical tools in accordance to the principles of green chemistry[2]. We report a proof-of-principle application of bio-chemiluminescent biosensing on cotton threads (fig. 1a). We first designed a bioluminescent (BL) thread biosensor in which the light-emitting molecule and the enzyme are immobilized onto two separate threads after twisted together to trigger the reaction. This spatial separation increases the shelf-life of the device and the possibility of quantifying different analytes in a small-volume sample (2 µL) in short time (5-10 min). The preliminary tests were performed for detecting ATP, used as indicator for microbial contaminants in food or hygiene monitoring[3]. In parallel, a thread-based chemiluminescent (CL) device which, to the best of our knowledge, has not been reported in literature yet, was tested. In this case, preliminary tests were performed exploiting the enhanced luminol/H_2O_2/horseradish peroxidase (HRP) CL system (fig. 1b), which can be adapted for different diagnostic applications such as the monitoring of the lactate levels for sport medicine[4]. To prompt future applications in point-of-care and point-of need settings we implemented smartphone detection for easy monitoring of the microfluidic thread-based analytical devices.

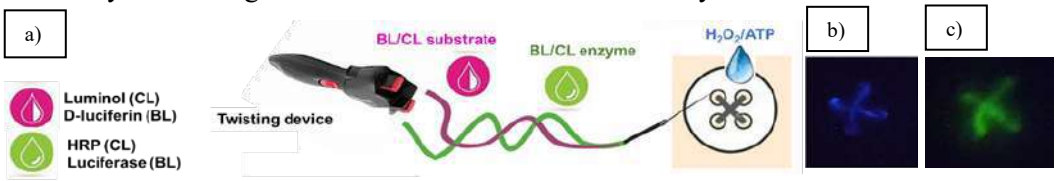

Figure 1: a) Scheme of the optimized thread-based BL-CL biosensor. b) and c) Respectively, BL and CL signals obtained with OnePlus 5 smartphone camera at 3200 ISO settings (30-s acquisition time).

arianna.ghignone@uniupo.it

Per- and poly- fluoroalkyl substances (PFAS) are a large group of compounds consisting of a hydrophobic carbon chain, partially or fully fluorinated, and a terminal hydrophilic group, such as a carboxylic acid, sulfonic acid, amine, or other. PFAS have been used in industry and consumer products since the 1940s because of their useful chemical and physical properties[1] due to their molecular structure. The highly fluorinated portion of the molecules brings them to not degrade through normal chemical, physical, or biological processes[2]. Despite being an attractive industrial property, perfluorocarbon resistance to degradation raises concerns about environmental fate and human health impact[3]. In humans, these substances are not metabolized, but they have a high affinity for proteins and are mainly found in biological samples such as plasma, serum, milk, and tissues[3]. Therefore, biological monitoring of traditional and emerging PFAS is a useful approach to conduct an integrated and representative screening of human exposure to these substances. The purpose of this project was precisely to develop and optimize an analytical method for the determination of different chemical classes of PFAS in serum, using liquid chromatography coupled with high-resolution mass spectrometry (UHPLC-HRMS, equipped with an Orbitrap mass analyzer). A particular focus was set on sample pre-treatment, which proved to be critical in breaking the bonds between proteins and PFAS in order to achieve good recoveries (between 80% and 120%). Pre-treatment was optimized by trying different types of solvents and a washing step after protein precipitation. After this, the optimal conditions were defined using Principal Components Analysis (PCA). Subsequently, the instrumental method (UHPLC-HRMS coupled with online-SPE) was optimized, starting with the online-SPE and the chromatographic conditions and then moving to the conditions concerning mass spectrometry. Validation of the method was performed in accordance with ISO 17025 evaluating linearity, inter- and intraday precision, LOD, LOQ recovery and matrix effect. Control charts were also used to estimate the stability of the instrument. Using this method, more than 25 traditional and emerging PFAS were determined. The method has been tested on real samples to accurately quantify the concentration of these substances in human serum.

This work has been developed in the framework of the SCENARIOS project (funding program H2020, project ID 101037509).

Development and optimization of a method based on online-SPE coupled to UHPLC-HRMS for the determination of per- and poly- fluorinated substances in water

A. Fabbris,[a] E. Robotti,[a] M. H. Belay,[a] A. Ghignone,[a] E. Marengo[a]

[a]*Università del Piemonte Orientale, Viale Teresa Michel 11, Alessandria*

alessia.fabbris@uniupo.it

Per- and poly- fluoroalkyl substances (PFAS) are a large group of synthetic chemicals, which represent an important class of emerging contaminants[1]. These compounds are characterized by highly fluorinated alkyl chains that may also contain different functional groups depending on their use. In the last fifty years, they have been used in several industrial sectors and currently, over 9000 compounds belong to this class.

Due to their unique physicochemical properties, they are generally characterized by high persistence in the environment, making PFAS contamination a serious environmental problem. Nowadays, PFAS are widespread in the global environment, including wildlife and humans: they have now been detected at trace levels in both the environment and biota, including water[2]. Dietary intake (from drinking water and food) is considered the main pathway of human exposure to these substances[3], and it can lead to immune, fertility and endocrine dysfunctions. For this reason, it is extremely important to assess the degree of PFAS contamination of waters.

The aim of this work is to develop a method based on online solid phase extraction (online SPE) and high-performance liquid chromatography coupled to high resolution mass spectrometry (UHPLC-HRMS) for the simultaneous determination of almost 40 PFAS in water. The validation was carried out according to ISO17025 and the analytical method was further applied to the analysis of real water samples. Recent studies normally found in the literature concerning the use of online SPE include the simultaneous determination of a restricted number of PFAS substances[4], whereas this work aims to broaden the number of compounds determined simultaneously to include more emerging substances and putting efforts in increasing the sensitivities. This may then facilitate analyses for environmental monitoring and perhaps promote future regulations, especially regarding relatively newer compounds.

The work is conceived within the framework of the SCENARIOS project, which is funded by the European Union's H2020 programme (Grant Agreement No. 101037509).

NIAS migration from polymeric materials in contact with dry food: optimization and validation of the extraction procedure

M. Roncoli,[a] E. Conterosito,[a] M. Ferretti,[a] V. Gianotti,[a]

[a] *Department of Sviluppo Sostenibile e La Transizione Ecologica, University of Piemonte Orientale, Piazza S. Eusebio 5, 13100 Vercelli*
maddalena.roncoli@uniupo.it

The release of Non-Intentionally Added Substances (NIAS) from polymeric articles into food poses a health risk. This scientific work was focused on the optimization of a analytical method that allows the identification and quantification of NIAS migration which could occur following contact of a silo's polyurethane gasket intended for dry food contact. The migration of aniline, acetyltributylcitrate, bis(2-ethylhexyl)adipate, 2,6-tertbutylhydroxytoluene (BHT) and 1,4-butanediol from this polymeric manufact was studied.

Migration tests were carried out as indicated by law regulation (EU Regulation 10/2011) simulating the worst conditions inside the silo [1], using Tenax as appropriate food simulant [2], and directly on real dry food (rice, flour, powdered milk, cocoa powder, sugar, corn starch). The analytical method is based on GC-MS analyses. During the method development phase, based on some articles in the literature, several analytical criticalities were evidenced. The most critical were the presence of matrix effect for several real dry food and some very low recovery yields. With the aim of overcoming the problems mentioned, an extraction method has been developed which involves the smallest number of steps possible and avoids the loss of the analytes through volatilisation. Finally, the extraction yields were evaluated and the correct migration values were calculated by external calibration or, where required, employing the standard addition method. Finally, the entire primary validation procedure is performed on the optimized method (Figure 1).
The results obtained show how the process is influenced not only by the chemical nature of the migrant, but also by the physical-chemical nature of the simulant or of the food matrix used.

daniele.tanzilli@unimore.it

In industrial processes, guaranteeing the high quality of final products is crucial. For this purpose, it is essential to identify the process phases that mostly affect product quality parameters in order to accurately estimate them before the process is completed. This not only helps to minimize waste and losses, but also enhances environmentally friendly manufacturing practices.

The case-study presented here concerns the industrial production of Acrylonitrile-Butadiene-Styrene (ABS). ABS is currently synthesized through a nine-stage process monitored using multiple sensors installed in different areas of the plant and that acquire physical (temperature, pressure, flow rate measurements) and chemical (near-infrared spectra) information during its progression. The objective of this work is to determine at which process stage the information acquired is sufficient for a correct prediction of ABS quality. To this end, various multivariate regression methodologies (namely, Partial Least Squares – PLS – Local-Weighted PLS – LW-PLS[1] – MultiBlock PLS – MB-PLS – Locally Weighted MultiBlock-PLS – LW-MB-PLS – and Response-Oriented Sequential Alternation – ROSA[2]) will be employed to model the ensemble of data blocks resulting from all the process phases in an incremental fashion. In other words, these different data blocks will be sequentially gathered and processed as if they were collected in real time during ABS manufacturing. By assessing how the predictive performance of the aforementioned regression methodologies evolves as the amount of available information increases, this approach will permit to highlight whether satisfactory estimates of ABS quality can be obtained before the end of the production process and, as outlined before, at which exact stage of its time evolution.

Recycled cellulose acetate microspheres doped with graphene oxide for the determination of xenobiotics from human urine via in-syringe-dispersive-solid phase extraction

M.G. De Cesaris[a], L. Antonelli[a], S. Grasso[a], A. Gentili[a]

massimogiuseppe.decesaris@uniroma1.it

Biopolymers are a suitable starting point for the development of sustainable sorbent materials thanks to their environmental friendliness, low toxicity, recyclability, and biodegradability. Moreover, most of them can be recovered from waste products, such as cellulose acetate from filters of cigarette butts. Although overlooked until recently, cigarette butts are harmful litter with dramatic effects on the environment being a source of contaminants and bioplastics, namely cellulose acetate. In fact, it was estimated that globally about 6 trillion cigarettes are smoked each year, 70% of which end up polluting terrestrial and aquatic ecosystems.
Looking at this worrying background, this study aimed at: i) developing an effective procedure to recover cellulose acetate from cigarette butt filters; ii) using the recovered biopolymer to prepare a microspheres in which graphene oxide can be dispersed; iii) applying the composite sorbent to isolate xenobiotics from human urine via in-syringe-dispersive-solid phase extraction.
The initial phase of the research was focused on obtaining clean cellulose acetate from cigarette filters. This was achieved by eliminating wrapping paper and unburned tobacco and washing the filters with hot water and hot ethanol to remove most impurities generated during cigarette combustion. The efficacy of the cleaning process was confirmed by characterizing the washed polymer by UV spectroscopy, attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR), and thermal analysis (TGA, DSC), and comparing the results with those from pristine cellulose acetate (obtained from unsmoked cigarette filters) taken as a reference. The synthesis of the composite sorbent took advantage of a microemulsion-solidification process in which the organic polymer solution was first forced to a fine dispersion in a saturated water solution of NaCl and n-dodecyl-amine (2% w/v); later on, the polymer was precipitated in form of microspheres shaped by the addition of milli-Q water drop by drop. The sorbent was characterized by ATR-FTIR, TGA and SEM, confirming the graphene oxide dispersion and its morphological characteristics (average diameter = 10-100 µm).
Finally, the microbeads were applied for the determination of several potential xenobiotics (63 analytes from different chemical classes) detectable in human urine performing in-syringe solid phase extraction. In this configuration, the sorbent was packed into a syringe and the device was used to carry out a low-cost, saving-time, simple, and effective method.

Synthesis of α-, β- and γ-cyclodextrin-based nanosponges as sustainable sorbents for the extraction of pesticides from water samples

N. Felli,[a] *I. Francolini*,[a] *L. M. Migneco*,[a] *A. Gentili*[a]

nina.felli@uniroma1.it

As recommended by the first principle of Green Analytical Chemistry (GAC)[1], direct analyses are the viaticum for sustainable methods. Nevertheless, in cases of analytes present at trace level and/or interfering compounds, a sample pretreatment is essential and, according to the 3rd criteria of Green Sample Preparation[2], sustainable, reusable, and renewable materials are the most attractive alternative to polymeric sorbents. From this point of view, cyclodextrin nanosponges (CD-NS) are biosorbents responding to all these requirements, being harmless, biodegradable, and biocompatible materials, based on CDs which are natural degradation products of the starch (one of the most abundant biomasses in the world)[3]. In this work, CD-NS were prepared by using α, β and γ-CD as the monomers; citric acid as the cross-linker and NaH2PO4 as the catalyst. Such reagents were homogeneously dispersed in the minimum volume of water and the polymerization was carried out at 160°C. The final products showed the distinctive morphology of a sponge and were characterised by means of thermal analysis (TGA, DSC), IR spectroscopy, and SEM imaging. Afterwards, α, β and γ-CD-NS were applied for the dispersive-solid phase extraction of pesticides from environmental water samples. In line with the 8th principle of GAC (multi-analyte or multi-parameter methods are preferred to methods using one analyte at a time) [1], eleven pesticides, belonging to different chemical classes and also including optical and geometric stereoisomers, were considered. In particular, after optimizing the best extraction conditions, the behaviour of the different sponges towards the target analytes was evaluated in terms of recoveries and reproducibility. The analyses were performed by high performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS) on a cholesteryl analytical column and on a chiral polysaccharide-column to assess the potential capability of stereo-discrimination of the different nanosponges.

Enhancing the specificity of CRISPR-based Sensing Platform via Triplex DNA Probe

A.C. Di Pede [a], A. Palone [a], E. Belforte [a], M. Rossetti [a], N. Bagheri [a], A. Porchetta [a]
[a] *Department of Chemistry, University of Rome, Tor Vergata, Via della Ricerca Scientifica 00133, Rome, Italy*
andreaceleste.dipede@students.uniroma2.eu

The last years have seen the emergence of Class II CRISPR-based diagnostic technologies as potent molecular diagnostic tool.[1] Among the different Cas effectors CRISPR-Cas12 incorporate both DNA target recognition along with enzyme reconfiguration, activating not only the well-known site-specific cleavage activity but also the collateral a-specific cleavage. As a result, in the presence of FRET-based DNA reporters, this collateral activity generates fluorescence signal amplification upon target binding, enabling highly sensitive diagnostic assays.[2] Cas12a-based detection, however, still exhibits limited specificity in detecting single base mutations on the DNA target.

We present a method to overcome this limitation by utilizing a carefully designed DNA-based hybridization network to switch Cas12a cleavage activity on by combining the superior selectivity of Triplex Clamp-switch probes for DNA/RNA detection.[3] Specifically, the formation of Triplex Clamp-switch probes occurs only in the presence of a homopurine DNA/RNA target in the solution. This triggers the reconfiguration of the DNA-based hybridization network, activating Cas12a's collateral activity and generating a concentration-dependent fluorescence output. By adjusting the pH, we are able to fine control the selectivity of a single mutant base on short DNA targets. This demonstrates how crucial well-planned secondary structures are to enhancing CRISPR-based systems' detection capabilities.

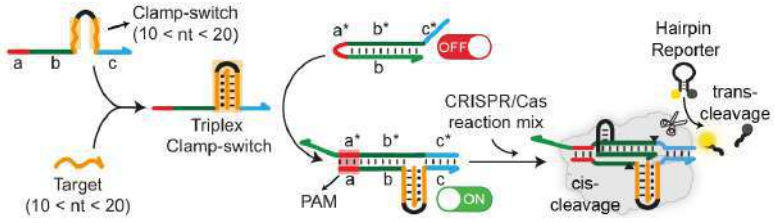

Figure 1: Schematic Clamp-like Triplex forming switch triggering Cas12a cleavage activity.

The escalating global incidence of infectious diseases caused by pathogenic bacteria, especially in developing countries, emphasises the urgent need for rapid and portable pathogen detection devices. As traditional techniques are time consuming, expensive and do not allow for a point-of-need analysis, biosensors represent a valid alternative, because of their low-cost, portability, ease of use and availability for point-of-care/need applications. This study introduces a sensitive and specific electrochemical biosensing platform utilising cost-effective electrodes fabricated by inkjet-printing gold and silver nanoparticles on a plastic substrate[1]. The biosensor exploits the CRISPR/Cas12a system for detecting a specific DNA sequence selected from the genome of the target pathogen[2]. Upon detection, the trans-activity of Cas12a/gRNA is triggered, leading to the cleavage of rationally designed single-strand DNA reporters (linear and hairpin) labelled with methylene blue (ssDNA-MB) and bound to the electrode surface, leading to the decrease of the square wave voltammetry (SWV) MB associated signal. In principle, this sensing mechanism can be adapted to any bacterium by choosing a proper guide RNA to target a specific sequence of its DNA. The biosensor's performance was assessed for two representative pathogens (a Gram-negative, Escherichia coli, and a Gram-positive, Staphylococcus aureus), and results obtained with inkjet-printed gold electrodes were compared with those obtained by commercial screen-printed gold electrodes. Our results show that the use of inkjet-printed nanostructured gold electrodes, which provide a large surface area, in combination with the use of hairpin reporters containing a poly-T loop[3] can increase the sensitivity of the assay corresponding to a signal variation of 86%. DNA targets amplified from various clinically isolated bacteria, have been tested and demonstrate the potential of the proposed platform for point-of-need applications.

Lupin seeds are the edible portion of lupin plants, included in the Fabaceae family. In recent years, they are gaining significant interest worldwide as a cheap alternative to other legume crops, for being stress-tolerant and climate-resilient plants and thanks to their potential nutritional value[1]. In fact, they are rich in proteins (>40%) and fibers (>28%), claiming a low-fat content (<6%); they also constitute a potential source of other nutrients, as minerals and vitamins. Lupins are rich in bioactive phytochemicals, such as polyphenols, phytosterols and triterpenes, providing antioxidant and anti-inflammatory properties; they are also known for a great presence of antinutritive compounds such quinolizidine alkaloids. The chemical composition of lupins could be influenced by several factors such as species or variety, geographical origin, farming practices, environmental stress, harvesting and processing methods[2].

In this work, *L. albus* L. samples originating from four southern-central Italian regions were subjected to an untargeted metabolomics approach using ultra-high performance liquid chromatography coupled to high-resolution mass spectrometry (UHPLC-HRMS). The aim was to distinguish samples based on their geographical origin and subsequently assess the metabolic variances resulting from distinct agricultural practices (conventional vs. organic farming). Unsupervised Principal Component Analysis (PCA) on lupins fingerprints was employed to have an overview of the natural tendency of the samples clustering. Additionally, a supervised Orthogonal Partial Least Square-Discriminant Analysis (OPLS-DA) was used for discriminative purposes, revealing good clustering capability and predicting power for further samples, allowing also the putative identification of over 30 markers, across various classes: alkaloids, amino acids, glycerophospholipids, fatty acids and other miscellaneous compounds.

The results highlighted the impact of the origin and farming techniques on the metabolomic composition and distinctiveness of lupin samples; this could be crucial for cultivation optimization, traceability and quality assessment of lupins, aiming to draw consumers attention and preferences, given their potential nutritional properties.

CRISPR/Cas systems have been widely utilized for the development of biosensing platforms for precision molecular diagnostics[1]. Despite significant advances, current CRISPR platforms mainly focus on nucleic acid detection. To fully exploit the advantages of CRISPR-based diagnostics, current research efforts aim to develop CRISPR sensors capable of detecting a wide range of analytes in addition to nucleic acids[2]. In the present work, we integrated the CRISPR-Cas12a detection system with established analytical methods, such as immunoassays, to expand its diagnostic capabilities. Using an innovative approach involving DNA strands conjugated with Anti-IgG antibodies, we implemented two different immunosensing platforms to detect SARS-CoV-2 infection. Specifically, we developed an ELISA assay, CRISPR Enzyme-Linked Immunosorbent Assay (CRISPR-ELISA), and an Immunomagnetic assay, called Cas12a-Linked Immunomagnetic Fluorimetric Assay (CLIF), for the detection of the virus-associated Spike protein. Both assays demonstrated high sensitivity (LOD 3 ng/mL and LOD 12 ng/mL respectively) and specificity for the Spike protein, even in the presence of protein interferers.

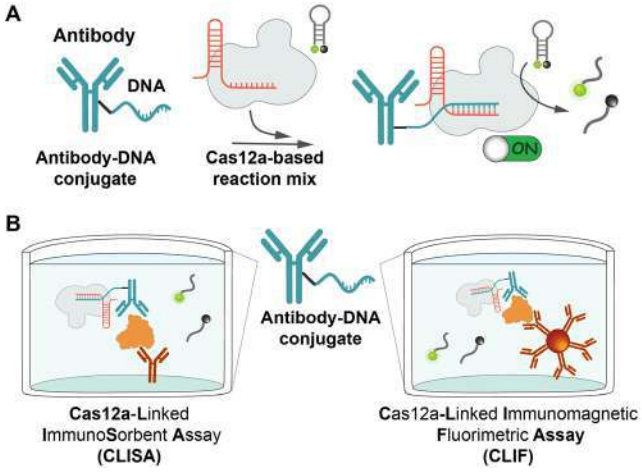

Figure 1: Schematic of the activation of Cas12a trans-cleavage activity on hairpin fluorescence reporters. (A) We explored the use of antibody-DNA conjugate as a recognition element for the detection of the SARS-CoV-2-associated spike protein. We implemented the assay in two formats (B), a standard sandwich ELISA (CRISPR-ELISA) and a sandwich assay based on magnetic beads (CLIF).

Hydrogen is an environmentally friendly fuel as it does not generate CO_2. Utilizing pipelines and reservoirs for hydrogen transport and storage are generally made of steel, and hydrogen can cause detrimental effects on their mechanical properties due to a phenomenon called hydrogen embrittlement (HE). Therefore, introducing a barrier in steel is essential to prevent this effect. This research aims to explore tungsten coatings as possible hydrogen permeation barriers (HPB) on X60 steel. The goal is to prevent or at least decrease the hydrogen that can penetrate into the steel and prevent HE.

In this context, physical vapor deposition (PVD) was employed to deposit tungsten onto a X60 steel substrate; the surface morphology and the composition of X60 steel and tungsten-coated X60 steel (W-coated X60 steel) were characterised by scanning electron microscopy- energy dispersive X-ray spectroscopy (SEM-EDS), X-ray photoelectron spectroscopy (XPS) and X-ray fluorescence spectroscopy (XRF). Additionally, an analytical method was optimized for performing hydrogen permeation measurements both on X60 steel and on W-coated X60 steel using Stachurski's cell.

The SEM and XPS results have indicated that a tungsten coating has been deposited on steel, with a thickness of 0.2mm. Preliminary electrochemical tests have shown that the tungsten coated X60 steel exhibits a promising reduction in hydrogen diffusion compared to uncoated steel. The findings from XPS and SEM-EDX analyses will be discussed together with the results obtained from the in-situ electrochemical measurements.

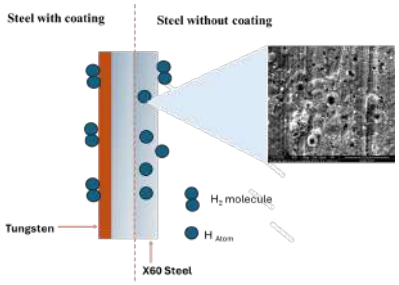

Figure 1: Hydrogen uptake in steel (right) and tungsten as a hydrogen permeation barrier (left)

Parkinson's disease (PD), ranking as the second most prevalent global neurodegenerative disorder, presents a multifaceted clinical profile[1]. The diagnostic process for PD remains a clinical endeavour, reliant on the expertise of healthcare professionals. This lack of definitive diagnostic tests poses significant hurdles, especially during the early stages of the disease, where subtle presentations may lead to misdiagnoses. Furthermore, distinguishing PD from related neurodegenerative disorders with overlapping early-phase symptoms, such as Multiple System Atrophy (MSA) and Progressive Supranuclear Palsy (PSP), poses its own set of complexities. This investigation aimed to characterize possible circulating lipid biomarkers for PD, MSA and PSP by untargeted and semi-targeted lipidomic analysis using LC-HRMS.

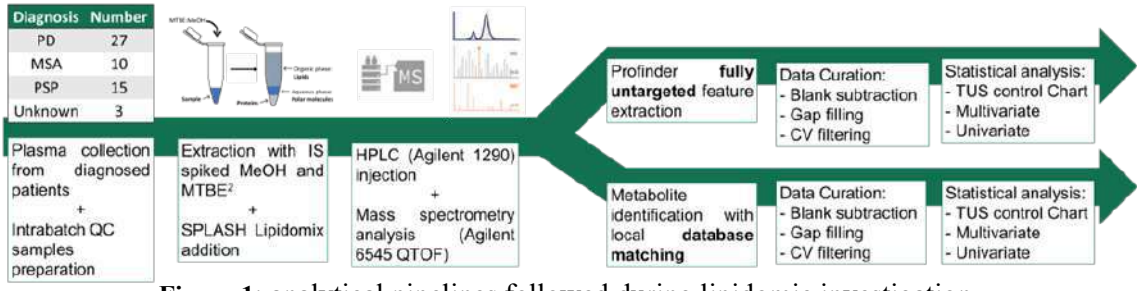

Figure 1: analytical pipelines followed during lipidomic investigation.

The lipidomics investigation was carried out on a HPLC coupled with a QTOF in an iterative DDA (Data Dependent Acquisition) mode. After data acquisition two different processing pipeline were essayed and compared, specifically a fully untargeted approach and a pseudo-targeted one (illustrated in Figure 1).

After dataset cleaning, a normalization method based on Total Useful Signal (TUS) was applied and after normalization both univariate and multivariate analysis were carried out. Finally, we refined our analysis to compare just two different groups: Parkinson's and non-Parkinson's. Employing this approach, we found 40 lipids that exhibited significant differences between these two groups and achieved an acceptable separation through PLS-DA.

giada.daltri2@unibo.it

Conductive polymers represent an affordable and reliable answer to the stiffness of conventional electronics. Polyaniline (PANI) in particular shows a peculiar doping/dedoping process, with high conductivity and exceptional tuneability. On the other hand, this material is fragile and not flexible. Different supports can enhance the mechanical properties of PANI, donating resilience, tenacity, and flexibility. This contribution would like to study the composite material based on PANI and paper or hydrogel and to report the fabrication of two different biocompatible devices, respectively a paper-like sensor for humidity[1] and an all-in-one supercapacitor (SC)[2]. PANI was polymerized with poly (2-acrylamido-2-methyl-1-propanesulfonic acid) (PAMPSA) for a more mechanically stable structure. With the addition of PAMPSA, the emeraldine state of PANI is achieved, providing enhanced conductivity. For the fabrication of conductive paper, the polymerization was conducted in situ on cellulose fibres, which were then dried and consequently pressed. Humidity sensors were fabricated by cutting the obtained sheets in rectangles. Due to humidity (RH%), cellulose/PANI-PAMPSA conductivity increases and the considered analytical signal is the measured current flow through the material by applying a constant voltage. Another interesting application is in the medical field, as a breath or ECG sensor. We then investigated the insertion of PANI-PAMPSA in polyvinyl alcohol (PVA) hydrogel systems. PVA powder was dissolved in PANI-PAMPSA solution, inducing a physical crosslinking through freeze-thaw cycles and providing a self-healing ability to the SC. Since PANI-based hydrogel partially functions as an electrode, the need of an electrolyte is covered by PVA-H_2SO_4 hydrogel, with a high adhesion between the layers. The resulting structure composes the all-in-one supercapacitor.

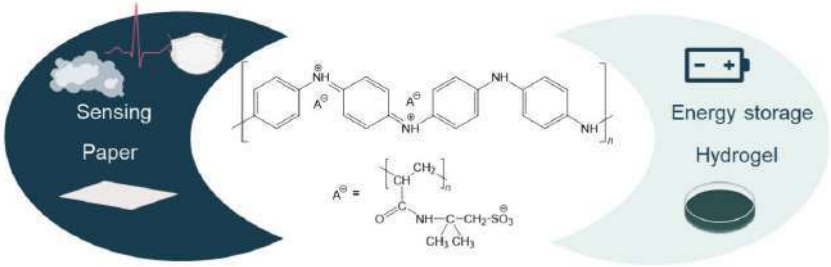

Figure 1: chemical structure of PANI-PAMPSA and a scheme of supports and their respective applications.

DoE and Chemometric Analysis for the Safe and Sustainable-by-Design Synthesis of the 2D-Materials

F. Pellegrino,[a] A. Rossi,[a] F. Sordello,[a] E. Alladio,[a] R. Santalucia,[a] A. Primieri,[a] M. Gouasmi,[a] D. Drobne,[b] V.-D. Hodoroaba,[c] J. Radnik,[c] V. Maurino[a]

francesco.pellegrino@unito.it

The synthesis of 2D materials with controlled morphology is having an increasingly prominent role in materials science, because the variation of the synthesis parameters allows optimizing the functional properties of the materials themselves. Not all the synthesis parameters can be modified as desired and the influence that each parameter has on the final characteristics of the product is different.[2] At the beginning, a proper definition of the chemical, structural and morphological characteristics that can drive the functional properties at nanoscale and molecular level can be scouted by an extensive literature search. In order to recognize the most significant parameters, a Design of Experiment (DoE) screening approach can be applied to the selected parameters to explain experimental variability. Starting from the synthesis conditions for the specific materials obtained through the screening DoE, series of morphology controlled 2D-materials can be synthetized and characterized with different analytical methods.[3] Finally, materials' characteristics can be collected and evaluated using Principal Component Analysis (PCA) and data fusion approaches. These chemometric techniques should allow us to establish the relationship between the synthesis parameters and the materials' characteristics. These relationships can be exploited to develop a DoE optimization model for the Safe and Sustainable-by-Design (SSbD) synthesis of specific 2D-materials.

Chemometric application for qualitative carbohydrates analysis using Yeast-Direct Catalytic Fuel Cell bio-device.

M. Tomassetti,[a] F. Marini,[a] M. Castrucci,[a] E. Dell'Aglio,[a] L. Campanella[a]

[a] *Department of Chemistry, University of Rome, "La Sapienza", P.le A. Moro 5, 00185 Rome, Italy*
mauro.tomassetti@uniroma1.it

Fuel Cells of different types and configurations are able to convert the chemical energy into electrical energy, using hydrogen or more complex compounds as fuel, such as methanol, ethanol, or glucose. Fuel cells have also been used in the past, by present authors, to quantify alcohol or glucose content in foods, or drinks, while in more recent papers authors investigated the analytical survey of the Direct Catalytic Fuel Cell (DCFC) for "qualitative" analysis too, of aliphatic alcohols and so on, using suitable chemometric methods for DCFC data elaboration. In the present research we tried to extend the same format, for qualitative determination to several carbohydrates (Glucose, Xylose, Fructose, Galactose, Sucrose). **Figure 1** shows the experimental apparatus used for batch analytical measurements, by Fuel Cel and Yeast incubation.

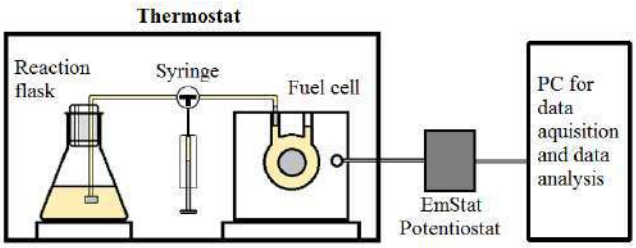

Figure 1: Incubation, DCFC and recording apparatus. Carbohydrates analysed at the same concentrations (0.03 mol L^{-1}). Incubation performed with 0.6 g of yeast, in glycine buffer, at 28.5 °C.

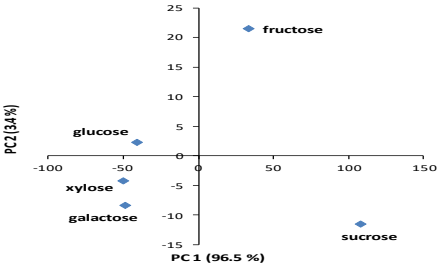

Figure 2: Projection of the five analysed carbohydrates, onto two first common components, extracted by PCA, (explaining 99.9% of the total variance).

Carbohydrates had to first be converted into alcohol using yeast solution. For this purpose, 50 mL glass flask, properly closed and filled with 30 mL of yeast-glucose-glycine solution, was kept at a constant temperature, for 12 h. At the end of the incubation time, 2 mL of solution was quickly extracted from the flask with a device made by graduated syringe, equipped with two small filters (see **Figure 1**), and injected in the DCFC. The end plate of the electrode of DCFC was made of a Pt-Ru black catalyst, assembled with a Nafion™ membrane. The cell was used in a potentiostatic mode, by measuring the so-called supplied current, using an EmStat potentiostat from Palmsens, connected to a PC. Current response trends to five investigated carbohydrate molecules have been recorded. Principal component analysis was then applied to the data set obtained by gathering all the data points of the response curves, after mean centering. The results of PCA are graphically displayed, in **Figure 2**, in terms of scores plot along the first two components, accounting for more than 99.9% of the total variance. The recoveries and differences about the behaviour among carbohydrates, can be appreciated by inspecting the scores plot reported in **Figure 2**.

Simultaneous quantification of indigotin and indirubin in industrially produced natural indigo pigment

Elia Frignani,[a, b] Laura Pigani,[a] Fabrizio Roncaglia.[a]
[a] Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, via G. Campi 103, 41125, Modena Italy.
[b] G2B s.r.l. Via Guareschi 25/27, 46010 Curtatone (MN).
elia.frignani@unimore.it

Historically, indigo has played a crucial role in textile dyeing processes[1]. Traditionally sourced from plants like Indigofera tinctoria, Isatis tinctoria, and Persicaria tinctoria[2], natural indigo consists of two main components: indigotin, responsible for the blue hue, and indirubin, contributing to the red-violet shade[3]. The combination of these compounds imparts a distinct color to the fabric, in contrast to synthetic indigo, which solely contains indigotin. The industrial, sustainable production of indigo necessitates a unique extraction process wherein calcium hydroxide is added to promote hydrolysis of the precursor inside the plant and facilitate the isolation of the pigment. Commercially accepted natural indigo is formed by approximately 80% calcium carbonate and the remaining organic components[4]; the inorganic portion poses a significant challenge for the determination of colored compounds, as it is insoluble in both water and organic solvents. It is necessary to implement a method for quality control of the industrial pigment obtained.

Presently, methods for determining indirubin are based on High-Performance Liquid Chromatography (HPLC), involving the extraction of the analyte from the powder using an organic solvent such as methanol or acetone. In these solvents, indigotin is not very soluble, requiring a different technique for its determination. Indigotin determination involves chemical reduction, forming a water-soluble leuco-indigotin subsequently determined using a spectroscopic technique. In an industrial setting, it is crucial to possess a method that can quantify both indigotin and indirubin in a sample. This allows for determining the ratio between these analytes and controlling various parameters in the industrial production process.

To address these challenges, dimethyl sulfoxide with the addition of hydrochloric acid was used as a solvent to promote the complete dissolution of analytes. This allowed for the injection of the solution into a UHPLC-PDA system. Separation of indirubin and indigotin was achieved using a reverse-phase C-18 column and a mobile phase consisting of water and acetonitrile. Identification of the two analytes was conducted by exploiting the different absorption spectra in the UV-Visible region. This novel procedure can also serve as a reference method in view of the development of faster and more cost-effective methodologies based on electrochemistry or UV-Visible spectroscopy for the characterization of natural indigo.

Tracing the evolution of street art materials: A study of contemporary mural paintings stratigraphies from Graffity Alley (Ghent, Belgium) and Galeria del Arte Urbana (Lisbon, Portugal)

J. La Nasa, S. Pizzimenti, I. Degano, F. Modugno
Dipartimento di Chimica e Chimica Industriale, Università di Pisa, Italy
francesca.modugno@unipi.it

Visual art in urban contexts consists of both commissioned and often non-commissioned street art. The ephemeral character, free access, and exposure to the environment and anthropic actions, make public paintings vulnerable to removal, vandalism, and degradation. Urban art is at present widely recognized by art history and by the wide society as an important part of contemporary cultural heritage, and a historical perspective on the evolution of materials and techniques is highly needed to gain a better knowledge of this form of art and to contribute to sustainable preservation strategies. The synthetic paint materials used by street artists in the last decades, such as spray paints, have undergone a fast evolution in their compositions. This aspect is related both to the implementation of new health regulations, leading to substances being banned from commercial use, and to the continuous improvement and evolution of commercial formulations. Targeted analytical experiments have been carried out to contribute to a comprehensive understanding of the chemical composition of paint materials used by street artists over the past decades, by studying samples which contain stratigraphies representing over 20 years of paint materials. Two case studies of great importance are presented: the Graffiti Alley and Galeria del Arte Urbana. These two locations are characterized by up to 25 years of repaintings on the same paint supports, giving a unique point of view on the evolution of the materials in a specific and well-defined time segment. The use of traditional analytical approaches on these samples did not provide an accurate evaluation of the distribution of the materials due to the thinness of the paint layers. In the presented study carried out at IPANEMA, a state-of-the-art European facility renowned for its expertise in multiscale and multispectral approaches in heritage science, we conducted Multi-spectral Luminescence Microscope, Mid-infrared Hyperspectral Imaging, and combined Micro-XRF/XRD analysis to obtain an exhaustive spatial resolution apt to study the stratigraphy of both the organic and inorganic materials. Moreover, SEM-EDX was carried out in Pisa to provide the elemental composition of the different paint layers. Subsection of the stratigraphies were also analysed by pyrolysis-gas chromatography-mass spectrometry (Py-GC-MS) to obtain a more detailed molecular composition of the samples. By applying this multiscale and multispectral approach combined with the micro destructive Py-GC-MS, we were able to obtain detailed chemical information about the different paint layers in the cross-sections. This allowed us to gain insight into the paint binder stratigraphy, differentiating between various classes of organic polymers, such as alkyds, acrylics, and nitrocellulose resins, present in each layer, and the evolution of their use in formulation during time. Additionally, the analysis provided valuable information about the inorganic content of the paint layers, revealing not only the presence of pigments and inorganic fillers. While some elements such as calcium and titanium were homogenously present in all the layers, specific metal were detectable only in the oldest paint layers. In particular, the presence of lead was highlighted only in the oldest layers. A detailed microscale element distribution can be crucial in the comparison with relevant literature to tentatively date the different paint layers.

The research has been carried out in the framework of the Italian PRIN2020 project SuPerStAr - Sustainable Preservation Strategies for Street Art.

Does the proline residue affect the coordination of divalent metal ions?

S. Leveraro,[a] D. Bellotti,[a] K. Garstka,[b] V. Dzyhovskyi,[a] M. Rowińska-Żyrek,[b] M. Remelli [a]

silvia.leveraro@unife.it

The aim of the present work is to investigate the interaction of metal ions with short model peptides containing proline residues next to the metal binding site. In these peptides, the metal binding site is represented by a histidine imidazole, an effective anchoring site for metal ions such as Cu(II), Zn(II) and Fe(II), already at acidic pH. In the case of Cu(II), increasing the pH value of the solution, the binding to backbone N-amides can occur towards both the N- or C-terminal direction, but with a different level of affinity.[1] On the other hand, the occurrence of this coordination behaviour for Zn(II) and Fe(II) is controversial.[2,3] The present study concerns the terminally protected short peptide Ac-AAAHAAA-NH_2 and two mutants: Ac-AAPHAAA-NH_2 and Ac-AAPHPAA-NH_2. In the former peptide, the Ala residue in position 3 has been replaced with a proline, while, in the latter one, the two alanines adjacent to the histidine residue (position 3 and 5) have been replaced with prolines.

The investigation allowed to better understand the coordination behaviour of the three metal ions under different pH condition, shedding light on the effect caused by the presence of proline residues close to the metal binding site. In fact, proline residues do provide greater structural rigidity to the peptide chain, hampering conformational changes and rearrangements around the metal center and making unavailable for the binding their corresponding backbone amide.

The thermodynamic and spectroscopic characterization of the metal complex-formation equilibria has been achieved by means of potentiometry, UV-Vis spectrophotometry, circular dichroism, electron paramagnetic resonance and mass spectrometry.

Financial support of the National Recovery and Resilience Plan (NRRP), Mission 4 Component 2 Investment 1.1-NextGenerationEU (PRIN PNRR 2022-P2022EMY52) is gratefully acknowledge.

giorgia.foca@unimore.it

Wine vinegar is produced through a two-phase fermentation of grape must: initially, yeast converts grape sugars into ethanol, and subsequently, acetobacteria oxidizes the ethanol into acetic acid. This process, spanning weeks, requires constant monitoring for ethanol and total acidity levels. To enhance the quality and efficiency of process monitoring, the food industry is shifting to faster, environmentally sustainable methods. Near-Infrared (NIR) spectroscopy, recognized for its non-invasiveness and speed, is ideal for online implementation in process control[1].

This study tracked dual fermentation in red wine must over an extended period, monitoring two batches simultaneously to assess fermentation kinetics and reproducibility. Ethanol and total acidity were analyzed in fermenting musts for almost four months, using both classical laboratory analyses and FT-NIR spectroscopy. Principal Component Analysis (PCA) was used to explore the spectral dataset, then Partial Least Squares (PLS) was used to develop calibration models predicting ethanol and acidity.

The models for the entire spectrum were compared with those obtained for two narrower zones, where more cost-effective and easily miniaturizable sensors are available on the market[2]. The FT-NIR analysis effectively determined the ethanol content and acidity ($R^2_{Pred} > 0.98$), both over the entire range (12500-4000 cm^{-1} corresponding to 800-2500 nm) and in the region 10526-6060 cm^{-1} (950-1650 nm). Although less optimal, still acceptable results were obtained in the 12500-9346 cm^{-1} (800-1070 nm) region ($R^2_{Pred} > 0.81$), confirming the potential for cost-effective devices in real-time fermentation monitoring.

giorgio.felizzato@unibg.it

Ion Mobility Spectrometry (IMS) has been proven to be a very effective analytical technique in security and police applications for the detection of explosives, chemical weapons and illicit drugs. This study focuses on a new IMS prototype, developed by MasaTech, and investigates its efficacy on the crime scene by analysing explosives within the scope of the RISEN project (Horizon 2020, Grant Agreement No 883116). The MasaTech prototype vaporizes chemical substances pointing a laser beam at different types of surfaces. Vapours are transferred into the IMS module by a pump, where molecules are ionized and separated in the gas-phase. The analytical outputs considered in this study were the drift time, ion mobility, reduced mobility and collision cross-section.

The effectiveness of the IMS prototype was established by analysing explosives and explosive products: TNT, RDX, PETN, 2,6-DNT, 2,4-DNT, and 3,4-DNT. Little amounts of chemicals were settled on different substrates, such as drywall, stainless steel, and ceramic to simulate realistic crime scenarios.

Chemometrics methods were employed for reliable data processing of plasmagrams. Multivariate data analysis was carried out using Python code within a Jupyter Notebook environment, using the following packages: NumPy, Pands, Matplot library, Plotly and Scikit-Learn. The data analysis workflow involved various pre-processing steps of raw IMS plasmagrams, unsupervised and supervised pattern recognition techniques and model evaluation through Leave-P-Out cross-validation. Moreover, following the guidelines developed by the European Network of Forensic Science Institutes (ENFSI), a complete validation of the method was carried out taking into account the repeatability, reproducibility, and sensitivity. The signal variation was assessed to evaluate each analyte's response repeatability and reproducibility. All the analytes showed a coefficient of variation lower than 1% for both repeatability and reproducibility.

Therefore, the data obtained was treated with different classification models, such as Linear Discriminant Analysis (LDA), Partial Least Squares Discriminant Analysis (PLS-DA), Logistic Regression (LR) and Support Vector Machines (SVMs), in order to establish the relevance in comparison to conventional IMS technologies. The results highlighted the importance of the data pre-processing method employed to obtain an accurate classification. A Design of Experiment (DoE) approach was used to identify the best combination of pre-processing techniques and determine which factors influence the model's response by using the accuracy of the final chemometrics model. The PCA-LDA model appears as the most effective classification model reaching an accuracy of 95% and showing satisfactory results for real implementation in forensic field applications.

Merit to its high sensitivity and ease of use, the instrument can be employed to detect latent traces on crime scenes, on small traces unsuitable to traditional approaches such as spot tests. In conclusion, the IMS prototype developed by MasaTech, coupled with the chemometrics approach, presents a promising methodology for the detection of explosives and explosive products in real forensic criminal cases.

elena.spezzani@unipr.it

The DNA origami technique streamlines the independent assembly of customizable DNA structures, enabling precise patterning at the nanoscale of a variety of conjugated biomolecules. With their inherent compatibility with biological systems and the ability to control shape, size, and ligand arrangement, DNA-based nanostructures hold great promise for applications in nanomedicine[1,2]. Despite demonstrations of effective binding in various scenarios, the underlying biophysical dynamics governing membrane binding remain largely unexplored. In this study, we explore the binding dynamics of two rod-shaped DNA origami nanoconjugates: one decorated with anti-EGFR (Epidermal Growth Factor Receptor) antibodies and the other with anti-EGFR aptamers. Through single-particle tracking (SMT) microscopy, we monitor the trajectories of ligand-modified DNA origami in both free solution and bound states on the cell membrane, enabling the calculation of their diffusion coefficient (D). We show that we can quantify the fraction of DNA origami specifically bound to the targeted receptor, distinguishing them from nonspecific bindings. Furthermore, SMT aids in determining the first-order rate constant for complex dissociation (Koff), a critical parameter revealing the average duration of the interaction between the DNA origami and the membrane receptors. The ability to finely adjust Koff values can be crucial for modulating potential therapeutic and stimulation effects[3]. Our DNA origami nanoconjugates demonstrate specific binding with a Koff profile potentially favoring preferential binding to cancer cells, opening new avenues in selective cell targeting for biomedical applications.

Liquid-liquid phase separation (LLPS) is a physical process that gives rise to membrane-less biopolymer condensates. Engineering LLPS processes has proven to be a powerful approach for creating mimics of cells and cellular organelles, driving advancements in the field of synthetic biology[1]. In particular, DNA-based condensates have garnered interest due to the versatile design capabilities of DNA, allowing for the fine-tuning of their physical properties and functions[2]. DNA condensates are generally formed by multi-armed DNA nanostructures, known as DNA nanostars, and their cross-linking can be mediated through sticky-ends[3] or through hydrophobic cholesterol molecules[4].

Although the traditional manual approaches have demonstrated to be effective for DNA condensates preparation, they are laborious and time-consuming. Motivated by these considerations, we propose here the development of a high-throughput method for DNA condensates fabrication that allows the production of a large number of samples in a relatively short amount of time. To do this, we employed pre-annealed DNA nanostars and we studied their isothermal assembly using the Opentrons® OT-2 liquid handling robot. We also performed a high-throughput analysis to characterize the size and stability of the condensates using Differential Dynamic Microscopy (DDM) technique, as developed for similar DNA condensates obtained through a manual approach involving thermal annealing[5]. The results showed that condensates exhibited varying sizes depending on incubation time and z-levels within the well. Notably, they were stable for at least to 8 days. The achievement of a high-throughput method for DNA particles synthesis and analysis allows for a rapid screening and testing of various compositions and parameters, facilitating a potential transition from laboratory-scale to industrial-scale production. Building upon these results, the next step involves exploring bioanalytical applications of DNA condensates.

Cell-free *in-vitro* transcription and CRISPR/Cas systems for ultrasensitive biomarker detection

F. Miceli,[a] S. Bracaglia,[a] S. Ranallo,[a] F. Ricci[a]

[a] *Chemistry Department, University of Rome, Tor Vergata, Via della Ricerca Scientifica 1, 00133 Rome, Italy*
francesca.cosimina.miceli@uniroma2.it

Detection of specific antibodies and other protein biomarkers plays a crucial role in disease diagnosis, infections, and other pathologies such as cancer and autoimmune diseases.[1] In recent years, the possibility to couple the advantages of synthetic nucleic acids (i.e., programmability of interactions, low-cost, and ease of synthesis) together with the sensitivity and the specificity offered by cell-free transcription/translation systems has led to the development of innovative sensors for the detection of different targets,[2] including antibodies. Despite this, most of the cell-free biosensors for the detection of antibodies reported to date reach high picomolar/low nanomolar detection limit that appear not enough to identify early stages of infections.[3,4] Motivated by this, we report here a cell-free biosensor for antibody detection that takes advantage of CRISPR/Cas system. We have designed a synthetic gene that contain the transcriptional sequence of crRNA for Cas enzyme and an incomplete T7 RNA polymerase promoter domain to prevent the efficient binding of the enzyme. The binding of the specific antibody to a pair of antigen-conjugated DNA strands triggers the reconstitution of the T7 RNA polymerase promoter domain and thus the *in-vitro* transcription of the crRNA. The developed cell-free biosensor allows the sensitive (low picomolar detection limit), specific (no signal is observed in the presence of non-specific antibodies) and selective (the system can be employed in complex media, including 50% blood serum) detection of target molecules. Due to the programmable nature of the sensing platform, it can be adapted to different target molecules (using a direct or competitive formats).
We demonstrate the detection of different antibodies, including the clinically relevant Anti-MUC1 antibody and Cetuximab and protein markers as Mucin1 and EGFR. Given all these advantages, the CRISPR/Cas-based cell-free biosensors may be of utility for different applications including point-of-care diagnostics.

Hypericum perforatum L. and *Sideritis scardica* (commonly known as Mountain tea) are two medicinal herbs widespread throughout the European Mediterranean region and commonly used for brewing herbal teas. These plants are known to possess a range of soothing properties[1,2], which can be attributed to the high abundance of polyphenols within the extracts obtained from these plants.

Polyphenols constitute an extremely heterogeneous class of metabolites produced by plants both for their growth and for protection against oxidative stress. These compounds are known to have various beneficial effects on human health, particularly due to their antioxidant activity[3]. For this reason, the analysis of the polyphenolic profile in products for human use has become increasingly sought.

Given the number of phenolic compounds present within the plant kingdom, their extreme variability, and the low quantities produced for some of these molecules, obtaining such results via conventional target methodologies is not feasible. Hence, the utilization of untargeted approaches based on ultra-high-performance liquid chromatography (UHPLC) coupled with high-resolution mass spectrometry (HRMS) becomes necessary[4].

The objective of this work is the characterization of *Hypericum perforatum* L. and *Sideritis scardica* extracts from Albania in terms of phenolic content by using a UHPLC-Q-Orbitrap system operated in untargeted data dependent acquisition (DDA) scan mode. To achieve orthogonal information, both C18 and Hydrophilic Interaction Liquid Chromatography (HILIC) columns (Waters, Milford, MA, USA) with the same geometry and particle size were employed.

Monoclonal antibodies (mAbs) constitute a primary therapeutic avenue in the management of chronic illnesses[1]. Therapeutic drug monitoring (TDM) offers a promising approach for personalized treatment strategies, particularly in chronic diseases where overtreatments can lead to significant side effects. Aiming to enhance TDM strategies, the NanoHybrid (NH) platform developed by Ulisse BioMed S.p.A.[2] has been re-engineered into a novel protein-DNA nanoswitch sensor. This new format leverages whole protein binding moieties to detect mAbs by exploiting the presence of different recognizable epitopes. Nanoswitch probes consisting of rationally designed DNA strands conjugated to whole tumor necrosis factor α (TNFα) proteins enabled the one-step quantification of various mAbs such as Infliximab, Adalimumab in a range between 2.4 µg/mL and 19 µg/mL directly in blood serum. Since mAbs can elicit patient-specific immune responses, anti-drug antibodies (ADAs) are often raised against biological drugs, which can significantly influence the actual bioavailability of therapeutic mAbs. Motivated by this, the nanoswitch platform was applied to the detection of Infliximab in the presence of an anti-Infliximab Ab, showing a substantial decrease in the detected concentrations of infliximab when in the presence of such ADA. These outcomes highlighted that the developed nanoswitch platform is capable of specifically discerning bioavailable antibodies, providing valuable insights for pharmacokinetic studies. Leveraging its modular design, the present nanoswitch platform holds potential as a multi-epitope nanosensor for the quantification of bioavailable mAbs and biosimilars.

m.innocenti@unifi.it

Electroplating is a key process in many industrial fields such as automotive, electronics and decorative applications; it allows to provide new properties to substrates materials like corrosion resistance, hardness and aesthetic value. Nonetheless, electroplating is considered one of the most non-sustainable industries related to the manufacturing sector, both from an environmental and social point of view[1].

For over two decades, sustainability in the plating industry has been one of the key concerns of the industry. This makes it critical for the industry to assess the entire sustainability of virtually every plating facilities and then come up with both short-term and long-term approaches for improving sustainability performance.

In our work, the state of art was evaluated regarding three different but complementary lines of actions to improve the sustainability in Agenda 2030 SDGs optic of the electroplating industry[2], especially in non-mandatory fields such as the decorative one. Either different plating techniques, *in-silico* simulations and the metal recovery are linked to each other in minimizing the material usage and, consequently, metal extraction.

It is fundamental to fashion designers to take care of the whole production processes, thinking out of the schemes for new sustainable geometries and for industries to embrace simulations to test them[3]. Hence, deposition techniques should improve by trying to merge the properties of modulated currents with three ways rectifiers engineering and calibrate the deposition parameters with analytical techniques such as spectroscopies. Furthermore, electroplating facilities are needed to dedicate forces to select and optimize recovery methods according to their specific internal needs.

Towards green NH_3: How to improve ammonia production and its reliable quantification?

F.Merlo,[a] C. Tedesco,[a] A. Speltini,[a] L. Malavasi,[a] A.Profumo[a]

[a]*Università di Pavia, Department of Chemistry, Via Taramelli 12, 27100 Pavia, Italy.*
antonella.profumo@unipv.it

In this current century, climate changes and energy production are some of the most significant and pressing challenges that humankind is facing. In this context, ammonia is a carbon-free energy-source for the end-users, thus resulting an alternative energy resource and also a promising energy vector, as it can be also used as an indirect H_2 storage compound. It is a matter of fact that photocatalytic N_2 fixation to achieve the so-called green NH_3 is emerging as hot area of fundamental and applied research[1]. Inspired by biological nitrogen fixation through nitrogenase enzyme, NH_3 can be photochemically produced from N_2 and H_2O in the presence of a semiconductor material and in this respect, the metal-free catalyst, namely graphitic-carbon nitride (g-C_3N_4), is considered a rising star material due to its excellent photocatalytic behaviour, suitable electronic properties (*viz.* band gap), and good photo-corrosion resistance. At the same time, its low absorption coefficient, fast recombination charge carrier and low surface area are challenges to overcome. Hence, in this work heterojunctions with metal halide perovskites ($Cs_2AgBiCl_6$) have been investigated in the whole weight ratio between perovskite and g-C_3N_4. The experimental results highlighted that g-C_3N_4-rich systems (90% wt) are more effective in the nitrogen photofixation reaction with ammonia production rates up to 40 μmol g^{-1} h^{-1}. Indeed, the active sites are the nitrogen vacancies in the nanostructure of g-C_3N_4, with a positive effect of small perovskite amounts mostly related to its superior light absorbance and reduced carrier losses. The design of an optimal photocatalyst is for sure the key step, but also the need for reliable methods for ammonia detection and quantification is a point to be addressed. NH_3 is typically detected by one of a number of possible methods, but serious concerns exist regarding the accuracy of current methods since different parameters can adversely impact ammonia detection and quantification. In this work, the Nessler's colorimetric assays and NH_3 Ion Selective Electrode (ISE) have been compared, evaluating the role of some possible interferences, namely the pH, colour and turbidity of the solution, the presence of certain metal ions and of sacrificial agents (mainly MeOH). Finally, the ammonia production rates have been accurately determined by ISE because an overestimation of the NH_3 concentration has been experimentally verified when using the colorimetric method. A calibration curve is daily constructed plotting the potential value recorded (mV) against the Log concentration, to verify the slope (varying in the range - 54 ÷ -60 mV).

Waste biomass reuse for preconcentration of emerging pollutants in environmental waters

P. Bianchini, F. Merlo, L. Ferrari, C. Milanese, A. Profumo, A. Speltini
Dipartimento di Chimica, Università di Pavia, via Taramelli 12 - 27100 Pavia
andrea.speltini@unipv.it

Industrialisation and population growth lead to the release of various types of pollutants from different sources into the environment, such as untreated municipal waste and effluents, agricultural releases, and industrial chemical discards. At this regard, among pharmaceuticals, the widespread of steroid hormones (SHs) and fluoroquinolone antimicrobials (FQs) residues in the environment, their fate, effects, and threats associated with their occurrence are reasons of great concern.[1] Proper analytical methods should be developed for their monitoring, possibly combining sensitivity and accuracy with sustainability, in the perspective of green chemistry.

Biochar is a carbon material produced by thermal decomposition of biomass in absence of oxygen, in the circular economy approach. It is distinguished by its unique characteristics such as high specific surface area, porous structure, and many surface functional groups (carboxylic, hydroxyl, and carbonyl units). Biochar is a relatively inexpensive and environmentally friendly sorbent because it can be produced from agricultural wastes that are abundant and do not have an economic value.[2]

In this work, biochar prepared from pumpkin, melon, and orange peels, packed in cartridge for Solid-Phase Extraction (SPE), were tested for antimicrobials and steroids preconcentration in environmental waters. Biochar was home-made obtained by a pyrolysis treatment performed at 650° C for 6 hours in a tubular furnace under N_2 flow and characterized by TGA, XRPD, IR, SEM and BET.

SPE tests were carried out to evaluate the adsorption of those analytes. Preliminary trials were performed on 50 mg of each material in tap water samples (50 mL, native pH) enriched separately with 5 μg L^{-1} of 16 SHs (8 glucocorticoids, 3 estrogens, 2 progestins and 2 androgens) or 11 FQs (6 for human and 5 for veterinary use) as bioactive compounds representative of water emerging contaminants.

Adsorption was quantitative for all FQs and SHs on all prepared biochar. Quantitative elution was obtained for antimicrobials with 2 mL of 10 mM TBAH-ACN (85:15, v/v) and for steroids using 2 ml EtOH, even if with a lower recovery for glucocorticoids. Quantification was performed by HPLC-ESI-MS/MS, MRM mode.

Immobilization of biochar on other supports to simplify the extraction procedure is ongoing to avoid the packed cartridge setting and increase the sample preparation throughput.

federica.pedrini@uniroma2.it

Supramolecular assemblies in biological systems exhibit a dynamic behaviour that is crucial to achieving environmental responsiveness. The possibility to develop chemically fuelled synthetic materials able to mimic such dynamic aspects of biological systems can lead to adaptable materials with unprecedented properties. Dissipative DNA nanotechnology, exploiting DNA programmability and the use of nucleic acids as chemical fuels to drive non-equilibrium processes, has recently emerged as a potential strategy to achieve adaptable and responsive biomaterials. Motivated by this, we propose here a novel approach to introduce a dissipative control over the Hybridization Chain Reaction (HCR). This is a DNA assembly technique based on the polymerization of two metastable DNA hairpins. Implementing a "tailed HCR" strategy[1], we introduce a dissipative behaviour via enzyme-mediated fuel consumption. Specifically, we have re-designed an RNA fuel that activates a strand displacement process followed by the disassembly of the DNA polymer. The presence of RNase H, an enzyme able to specifically recognize the RNA/DNA heteroduplex, can induce the degradation of this heteroduplex and the consequent rebuilding of the DNA nanostructure, thus driving a cyclic dissipative reaction.[2] This approach enables programmable assembly/disassembly of DNA nanostructures, suggesting the potential of dissipative DNA nanotechnology in creating time-controlled responsive biomaterials. Exploiting dissipative strategies, we equip DNA polymers with new properties that can have important analytical applications, including concentration-dependent adaptability and reversible multicomponent analysis.

s.pellegrino@unito.it

The removal of contaminants of emerging concern in water represents a challenge for the sustainable development of the society, where advanced oxidation processes are the main method for their abatement. This work focused on the synthesis of carbon nitride[1] (g-C_3N_4) based materials, added with iron. It is possible to introduce iron metal centers to extend Fenton reactions at neutral pH, otherwise hindered at pH > 4 by iron precipitation[2]. At the same time, the UVA irradiation of carbon nitride allows the production of H_2O_2 *in situ*, which can be used for Fenton reactions, through the reduction of dissolved oxygen.
The synthesis of the photocatalyst was carried out by adding $FeCl_3$•$6H_2O$ to melamine through a thermal polycondensation reaction under anoxic conditions at 500°C. The quantitative transfer of iron in the structure was confirmed by determining the Fe content after the thermal decomposition of the organic fraction. The photocatalytic performance was evaluated by measuring phenol (PhOH) 100 μM degradation under UVA irradiation, with a fixed amount of photocatalyst of 1.65 g L^{-1} at initial pH = 7.0. When needed, H_2O_2 1.0–25 mM was also employed.
Studies at different iron concentrations have shown that content of 0.28% w/w iron is optimal for the degradation of PhOH in the absence of external H_2O_2. In experiments carried out with 1 mM H_2O_2, the degradation rate of PhOH increased using g-C_3N_4, but this did not happen for Fe-g-C_3N_4. These observations and the disappearance of over 90 % of H_2O_2 in just 30 minutes of irradiation with Fe-g-C_3N_4, suggest that: 1) the reactive oxygen species (ROS) formed at the metal centers can react more easily with the structure of the photocatalyst than with the model contaminants; 2) high valent oxoiron complexes could contribute more to phenol degradation than ROS species.
Increases in the reaction kinetics with Fe-g-C_3N_4 was observed for additions of H_2O_2 concentrations > 5 mM. In these cases, the contribution of the photolysis of H_2O_2 is not negligible and industrial applications in wastewater treatment plants would be expensive.
Further studies are currently underway to study the working mechanisms by using spectroscopic techniques (i.e., EPR) and selective scavenging of the main ROS species ($^{\bullet}OH$, $^1O_2$, $^{\bullet}O_2^-$) involved in the degradation of phenol. This work will include material characterization and analysis on catalyst reuse.

ciro.orecchio@unito.it

Tomato spotted wilt virus (TSWV; species *Tomato spotted wilt orthotospovirus;* genus *Orthotospovirus;* family *Tospoviridae*) is a thrips-transmitted virus that induces outstanding economic losses in the agriculture, since infects more than 1000 different plant species from 90 botanical families, including ornamental, fruit, horticultural, and agronomic crops[1,2]. On tomato plants, it induces leaf bronzing, small brown flecks, dieback of growing tips, and ultimately death[3]. The leading management and containment strategies to fight TSWV infection consist in using resistant cultivars and spraying insecticides for thrips control. Early detection of plant pathogens is fundamental in a sustainable crop management context. The aim of this research is to disclose the presence of TSWV infection using a hand-held Raman device and Machine Learning (ML) approaches. For this purpose, four healthy plants and four TSWV-infected ones were analysed. Raman spectra were collected at 3 and 7 days post inoculation (dpi), acquiring six spectra per plant, obtaining a final data matrix of 96 spectra. Plants were scored for symptom development and the typical chlorotic spots appeared at 21 dpi. After a preliminary phase of spectra pre-processing using three different algorithms - asymmetrically reweighted penalised least squares (arPLS) smoothing, Savitsky-Golay filter, and Standard Normal Variate (SNV) transformation - a filter method based on Partial Least Squares Discriminant Analysis (PLS-DA) coefficients[4] was applied, to remove the redundant or irrelevant variables. The resultant reduced dataset was finally used for exploratory purposes with Principal Component Analysis (PCA) and then to build the PLS-DA model[5]. Interpreting the classification metrics, resulting from ten different train-test splits, we observe that Raman spectroscopy coupled with ML techniques provided promising results for an early detection of TSWV infection on tomato plants within the first 7 dpi, with an average accuracy >90%. Early detection of TSWV infection when symptoms are visually undetectable represents an important advantage from a productivity point of view. Moreover, these results have been obtained with a hand-held Raman spectrometer, easy-to-carry for field measurements in real time and less expensive than a corresponding benchtop instrument.

Development of a UHPLC-HRMS method for simultaneous determination of abuse substances in whole blood by Salting-out Assisted Liquid-Liquid Extraction (SALLE)

G. Pezzuti,[a] F. Vincenti,[a] G. Fiorini,[a] F. Bartolini,[a] I. Bracaglia,[a,b] G. Di Francesco,[a] M. Croce,[a,b] A. Gregori,[c] F. Di Rosa,[c] C. Montesano,[a] Manuel Sergi[a]

gianmarco.pezzuti@uniroma1.it

New psychoactive substances (NPS) are increasingly being used and their recognition, both in samples from findings and in biological samples, is a very topical analytical problem [1]. The purpose of the proposed work was the development of a UHPLC-HRMS/MS based method for the determination of 150 drugs (classical drugs and NPS) in whole blood. One of the objectives was to achieve a rapid, economical and versatile pretreatment method, suitable for the different classes of molecules considered. In this regard, Salting-out assisted liquid liquid extraction (SALLE) [2] was selected and, at a preliminary stage, it was essential to find the most suitable conditions for the development of the extraction parameters. The analysis was initially carried out on a smaller number of analytes (47 of 150), and for this purpose was performed a HPLC- MS/MS method with a triple quadrupole mass spectrometer. The work was then extended to all analytes (150) using a UHPLC-HRMS with orbital ion trap analyser at the Department of Scientific Investigations (Carabinieri) of Rome. It was possible to validate the entire HRMS analytical method for the multi-screening determination of drugs from whole blood in order to obtain the simultaneous extraction and quantification of 150 drugs. The proposed procedure allowed to speeding up of the SALLE extraction technique: the number of steps required and the volume of organic solvent have been reduced making the extraction process more sustainable on a long scale in terms of cost and environmental issues. The pre-treatment maintains also a higher concentration of the analytes, thus providing improved LODs and LOQs than reported in literature.

Another strength of the presented method was the applicability to an extensive and heterogeneous drugs and not limited to a specific class of psychotropic substances. The entire analytical procedure, once validated, was accurate, precise, sensitive, with a low matrix effect (for both low resolution and high resolution methods).

Development of a decentralized in-flow electrochemical platform for continuous monitoring of heavy metals

S. Laschi, E. Orsillo, P. S. Sfragano, I. Palchetti

Università di Firenze, Dipartimento di Chimica "Ugo Schiff" (DICUS), via della Lastruccia 3-13, 50019 Sesto Fiorentino, Firenze (ITALY)
Email: serena.laschi@unifi.it

Year after year, the need for decentralized tools to monitor heavy metals levels in the environment continually increases. Suitable electrochemical surfaces are widely established and particularly attractive for the production at low costs of miniaturized devices that can be applied as field-deployable analytical platforms.

This work reports the development of a fully automatable system based on electrochemical detection for the continuous on-site monitoring of heavy metals. The surface of electrochemical sensors is appropriately modified and then coupled to an optimized electrochemical procedure in order to achieve selectivity against the desired analytes.

At the same time, a suitable electrochemical cell coupled to a stirrer and connected to an integrated pump-based fluidic system was designed. This combined system allowed for the achievement of fast results while minimizing the sample volume used. To complete the prototype, a proprietary software capable of controlling both the fluidic system and the electrochemical measurement with the final data processing was developed.

Parameters such as flow speed, sample volume, and stirring steps were experimentally optimized, together with the parameters of the electrochemical measurement so as to obtain the best combination between analysis time and sensitivity.

The developed device was then applied to the multi-element analysis of heavy metals including, among others, Nickel, Aluminium, Cadmium, Lead, and Copper.

Valorization of Tomato Sauce Industry Wastes by Identification of High-added value Compounds.

L. Strani, S. Pellacani, M. Cocchi, G. Farioli, C. Durante

Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Via G. Campi 103, 41125, Modena
marina.cocchi@unimore.it

The development and implementation of innovative techniques are crucial for the valorisation and reuse of industrial waste products. In addition, the climate crisis has posed new challenges to our society, including how to make it sustainable despite large volumes of production. Therefore, the use of eco-sustainable (bio-based) raw materials and waste materials paves the way for a new and possible solution to this global issue. The food processing industry is responsible for producing considerable amounts of residues and by-products. Among the different food transformation and production chain, the vegetable processing industry generates significant amounts of various types of waste. One of the most significant global food markets is related to the tomato processing industry, which produces substantial by-products that are often discarded as waste rather than reintegrated into the supply chain with a new purpose [1]. However, these by-products could be excellent sources of ingredients, such as bioactive compounds including carotenoids, fibers, peptides, proteins, lipids, polysaccharides, polyphenols, antimicrobial compounds, and natural pigments [2].

Existing studies mainly focused on the revaluation of tomato pomace, peels, or seeds. On the other hand, the re-evaluation of tomato-based sauces discarded due to various errors in the production line, such as packaging or recipe errors, which make the product unsuitable for sale but potentially rich in bioactive compounds, remains unexplored. In this case, the production waste is a mixture of sauces (e.g., pasta condiments) in which tomatoes coexist with various other ingredients such as cheese, meat, and basil. From these premises the objectives of this work, aimed at finding one or more extracts of high-value components from finished product waste. Therefore, various sauce samples and a mixture of these were chemically characterized using different analytical techniques (UV-Vis, GC-MS, NIR), and the stability of their chemical composition was also investigated over time.

Moreover, a preliminary attempt to develop form this by-products a renewable raw materials for use in biobased packaging materials, has also been proposed.

nicola.cioffi@uniba.it

Food deterioration due to pathogen contamination causes a considerable economic burden and significant waste. Nowadays, plastic-based food packaging materials are the most used systems for preserving perishable goods. However, the environmental impact of plastic abuse should be limited, promoting the use of alternative greener materials, to improve food preservation. It is then envisaged to develop all-in-one biodegradable, renewable and antimicrobial materials. Biopolymers belonging to different families, such as carbohydrates (starch, cellulose, pectin, chitosan and alginates), proteins (whey proteins, wheat and corn proteins) and lipid derivatives may be used as valid substitutes[1]. Alginates are tasteless and odorless hydrophilic polymers extracted mainly from marine brown algae, showing good film-forming properties, low gas permeability, flexibility, water solubility[1]. Additionally, crosslinking with appropriate divalent cations (e.g. Ca^{2+}) improves physical-chemical and biological properties of alginate films. Such films can be further modified by blending with suitable additives to confer additional properties. To this aim, biodegradable coatings embedding antimicrobial nanostructures (NSs) can prolong product shelf-life, thus limiting pathogen growth and/or biofilm formation. In this communication, novel crosslinked alginate films embedding zinc oxide nanostructures (ZnO NSs) are presented. A green electrochemical-thermal method based on zinc anode oxidation in hydrogen carbonate solution in the presence of sodium dodecyl sulfate as a stabilizer was used to prepare ZnO NSs[2]. A suitable protocol for fabricating self-standing ZnO NSs/alginate films was developed. Morphological and spectroscopic (FTIR, XPS) characterizations were performed on NSs to evaluate their composition and morphology. Films were characterized by FTIR, XPS and water uptake experiments, showing that the addition of ZnO NSs improves significantly the film resistance, and supporting their potential application in food packaging studies. Finally, zinc release was also assessed spectrophotometrically and then used for the indirect prediction of antimicrobial efficacy.

Large freestanding 2D Covalent Organic Framework nanofilms

L. Gazzato,[a] M. Frasconi[a]

[a] *Department of Chemical Sciences, University of Padova, Via Marzolo 1, 35131 Padova, Italy*
luana.gazzato@phd.unipd.it

Covalent Organic Frameworks (COFs), a class of organic materials known for their highly ordered, porous structures extended into two or three dimensions, have gained significant attention across various fields such as catalysis, gas storage, and sensing due to their fascinating properties, which include high surface area, tunable pore sizes, and chemical stability.[1] Among the different kinds of COFs, two-dimensional covalent organic frameworks (2D COFs) offer excellent platforms with high porosity for new technological applications, especially those involving film morphology. Here, we present the synthesis and characterization of freestanding imine-linked 2D COF nanofilms. 2D COF nanofilms have been successfully synthesized by condensation reactions at air-water and liquid-liquid interfaces. The develop method provides uniform centimeter-scale 2D COF films with thicknesses that can be tuned by the reaction times as well as the concentration of the monomers.[2] Our approach enables the direct transfer of the synthesized large-area COF nanofilm onto patterned substrates for physicochemical and mechanical characterization. Tensile tests are conducted on three different kinds of COF films measuring about 80 nm in thickness, with a testing area extending to 0.3 mm^2. The strength and the Young's modulus of the imine-linked COF nanofilms are 188 ± 57 MPa and 37 ± 15 GPa, respectively. The exceptional stiffness and strength of COF nanofilms across large areas render them suitable for applications necessitating robust mechanical performance, such as sensing and environmental remediation. This study paves the way for a fundamental understanding of the relationship between the macroscopic mechanical properties of 2D COFs with their composition and structure.

This study was carried out within the MICS (Made in Italy – Circular and Sustainable) Extended Partnership and received funding from Next-GenerationEU (Italian PNRR – M4 C2, Invest 1.3 – D.D. 1551.11-10-2022, PE00000004).

Environmental impact assessment of e-fuels – a review of LCA studies

E. Bianco,[a] R. Depetris,[a, b] F. Pellegrino,[a, b] V. Maurino [a, b]

[a] *Chemistry Department and NIS Center, University of Turin, Via Giuria 5, 10125, Turin*

ettore.bianco@unito.it

In 2019, the transportation sector accounted for about 26% of the total greenhouse gas (GHG) emissions in the European Union (27), significantly contributing also to the emission of other pollutants such as NO_x and $PM_{2.5}$, especially in densely populated areas.

According to the IPCC, in order to limit the global temperature rise below +1.5 °C by 2100 compared to preindustrial levels, it is mandatory to achieve net zero GHG emissions by 2050. In this context, e-fuels, which are produced combining CO_2 and (green) H_2, are gaining considerable attention as possible alternative to reduce CO_2 and pollutants emissions caused by the use of fossil fuels in private and commercial vehicles.

Several Life Cycle Assessment (LCA) studies examined the manufacturing/use of e-fuels and indicated they can effectively lower GHG emissions compared to their fossil counterpart;[1, 2] yet, results are highly affected by the considered electricity source and only a few have taken into account other impact categories such as acidification or eutrophication potential.

In this work, we reviewed multiple LCA publications discussing the environmental impacts of e-fuels production in order to emphasize both the potential benefits and drawbacks originating from their integration in the current transportation network.

Development and validation of a UHPLC-MS/MS method for selected organophosphate esters flame retardants in gas-phase and aerosol of urban and mountain areas

A. Alterio,[a] E. Favaro,[a] G. Mazzi,[a] M. Feltracco,[a] E. Barbaro,[a,b] A. Gambaro[a,b]

[a]*Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, Via Torino, 155-30172 Venice Mestre, VE, Italy*
[b]*Institute of Polar Sciences, National Research Council (CNR-ISP), Via Torino, 155-30172 Venice Mestre, VE, Italy*
agata.alterio@unive.it

Organophosphate esters (OPEs) have emerged as alternative flame retardants due to strict regulatory measures (Regulation (UE) 2019/1021) that have banned or restricted more hazardous substances such as polychlorinated biphenyls (PCBs) and the major brominated flame retardants (BFRs). These compounds are included in the Stockholm Convention as persistent organic pollutants (POPs) both in Annex A to eliminate their production and use and in Annex C to reduce their unintentional release. These regulatory measures have been motivated by the recognized toxicity of these compounds to both the environment and human health, their tendency to bioaccumulate in the fatty tissues of organisms, their ability to biomagnify and to undergo long-range atmospheric transport even in remote areas[1]. OPEs also act as plasticizers and defoamers, expanding their potential scope of production, consequently increasing their diffusion into the environment[2]. Those compounds have been found in various matrices such as water, dust, sediment and air and are proving to be emerging environmental contaminants due to their various side effects and bioaccumulation potential, becoming a threat of exposure to human health and the environment[3]. The aim of this study is to develop and validate a highly sensitive and rapid UHPLC-MS/MS method for environmental matrix to determine with high selectivity six OPEs: *tris(2-chloroethyl)phosphate* (TCEP), *tris(2-chloroisopropyl)phosphate* (TCPP), *tris(1,3-dichloro-2-propyl) phosphate* (TDCP), *triphenyl phosphate* (TPP), *triethyl phosphate* (TEP), *trimethyl phosphate* (TMP). Isotope patterns have been investigated due to the presence of different combination of ^{35}Cl and ^{37}Cl in chlorinated OPEs. This analytical method allow to determine the presence of these emerging analytes in gas-phases and aerosols collected in urban (Mestre, Venice, 0 m a.s.l.) and mountain (Col Margherita, Falcade, Belluno, 2543 m a.s.l.) areas and to study their distribution and evaluate regional differences. Gas-phase and aerosol sampling was carried out using both high and low volume impactors. OPEs were found in urban samples with higher concentrations than at the mountain site; however, this confirms the potential for long-range transport to regions uncontaminated by human action[4].

The distribution of mercury (Hg) and selenium (Se) in marine mammals is crucial for assessing potential marine pollution and biological health. Understanding the distribution of these elements in various organs provides valuable insights into the physiological processes and potential detoxification mechanisms within these marine mammals [1]. This study investigates the concentrations of Hg and Se in different tissues of a sperm whale (*Physeter macrocephalus*) stranded in Forio (Na), Italy, in January 2019.

Tissue samples including liver, kidney, muscle, fat, intestine, stomach, pharynx, lung, heart, and testicle were collected and analyzed using DMA and GFAAS instrumentation. Our findings reveal significant variations in Hg and Se concentrations among the sampled tissues (**Figure 1**). Liver, kidney and stomach exhibited relatively high levels of Hg and Se, indicating these organs as potential sites for bioaccumulation of these elements. Moreover, a statistically significant positive linear correlation (p=0.0001, r=0.92) was recorded among Hg and Se concentrations.

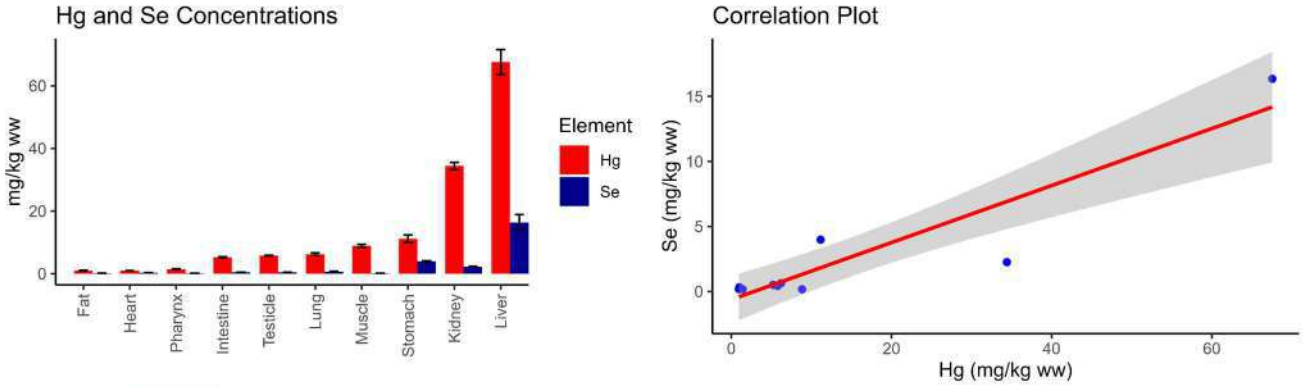

Figure 1: Hg and Se concentration (mg kg^{-1} ww) in different *P. macrocephalus* biological tissues.

A GC-QEPAS prototype for the detection of chemicals of forensic interest: a chemometrics approach

F.S. Romolo,[a] G. Felizzato,[a] N. Liberatore,[b] R. Viola,[b] Sandro Mengali[b]
[a]University of Bergamo, Department of Law, Via Moroni 255, 24127 Bergamo, Italy
[b]Consorzio CREO, 67100 L'Aquila, Italy
francescosaverio.romolo@unibg.it

GC-QEPAS, a compact gas sensor designed for real-time analysis of Volatile Organic Compounds (VOCs) and Semi-volatile Organic Compounds (SVOCs), has been developed by CREO and validated within the scope of the RISEN project (Horizon 2020, Grant Agreement No 883116). This study focuses on the analysis of drug precursors and chemical weapons in the forensic field, to ensure the safety of operators. Compounds are transferred into the sensors by a pump and then concentrated employing two graphitized carbon sorbents (Carbograph 5TD and Carbograph 2TD). Thereafter, compounds are separated by a MEMS-based fast-GC and analysed by an IR sensor based on Quartz Enhanced Photoacoustic Spectroscopy (QEPAS).
The effectiveness of the GC-QEPAS prototype was established by analysing the following drug precursors and chemical weapons simulants: safrole, benzyl methyl ketone (BMK), benzaldehyde, acetone, piperidine, toluene, methyl ethyl ketone, dimethyl-methylphosphonate (DMMP), di-propylene-glycol-methyl-ether (DPGME) and methyl salicylate, diethyl sulfide (DES), diethyl methylphosphonate (DEMP) and trimethyl phosphonate (TMP). Following the ENFSI guidelines, a complete validation of the method was carried out considering the repeatability, reproducibility, and sensitivity. Repeatability and reproducibility calculated for IR spectra correlation were close to 100%. The Limit of Detection (LoD) for the majority of analytes, determined through the signal-to-noise ratio of chromatograms, was lower than 1 ppm.
Therefore, a chemometrics approach was developed for robust data analysis and forensic interpretation. Multivariate data analysis was carried out using Python code within a Jupyter Notebook environment, using the following packages: NumPy, Pands, Matplot library, Plotly and Scikit-Learn. The data analysis of QEPAS spectra workflow involved various pre-processing steps of raw data, unsupervised and supervised pattern recognition techniques, and model evaluation through Leave-P-Out cross-validation.
Analytical method performances obtained by the validation were evaluated as reliable and relevant for the criminal justice system. Therefore, the analytical data was treated with different classification models, such as Linear Discriminant Analysis (LDA), Quadratic Discriminant Analysis (QDA), Partial Least Squares Discriminant Analysis (PLS-DA), Logistic Regression (LR) and Support Vector Machines (SVMs), in order to establish the improvements in comparison to conventional hyphenate GC-spectroscopy instruments. The results highlighted the importance of the data pre-processing method employed to obtain an accurate classification. The PCA-LDA, PCA-QDA and PCA-LR, using the standard normal variate pre-processed spectra, appear as the most effective classification models, showing satisfactory results for real implementation in forensic field applications. In addition, SVM showed lower model accuracy than the beforementioned methods but appeared still adequate.
Merit to its good analytical performances and ease of use, the instrument can be employed to detect chemical traces on crime scenes, such as drug precursors, hazardous materials and chemical weapons to protect the health and safety of forensic personnel. In conclusion, the GC-QEPAS prototype developed by CREO, coupled with the chemometrics approach, presents a promising methodology for the detection of chemical substances of toxicological interest in the forensic field.

Dried Saliva Spot and Parallel Artificial Liquid Membrane Extraction – Design a combinate green microsampling and microextraction procedures for drugs of abuse

G. Di Francesco,[a] M. Croce,[a,b] F. Bartolini,[a] I. Bracaglia,[a,b] G. Pezzuti,[a] C. Montesano,[a] R. Curini,[a] M. Sergi[a,b]

gaia.difrancesco@uniroma1.it

Novel Psychoactive Substances (NPS) are a wide group of substances, principally of synthetic production, characterised by harmful pharmacological and toxicological properties. They can be grouped into different classes, according to their biological activities (e.g., hallucinogens, psychostimulants, sedatives, hypnotics) or to their chemical structures (e.g., cathinones, synthetic cannabinoids, synthetic stimulants, phenethylamines, and synthetic opioids). Oral fluid (OF) is a useful alternative biological matrix for forensic toxicology due to its correlation with blood concentration[1] and the advantages in terms of sample collection. The dried matrix spots (DMS) sampling approach is acknowledged as a useful collection technique, simplifying transport and storage, since a liquid matrix is dried on a filter paper. DMS typically involve blood samples, while there is a reduced number of studies which consider alternative matrices. Parallel artificial liquid membrane extraction (PALME) is a recent approach for liquid-phase microextraction based on a multiple-well filter plate that divides the acceptor and the donor solution by a hydrophobic polymeric flat and porous membrane. In this study, dried saliva spot (DSS) sampling and PALME were combined to develop a new method for multi-class illicit drug analysis in OF exploiting LC-MS/MS as detection technique. For the microsampling procedure a volume of 20 µL of fortified OF were deposited on a Whatman® 903 protein saver cards and let dry for ten minutes. After that the spot were cut and inserted into the PALME well with 96 positions. For what concern the microextraction, for the acceptor solution the acidic pH was achieved by adding formic acid at 0.1% v/v, acceptor volume was set at 40 µL meanwhile the basic pH in the donor solution was achieved by adding a carbonate/bicarbonate buffer (pH 10,5). The addition of 0.4 g NaCl to the donor solution was useful to increase the recovery of the procedure, ionic strength was shown to influence the partition the donor solution and organic solvent membrane (diesyl ether with 1% of trioctylamine) because of salting out effect. The results showed that PALME allowed to obtain a good clean-up removing the interferences of the matrix, enhancing the accuracy and the precision of the method. The method was validated according to SWGTOX guidelined by evaluating stability, precision, accuracy, recoveries, and matrix effect. This new approach could expand the possible application and combination of microsampling and microextracting strategies, winking to green chemistry, in the forensic toxicology field.

ilenia.bracaglia@uniroma1.it

The detection and analytical recognition of New Psychoactive Substances (NPSs) is one of the main challenges in the clinical, toxicological and forensic field due to their rapid development and structural similarity to illicit substances already widely monitored [1][2]; for the latter reason, they are often not detectable with immunological tests and targeted methods that are designed for traditional drugs. They are not controlled by Single Convention on Narcotic Drugs (1961) or by Convention on Psychotropic Substances (1971), but represent a threat to public health, also because the purity and composition of such substances are still unknown. This situation underlines the need to develop new analytical strategies for their identification; actually, the development of new detection methods is also not easy due to the lack of analytical standards. For this purpose, this study, carried out in collaboration with the Italian Scientific Police Service, was aimed to the development of an analytical UHPLC-HRMS workflow for target and untarget determination of classic and newly introduced abuse substances in law enforcement seizures. UHPLC-HRMS has been used to perform target analyses both in Full Scan mode and MS/MS of known analytes belonging to the most common illicit substance classes, such as synthetic cannabinoids, synthetic opioids, stimulants, dissociative, hallucinogenic, sedative/hypnotic but also classical drugs; in this way, the information obtained from such analyses have been used for the creation of a chemometric model, based on their fragmentation spectra and neutral losses in a reasoned range of collision energy according to the chemical characteristics of the examined molecules.

The chemometric analysis represents the basis for the creation of a model capable of predicting the class of an unknown substance based on its fragmentation pattern, including neutral losses, thus allowing to perform untarget analysis on seized substances and potentially detect even unknown NPS. This approach promises to be interesting in addressing the growing number of new drugs flooding the market and at the same time in reinforcing existing sources of interest (such as opensource databases) with analytical information useful for the identification of new identifiable chemical structures with untargeted screening.

Multiclass analysis of psychoactive substances and NPS in oral fluid exploiting magnetic solid phase extraction (m-SPE) clean-up and HPLC-MS/MS

M. Croce,[a, b] G. Di Francesco,[b] F. Marcolini,[b] I. Bracaglia, [a,b] F. Bartolini,[b] G. Pezzuti,[b] A. Ciccola,[b] C. Montesano,[b] R. Curini,[b] M. Sergi[b]

martina.croce@uniroma1.it

The recent rapid spread of new psychoactive substances (NPS) has become a topic of interest for researchers, healthcare professionals and law enforcement. NPS are defined as new narcotic drugs that are not controlled by the United Nations Conventions on Narcotic Drugs (1961) or Psychotropic Substances (1971), but which may pose a comparable threat to public health[1]. In recent years, the interest in so-called "alternative" matrices to conventional ones (plasma, whole blood, serum, urine) used for toxicological analysis in the clinical and forensic field is growing sharply. Among these, oral fluid (OF) offers a series of advantages that justify its use in different fields of application. OF is a relatively clean matrix, collection is simple, non-invasive, no special skills are required in sampling which can be supervised without violation of privacy, while reducing the possibility of specimen adulteration or substitution. The aim of the present work is to develop a new method for the determination of several substances of abuse and NPS in OF. Magnetic solid phase extraction (mSPE) was applied as a sample clean-up technique and subsequently an HPLC-MS/MS analysis was performed for the determination of the analytes of interest. The magnetic nanoparticles (MNPs), designed synthetized for this work, have a core-shell structure of Fe_3O_4 -SiO_2-C_{18}[2]. Their characteristics of MNPs, dimensional distribution and functionalisation degree, were subsequently verified using FT-IR, DLS and microscopic techniques. The proposed procedure was then validated following the international guidelines SWGTOX showing good results in terms of recoveries and matrix effect, which proved the efficiency of the clean-up step; also, the limits of quantification and identification are low, in the order of pg/mL for almost all the analytes considered, thanks to the enrichment factor in pretreatment and the sensitivity of the HPLC-MS/MS analysis. In conclusion, this magnetic extraction in the solid phase allows the sample to be pretreated in a simple way, with benefits both in terms of time and solvent consumption, avoiding centrifugation and filtration phases and giving a "green" footprint.

Deep eutectic solvent-assisted matrix solid-phase dispersion extraction of phenolic compounds from pigmented wheat

M.C. Frondaroli,[a] S. Della Posta,[a] C. Fanali[a]

[a]*Department of Science and Technology for Sustainable Development and One Health, Unit of Food Science and Nutrition, University Campus Bio-Medico of Rome, Via Álvaro del Portillo 21, Rome*
m.frondaroli@unicampus.it

Wheat is a crop grown globally and consumed as a staple food in many countries[1]. Wheat-based foods can lower the risk of certain serious diseases, such as cardiovascular ones and some types of cancer. This work focuses on black wheat, a species that exhibits higher protein, essential amino acids, dietary fiber, vitamin K, total flavonoid (TF) and phenolic (TP) contents than soft wheat[1]. The incredible properties of wheat-based foods are attributed to the phytochemicals present in them, phenolic compounds in particular[2].

The aim of the work was to develop a green analytical method for the analysis of phenolic compunds improving the extraction yield of these compounds, using a deep eutectic solvent (DES) during the homogenization step of a matrix solid phase dispersion (MSPD) extraction. FLORISIL® was chosen as sorbent phase, and the analytes extraction was carried out by using a MeOH:H_2O mixture, 80:20 (v/v) ratio.

Type III DESs were prepared, characterized by a strong hydrogen bond between a hydrogen bond acceptor (HBA) and a donor (HBD), mixed at a specific molar ratio. In this case, choline chloride (ChCl) and betaine (Bet) were tested as HBAs while glycerol (EG) and ethylene glycol (Gly) were tested as HBDs.

An OVAT (one-variable-at–a–time) optimization permitted to evaluate the parameters able to give the highest extraction yield. The results, evaluated by the Folin-Ciocateau spectroscopic assay, were analyzed using the Box Behnken statistical program. By means of the response surfaces, it was possible to find the following optimal conditions: 1:3 as sample:dispersant material ratio (w/w), 87.65 µL as DES volume, 1 cycle and 1.42 mL as extraction phase volume. The final extract was analyzed by means of a high-performance liquid chromatography with diode array detection (HPLC-DAD) system. Finally, comparison with standard solutions permitted the identification of the following analytes: gallic acid, protocatechuic acid, kampferol, catechin, kampferol 3-o-rutinoside, and ferulic acid.

Extraction and analysis of bioactive compounds from rocket: development of a green and innovative analytical method

V.Terrigno,[a] S. Della Posta,[a] L. De Gara,[a] C. Fanali [a]

[a] *Department of Science and Technology for Sustainable Development and One Health, Unit of Food Science and Nutrition, Campus Bio-Medico University of Rome, Via Alvaro del Portillo 21, Rome*
vittoria.terrigno@unicampus.it

Bioactive molecules are substances of very varied chemical composition widely distributed in the plant world, in fact they are mainly found in fruits and vegetables. In recent years, rocket has been widely studied for its beneficial properties on human health as it is rich in antioxidant compounds that can been used in multiple applications, including cosmeceutical, nutraceutical and pharmaceutical industries[1]. However, the phenolic profile depends on several factors such as the species of the rocket, geographical area of origin, climate and sunlight. Modulation of growing parameters in experimental laboratories can increase phenolic compounds synthesis. Generally, bioactive compounds extraction is performed using organic solvents such as ethanol and methanol[2]. In recent years, the main engine of analytical chemistry is to move towards increasingly green and sustainable applications[3]. Following these principles, in this work traditional organic solvents were replaced by innovative and green solvents, such as deep eutectic solvents (DESs). They are easy to prepare using low-cost constituents, are non-toxic and biodegradable.

DESs are mainly a combination of two compounds: hydrogen bond acceptor (HBA) and hydrogen bond donor (HBD), which can interact through extensive hydrogen bonds.

An analytical method based on the use of deep eutectic solvents was developed and optimized to determine nutraceutical compounds in rocket plants growth at different conditions of light (80 PAR+LED; 80 PAR- no LED; 80 PAR + NEON), temperature (16°C; 22°C; 23°C) and salt stress induced with sodium chloride (0 mM NaCl, 150 mM NaCl, 300 mM NaCl). The optimization of the extraction procedure involved the study of type of DES, quantity of water to add to the selected DES, matrix to solvent ratio, times and temperature of extraction. Among the tested DESs, the best was choline chloride glucose (molar ratio 2:1), which gave the best quantitative results under the following optimized conditions: 1:50 w/v as matrix to solvent ratio; 30% of water added to the DES, extraction time of 30 min and extraction temperature of 50°C.

The rocket phenolic compounds profile was determined through high-performance liquid chromatography coupled with mass spectrometry (HPLC-MS): isorhamnetin, quercitin-3-O-galactoside, roseoside, quercitin, ferulic acid and chlorogenic acid were tentatively identified.

Sustainable Supramolecular Deep Eutectic Solvents based extraction for the recovery of bioactive phenolic compounds from olive pomace

G. Pietrangeli,[a] S. Della Posta,[a] C. Fanali,[a]

[a]*Department of Science and Technology for Sustainable Development and One Health, Unit of Food Science and Nutrition, University Campus Bio-Medico of Rome, Via Alvaro del Portillo 21, Rome*
giorgia.pietrangeli@unicampus.it

Agri-food industries generate large amounts of waste and the circular economy promises to be a valid solution: the reuse of by-products allows the extraction of some compounds, such as phenolic compounds, and at the same time, minimizes waste[1]. Bioactive phenolic compounds are secondary metabolites, which are present in many vegetable matrices, and thanks to their antioxidant power, prevent the onset of many diseases. According to the principles of green chemistry, the recovery of phenolic compounds from food waste chains should respect the use of economical, sustainable and environmentally friendly methods[2]. For this reason conventional organic solvent, such as methanol, hexane or acetone, are not suitable for this purpose and can be replaced with other green solvents, such as water and ethanol. In recent years, interest in innovative and sustainable new solvents has increased. Among these, Deep Eutectic Solvents (DESs) are widely studied in the literature, particularly for the extraction of phenolic compounds from food matrices and wastes[4]. In recent years, DESs have been also evaluated with the addition of β-cyclodextrins, which are cyclic oligosaccharides produced by enzymatic modifications of starch, and are characterized by a selective interaction with specific analytes, thanks to their structural characteristics. These innovative solvents are called Supramolecular Deep Eutectic Solvent (SUPRA-DESs) and promise to be a valid solution, instead of organic solvents, for the extraction of phenolic compounds[5]. The aim of this work was to develop and optimize an innovative extraction method based on the addition of β-cyclodextrins in the DES composed by ammonium acetate-lactic acid (1:7), in order to increase the analyte extraction yield. Specifically, the method was optimized by analyzing the time (30, 90 and 180 min) and temperature (30, 50 and 80 °C) of the extraction, the solid-liquid ratio (1:5, 1:10 and 1:50) and the different concentration of β-cyclodextrins (0.7, 1.8, 2.1, 4.5 % w/w). The optimized extraction procedure consists on the best extraction time of 30 minutes, temperature of 80 °C, solid-liquid ratio of 1:50 and the concentration of 1,8 % (w/w) of β-cyclodextrins. Furthermore, the extraction using SUPRA-DES enabled an increase in the extraction yield in comparison to the use of DES and also to conventional organic solvents. Finally, the olive pomace bioactive phenolic compounds were determinated through High-Performance Liquid Chromatography coupled with Mass Spectrometry (HPLC-MS).

Horseradish peroxidase (HRP) has emerged as a versatile enzyme in the field of electrochemical biosensors, offering numerous advantages for sensitive and selective analysis. Its ability to catalyze a wide range of substrates makes it suitable for detecting various analytes, including small molecules, biomolecules, and environmental pollutants[1]. Furthermore, the enzyme exhibits high stability under a variety of conditions, enabling long-term storage and use in complex sample matrices. HRP has been widely used in the biosensing field exploiting both direct and indirect strategy of detection. Generally, establishing direct electron transfer between HRP and an electrode is difficult because the active sites of HRP are deeply embedded in the thick protein shell. The role of the mediator is to shuttle electrons efficiently between electrode and the active site of the enzyme, i.e. the heme group[2]. When the redox mediator (Med) is added, the reaction mechanism with the substrate, namely H_2O_2, can be summarized as shown in Figure 1. By selecting an appropriate mediator, sensitivity can be improved due to an optimized electron transfer kinetics[3]. The aim of this work is to unravel the effect of the redox mediator on the overall performance of HRP-based sensors. In particular, the study considers the storage and operational stability of the mediator, the efficiency of the catalytic enzymatic cycle and the kinetic of the enzymatic reaction with HRP through cyclic voltammetry and chronoamperometry.

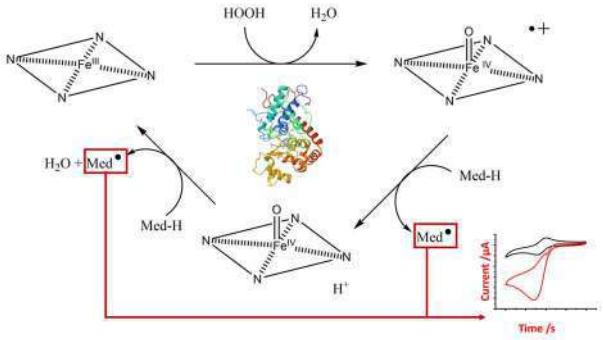

Figure 1: reaction mechanism of HRP for the reduction of H_2O_2 in presence of a generic redox mediator

giulia.cazzador@unive.it

During the past years, the increasing need to monitor biophysical parameters and enhance quality of life has led to the spreading of Internet of Things (IoT) and the development of smart and wearable devices. While these types of devices, which monitor physical parameters, are now part of our everyday life, the development of wearable electroanalytical platform for the monitoring of chemical parameters is more complex. Indeed, they need to be flexible, thin, conformable, but simultaneously resistant and low cost, possibly using sustainable and biodegradable materials.[1] Since urgent actions are required to ensure sustainable consumption and production patterns, a new revolution concerning the use of green technologies in the manufacture of electrochemical platforms is taking place.

This study aims to investigate the application of sustainable materials and technologies in the production of electroanalytical devices, such as biodegradable and flexible polymers [2] and thin graphitic carbon electrodes. Indeed, we explored different techniques to draw the conductive traces, such as graphitization of the surface using a CO_2-laser [3], the use of conductive inks [4], or a graphene-based paper [5], facilitating the manufacture, and reducing the costs of the electrodes.

The electrochemical performances of these innovative platforms were demonstrated through Cyclic Voltammetry (CV), Chronoamperometry (CA), and Electrochemical Impedance Spectroscopy (EIS). Their applicability as an amperometric sensor was assessed using glucose oxidase as a benchmark enzyme in the biosensing strategy. Furthermore, the electrocatalytic effect of these platforms for the detection of biomolecules belonging to the class of catecholamine was also evaluated, due to their importance in the biomedical field.

In conclusion, all the investigated platforms give promising results, making them suitable to replace commercial ones. Indeed, they also are flexible, thin, low cost and have low environmental impact that make them attractive candidates for sustainable and wearable sensing platforms.

francesco.bartolini@uniroma1.it

Short-chain fatty acids (SCFAs) are generated as end products by the degradation and fermentation of indigestible carbohydrates by the gut microbiota, a process termed saccharolytic fermentation[1]. They can act as signaling molecules as ligands of G-protein-coupled receptors and they are implicated in the increase of anorexic hormone production and energy expenditure[2]. Consequently, SCFA production has been linked to preventing the progression of obesity and related complications, such as type 2 diabetes mellitus and nonalcoholic fatty liver disease (NAFLD)[3]. SCFAs are typically quantified by gas chromatography (GC), liquid chromatography (LC), nuclear magnetic resonance (NMR), and capillary electrophoresis (CE)[4]. The detection of the low-molecular weight fatty acids in negative-ion ESI, without chemical derivatization, is often problematic. LC coupled with mass spectrometry (MS) with electrospray ionization (ESI) is now the most widely used analytical technique in metabolomics and reversed-phase LC–MS with post-column neutralization, previously used also for the determination of SCFAs in the pig colon and blood. The complex instrument setup for these two methods, however, makes them unsuitable for routine analysis in most laboratories. This work aimed to develop a new analytical method for SCFA based on 3-nitrophenylhydrazone (3-NPH) derivatization followed by SPE clean-up, we decided to derivatize the molecular markers with the aim of improving their chromatographic retention, the ionization efficiency and the fragmentation behaviour. While the SPE clean-up was used to minimize the matrix effect and improve extraction selectivity. The LC-MS/MS method was performed both in Multi Reaction Monitoring (MRM) for quantitative analysis and in precursor ion scan analysis (PIS) to achieve semi-targeted analysis for an extended range of SCFA compounds based on derivatization reactions. This approach can be used for putative identification and screening of SCFA compounds in biological samples. Moreover, the derivatization process allows for greater stability of the analytes in the sample over the course of storage time.

Comparison of colorimetric methods for the online measurement of hydrogen peroxide in a photo-Fenton process

A. Bianco Prevot,[a] D. Palma,[a] D. Fabbri,[a]

[a]*University of Torino, Chemistry Department, Giuria Street 5, Torino*
alessandra.biancoprevot@unito.it

The scale-up of a photocatalytic process for the removal of pollutants from water encompasses several relevant aspects, among them, the timely analytical control and the optimization of operational parameters, to maximize efficiency and minimize reagent consumption. Indeed, when running Advanced Oxidation Processes, reagents consumption represents one of the main costs; in the specific case of photo-Fenton processes, that rely on the generation of hydroxyl radicals through the reaction between hydrogen peroxide and Fe(II) ions, an excess of H_2O_2 could even hinder the pollutant degradation kinetics, making therefore its proper dosage a key issue.

The automation of H_2O_2 concentration control and dosage is therefore worth to be implemented, seeking for reliable, fast and cheap devices.

In this work two different colorimetric methods were applied and compared for the online determination of H_2O_2 ; moreover, the role of H_2O_2 dosage on the photo-Fenton degradation of paracetamol and caffeine was studied.

The kinetics of substrate degradation, organic carbon mineralization and H_2O_2 consumption were compared to define the most suitable H_2O_2 dosage procedure to maximize process efficiency.

A peculiar H_2O_2 consumption trend was observed during caffeine degradation; HPLC-MS preliminary test suggest the formation of intermediate degration products capable to generate H_2O_2.

The results obtained in the present work evidence two opposite trends for kinetics and overall H_2O_2 consumption when moving from single, stoichiometric H_2O_2 dosing approach to a fractioned dosing one. In fact, both substrate and DOC removal rates were higher when a single and stoichiometric H_2O_2 dose was added at the beginning of the process, while H_2O_2 consumption took advantage from small successive H_2O_2 addition as long as the previously added H_2O_2 was consumed before the following dose was added.

The advancement of disposable and cost-effective electrochemical devices for biomedical uses has seen a notable rise alongside the spread of remote diagnostic technologies. This surge can likely be attributed to the necessity of rejuvenating traditional sensor surfaces and the demand for manufacturing processes enabling the creation of disposable and portable electrochemical devices. These devices facilitate sample volume reduction, on-site detection, and cost reduction.[1]

Conductive inks play a crucial role in fabricating disposable electrochemical sensors, enabling the construction of screen- or stencil-printed electrodes with comparable efficiency to solid electrodes.[2] Specifically, eco-friendly conductive inks are formulated and stencil-printed onto a flexible substrate, facilitating their integration into smart devices for continuous and monitoring of substances like lactate and glucose. The optimization of conductive ink formulations is achieved through electrochemical and rheological measurements, utilizing a multivariate analysis model. Subsequently, active carbon electrodes are modified with osmium redox polymers (ORPs) to establish an electronic connection with enzymes, as glucose oxidase (GOx) cannot directly transfer electrons.[3,4] Finally, the prepared biosensors undergo testing in model solutions and industrial bioreactors sludges to determine various analytical parameters such as limit of detection (LOD), limit of quantification (LOQ), linear range, sensitivity, selectivity, reproducibility, stability, and storability.

Development and optimization of analytical method for the extraction of polyphenols and phycocyanin from spirulina followed by HPLC-MS analysis

E. Cutè[a], S. Della Posta[a], L. De Gara[a], C. Fanali [a]

[a] *Department of Science and Technology for Sustainable Development and One Health, University Campus Bio-Medico of Rome, Via Alvaro del Portillo 21, 00128, Rome, Italy*
erica.cute@unicampus.it

Spirulina (Arthrospira platensis) is a cyanobacterium that is considered an environmental friendly microalga. This cyanobacterium has received significant attention because of its high protein content, which accounts for up to 70% of its dry mass. Among the various nutrients that constitute spirulina, phycocyanin, phycobiliproteins responsible for the blue-green color of spirulina and polyphenol compounds, were known as important natural antioxidants [1,2]. Phycocyanin is known for its antioxidant properties and anti-inflammatory properties. It is a protein formed by an alpha chain with 162 amino acids and a beta chain with 172 amino acids, bound to three chromophore groups, called phycobilines. These monomers form a hexamer with a molecular weight of about 230 kDa. Usually, for the extraction of these bioactive compounds water is used as extractive solvent, but the obtained extract is unstable over time. For this reason, we evaluated the use of other extractive solvents. Deep eutectic solvents (DESs) are green solvents, formed by combining two or more components, that can act as hydrogen bond donors (HBDs), sugars, amine, or as hydrogen bond acceptors (HBAs), ammonium quaternary salts, according to specific molar ratio to form an eutectic mixture. The peculiar characteristics of DES (polarity, viscosity, and solvent capacity) are easily modulated varying the molar ratios of the components and the water content. In this work an ultrasound-assisted solid-liquid extraction, using DESs, was developed to recover phenolic compounds and phycocyanin from Spirulina. Many DESs were tested and the extraction procedure was optimized based on the obtained maximum content of phycocyanin and total phenolic content (TPC), obtain through spectrophotometric method. The optimized extraction procedure, applied for phenolic compounds and phycocyanin extraction from spirulina, provided the use of a DES composed by betaine and glucose in a molar ratio of 1:2 (with 30% water), added to 0.5g of spirulina powder with a matrix-to-solvent ratio of 1:20 w/w, in an ultrasonic bath for 1 hour at 50°C. The extraction procedure guaranteed to extract an amount of phenolic compounds of 11.77 ± 1.23 g GAE/100g and 25.56 ± 2.47 mg/g of phycocyanin from spirulina powder. DES extract stability was evaluated using spectrophotometric test, resulting better than that of water extract. The profile of the polyphenol content was evaluated through high performance liquid chromatography coupled with photodiode array and mass spectrometry detection and some phenolic compounds were identified.

Addressing food safety and detecting food fraud while fulfilling greenness requisites for analysis is a challenging but necessary task. The use of sustainable techniques, with limited pretreatment, non-toxic chemicals, high throughput results, is recommended. A combination of Field Flow Fractionation (FFF), working in saline carrier and with minimal preprocessing, and chemometrics was for the first time applied to bovine milk grouping.

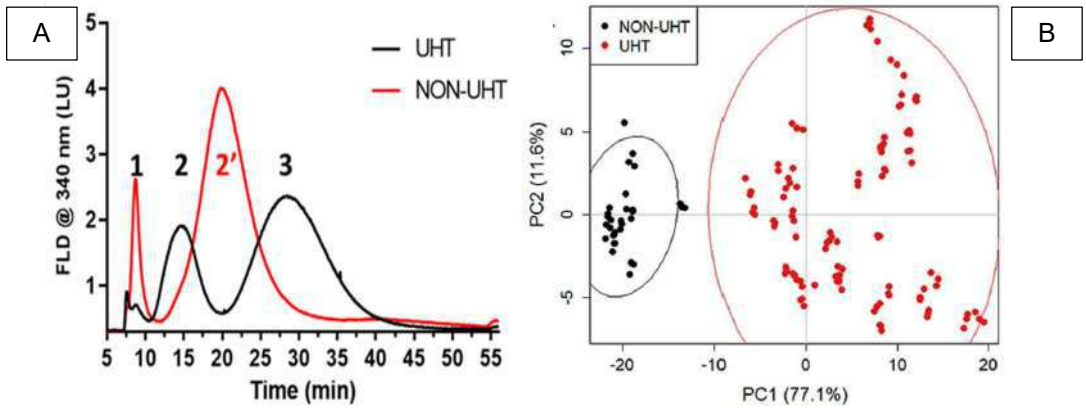

Figure 1: A shows the fractograms of UHT and not UHT milk. Figure B shows the grouping of these two classes

A set of 50 bovine milk samples was analyzed: a single analysis yielded a characteristic multidimensional colloidal dataset, that once processed with multivariate tools allowed simultaneously for different discriminations: fat content, thermal treatment, brand and manufacturing plant. The analytical methodology is fast, green, simple, and inexpensive and could offer great help in the field of quality control and fraud identification[1]. This work represents also the first attempt to identify milk sub-typologies based on colloidal profiles, and the most complete study concerning multivariate analysis of FFF fingerprint.

Geopolymers, based on aluminosilicate powders via alkali activation, have been developed and successfully used to sequester and stabilize sludge from electroplating plants. Their semi-crystalline three-dimensional silico-aluminate structure consisting of linked SiO_4 and AlO_4 tetrahedra, allows them to be used in a variety applications.
Analyses carried out 28 days after geopolymer preparation have shown the encapsulation of all pollutants present in the sludge, such as soluble metal ions, anions and surfactants.[1]
Leachate analyses, carried out according to the UNI EN 12457-2-2004 standard and at well-defined time intervals, allow the stabilization capacity to be studied in order to guide the reuse or correct disposal of the resulting materials. The results showed a good retention capacity of the effluent components.
Additional analyses carried out on the leachate were aimed at evaluating the release of the 3D aluminosilicate network formers (mainly Al and Si). These main constituents of the geopolymeric matrix are found in high concentrations in the leachate when the reticulation process is inefficient. This second part of the investigation allowed the optimisation of waste treatment, geopolymer paste formulation and curing conditions to improve encapsulation performance.

marco.giannetto@unipr.it

A magnetic electrochemical assay based on the use of bacteriophages as innovative receptors was developed for rapid and point-of-care (POC) detection of bacterial infections that hospitalized patients acquire while receiving health care. Additionally, various types of foodborne, airborne and/or waterborne bacteria are responsible for moderate to severe illness. Early detection and classification of the bacterium responsible for the infection are crucial to determine the most appropriate therapy. Conventional bacterial detection techniques, such as cell culture and colony counting, PCR, and ELISA testing, are time-consuming, expensive, and typically require highly skilled operators.[1] Recently, bacteriophages have been successfully used as innovative receptors for the detection of bacteria. Their advantages include high specificity, tolerance to organic solvents, high temperatures and pH, as well as ease and low cost of production in large amounts.[2]

To meet the demand for early detection, there is a need for portable POC diagnostics based on inexpensive, rapid, and sensitive methods for the detection of bacterial infections.

To achieve this goal, we functionalized the surface of magnetic beads with engineered bacteriophages that specifically recognize *Escherichia Coli* and exploited electrochemical transduction to enable portability of the sensing device.[3] The analytical signal was obtained using a labelled phage that binds both the bacterium and an enzyme used for the electrochemical signal generation. Different immobilisation strategies were investigated, comparing the performance of amino-modified beads with carboxyl-modified beads. Although the former showed a more intense signal, they also showed a higher non-specific interaction. Furthermore, comparing carboxyl-modified beads of different size, smaller magnetic beads (1 μm) were more effective in capturing bacteria than larger beads (2.8 μm), showing a positive/negative ratio of 20 for the determination of for the determination of 10^6 CFU/mL *E.Coli*. The proposed magneto-assay successfully demonstrated proof-of-concept rapid and sensitive detection of bacteria at clinically relevant concentrations and could provide wide potential applications in POC testing.

As reported by the Codex Alimentarius[1]: "*Food hygiene is the set of all the conditions and measures necessary to guarantee the safety and suitability of food at every stage of the food chain*", implying that a food will not cause harm after it has been consumed according to the use for which it is intended. The food can be a source of chemical, physical or microbiological dangers, where the last mainly include pathogenic bacteria such as *Salmonella, Clostridium botulinum, Listeria monocytogenes* and *viruses*. Therefore, the development of innovative diagnostic approaches for detection of microorganisms responsible for food poisoning is increasingly in demand. From this perspective, the development of new biotechnologies and their integration into miniaturized devices has opened up new interesting scenarios in the biosensor sectors. Specifically, the present work involves the development of an electrochemical apta-sensor for detection of pathogenic microorganisms *Lysteria monocytogenes*. For this purpose, screen printed electrodes, appropriately modified with specific aptamers immobilized on poly-L-DOPA electropolymerized film, have been studied. A fully electrochemical and spectroscopic characterization of the proposed biosensor has been reported together with the electroanalytical performances in terms of LOD, linear and/or dynamic range, and sensitivity.

Nucleic acid analysis is rapidly becoming a pillar for clinical diagnostics [1], food safety [2], genomics [3], and microbiology [4]. Usually, nucleic acids amplification is performed by polymerase chain reaction (PCR). This method is widely known for its reliability and flexibility but requires the employment of specialized laboratories and competent personnel, the use of complex and expensive equipment, and rather long analysis times. In recent years, an alternative technology named loop-mediated isothermal amplification (LAMP) has been developed. Differently from classical PCR, this technique not requires a thermal cycler, allowing the analysis of extracted DNA/RNA directly from material collected on site.

A critical aspect of such procedures is the low tolerance to interfering constituents within complex biological, food or environmental sample matrices [5,6].

In the present study, a promising liquid/liquid extraction (LLE) method based on the use of ionic liquids (IL) was taken into consideration for DNA and RNA extraction from food and biological matrices. The optimized procedure, easy to automatize, not requires the use of any organic solvents, in line with the Green Chemistry principles. The nucleic acid amplification was performed through an innovative all-in-one molecular biology system that takes full advantage of the LAMP technology (ICgene Plus). This portable equipment, coupled with a fluorescence detector, has been employed for the rapid isothermal amplification of nucleic acids, real-time detection, and automatic interpretation of obtained data.

carmelo.coppolino@unime.it

Hydrocarbons are the principal constituents of petroleum, which represents a very important raw material, as it can be used to produce fuels lubricants, plastics, fibers, rubbers, solvents, industrial chemicals, etc. Understanding the composition of such complex samples is particularly challenging because of the huge number of chemical compounds they have.

The hyphenation of gas chromatography and mass spectrometry (GC-MS) with electron ionization (EI) source is the gold standard for identification of unknown volatile compounds. However, for hydrocarbons, the high number of possible geometric and positional isomers makes the identification challenging because of the identical molecular weight as well as their similar fragmentation pattern. On the other hand, Fourier Transform Infrared Spectroscopy (FTIR) provides a wealth of molecular information of GC-separated analytes, related to the vibration of molecular functional groups which are complementary to the MS ones.

In this research, a new GC-*sd*-FTIR/MS instrument was developed, based on post-column GC flow splitting to GCMS-QP2020 NX mass spectrometer (Shimazdu, Kyoto, Japan) and DiscovIR-GC solid phase FTIR detector (Spectra-Analysis Instrument Inc., Marlborough, MA, USA). By means of this integrated instrumentation, it was possible to obtain three complementary information from a single analysis: the linear retention indices (LRI) of the separated compounds, their *m/z* spectra and IR fingerprint. Therefore, the definitive discrimination of hydrocarbon isomers was achieved.

filippo.alibrando@chromaleont.it

Finger lime (*Citrus* australasica L.) is a *Citrus* species endemic to Australia but it is also cultivated in other parts in the world. This fruit, whose interior is characterized by spherical vesicles, is widely used in cooking to embellish fish dishes and in making cocktails.

In addition to its function as a flavoring agent, this fruit can be used also for the production of juices and essential oils, which contain a good amount of bioactive molecules: these and other characteristics classify finger lime as a functional food.

The fruits used for the present study were collected in Calabria (South Italy) throughout the entire productive season, from October 2022 to June 2023.

The aim of this research was to investigate volatile and non-volatile fraction of the essential oil obtained by cold pressing extraction of the finger lime peels, also allowing the evaluation of differences in chemical composition during the production season.

The volatile fraction was investigate by gas chromatography coupled to mass spectrometry (GC-MS) and flame ionization detector (GC-FID). The enantiomeric distribution of some volatile components was studied by employing a multidimensional GC (MDGC) system and a chiral column in the second dimension, with an approach based on the heart-cut mode.

Additionally, the oxygen heterocyclic compounds (coumarins, furocoumarins and polymethoxyflavones) were analysed by liquid chromatography coupled to a triple quadrupole as mass spectrometer (HPLC-MS/MS).

The results reported in the present study were compared to the literature and provides new elements, in particular referred to the quali-quantitative profile of OHCs in cold-pressed finger lime essential oil and about the investigation of thirteen chiral couples, more than half never studied so far.

Research studies have showed that exposure of marine specimens to microplastics (MPs) induces a variety of toxic effects, including oxidative stress, metabolic disorder, changes in immune response, neurotoxicity, reproductive and developmental toxicity [1, 2]. The purpose of the present study was to evaluate for the first time the effects of MPs on the muscular lipid component in specimens of wild *Trematomus bernacchii*. The fish were caught during the 37th Italian Antarctic Expedition (2021-2022) for the SBAM - PNRA project. In Italy, the gastrointestinal tracts (GITs) of each fish were digested in order to isolate the MPs. Twenty *T. bernacchii* specimens were classified in positive (samples found to be contaminated by MPs in their GITs) and negative (samples MPs free) groups according to RAMAN spectroscopy analyses. The lipid fraction of the selected *T. bernacchii* samples was analyzed by gas chromatography technique coupled to mass spectrometry and flame ionization detectors. A total of fifty fatty acids methyl ester (FAME) compounds were identified and quantified in the analyzed samples. The lipid distributions among the positive and negative fish groups were correlated in order to evaluate the impact on the metabolic activities of fatty acids in muscle tissues. This is the first research study in which the effects of MPs are used for establishing the nutritional quality of wild marine species.

Knowledge of the composition of TAGs in vegetable oils is important for dietary and nutritional reasons, due to the influence of the different properties of each fatty acid on the human organism. Specifically, olive oil is a popular food ingredient worldwide, and for this reason, detecting economically motivated adulteration is important to protect consumers' interest and health [1].

Current research on the fraud detection of olive oil involves a wide array of methods, including infrared spectroscopy, Raman spectroscopy, liquid chromatography (LC), and gas chromatography [2]. In this study, a fast, simple and green methodology was optimized to detect intentionally adulterated olive oil with common seed oils at different levels (between 5% and 50%), by means of subcritical fluid chromatography (SubFC) with UV detection, followed by statistical analysis.

The developed method is a more sustainable alternative to conventional non-aqueous reversed phase methods (NARP-LC), for routine analysis aimed to guarantee olive oil quality. Separation was achieved on four Ascentis Express C18 columns serially coupled (for a total stationary phase length of 60 cm), with a CO_2-based green mobile phase, which provided high efficiency without reaching a prohibitive backpressure. Remarkably, small amounts of organic modifier (5%) were sufficient for elution, thus minimizing both solvent consumption and waste (around 1.5 mL per analysis).

tsalerno@unime.it

Gas chromatography coupled to mass spectrometry detector (GC-MS) with electron ionization (EI) source is a widely used analytical technique for identification of volatile compounds. The highly reproducible fragmentation pattern provided by MS, allows reliable identification by comparing experimental spectrum with commercial spectra database, but in many cases, misidentification can occur due to a high spectral similarity. The Linear Retention Indices (LRI) approach can be used in combination with conventional mass spectral search with the goal of boosting the identification of "challenging" molecules.

However, when it comes to molecules which present a high number of positional, as well as geometrical isomers such as hydrocarbons, the identification by GC-MS becomes challenging, because they show the same *m/z* fragmentation and a very similar retention behaviour. On the top of that, the lack of reference materials and of published retention data makes the reliable identification trickier. On the other hand, Fourier Transform Infrared (FTIR) spectroscopy can provide a wealth of molecular information of GC-separated analytes which are related to the specific vibrations of the chemical bonds present in a molecule. Such vibrations are different for each isomer, therefore making possible their discrimination.

For this reason, in this research, a database containing the spectra obtained by GC-FTIR analyses of hydrocarbon standard mixture was created, and it was successfully applied for the identification of unknowns. It allowed the reliable discrimination of the isomers which presented a very similar mass spectrum, as well as linear retention index. Such isomers, indeed, presented a considerable difference in terms of similarity score in the FTIR library search.

Oxygen Heterocyclic Compounds (OHCs) are a group of secondary plant metabolites mainly represented by coumarins (Cs), furocoumarins (FCs) and polymethoxyflavones (PMFs). These molecules are characteristic of *Citrus* fruits, often employed to flavour foods and cosmetics. Unfortunately, these molecules can cause harmful effects by ingestion and following exposure to UVA. So, coumarin content is regulated both in food and cosmetic, while FCs content is regulated only in cosmetic products[1,2,3]. For these reasons, over the years differents analytical approaches were applied to determine OHCs in *Citrus* products (GC-FID, HPLC and SFC coupled with UV, fluorimeter, or mass detectors). These methods involve long analysis times or the use of toxic solvents.

Therefore, this work will focus on the development of a fast and more eco-sustainable liquid chromatography tandem mass spectrometry method (HPLC-QqQ-MS) to determine OHCs in complex matrices. The analyses were carried out on a liquid chromatographic Nexera X2 system coupled with a triple quadrupole mass spectrometer LCMS-8060 (Shimadzu Europe, Germany) via an APCI interface, set in positive ionization mode. Water and Ethanol were employed as mobile phase A and B, respectively; the column was an Ascentis Express C18 (50 x 2.1 mm, 2.7 µm) (Merck, Darmstadt, Germany). The quantitative characterization was based on calibration curves built in Multiple Reaction Monitoring (MRM) acquisition mode for each target. Method validation was performed in terms of linearity range, limit of detection (LoDs), limit of quantification (LoQs), repeatability, and accuracy.

The proposed analytical method allowed to determine 36 OHCs in 3.5 minutes with a consumption of about 3 mL of ethanol per analysis. LoDs and LoQs were less than 1 ppb for most target compounds. This method can be used to quantify OHCs, contained at trace levels, in *Citrus* products.

The implementation of recycling techniques represents a potential solution to the plastic pollution issue. To date, only a limited number of plastic polymers can be efficiently recycled. In the Italian plastic waste stream, the residual, non-homogeneous fraction is called 'Plasmix' and it is intended for low-value uses.

Figure 1: From Plasmix to materials.

However, Plasmix can be used to create new materials through mechanical recycling but, before being used, needs to be tested for its eco-safety because, once in the environment, it can interact with aquatic and terrestrial organisms, mainly after its breakage and/or fragmentation in microplastics. Naïve (*Px*) and additivated Plasmix-based (*APx*) materials obtained by mechanical recycling procedure were characterized. Then were grinded to obtain microplastics (*MPs*) and tested to assess their eco-safety.

The potential acute and chronic toxicities induced by the exposure to different concentrations of microplastics were evaluated on two organisms: the terrestrial earthworm *Eisenia fetida* and the freshwater Cladoceran *Daphnia magna*. The obtained results were correlated to the potential bio-disponible compounds that can migrate and up taken by the organisms.

Head-space sampling coupled to GC-MS analyses were used to determine the release via volatilization of chemical compounds from *Px-MPs* and *APx-MPs*, simulating the exposure of organisms occurring in soil.

Instead, to simulate the release that can occur in the aqueous media a water extraction of the *Px-MPs* and *APx-MPs* followed by GC-MS analyses were performed.

silvia.berto@unito.it

The constituents of the atmosphere, and in particular the particulate matter (PM), play important roles in the geochemical cycles of the metal cations. The atmospheric deposition of mineral dust from continental regions is a significant source of both iron and aluminium to the ocean[1,2], and Fe is essential to control of biomass production in ocean water. To better understand the biogeochemical cycles of the elements, it is important to evaluate their distribution between solid phase and solution as well as to define the main species that can be formed, because chemical processes occurring in the soluble fraction of the aerosol may affect the photo-reactivity and the bioavailability of metal cations[3-5]. In a previous work[6] the main ionic components occurring in water extracts of Artic atmospheric depositions were quantified, and a chemical model was applied to identify the main species occurring in the samples. The speciation models suggested a significant role of oxalate as ligand for Al^{3+}, Fe^{3+}, and Cu^{2+}, but the chemical model used was just a first approximation of the chemical speciation of the real samples, because the formation constants used were referred to 25 °C and infinite dilution. In this work the model capability was enhanced, by considering formation constants defined in the temperature range 5 – 25 °C and at ionic strength 0.05 – 3 mol L^{-1} in NaCl medium, especially for iron – oxalate complexes that mainly affect the chemical system. Hence, new models were proposed varying the temperature and the ionic strength, and highlighting the role of both parameters on Fe(III) speciation. Moreover, the formation constants here defined allow for improving the reliability of the modelling process, thereby making the chemical model more suitable to describe the chemistry of the PM soluble fraction in real environmental conditions.

The present study aimed to support police forces in their battle against illicit drug trafficking by means of a multi-technique approach, based on gas chromatography. The research was carried out in collaboration with the Scientific Investigation Department RIS Carabinieri of Messina, which provided 25 essential oils extracted from the seized *Cannabis* flowering tops. All the samples were distilled by using microwave-assisted hydro-distillation (MAHD) system. In a first step, the Δ^9-tetrahydrocannabinol (THC) content, useful to classify cannabis plant as hemp (≤ 0.2% of THC) or as marijuana (> 0.2%), was investigated. On the other hand, the terpene profile was determined by GC-MS and GC-FID analyses. Lastly, a heart-cutting multidimensional gas chromatography (MDGC) approach was implemented, based on the combination of apolar and chiral stationary phases in the first and second dimension, respectively. The system was coupled in parallel to an isotope-ratio mass spectrometry (C-IRMS) and MS detection, for studying the enantiomeric and carbon isotopic ratios of selected chiral compounds. Finally, all the data were combined in a statistical model, to demonstrate the existence of useful parameters to be used for the classification of confiscated samples.

federica.bianchi@unipr.it

The growing demand for an antibiotic-free food chain requires both the use of effective analytical strategies in monitoring raw materials and the improvement of production processes. To date, many analysis methods are based on targeted approaches[1]; however, the comprehensive evaluation of the metabolomic changes related to the use of antibiotics requires the development of untargeted strategies.

In this context, ultra-high-performance liquid chromatography-ion mobility-high-resolution mass spectrometry (UHPLC-IMS-HRMS) currently represents the best tool to address the challenges related to the complexity of the metabolome. UHPLC provides fast and efficient separation of compounds, whereas HRMS is characterized by enhanced specificity, sensitivity and availability of large spectral databases. In addition, IMS offers great potential for improving throughput and depth of coverage in metabolomics studies, being able to separate ions according to their collisional cross-section (CCS)[1].

In the present study, UHPLC-IMS-HRMS is proposed for the evaluation of the metabolomic response of the different organs from antibiotic-treated and untreated pigs. Spectra were acquired in both positive and negative electrospray ionization modes, operating in data independent High-Definition MS^E acquisition mode, allowing for the simultaneous acquisition of CCS values, precursor and fragment ions which are key parameters for univocal identification of the metabolites[2]. Relative standard deviation within QCs samples <30%, percentage of missing values (cut-off of 40%) and a minimum 3-fold change compared to the method blanks were used for data filtering. A supervised Partial Least Squares-Discriminant Analysis pattern recognition approach was applied on the autoscaled data allowing for the annotation of features responsible for the discrimination between antibiotic-free and antibiotic-positive samples.

Advanced mass spectrometry (MS)-based proteomics is a powerful approach for discovering new disease biomarkers, towards the development of reliable diagnostic tests for early and accurate diagnosis.[1,2] Colorectal cancer (CRC) stands as the second leading cause of cancer death, for which non-invasive diagnostic screening tests are strongly needed to improve the prognosis and the efficacy of the pharmacological therapy.[3] In order to increase participation in preventive care screening it would be ideal to find a biomarker detectable in samples collected through a totally non-invasive method such as stools.

The present work is part of a research project aimed at combining the discovery of faecal CRC biomarkers, with the perspective to implement point-of-care testing based on smart electrochemical sensing devices.

Stool samples were obtained from a cohort of patients subjected to colonoscopy and carrying at least one adenomatous polyp or carcinoma. Patients were stratified according to histology into three groups: low-grade dysplasia, high-grade dysplasia, and carcinoma; healthy controls were also included in the study.

A nano-LC coupled to an Orbitrap Exploris 480 with a High-Field Asymmetric Waveform Ion Mobility Spectrometry System was used for untargeted MS-based shotgun proteomics. Different sample preparation strategies were investigated and the extraction procedure that allowed the highest number of identified human proteins involved a lysis buffer combined with sonication and protein precipitation with acetone/ethanol (1:1 *v/v*). In particular, a total of approximately 500 proteins were identified and quantified across all the samples. Statistical analysis highlighted the presence of several enriched proteins compared to healthy subjects in low-grade dysplasia, high-grade dysplasia, and carcinoma patients.

The developed MS-based proteomics strategy permitted the shortlisting of potential CRC biomarkers for further validation.

In the last years, agrifood processing wastes have been used for the development of multifunctional materials possibly capable of effectively and selectively interacting with organic (pesticide, dyes) and inorganic (metals, anions) pollutants, through adsorption mechanisms[1]. This contribution presents the preliminary results of an investigation focused on the characterization of bergamot (BP), grape (GP) and olive (OP) pomace samples from different cultivars, representative of various harvesting seasons. The waste biomasses were provided after juice and essential oil extraction, berries pressing for the must production and olive oil extraction, respectively. Aliquots of the pristine pomaces were mechanically ground using a grinder, dried in an oven at T = 333 K until constant weight and blended again to gain a fine powder. The resulting solids (*raw*) were divided in diverse portions and pretreated for 6 hours at T = 303 K using deionized water and nitric acid solutions, according to procedures reported in literature[2]. The *raw* and pretreated samples were characterized by means of BET and SEM-EDX techniques to get information on the superficial area and the particles sizes distribution. The TG-DTA and the FT-IR ATR spectroscopy were used to study the pomaces thermal properties and to confirm the presence of functional groups possibly capable to interact with metal cations, respectively. The acid-base properties of the biomasses active sites were potentiometrically investigated at I = 0.10-1.00 mol dm^{-3} in $NaNO_{3(aq)}$ and T = 298.15 K. To confirm the obtained results, some checks were also carried out on grape and olive pomaces pretreated with H_2O by using the classic volumetric method with calcium acetate[3]. Lastly, the dependence of protonation constants on ionic strength was modelled using an extended Debye-Hückel type equation.

riccardo.desanto@uniroma1.it

Microplastics (MPs) are particles with sizes in the 5 mm – 1 µm range in their largest dimension. MPs can easily enter the environment through various routes and persist for many years in the oceans; recent studies have shown that polypropylene (PP), polystyrene (PS), and polyethylene (PE) are the most frequently detected MPs in the aquatic environment[1]. Although MPs can already pose a risk on their own, they also have the capacity to act as carriers for many substances, both inorganic and organic[2]. For this reason, kinetic and isotherm sorption studies involving MPs are extremely valuable assets to consider since they allow to provide information on the efficiency of the adsorption process and its nature, to know the limits of the sorption process and the performance of the sorbents, and to evaluate the maximum capacity and the rate of the sorption process[3]. To carry out these types of studies, kinetic and isothermal models can be applied to experimental data to understand the mechanisms involved in the retention of analytes on sorbents. In this work, a complete study of the sorption behaviour of a natural glucocorticoid, cortisone, in polypropylene (PP), polystyrene (PS), and high-density polyethylene (HDPE) MPs in two different matrices (Milli-Q water and artificial seawater) was carried out, using high-performance liquid chromatography coupled to an ultraviolet detector for the determination of the analyte. Cortisone is frequently found in natural environments, especially in aquatic ones, and it could potentially become a risk if preconcentration occurs within the MPs and their migration to a living organism that has ingested them, leading to adverse health effects[4]. Kinetic and isotherm studies were performed through batch sorption experiments under controlled conditions: 1 g of MP pellets of 3 – 5 mm diameter, magnetic agitation at 1000 rpm, and 20 ± 2 ºC. For this purpose, sorption kinetics and isotherms have been obtained and their fitting to different models (pseudo-first order, pseudo-second order, intra-particle diffusion, Langmuir, Freundlich, Temkin, Henry, Redlich-Peterson, Dubinin-Radushkevich) have been studied and commented. Despite all types of plastics showed sorption affinity towards cortisone, the comparison of results in Milli-Q water and artificial seawater revealed changes in sorption capacity and the predominant sorption mechanism involved.

elena.sossich@unive.it

Therapeutic drug monitoring (TDM) is crucial for evaluating and improving treatment effectiveness, enabling personalized treatments and precision medicine to enhance patient survival. Since drug effects vary among individuals, adjusting dosages based on individual pharmacokinetic profiles maximizes treatment benefits and minimizes adverse effects.

Biosensors represent an innovative technology that can offer an opportunity for the rapid, sensitive and specific detection of analytes (drugs, protein biomarkers, etc.). Selective receptors are the key to allow any biosensing platform to properly work. For decades antibodies (Abs) were employed as the receptors of election, and so it is nowadays. However, although Abs are very specific for proteins, they might not for small molecules. Moreover, they are also sensitive to environmental conditions such as pH, temperature, which could limit their stability and biosensor performance. Finally, their production can be expensive and time-consuming.

In this respect, aptamers and peptides might offer a valuable alterantive.[1-4] Aptamers are single-stranded oligonucleotides that can be designed to target a wide range of molecules, including small molecules. Their defined structure facilitates their binding to targets with high specificity and affinity. Furthermore, aptamers exhibit remarkable stability, superior to that of proteins or antibodies. Peptides are also a promising category of bio-recognition elements, primarily valued for their stability and selectivity towards a specific target analyte. Furthermore, they can be both chemically synthesized, which allows for straightforward production and modification. This process is typically more rapid and cost-effective compared to the production of Abs, thus making them suitable for the development of novel biosensing architectures.

Herein we discuss aptamer- and peptide-based biosensing platforms enabling the recognition of small molecules with high specificity and selectivity.

Biochar: an environmentally sustainable approach for removing potentially toxic elements (PTEs) from contaminated water

G. Marussi,[a] E. Pavoni,[b] M. Crosera,[a] N. Greggio,[c] A. Montanari,[a] S. Covelli,[b] G. Adami[a]

giovanna.marussi@units.it

Nowadays, to mitigate the negative effects caused by pollution, particular attention is being paid to the eco-sustainability of human and industrial activities and the development of alternatives to the use of charcoal as a source of energy production. Biochar fits perfectly into these objectives, being used as a soil amendment or as an adsorbent of organic and inorganic environmental contaminants. Moreover, it is obtained through a sustainable process, which yields biofuels, synthetic gases, and clean energy as by-products.

An important source of contamination in the Friuli Venezia Giulia Region is the Raibl dismissed mining district, located in Cave del Predil (UD), which was active for the extraction of galena (PbS) and sphalerite (ZnS) until 1991. A large amount of mineralised waste-rocks and tailings from the flotation plant operating at the Raibl mining district were disposed from 1976 to 1991 in tailings impoundments set up on the western bank of the Rio del Lago stream. Leaching processes involving tailings and the subsequent release and dispersion of potentially toxic elements (PTEs), especially Thallium (Tl), are promoted during periods of intense rainfall and high flow river conditions. The main aim of this study was to experimentally determine the ability of biochar to adsorb PTEs (such as Pb, Tl and Zn) from contaminated water. The biochar used in this study is obtained from the processing of vineyard pruning waste, produced by slow pyrolysis, and characterised by a high degree of carbonisation, aromaticity, hydrophobicity, and porosity.

Several adsorption tests were performed with two types of biochar, fine-grained and heterogeneous coarse-grained, in different solvents (MilliQ water and fluvial water from the Tagliamento River). A quantity of 200 mg of biochar was exposed to 20 mL of solutions with concentrations of 1, 5, 10, 25 and 50 mg/L of the three elements individually. The tests were also repeated with solutions containing the three elements in a mixture to assess if competition occurred between them in absorption. Using ICP-AES, the residual metals in solution were quantified, and then the adsorbed metals were calculated, expressed both as a percentage in solution and per gram of biochar used. The tests showed that fine biochar has a higher adsorption capacity than coarse biochar due to its greater homogeneity, and that the maximum amount adsorbed by this type of biochar was approximately 2000 µg/g of metal. Furthermore, neither pH nor the presence of cations in fluvial waters (Na, Ca, Mg and K) affect adsorption. By comparing the results of the single-element and multi-element tests, it was concluded that the three metals compete in adsorption, with a recurring order of affinity $Pb^{2+} > Tl^{+} > Zn^{2+}$ most likely due to the formation of a double layer on the surface of the biochar in contact with the solution, in agreement with Stern's theory.

Unveiling Sasanian secrets: Elemental analysis of ancient drachmas using μ–EDXRF

G. Marussi,[a] M. Crosera,[a] B. Callegher,[b] A. Gariboldi,[b] G.Verk,[a] G. Adami [a]

gadami@units.it

Chemical analysis of ancient coins provides valuable information about the metallurgy and economy of the time when the coins were minted[1]. Due to the high value and rarity of ancient coins, museums and collectors of numismatic items often require chemical analyses using exclusively non-destructive techniques. Among these, X-Ray Fluorescence (XRF) has firmly established itself in the field of cultural heritage and, more specifically, in the analysis of ancient coins due to its cost-effectiveness, non-destructive nature, speed, and its ability to analyse the sample as is, without requiring pre-treatment or cleaning[2].

In this study, 29 drachmas minted during the Sasanian dynasty (6^{th} – 7^{th} century AD) were characterised using μ-EDXRF. Specifically, these coins were issued between 498 and 628 AD, during the reign of four Sasanian kings (Kavad I, Khosrow I, Hormizd IV, and Khosrow II) and today belong to a private collection of the Department of Humanities of the University of Trieste.

As the availability of other historical evidence from this period is limited, the coinage of the Sasanian dynasty remains the most critical source for the study of its political and economic history[3]. Therefore, this study aimed to determine the elemental composition of the alloy's surface, with the objective of ascertaining the fineness of the 29 drachmas and identifying any potential forgeries or devaluation processes that may have occurred during the period covered by these coins.

After cataloguing the coins and measuring their mass, diameter, and thickness, eight XRF spectra were acquired for each sample using a micro-XRF spectrometer ARTAX 200 (Bruker Nano GmbH). From an initial qualitative analysis of the collected XRF spectra, it was concluded that the drachmas were primarily composed of Ag, with traces of Cu, Au, and Pb. Thanks to the availability of a sterling silver standard (92.5% Ag, 7.5% Cu supplied by Goodfellow, UK), it was possible to semi-quantitatively determine the contents of these two elements in all 29 coins. The Ag content was above 95% in almost all the coins, with the exception of one coin that had a high copper content and the presence of characteristic zinc and mercury peaks: this led to the hypothesis that it might be an ancient forgery. In addition, a group of five coins with a higher silver content (> 99.8%) was observed. These coins bear the inscription "afid" on the recto, which means "good" or "excellent" in ancient Persian. The analyses conducted in this study affirmed the superior quality of these coins compared to similar coins minted in the same period but lacking the inscription, corroborating the historical hypothesis. Finally, the Au/Ag ratio, which can provide additional insights into the silver's origin, potentially identified two distinct groups of coins that may have been forged from two different raw minerals. In order to confirm the results obtained, the 29 drachmas will be analysed using the quantitative LA-ICP-MS technique.

This work presents two forensic case studies where the application of chemometrics played a crucial role.

The first study explores the potential of a multiblock platform (IRIS, XGLab SRL – Bruker Nano Analytics, Milano, Italy) capable of simultaneously capturing X-ray fluorescence (XRF) data along with visible & near-infrared (VNIR) and short-wave infrared reflectance spectra (SWIR) to identify dehydrated biological fluids. Various fluids including blood, urine, semen, and saliva from different donors were analysed on wood specimens at different deposition times using chemometric methods. The study aims to achieve two objectives: firstly, to detect the presence of biological fluids on the substrate and, secondly, to differentiate between them. Chemometric analysis, including Principal Component Analysis (PCA) and Multivariate Curve Resolution - Alternating Least Squares (MCR-ALS), proved highly effective in recognizing and distinguishing between biological fluids through detailed chemical maps, even in cases with similar vibrational bands and elemental compositions, like urine and saliva.

This research contributes to the development of new techniques for forensic investigations, addressing the challenges of complex sample matrices and degradation effects commonly encountered in this field.

The second study focuses on the estimation of the time since the discharge of firearms, analysing the decay of gunshot residues (GSR) over time. GSR consists of a complex mixture of organic (O-GSR) and inorganic (I-GSR) compounds, released after the firing of a firearm. So, this research employs solid phase microextraction followed by gas chromatography - mass spectrometry (SPME-GC-MS) for the detection of O-GSR in weapon and ammunition components. The initial phase involves optimizing and validating a method to detect O-GSR in spent shells. Chemometrics, using a multivariate statistical approach based on Principal Component Analysis (PCA) and Design of Experiments (DoE), was utilized to define both the target compounds to be investigated and the optimal experimental conditions to analyse them. In the second phase, the developed method was applied to the analysis of O-GSR in semi-automatic pistol barrels, monitoring decay over time with multiple linear regression.

Preliminary findings suggest that SPME-GC-MS analysis of firearm components could offer valuable insights into recent firearm use, paving the way for potential advancements in forensic firearm investigations.

Ventilator-associated pneumonia (VAP) is one of the most common infections in the Intensive Care Unit (ICU)[1]. The diagnosis of VAP is complex, invasive, non-specific and slow, and results can take days; hence, it is often necessary to initiate a broad-spectrum antibiotic therapy, which in many cases leads to overtreatment of the patients[2,3]. Therefore, the need for new diagnostic biomarkers, which can limit the inappropriate use of antibiotics and contribute to the reduction of antibiotic resistance, remains very important.

Exhaled breath condensate (EBC) is the exhalate from breath which has been condensed using a cooling device. It is a promising source of biomarkers, especially for lung diseases. Several biomarkers of pathogens responsible for viral infections were already identified in the EBC through metabolomics analyses[4], while knowledges on proteins are still limited.

The aim of this work was to identify novel bacterial-derived proteins responsible for infections in the ICU, through untargeted proteomic analysis of the EBC collected by condensation with a non-invasive technique. After the collection of EBC, proteins were precipitated, then digested with trypsin and peptides were desalted and analysed using nano liquid chromatography coupled with high resolution mass spectrometry (Orbitrap Exploris 480, Thermo). Using this approach, several novel biomarkers from both GRAM+ and GRAM- bacteria were identified.

Hence, with our work, we aim to make a step forward on the non-invasive diagnosis and monitoring of VAP.

Immobilized Lipases on Spent Coffee Grounds for Enhanced and Sustainable Oil Hydrolysis

V. Chiappini[a], A. M. Girelli[a]

[a]*City1Department of Chemistry, Sapienza University of Rome, P.le A. Moro 5, 00185, Rome, Italy*
viviana.chiappini@uniroma1.it

Free fatty acids (FFAs) play a fundamental role in industry as they are used in various sectors, from the food and pharmaceutical industry to biofuels production. Traditionally these molecules are produced employing aggressive chemicals and high temperatures [1], so, the use of immobilized lipases has recently emerged as a promising alternative. Also, the use of lignocellulosic wastes as lipase supports has aroused great interest [2] due to their wide availability, non-toxicity, renewability, etc. [3,4]. For these reasons, this work aimed to use spent coffee grounds (SCG) for the synthesis of solid biocatalysts capable of synthesizing FFAs from olive oil. Three solid biocatalysts derived from the immobilization of commercial lipase from *Candida rugosa* (C-CRL), lipase (isoenzyme 1) from *Candida rugosa* (Lip1), and lipase from *Rhizopus oryzae* (ROL) were studied. The solid biocatalysts were obtained through adsorption [5] on the treated waste material and immobilization parameters such as time, pH, and initial activity in the immobilization mixture were optimized for all three types of enzymes. The aim was to obtain the solid biocatalyst with the highest possible activity and the success of the immobilization procedures was evaluated by considering the activity recovery (%), immobilization efficiency (%), and activity of the solid biocatalyst (U/g). The synthesized solid biocatalysts were also characterized in terms of pH and thermal stability and each was found to be more stable than the starting free enzyme. Finally, all optimized solid biocatalysts were used in the hydrolysis of olive oil at 30 °C. Operational stability was also tested by repeating the hydrolysis procedure for several cycles and washing the solid biocatalyst after each use. All three solid biocatalysts demonstrated excellent operational stability, being able to be reused for up to 6 consecutive cycles. However, immobilized C-CRL showed the best hydrolysis percentage (23%) and the best specific Space-Time Yield (STY) [6] (8.8 g L^{-1} d^{-1}).

In conclusion, this study addressed the pressing need for sustainable methods of raw material production using lipases immobilized on a lignocellulosic waste. The procedure was proved to be a promising alternative to traditional methods, offering advantages such as eco-friendliness and enzyme reuse.

The present study focuses on the development and validation of an HPLC-DAD methodology for the detection of a potent chemotherapeutic agent, Maytansinoid Ravtansine (DM4), and its metabolite, S-methyl-DM4 (S-Me-DM4), in plasma samples.

Methodologically, after a simple protein precipitation with acetonitrile and after drying 1 mL of supernatant, the sample was directly analyzed by HPLC under isocratic elution. Employing a flow rate of 1.0 mL/min and a reversed-phase GraceSmart RP18 column thermostated at 40°C, a complete resolution and separation of DM4 and S-Me-DM4 within 13 min was achieved. The optimized injection volume of 20 µL and the wavelength set at 254 nm were utilized for quantitative analyses. The limit of detection and quantification of the method were 0.025 and 0.06 µg/mL for both the analytes, respectively. The calibration curve showed a good linearity in the range 0.06–20 µg/mL. For both analytes, the intraday precision and trueness were 2.3–8.2% and -1.1 to 3.1%, respectively, while the interday values were 0.7–10.1% and -10.4 to 7.5%, respectively.

The developed methodology [1] enables the concurrent determination and quantification of free DM4 and its metabolite, free S-Me-DM4, making it a valuable tool for assessing the pharmacokinetics and pharmacodynamics of DM4-based therapies. In addition, the procedure was successfully applied to analyse the presence of free DM4 or its metabolite, free S-Me-DM4, in human plasma samples spiked with the 1959-sss/DM4 antibody-drug conjugate (ADC). The utilization of the herein validated methodology allowed confirming the presence of these analytes, thereby providing insights into their potential release from the ADC structure.

Monoclonal antibodies (mAbs) are currently almost the only choice in the field of molecular recognition applied for the development of bioanalytical assays, therapies, or diagnostics. Due to their high production costs and low stability, new systems need to be developed to replace them. In this context, molecularly imprinted polymers offer an effective alternative. With the ability to create selective recognition sites in synthetic polymers, MIPs offer the specificity and selectivity of naturally occurring receptors with the added benefits of ease and speed of preparation, low cost, and good stability under various environmental conditions. Among the potential polymers, polycatecholamines (pCAs) have gained prominence in the scientific literature. Inspired by the adhesive system of mussels[1], polymers derived from endogenous neurotransmitters such as dopamine (DA) and norepinephrine (NE) can be used for the synthesis of nanofilms or nanoparticles with remarkable adhesive properties on virtually any surface and are easily molecularly imprintable to obtain mimetic receptors of a new generation, namely Molecularly Imprinted Bio-Polymers (MIBPs)[2]. In particular, the synthesis of polynorepinephrine nanoparticles (PNE-NPs), achieved through alkali-induced autoxidation of NE, has been investigated and tuned by a multivariate approach of the synthesis conditions to optimize their use for various applications, from clinical diagnostics to therapy. The approach has been performed first on non-imprinted PNE NPs, and then on MIBPs. Noncovalent molecular imprinting has been exploited to create molecular recognition cavities within the polymer matrix by incorporating the protein template (or a portion of) after the initial nucleation step of PNE-NPs. Several analytical techniques can be coupled with these PNE-NPs: benchtop sensors based on Surface Plasmon Resonance (SPR), Quartz Crystal Microbalance (QCM), or Fiber-Optic Bio-Layer Interferometry (BLI). MIBPs also hold promise as an alternative to mAbs, emulating the natural process of antibody-antigen recognition in vivo, with potential applications in the treatment of diseases such as cancer, autoimmune disorders, or infections[3].

giumicalizzi@unime.it

The goal of the present research is to develop innovative, fast, reliable, and environmentally friendly analytical methods to determine pesticides in *Cannabis Sativa L.* inflorescences. The cultivation of cannabis has significantly increased in proportion to market demand and with it the use of pesticides in order to increase the crop yield. Although there are numerous analytical methods for the extraction and characterization of bioactive compounds in cannabis, the determination of pesticides in this matrix is still a relatively new area that requires further study and evaluation. Bureau of Cannabis Control Text of Regulations, the California regulation concerning the limits admitted for pesticides in *Cannabis sativa L.*, describes the Residual Pesticides Testing criteria. Pesticide residue admitted in cannabis plant materials in any case should not exceed action levels expressed as low part per billion (ppb) [lower limit of quantification (LLOQ)].

In this research study particular emphasis has been placed on the development of analytical strategies in order to meet the criteria of green and especially white chemistry, the latter aimed at encouraging the ecologic approach of researchers in the development of new instrumentations and methods, but without loss of functionality at the expense of analytical performance. Based on this assumption, a reliable and miniaturized strategy has been developed for the extraction of pesticides from hemp inflorescences with the objective of automating the entire analytical workflow. The characterization of specific pesticides or chemical classes of pesticides in hemp inflorescences was carried out by using gas chromatography coupled to a triple quadrupole mass spectrometer. For this purpose, selective MRM transitions have been optimized for each pesticide by injecting pure analytical standards. One of the main issues in pesticides context concerns the large number of compounds belonging to a broad spectrum of chemical classes. As a result, particular care has been paid to the selection of pesticides present in the agricultural cannabis scenario in order to embrace a broader spectrum of compounds.

Acknowledgments: The project was funded by the Italian Ministry for the University and Research (MUR) with a "PRIN: Progetti di ricerca di rilevante interesse nazionale Bando 2022" Codice Identificativo n. 202224R9NL_002 "Reliable and rapid profiling of pesticides in Cannabis sativa L. by real-time in electron ionization detection (REI) and gas chromatography-mass spectrometry techniques, with particular emphasis on the miniaturization and automation of sample preparation procedures". antonella.cavazza@unipr.it

The new Regulation on Packaging and Packaging Waste encourages the diffusion of reused and recycled plastic items to replace single-use plastics. The conformity of materials for repeated use is checked according to the EU Regulation 10/2011 based on three consecutive migrations, considering that contaminant amount decreases with increasing number of uses. It is generally accounted that migrant amount is proportional to its initial concentration, according to the law of diffusion based on coefficients constant over time[1]. However, it is not taken into account that aged materials exhibit a different behaviour respect to new items, since washing procedures before reuse, and recycling processes, result in mechanical, thermal and chemical stress affecting additives amount, and leading to the potential formation of non-intentionally added substances (NIAS) from degradation reactions[2]. Therefore, there is a need for deeper analytical controls, and for performance evaluation of the material during ageing and after repeated industrial processing.

Within a collaboration with some companies, a series of experiments was performed on food contact articles for repeated use, and on virgin and industrial processed PET. To determine the identity of potential contaminants, solvent extraction was carried out before performing migration in simulants. The effect of the use of different solvents has been investigated, and showed a variable patterns of extracted analytes. Additives and NIAS have been identified by chromatographic techniques coupled to mass spectrometry, and quantification was then performed on simulants for the substances whose standards were available.

A different trend depending on the substance was observed: a decrease with ageing was shown for colorants in reused items, whereas compounds deriving from material degradation increased. As for recycled plastics, the effects of industrial processing and recycling procedures were investigated to explore if could lead to additives degradation and formation of NIAS. Preliminary results showed differences in the profile of analytes in PET virgin granules compared to processed material. Aged and recycled bottles were also investigated.

Activity-based biosensors for the monitoring of MutyH DNA glicosylase

Erica Belforte,[a] Andrea Celeste Di Pede,[a] Alessandro Porchetta,[a]

[a]*Department of Chemistry, University of Rome, Tor Vergata,Via della Ricerca Scientifica 00133, Rome, Italy*

erica.belforte98@gmail.com

DNA is continually subject to interactions with mutagens which can lead to structural damage of the molecule, affecting human health. The most frequent oxidation-induced lesions in DNA are 8-oxo-7,8-dihydroguanine, often resulting in G:C to T:A transversion mutations. When this modified base pairs with cytosine on the double helix, it is recognized by the DNA glycosylase OGG1 and removed, initiating the base excision repair (BER). However, if OGG1 fails or the damage occurs during replication, it leads to a mismatch of 8-oxo-guanine:A, recognized by a specific glycosylase, MUTYH, which removes the adenine. The literature presents various molecular methods for assessing DNA repair activity, primarily centred on the use of indirect techniques.[1] However, these methods have a variety of issues, including long analysis times, limited applicability in clinical settings. To enable direct monitoring of MUTYH activity, only few examples using chemically modified DNA probes with fluorescence readout have been reported.[2] Although they offer advantages as simplicity, rapidity, good specificity, and sensitivity. Here I propose developing a synthetic biology toolkit for real-time analysis of MUTYH activity. I will design programmable nucleic acid capable of transducing glycosylase activity into downstream CRISPR-powered ultrasensitive detection. This is achieved by using a rationally designed DNA-based hybridization network based on the switching activity of a DNA probe called "DNA activator module" whose structural switch is controlled by glycosylase activity. Only when the DNA activator module populates an ON state the CRISPR/Cas12a is activated, thus generating a fluorescence signal output. (Figure 1)

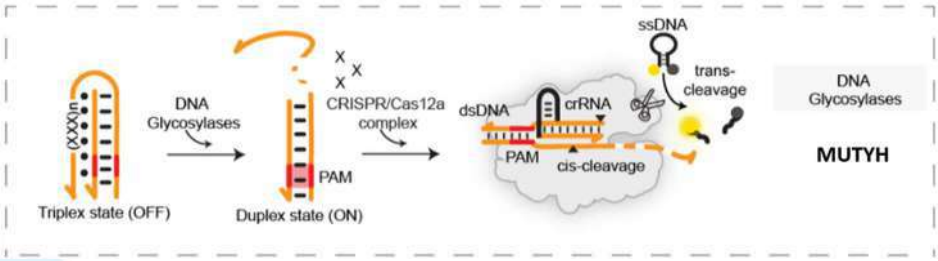

Figure 1: Description of Glycosylase-triggered CRISPR-Cas12 activity assay where the DNA activator module is identified in a DNA Triplex module.

costar@unime.it

Hemp seed cake flour (HSCF) is obtained by industrially processing the press cake derived from the extraction of the oil from the seeds of *Cannabis sativa* L. The hemp market has today grown exponentially, becoming distant from that of a decade ago or so, when it was bound to the textile, biofuel, and papermaking fields. The proven health-promoting effects of hemp and hemp-based products have become strongly appealing to the public interest. As an example, hemp seed oil (HSO) represents an active ingredient in the formulation of food supplements and cosmetic products, useful for the relief from a variety of ailments, such as psoriasis, dermatitis, hypertension, dyslipidemia. Hemp seed cake has been widely demonstrated to contain important bioactive molecules: up to 50% proteins, 9-20% lipids, 6-7% dietary fiber, considerable amounts of minerals [1]. On November 2023 the European Commission has published a revised version of the Novel Food Catalogue which includes cannabinoids and cannabidiol as new entries, confirming the importance acquired by hemp products in the Union. Furthermore, the use of HSCF fits a virtuous model of circular economy: only in 2018 the amount of press cake produced in Europe from HSO processing was estimated to be 2.18 Mtons [2]. Recovering hemp by-products meets therefore the criteria of environmental protection, both in terms of waste removal and of providing functional ingredients with no further depletion of natural sources. In this scenario, scope of the present study was the evaluation of the physical, chemical and sensorial properties of some samples of HSCF produced in Sicily. Beyond the flour, bread samples were prepared by using mixtures of wheat flour and HSCF at different ratios - 0%, 10%, 20%, and 30% HSCF, respectively. Moisture, ashes, fiber, carbohydrates, proteins, polyphenols, tocopherols, sterols, and fatty acids were assessed in HSCF samples. Additionally, Headspace-Solid-Phase Microextraction (HS-SPME) was applied to the analysis of the volatiles released by bread samples; alongside, a panel test was carried out by trained personnel in order to evaluate the sensory quality of bakery products containing HSCF, hence, consumer's acceptance.

Cardiovascular diseases (CVDs) are a group of heart and blood vessels disorders including heart failure, thromboembolism, coronary artery disease, and chronic kidney disease[1]. They currently stand as the leading cause of global mortality because of their challenging diagnosis and their non-specific symptoms[2]. Current diagnostic strategies rely on assessing risk factors and dosing biomarkers i.e., protein and peptide levels in human plasma, by using commercial immunoassays. However, the approaches are typically employed when symptoms are already present. Moreover, the analysis of CVDs biomarkers can be hampered by the high cross-reactivity with structurally similar species[3].

Here we present, an ultra-high performance liquid chromatography-electrospray ionization-tandem mass spectrometry (UHPLC-ESI-MS/MS) method to determine targeted plasma peptidomics overcoming immunoassay limitations. The importance of a reliable plasma sample pre-treatment procedure for the determination of low-abundant (unit-tenths of pg/mL) intact peptides (such as endothelins, fibrinopeptides, guanylins, urotensins) is discussed. Additionally, strategies to mitigate the potential risks, such as secondary adsorption phenomena and peptide degradation have been also investigated.

Microextraction by packed sorbent (MEPS) technique has been tested as an alternative procedure for sample pre-treatment and analyte pre-concentration. Finally, the suitability of this methodology will be established for the analysis of human plasma from patients affect by CVDs.

PERICARD seeks to meet the need for an efficient, high-throughput tool for early identification of at-risk individuals. Its potential applications such as diagnosis, prognosis, prediction of disease recurrence, and therapeutic monitoring, may pave the way in the management of CVDs.

Penetration depth in NIR and XRF spectral imaging: the INSIDE research project

P. Oliveri,[a] G. Sciutto,[b] E. Alladio,[c] S. Gariglio,[a,d] C. Malegori,[a] J. da Silva Santos,[a] E. Catelli,[b] Z. Li,[b] A. Mazzoleni,[c] C. Scagliarini[c]

[c] *Department of Chemistry, University of Torino, Via Pietro Giuria, 5, Torino*
[d] *Department of Chemistry and Industrial Chemistry (DCCI), University of Genova, Via Dodecaneso, 31, Genova*
paolo.oliveri@unige.it

The two-year research project INSIDE, funded by the Italian Ministry of Universities and Research – MUR as a frame for the "PRIN 2022" call, involves three Italian universities: Genova, Bologna and Torino. The project is aimed at revolutionising the concept of hyperspectral imaging (HSI) in the near-infrared (NIR) and X-ray fluorescence (XRF) spectral domains, evolving from a surface analytical technique to an in-depth 3D spectral tomography. The impact of such a cutting-edge analytical solution will be exploited and validated in three main application fields: food analysis, cultural heritage, and forensic sciences.

After a systematic literature analysis of research studies published on this topic, for a comprehensive recognition of the state of the art, key factors affecting the penetration depth of NIR and X radiations, as well as their interactions, will be investigated by application of multivariate design of experiments (MDOE). Moreover, applying proper sampling design techniques will ensure the collection/preparation of samples capable of guaranteeing maximum representativity and the development of analytical strategies characterised by an effective capacity to address the predetermined targets. During these initial phases, ad hoc samples, with a well-defined stratigraphy, will be designed and built employing a multi-material 3D printer, using polymers with distinct spectral signatures.

Multivariate unmixing strategies – including multivariate curve resolution (MCR) and super-resolution algorithms – will be applied for efficiently gathering 3D chemical information from hyperspectral data.

Confirmatory analyses will be performed to validate the analytical protocols developed by using scanning electron microscopy (SEM), gas chromatography-mass spectrometry (GC-MS) and ultra-high performance liquid chromatography tandem mass spectrometry (UHPLC–MS/MS).

Suitable tools for 3D graphics will be implemented for the conversion of deconvoluted NIR and XRF hyperspectral information into 3D chemical maps, including the development of a stand-alone app with a user-friendly GUI, which will be distributed to the project stakeholders for testing, and will demonstrate the way forward for establishing new opportunities in research and industrial sectors.

ngalic@chem.pmf.hr

Nabumetone (NAB) is a nonsteroidal anti-inflammatory prodrug, categorized as a class II drug according to the Biopharmaceutical Classification System. Very recently we have reported the results of spectroscopic, spectrometric and calorimetric studies on its complexes with β-cyclodextrins (β-CDs) in solution.[1] β-CDs form 1:1 inclusion complexes with NAB in water and simulated biorelevant media (Figure 1), and increase its solubility. In the continuation of our work, we have prepared and analyzed NAB-β-CDs systems in the solid state as well. Herein, we present the results of long-term and photostability of NAB solid mixtures with various cyclodextrins (CDs): β-cyclodextrin (β-CD), hydroxypropyl-β-CD (HP-β-CD), randomly methylated β-CD (RM-β-CD), and sulfobutylether sodium salt β-CD (SBE-β-CD).

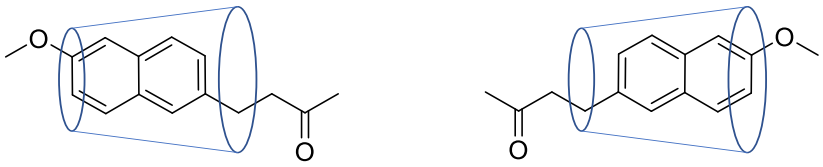

Figure 1: Two orientations of NAB in β-CD cavity.

The solid mixtures were kept under the following conditions: (*i*) 141.2 h under day light source (8.5 klux) + 40 h under UV source (5 W/m^2) to ensure that standard ICH Q1B photostability testing conditions were achieved; (*ii*) 25 °C and 60 % RH long-term storage condition according to ICH Q1A(R2). The samples were analyzed by previously developed and validated UHPLC-DAD stability-indicating method for NAB determination in the presence of its degradation products formed under the stress conditions. Chromatographic analysis was achieved on Agilent C18 column (2.1×50 mm, 1.8 µm) in gradient mode (15 min) using mobile phase consisting of 0.1 % formic acid in water and methanol with the flow rate set to 0.20 mL/min. NAB was detected at 231 nm. All prepared complexes and pure NAB appeared stable under tested conditions and no CD-mediated drug degradation was observed.

Scanning electron microscopy for tear film analysis: identification, characterisation and quantification of particulate matter as a useful marker of urban air pollution.

E. Porru, R. Comito, S.B. Clougher, C. Zunarelli, P. Versura, F.S. Violante

Department of Medical and Surgical Science, University of Bologna, via P. Pelagi 9, 40138-Bologna, Italy
emanuele.porru2@unibo.it

It is widely recognized today that outdoor air pollution can affect human health. Various chemical components that are present in ambient pollution may have an irritant effect on the mucous membranes of the body, particularly those of the respiratory tract. Much less attention has been focused on the adverse effect on the ocular surface, even though this structure is even more exposed to air pollution than the respiratory mucosa.

Tear analysis has emerged as a promising technique for non-invasive monitoring of various physiological and pathological conditions. Tears, often overlooked in clinical diagnostics, contain a diverse array of biomarkers reflective of systemic health, including environmental exposures[1]. Pollutants such as heavy metals and volatile organic compounds (VOCs) can be detected in tears, providing valuable insights into individual exposure levels and associated health risks[2]. However, challenges remain in standardizing tear collection protocols and refining analytical techniques for pollutant detection at trace levels.

Here, scanning electron microscopy (SEM) was employed for the first time to analyse and characterize particulate matter (PM) present in tear films. The final goal was to assess the extent of PM deposition on the ocular surface and its potential correlation with pollution levels in urban areas. Twenty healthy subjects were enrolled in the study after being exposed to urban traffic in Bologna. Tears were collected using a micropipette directly from the lower conjunctival sacs at different time points after the beginning of the exposure (0.5h, 1 h, 2h, 4h).

SEM analysis revealed the presence of various PM types on the surface of tear films collected. Particles were categorized based on size, morphology, and elemental composition. The average particle count per unit area was quantified, showing a range of particle densities across different samples. Results indicated a predominance of fine particles (PM2.5) adhering to the ocular surface, with occasional larger particles (PM10) observed. Energy-dispersive X-ray spectroscopy (EDS) was employed to perform elemental analysis of selected particles. Results identified common elements associated with PM pollution, such as carbon, oxygen, sulfur, nitrogen, and trace metals (e.g., iron, calcium).

In summary, SEM analysis of tear films from healthy subjects in the urban area of Bologna demonstrated significant deposition of PM. Statistical analysis revealed a positive correlation between PM levels in tear films and the exposure duration to urban environment.

alessandra.biancolillo@univaq.it

The objective of this study was to evaluate the elemental composition of four distinct Italian celery varieties, with a special interest for two traditional cultivars, Torricella Peligna Black and Trevi Black, protected by the Slow Food Presidia. All samples were cultivated in an experimental field in Torricella Peligna (Abruzzo). Celery leaves were frozen, dried (85°C, 24 h), ground, mineralized and then analysed using Inductively Coupled Plasma-Mass Spectrometry. Accuracy and precision were assessed through spiking recovery analysis. 70 observations were available for the subsequent analysis. Covariance Selection-Linear Discriminant Analysis, Partial Least Squares-Linear Discriminant Analysis, and Soft Independent Modelling of Class Analogies, validated through double cross-validation, were employed to identify the most discriminating elements, with the aim of evaluating the potential of the multi-elemental profile to distinguish and authenticate these varieties from the common ones.

A study of emerging contaminants present in Antarctic matrices by means of high-performance liquid chromatography coupled with mass spectrometry

J. Gambetta Vianna,[a,b] B. Benedetti,[a] M. Di Carro,[a] E. Magi[a]

[a]*Department of Chemistry and Industrial Chemistry, University of Genoa, Via Dodecaneso 31, Genoa*
[b] *Department of Environmental Sciences, Informatics and Statistics, University of Venice, via Torino 155, Venice*
emanuele.magi@unige.it

Emerging contaminants (ECs) are chemical compounds not commonly present in the environment and whose dispersion may cause known or suspected damage to the environment and human health. Despite their potential adverse effects, these compounds have not yet undergone international regulation[1]. Recent scientific inquiries confirmed the presence of several categories of ECs in remote regions, including Antarctica. These compounds include pesticides, pharmaceuticals and personal care products, and hormones and are characterised by their poor degradability and pseudo-persistence[2,3]. Different approaches can be adopted to assess and monitor the impact of ECs on the Antarctic ecosystem. Filter-feeding organisms, such as bivalves, are often utilised in literature as biomonitoring species due to their capacity to accumulate pollutants through their feeding habits[4]. However, the inherent complexity of the sample poses a significant challenge in interpreting biomonitoring results. In response to these challenges, passive samplers are indicated as a valid alternative for environmental monitoring. These samplers offer advantages such as simplicity of deployment and the ability to provide integrated measurements over time, offering valuable information into temporal trends of EC levels in Antarctic waters[5].

In this study, a comprehensive assessment of Antarctic contamination was undertaken by evaluating two distinct approaches. The bioindicator species Adamussium colbecki was analysed alongside the Polar Organic Chemical Integrative Sampler (POCIS) deployed during the 2022-2023 Antarctic campaign. A. colbecki samples underwent a QuEChERS (Quick, Easy, Cheap, Effective, Rugged, and Safe) pre-treatment procedure that was optimised using an experimental design technique. POCIS sorbents were eluted with a two-step elution by using methanol and a dichloromethane-isopropanol mixture. The resulting extracts were run dry and resuspended with methanol. The extracts obtained from the two methods were analysed using high-performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS).

Optimizing a sustainable approach: green extraction of anthocyanins from Apulian pigmented wheat landraces

davide.coniglio@uniba.it

Among the most common staple cereals, bread (*Triticum aestivum* L.) and durum wheat (*Triticum durum* Desf.) are broadly employed to produce several wheat-based food items[1]. While conventional varieties of grains are scarce in anthocyanins, thus lacking a pillar in fighting the metabolic syndrome[2], pigmented ones were found to provide significant burdens of these secondary metabolites[3]. To meet the current market needs, Granomischio® offers a wide product lining of grain derivatives based on three wheat landraces harvested in Foggia (Apulia, Italy). The most promising genotypes have already received attention as potential primary commodities to produce nutraceutical supplements[4]. Although the use of acidified methanol with high amounts of HCl (MeOH/HCl) has led the way for the extraction of anthocyanins from pigmented grains, novel green approaches have extensively been explored to pursue food security[5]. At first, an analytical method relying on reversed-phase liquid chromatography in conjunction with UV–diode-array detector and electrospray ionization high-resolution mass spectrometry (RPLC-DAD/ESI-HRMS) was developed for the detection of three of the most abundant anthocyanins occurring in pigmented wheat, namely cyanidin-3-glucoside, peonidin-3-glucoside, and cyanidin-3-rhutinoside[6]. To find the most sustainable green extraction approach of anthocyanins from Apulian wheat landraces, we used a computer-aided plan called D-optimal design. This helped us identify key factors like acid content, solvent mix, solvent amount, and temperature. We also investigated whether using ultrasound waves during extraction could be beneficial. Next, we fine-tuned these factors to see if this new method could outperform the traditional one using MeOH/HCl. This communication will discuss the results, focusing on the trade-offs between different extraction strategies and how they can be used to maximize the value of these unique wheat varieties.

fabio.biffoli@unifi.it

Acid copper (AC) electroplating is a fundamental process both in technological and decorative fields. AC electroplating is a necessary step for Ni-free production cycles which are trending given the increased awareness of the toxicity of Ni and Ni^{2+} salts[1]. Commercial AC baths are made by $CuSO_4$, H_2SO_4, NaCl and a set of three organic additives (suppressor, brightener, and leveller) that are needed to obtain shiny and adherent deposits. Despite the widespread use of those in industrial processes, their mechanism of action and the role of NaCl during the deposition are not clear yet. An in-depth understanding of this topic is essential to achieve the environmental sustainability goals of reducing organics in wastewater and replacing toxic additives (e.g. thiourea) with eco-friendly alternatives such as L-cysteine[2]. This work aims to develop a protocol where analytical spectroscopy is intimately aided by microscopy and computational chemistry to characterize the mechanisms of action of additives during industrial electroplating processes. X-ray photoelectron spectroscopy (XPS) experiments were implemented to study the surface composition of the deposits, and to define the correct oxidation state and spin multiplicity of Cu clusters in simulations. Thanks to the XPS results and Raman experiments it has been possible to define the type of adsorption (chemical or physical) of species on top of the Cu surface. Moreover, the effect of additives on morphology (grain dimension and roughness) was investigated by Scanning Electron Microscopy (SEM) and Atomic Force Microscopy (AFM). X-ray diffractometry (XRD) was employed to verify and quantify the magnitude of preferential orientation due to the additives and, linking XRD with AFM and SEM imaging, it was possible to unveil the influence of brighteners on the very first step of growth and to identify a seminal 2D structure[3]. All the hypotheses and doubts coming from empirical experiments were validated and dissipated thanks to a computational approach. Classical molecular dynamics, within the gaff2016 protocol, were performed to study how electrolytes behave under an electric field and if physisorption was possible. Finally, *ab-inito* calculations at CAM-B3LYP(D3BJ) level, employing a mixed 6-31G(d,p)-LANL2DZ basis set, where needed to define the chemisorption and explain the influence of additives on the shifting in preferential growth direction of copper nuclei.

The authors acknowledge for the support offered by Fondazione CR Firenze, Fondazione per la Ricerca e l'Innovazione dell'Università degli Studi di Firenze and Confindustria Firenze within the FABER4 project.

eugenio.aprea@unitn.it

In the present contribution we report our investigation on the relationship between chemical composition and taste, odour and flavour sensory descriptors in honey using O-PLS regression models.[1] Thirty multifloral honey from Trentino region (Italy), produced and collected in 2021, were characterised by NMR, GC-MS and sensory analysis (Check-all-that-apply).[2] The sensory panel was made up of 47 judges (Gender: 74% female; Average age: 49.3 years) registered in the Italian register of experts in sensory analysis of honey.[3]

Significant coefficients (after cross validation) of the regression models were calculated to establish the contribution of the single metabolite on each of the 68 sensory attributes used by the sensory panel.

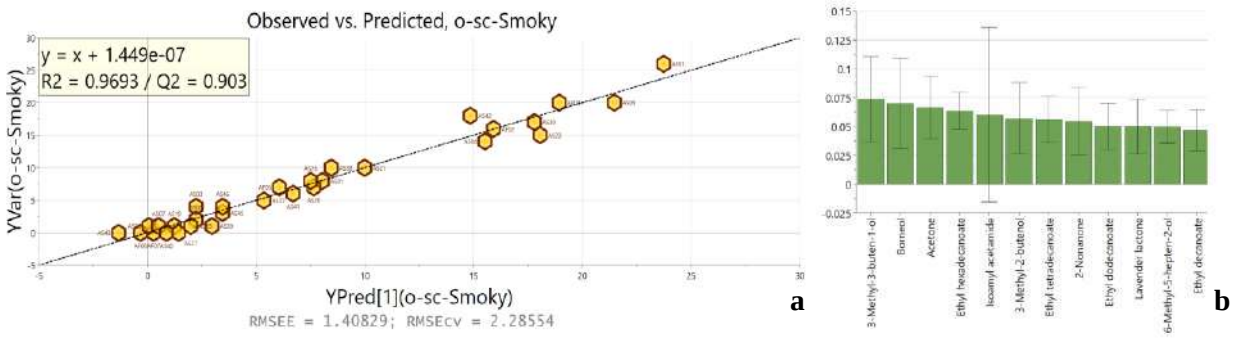

Figure 1: Odour "smoky" sensory descriptor: a) Scatter plot of the observed versus predicted values. b) Plot of the coefficients referring to scaled and centred data with confidence intervals derived from jack-knifing.

As an example, in Fig.1, is reported the regression model for the "smoky" odour attribute for which the five most contributing metabolites are 3-Methyl-3-buten-1-ol, Borneol, Acetone, Ethyl hexadecanoate, 3-Methyl-2-butenol.

Astaxanthin is a carotenoid with remarkable antioxidant properties, which is conventionally obtained through chemical synthesis or natural extraction[1]. However, both methods struggle to keep pace with the burgeoning market demand across various industrial sectors[2]. This study explores a fermentation-based approach for the bioconversion of leftover food (LF) into astaxanthin by *Phaffia rhodozyme*. The aim is to create a value-added product through a sustainable and cost-effective process. LF with a heterogeneous composition rich in carbohydrates, lipids, proteins, and minerals, was sourced from university canteens and it was used as fermentation medium for *P. rhodozyme* ATCC 74219. Previously the LF was pretreated via drying and grinding in order to obtain a fine powder, subsequently subjected to a comprehensive analysis, including proximate composition, elemental and fatty acid profiles, as well as reducing sugar content. For fermentation, 2.5 mL of *P. rhodozyme* inoculum was introduced into sterilized LF with pH adjusted to 5.0. Fermentation took place at 23 °C and 220 rpm agitation over a period of 115 hours, resulting in an astaxanthin yield of 132.6 mg· L^{-1} through direct fermentation (DF) in a lab-scale bioreactor. To enhance DF productivity, four substrate concentrations were tested, evaluating their impact on astaxanthin accumulation in *P. rhodozyme*. At the optimal 20% substrate concentration of LF, the mass balance at the end of fermentation yields 0.25% and 0.20% for carotenoids and ethanol, respectively. The purpose of the work was achieved through the implementation of an experimental design, based on three crucial steps: i) nutrient optimization (low-cost raw materials); ii) optimization of strain culture conditions; iii) optimization of fermentation variables with selection and inclusion of Barley extract as fermentation promoters.

Modulating the nutritional profile of the novel food *Acheta domesticus* by dietary supplementation with the eco-sustainable alga *Ascophyllum nodosum*

B. Ajdini[a], I. Biancarosa[b], G. Cardinaletti[c], S. Illuminati[a], A. Annibaldi[a], F. Girolametti[a], M. Fanelli[a], L. Massi[a], C. Truzzi[a]

b.ajdini@pm.univpm.it

The house cricket (*Acheta domesticus,* AD) is considered one of the most promising farmed insect species to be used as novel food, due to its attractive nutritional profile especially high in protein level [1]. However, being a terrestrial insect species, AD is poor in unsaturated fatty acids (UFAs), particularly the health promoting omega-3 long chain polyunsaturated fatty acids (n-3 LC PUFAs) such as docosahexaenoic acid (DHA, 22:6n-3) and eicosapentaenoic acid (EPA, 20:5n-3). One of the advantages of insects is their plasticity in response to varying rearing substrates [2]. As such, this study aimed to evaluate the use of the brown alga *Ascophyllum nodosum* (AN) (rich in n-3 PUFAs and omega-6 FAs [3]), as dietary for AD rearing, in different percentages (20% and 40% of the diet), to improve the nutritional quality of crickets. FA composition (GC-MS), proximate composition (AOAC method) and amino acid composition (HPLC) were determined. Results showed that the protein content of AD, as well as the amino acids profile, were not influenced by the experimental diets, with protein levels up to 55.9 g/100 g dry matter. The lipid content of AD significantly decreased ($p=0.0013$) with increasing seaweed inclusion in the diet, while a significant increase of UFAs ($p=0.0105$) (including EPA and DHA), and a significant decrease of SFAs ($p=0.0001$) was found compared to AD fed the control diet. Additionally, the assessment of the nutritional indices based on FA profile of crickets, in relation to cardiovascular disorders prevention in human, has been evaluated. In AD fed AN-enriched diets, Atherogenic and Thrombogenic indices significantly decreased ($p=0.0021$ and $p=0.0474$, respectively), while hypo-cholesterolemic to hyper-cholesterolemic ratio significantly increased ($p=0.0012$) compared to AD fed the control diet. These findings suggest that AN-enriched diets effectively improved the nutritional profile of crickets, leading to a reduced lipid content and an improvement in the quality of FAs in crickets, making them a valuable resource for human consumption.

Enzymatic protein hydrolysis of meat and poultry by-products: chemical characterization, process optimization and techno-functional properties.

B. Prandi,[a] S. Samaei,[a] L. Del Vecchio,[a] M. Cirlini, [a] F. Beninati,[b] A. Nardi,[b] T. Tedeschi[a]

[a] *Department of Food and Drug, University of Parma, Parco Area delle Scienze 17/A, 43124 Parma, Italy*

barbara.prandi@unipr.it

Protein hydrolysis is a well-known reaction with multiple applications in food production.[1] It is use for example to increase the water solubility of some proteins, to produce bioactive peptides with different bioactive properties (e.g. antioxidants, ACE-inhibitors, anti-tyrosinase, etc.),[2] to improve the digestibility of proteins and to obtain proteins with techno-functional properties. Compared to acid or basic catalyzed hydrolysis, the use of specific proteolytic enzymes allows working in mild conditions, avoiding the use of high temperatures or extreme pH which can cause unwanted side reactions, such as the racemization of amino acids.[3] Enzymatic protein hydrolysis can be applied directly to heterogeneous mixtures containing water and the food matrix to be hydrolyzed, combining the protein extraction and hydrolysis steps in a one-step process called enzyme-assisted protein extraction,[4] which produces an aqueous solution of peptides and free amino acids.

Enzyme-assisted protein extraction was then applied both to recover poultry industry by-products, such as bone and skin mixtures from poultry cuttings and mechanically separated meat residues, and to produce poultry hydrolysates with techno-functional and flavouring properties.

The protease from *Bacillus licheniformis* has been successfully used to recover proteins from poultry industry by-products, obtaining a protein hydrolysate with a high protein content (79-86%), a good amino acid profile (chemical amino acid score of 0.7-0.8) and good gastric digestibility (about 30% of hydrolysed peptide bonds). Regarding the production of poultry protein hydrolysates with techno-functional properties, pepsin provided the best hydrolysis yields (70.94 and 83.70 for mechanically separated meat and chicken breast, respectively) and technical-functional properties (solubility up to 95.5%, swelling up to 3.18 g/g, oil holding capacity up to 8.80 g/g, emulsifying properties up to 34.37%, foaming capacity up to 286.66%), with hydrolysis dependent on the raw material but still between 60 and 90 min.

Therefore, tailoring the process by choosing the right proteases and suitable hydrolysis conditions allows to recover the protein fraction of different poultry fractions, and to obtain hydrolysates with the desired techno-functional properties.

ALI-OR-005

Potential antihypertensive effects of environmentally sustainable glucosinolate-extracts from radish microgreens

M. Maisto,[a] A.Marzocchi,[a] V.Piccolo,[a] G.C. Tenore[ab]

[a] *Department of Pharmacy, University of Naples Federico II, Italy.*
maria.maisto@unina.it

The term biofactories refers to various biological platforms for the sustainable and inducible production of phytochemicals with potential nutraceutical applications. The main bio-factory models include microgreens, cell cultures, and cell suspensions. Specifically, microgreens are defined as "tender immature greens produced from seeds of vegetables and herbs having fully developed cotyledons with or without the emergence of a rudimentary pair of first true leaves"[1].

Glucosinolates (GSLs) are anionic sulfur-containing secondary metabolites found almost exclusively within the *Brassicaceae* plant family including, cabbage, rapeseed, and radish. Recently, these compounds have gained valuable attention for their role in the management of hypertension conditions, mainly related to their intrinsic capacity to be natural H_2S donors, a well-known vasodilating signalling molecule [2].

In this scenario, the increasing number of research demonstrating the health benefits of GSLs led to the need to improve their available concentration in existing cultivars. Thus, the main aim of the current work was the optimization of microgreen growth conditions of different radish cultivars, *Raphanus sativus L.* cv. Red Giant, Saxa, and White Tip, in order to maximize GSLs production useful for the formulation of nutraceuticals with antihypertensive potential. The seed germination was carried out using specific perforated trays, in darkness, at 23±1°C for 4 days. The sprouts obtained were transferred in a hydroponic culture supplied with nutrient solutions and harvested after 6, 9, or 12 days of cultivation. The determination of GSLs concentration at different growth-time samples was performed using an opportunely validated HPLC-HESI-MS-MS method. Our results indicated that the maximum GSLs amount was achieved in the Saxa samples after 9 days of cultivation (glucoraphanin 0.299 ± 0.008, glucoraphenin 34.802 ± 6.409, glucoraphasatin 65.629 ± 1.839, neoglucobrassicin 1.21± 0.02 mg/g of dw). Given these promising results, the ability of GSLs water extracts from 9 days-Saxa microgreens, to act as an H_2S donor in fluorescence-based assay and to induce vasorelaxant effects in a model of aortic rings were investigated. The data obtained showed that GSLs extract has shown the ability to release H_2S *in vitro* in a concentration-dependent manner, reaching the H_2S maximum release of 30 mM from 3 mg/ml of GSL extract. Finally, in terms of vasorelaxant activity, the GSL extract relaxed the pre-contracted aortic rings in a concentration-dependent manner, with the maximum effect achieved by treatment with 200 µg/ml of GSL extract (**** $p < 0.0001$, compared to the vehicle).

Chemical and rheological profile of fermented animal milks and isolation and characterization of exopolysaccharides from kefir grains

Chiara La Torre[a], Alessia Fazio[a]

[a] *Department of Pharmacy, Health and Nutritional Sciences, University of Calabria, Via Alberto Savinio, 87036, Arcavacata di Rende (CS)*

chiara.latorre@unical.it

Kefir is an acidic, low-alcohol probiotic beverage made by inoculating whole, semi-skimmed, or skimmed milk with kefir grains, a complex mixture of microorganisms, including lactic acid bacteria (LAB) and acetic acid bacteria (AAB) and yeasts, that coexist in a synergistic relationship in a matrix of polysaccharides and proteins. During the fermentation process, the microflora of kefir grains produces an exopolysaccharide called Kefiran which has been chosen for a variety of applications due to their biological activity in vitro and in vivo[1]. The health-promoting and physicochemical properties of kefiran vary according to the type of milk and extraction method[2].

Six types of animal milks (cow, camel, buffalo, donkey, goat, and sheep) were used as raw materials for fermentation. Fermented samples showed a significant reduction of total sugar content (<0.05%) and a significant increase (**** $p < 0.0001$) of total phenolic content if compared to the starting milks. Both unsaturated and saturated fatty acids of fermented milks were found to be slightly higher than their unfermented counterpart, except for buffalo sample. Particularly important were the results for the content of conjugated linoleic acids (CLA) in fermented milks, which were found to be increased especially in the sheep sample if compared with the initial value (187.4 ± 6.0 mg/g *vs* 40.3±1.0 mg/g, **** $p < 0.0001$).

Three extraction methods were applied to isolate kefiran in order to identify the conditions leading to the highest yield. Exopolysaccharides were characterized by FT-IR, SEM, DSC, HPLC-RI, and rheological measurements. Yield, thermal properties, and morphological features of kefiran differed according to both the type of the milk and the extraction method. However, all kefiran were thermally stable, showing a degradation temperature ranging from 264 to 354°C. The resulting morphological and thermal differences could lead to different practical applications of kefirans in the fields of nutrition and pharmacology. In addition, biocompatibility tests were conducted, and the data highlighted both the non-cytotoxicity and the absence of haemolysis of the polymers, an essential characteristic of biomaterials to be used for tissue engineering applications[3].

pierluigi.plastina@unical.it

Lipophenols are an emerging subclass of phenolic compounds, characterized by the presence of a lipid moiety. Tyrosyl oleate and hydroxytyrosyl oleate (TyOle and HtyOle, respectively, Figure 1A) have been identified in olive oil and by-products (pomace and olive mill waste waters), and represent a significant form in which the corresponding phenolics (tyrosol and hydroxytyrosol, respectively, Figure 1B) occur. Moreover, TyOle and HtyOle were found to display antioxidant, anti-inflammatory and anti-diabetic properties.[1-4]

In this communication, the occurrence of TyOle and HtyOle in other oil matrices (palm oil and grapeseed oil) is disclosed. Moreover, the identification of another member of this family, namely homovanillyl oleate (HvOle, Figure 1), as well as its antioxidant properties against DPPH and ABTS radicals, and by H_2O_2-treated HaCat human keratinocyte cell line is reported.

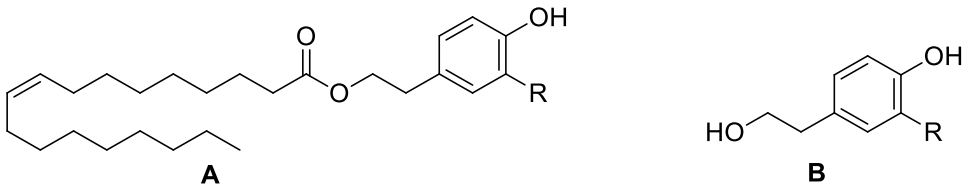

Figure 1: **A** Structure of lipophenols, namely tyrosyl oleate (TyOle, R=H), hydroxytyrosyl oleate (HtyOle, R=OH), and homovanillyl oleate (HvOle, R=OCH_3) and **B** of the corresponding phenolics, namely tyrosol (R=H), hydroxytyrosol (R=OH), and homovanillyl alcohol (R=OCH_3).

francesco.limongelli@uniba.it

Nowadays, the extraction of antioxidant compounds, particularly polyphenols, from fresh plant materials is widely used to produce promising and efficient nutraceutical supplements for human and animal health. In this context, *Salicornia europaea* L., commonly known as glasswort or sea asparagus, is a halophyte plant native to coastal sites worldwide. *S. europaea* has applications in traditional Chinese medicine as an antioxidant and is consumed seasonally as an edible plant for its beneficial properties in the prevention of chronic diseases. Numerous studies have demonstrated the presence of bioactive compounds in *Salicornia* species, including vitamins (A and C), fatty acids, polyphenols and minerals[1]. Natural deep eutectic solvents (NADEs) have shown the greatest potential in the field of green chemistry being abundant, inexpensive, recyclable and attractive for food, cosmetic and pharmaceutical applications. To extract these highly valuable compounds in a green and eco-friendly approach, NADEs and ultrasound-assisted extraction (UAE), are innovative and promising tools nowadays. In this study, NADEs and UAEtechniques have been applied to *S. europaea* collected from the Apulian Adriatic coast. The plant material was dried in an oven at 40°C for 48 hours and ground to a particle size of 200 μm. A software-based prediction approach (BIOVIA COSMOtherm) was applied to optimize the acceptor of hydrogen bond (HBA) and donator of hydrogen bond (HBD) solvents for the polyphenol extraction from *S. europaea*. NADEs were synthesized at 50°C for 2 hours, with subsequent polyphenol extractions conducted in an ultrasonic bath at 30°C for 30 minutes[2,3]. The most promising extraction in terms of total polyphenol content (TPC) was obtained by using proline as the HBA and choline chloride as the HBD green solvents. With this method, polyphenols extracted from *S. europaea* through NADES could potentially be ready for use in food and pharmaceuticals without time-consuming and costly downstream purification steps.

Protein-hydrolysates are among the most widely used biostimulants in agriculture, although molecular mechanisms underlying their effects on plants are still unclear [1]. Moreover, limited information related to their use in the cultivation of officinal and culinary plants has been published so far. As already reported in literature [2], metabolomics represents a suitable strategy for investigating the biochemistry of plants and how this is affected by external stimuli.

In this work, *Calendula officinalis* plants were treated in greenhouse with a soy-protein hydrolysate (SPH) at different dosages, i.e. 0, 1, 2.5, 5, and 10 g/L, for 21 days, and with different application methods, namely soil drenching (SPH-S) and foliar spraying (SPH-F). The effects of treatments on flower count and plant yield were documented, and the underlying molecular mechanisms were assessed by UPLC-QToF-MS-based untargeted metabolomics. Results indicate that the SPH-S treatment can induce both flower and total plant biomasses, conversely to SPH-F. The effect on plant biomass was dose-dependent, while the highest effect on flower biomass was observed with the application of the lowest (1 and 2.5 g/L) SPH-S dosages. The application of SPH-S at 1 g/L resulted also the best treatment to induce the average flower count *per* plant (14.30 for SPH-S 1 g/L *vs.* 8.00 for control). Conversely, no significant effects were observed for SPH-F. Both SPH-S and SPH-F treatments induced changes of the flowers' metabolome: hexadecanoyl- (16:0) and linoleoyl- (18:2) lysophosphatidylethanolamines, known as regulators of plant growth, were induced, together with dipeptides, diglycerides, and saponins, while the amount of several flavonoids was decreased. Importantly, these effects were reversible, since floral metabolome resembled that of untreated plants after suspending SPH application. Carotenoids were significantly induced only by 10 g/L SPH in flowers collected 7 days after the suspension of treatment.

Overall, this work is the first to show the efficacy of SPH in inducing the growth of *C. officinalis*, indicating that these products can be efficiently used to enhance the biomass and phytochemical content of officinal and culinary plant species. Furthermore, metabolomics data contribute to partially elucidate the molecular mechanisms underlying the effects of SPH on plants. These results may be useful for researchers and practitioners to optimize the use of SPH in order to increase the productivity of officinal plants.

laura.mattioli13@unibo.it

Introduction: Inflammatory Bowel Disease (IBD) poses a significant health challenge globally, with rising incidence rates and associated complications. Current therapeutic options often carry side effects, necessitating exploration into adjunctive non-pharmacological approaches. Diet plays a crucial role in IBD management, prompting interest in food-based interventions[1,2]. Lentils (*Lens culinaris*) have emerged as a source of bioactive compounds with potential health benefits[3-4]. However, the effects of lentil waste extracts remain relatively unexplored for their potential in IBD management. Building upon the study of spontaneous contractility, this research aims to investigate the potential spasmolytic effects of lentil hull extracts for a novel approach to IBD treatment.

Objective: This study aims to investigate the potential spasmolytic effects of lentil hull extracts for managing IBD symptoms, particularly diarrhea and abdominal cramps, which are prevalent manifestations of the condition.

Methods: Lentil hulls were subjected to conventional and microwave-assisted extraction methods using various solvents to obtain extracts enriched with bioactive compounds. Total phenolic content was determined using the Folin-Ciocalteu assay. In organ bath solutions experiments, spasmolytic activities were evaluated using guinea pig ileum and colon segments.

Results: Evaluation of spasmolytic activity revealed dose-dependent effects of the extracts on longitudinal and circular muscle contractions in guinea pig ileum and colon segments. Specifically, certain extracts demonstrated significant modulation of muscle tone, transit speed, pain perception, and bolus fragmentation, suggesting their potential utility in alleviating IBD symptoms. Notably, microwave-assisted extracts demonstrated superior activity compared to conventional extracts.

Conclusion: Lentil waste extracts exhibit promising spasmolytic effects, highlighting their potential as adjunctive therapies for managing IBD symptoms. Further studies are warranted to elucidate the underlying mechanisms and assess their efficacy in clinical settings. This research underscores the importance of exploring natural sources for novel therapeutic interventions in chronic inflammatory conditions like IBD.

A multi-platform metabolomics approach for the characterization of novel food ingredients

Andrea Fuso [a], Franco Rosso [b], Ginevra Rosso [b], Ileana Manera [b], Augusta Caligiani [a]

[a] *Food and Drug Department, University of Parma, Via Parco Area delle Scienze 17/A, 43124 Parma, Italy*
[b] *Soremartec Italia Srl, Ferrero Group, 12051 Alba, CN, Italy*
andrea.fuso@unipr.it

The current historical context is characterized by a marked attention to food and health. This is reflected in the search for high-quality food that is nutritionally favorable and organoleptically appealing. Consequently, more and more companies are incentivized to design and produce new foods or formulations. Indeed, the European Food Safety Authority (EFSA) has registered a significant increase in Novel Food proposals over the years, from 39 applications in the period 2000-2010 to an impressive 372 applications in the period 2010-2024 [1]. What is still missing, however, is the detailed chemical characterization of the new ingredients that are placed on the market. To date, there are no analytical techniques advanced enough to allow a comprehensive understanding of all the compounds that are contained within a food, especially in the case of food ingredients deriving from new sources (e.g., food by-products) or severe extraction processes. Food chemistry, in this sense, must strive to extrapolate as much detailed data as possible on the molecular structure of the compounds present, whether beneficial or potentially toxic.

Dietary fibers and oligosaccharides are nowadays found within foods or supplements and are passed off as functional compounds with alleged properties such as prebiotic, anti-cancer, etc. It is commonly recognized in the scientific literature that a very close relationship between the chemical structure and functional properties of the molecules exists [2], and it is equally evident that these molecules within dietary fiber ingredients are generally not characterized in such detail.

In this context, a multi-platform targeted and untargeted approach involving different combined techniques, namely GC-MS, LC-MS, NMR, and LC-IM-QTOF-MS, has been developed and applied to investigate the detailed composition of several potential hemicellulose-derived ingredients. The in-depth molecular characterization achieved for both oligosaccharides and lignocellulose degradation compounds highlighted that hemicellulose ingredients/supplements were very different in terms of both target molecules (i.e., xylo-oligosaccharides) and some contaminants resulting from matrix degradation, such as furans and phenols. It will be necessary in the future to further refine instruments and analytical capabilities to clarify these molecular structures, which may have a decisive impact on consumers' health.

Olive pomace (OP), the polluting biomass deriving from the production of olive oil, contains the major part (>98%) of the phenols present in the olive fruit[1]. The OP most representative phenolic compounds, namely hydroxytyrosol (OH-Tyr), tyrosol (Tyr), and their precursors, are thought to have several health-promoting properties, in particular in the prevention of many non-communicable diseases[2]. In this study, OP phenolic compounds have been extracted and encapsulated into food-grade nanoparticles (NPs) by ionic gelation to increase their resistance to environmental and chemical stress. The reticulation of chitosan, a polysaccharide deriving from the deacetylation of chitin, with sodium tripolyphosphate, a GRAS salt, resulted in a monodisperse (PDI: 0.21 ± 0.01) population of cationic NPs (ζ-Potential: 32.77 ± 0.37 mV, size: 229.20 ± 80 nm), with an encapsulation efficiency (EE%), expressed as total phenolic content (TPC) and total OH-Tyr + Tyr content, higher than 60%. Two different antioxidant scavenging assays, ABTS and FRAP, confirmed the NPs Antioxidant Capacity (AOC). NPs were characterized using several spectroscopic approaches. The most effective lyoprotective conditions were evaluated in order to obtain a suspendable powder which was ultimately subjected to an *in-vitro* static digestion protocol (INFOGEST®) to assess the bioaccessibility of the main phenolic compounds.

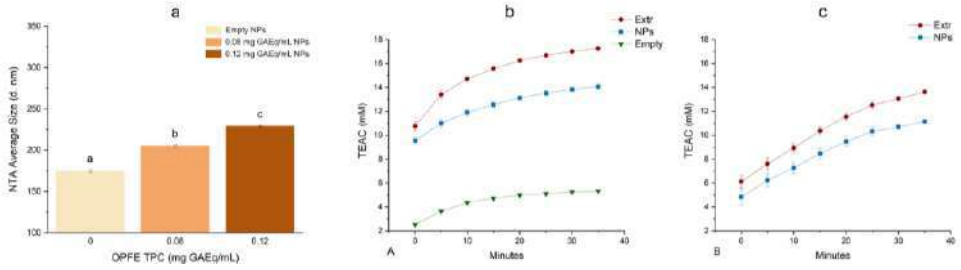

Figure 1: Effect of OP Fluid Extract concentration on the Nano Tracking Analysis (NTA) average size of NPs (a). AOC measured by ABTS (b) and FRAP (c) of extract, liqNPs and empty NPs (ABTS only). All data are expressed as mean ± standard error (SE) from triplicates. AOC data are expressed as mM Trolox Equivalent Antioxidant Capacity (TEAC).

nicola.marchetti@unife.it

The consumer requests and shift towards poultry meat consumption have pushed farmers to increase meat production, sometimes with no sufficient attention to meat quality and animal wellbeing. Nowadays, chicken growing rate in industrial farming increases considerably and a lower amount of time is required to obtain a mature chicken for meat production: from 120 days around 70 years ago to 30 days. Conversely, the feed conversion ratio (i.e., livestock production efficiency) was decreased from roughly 4.5 to less than 2.0, that means less than 2 kg of feed intake to let the animal gain 1 kg in muscle mass. This allowed the reduction of production costs, but some selected genetic variants were needed to permit such a fast growing rate. The dynamic process to obtain fast growing hybrid chickens produced important changes in poultry physiology and anatomy with strong consequences on animal wellbeing: muscle anomalies, stress-induced myopathies, white striping and wooden breast are the most common ones affecting animal health and organoleptic characteristics of meat. Ten years ago, slow growing broilers were introduced for improving the mentioned issues. In this preliminary study, two genetic variants (fast growing broiler, namely Ross308; slow growing broiler, namely Ranger Gold) were studied and compared for evidencing differences in biomarker expression that could be related with chicken diseases developed during farming and animal wellbeing. Expression and abundance of two chicken micro-RNAs (miRNAs), miR-21 and miR-126, have been analysed across different tissues (i.e., liver, lung, spleen, breast muscle, kidney) by quantitative reverse transcription polymerase chain reaction (RT-qPCR). Lung, spleen and muscle tissues revealed a higher expression and they have been further investigated in 13 animal biological samples. Results evidenced levels of miR-126 in lung tissue higher for Ranger Gold than Ross308: this could be explained in terms of higher respiratory capacity and higher oxidative metabolism for slow growing broilers, but it also has consequences in tracing hybrids. During sampling, some Ross308 broilers display diseases and anomalies, such as airsacculitis (bacterial inflammatory condition of air sacs), hepatic steatosis (intrahepatic fat deposition) and enlarged spleen. Fast growing broilers with both hepatic and respiratory diseases revealed up-regulation of miR-21 and miR-126 in breast muscle tissue. On the contrary, slow growing chickens exhibited lower levels of both miRNAs, even lower than healthy Ross308. Despite the limited extent of the sample set, these findings are quite promising and can suggest the use of specific miRNAs as biomarkers for the identification of bacterial or viral diseases in poultry breeds that can negatively influence the meat quality and the animal wellbeing.

lorenza.marinaccio@unich.it

The valorization of food waste is gaining attention in the wine sector. Grape processing annually leads to the production of 9 million tons of grape pomace as waste[1].

The aim of this work is the valorization of grape pomace extracts obtained by decoction, ultrasound-assisted extraction and microwave-assisted extraction by investigating their phytochemical profile and biological activities which were compared to extracts of raisins and edible commercial berries.

For each extract, the total phenolic content was assessed preliminarily by colorimetric assay and the phytochemical profile was determined by HPLC-ESI-Q-TOF-MS. The highest amount of polyphenols was characterized in grape pomace extracts justifying their strong antioxidant activity, especially in DPPH, ABTS, CUPRAC and FRAP assays (Table 1). The inhibition against cholinesterase, amylase, glucosidase and tyrosinase was determined by *in vitro* assays. Grape pomace extracts present the best inhibitory effect against tyrosinase compared to the other extracts. Its inhibition is associated with the reduction of hyperpigmentation disorders[2].

This work underlines the potential value of grape pomace as a by-product rich in beneficial compounds prompting its further valorization and involvement in the production of nutraceuticals and cosmetics.

	Extraction methods	DPPH (mg TE/g)	ABTS (mg TE/g)	CUPRAC (mg TE/g)	FRAP (mg TE/g)	MCA (mg EDTAE/g)	PBD (mmol TE/g)

LIPIDOMICS OF SHEEP AND GOAT MILK BASED INFANT FORMULAS AFTER DYNAMIC IN VITRO DIGESTION

Caboni, Pierluigi (1); Manis, Cristina (1); Casula, Mattia (1); Scano, Paola (1); Menard, Olivia (2); Dupont, Didier (2)
Organizzazione/i: 1: Università di Cagliari, Dipartimento scienze della vita e ambiente, Cagliari, Italia; 2: Institut Agro UMR 1253 STLO 65 rue de Saint-Brieuc 35042 Rennes Cedex

In this work, we studied the lipid profile, after the dynamic in vitro gastrointestinal digestion, of 0-6 months infant formulas (IF) based on sheep and goat whole milk. Fatty acids methyl esters analysis indicates that the two formulates differed in the levels of polyunsaturated and short chain fatty acids. QTOF/MS analysis revealed distinct lipids profiles for goat and sheep IFs. This analysis also allowed us to monitor the lipolytic process through the quantitative analysis of complex lipids and their lypolysis products during digestion. Triacylglycerols digestibility decreased as a function of the fatty acid chain length, irrespectively of the unsaturation degree, and was found slightly higher in sheep IF. Additionally, lipid compounds in sheep IF were found more prone to hydrolysis than in goat IF during the gastric phase. Despite the differences observed between goat and sheep IFs, the overall digestion outcomes of complex lipids were found similar. Our results suggest that sheep whole milk can be considered as viable alternatives to cow milk when designing IF.

federica.turrini@unige.it

Ecoefishent ("Demonstrable and replicable cluster implementing systemic solutions through multilevel circular value chains for eco-efficient valorisation of fishing and fish industries side-streams") project goal is to deploy sustainable and efficient use of fish-processing side streams by obtaining bio-actives for high value-added food supplements and cosmetic products, as well as compostable and biodegradable barrier layers for food packaging [1].

The project deals with the valorisation of unsorted non separated fishery side streams, avoiding the onerous sorting step of fish leftovers, and their transformation into high value bioactive compounds, mainly proteins and hydrolysed peptides such as gelatine (G), hydrolysed collagen peptides (HCPs), and non-collagenous peptides (NCs) [2]. The highly perishable unsorted biomasses, both tuna side streams (raw and cooked) and aquaculture products (seabreams and seabass), have been previously stabilized microbiologically, by a patented industrial dehydration process that enhances the logistics in their valorisation.

Then, a scalable extraction method represented by a single cascade flowchart, which exploits environmentally friendly techniques such as enzymatic-assisted extraction, has been applied for the upcycling of the protein fraction [3]. All the extracted proteins after their isolation/purification, and dehydration, were characterized in terms of proximate and ultimate analyses, biological activity, and functional properties, and in order to assess their potential applicability in different fields.

The extraction flowchart proposed allowed to obtain the following most promising compounds: 1.7 g of G, 3.2 g of HCPs, and 14.6 g of NCs per 100 g of dehydrated starting material. In particular, gelatine extracted has shown to have specific viscoelastic properties (5 mPa·s of viscosity and 14.3 °C of gelling temperature) and demonstrated encouraging technological and filming properties. HCPs demonstrated promising antioxidant activity and NCs demonstrated a good content of nutritionally valued proteins exploitable in dietary products and high-protein foods.

Due to healthy lifestyle of modern society, the preference for bio-compounds derived from natural sources is rapidly expanding. On the other hand, according with both European and US regulation (EMA and FDA), processing natural starting material with biocatalytic approaches let the commercialization of the final product as natural too, thus increasing its market value.[1] In this scenario, the combination of biocatalysts (whole cells and cell-free enzymes) with flow facilities, represents an emerging technology to enhance reaction productivity and sustainability. Through immobilization techniques, the biocatalysts can be easily integrated in flow chemistry reactors, while their stability under operational conditions is dramatically improved.[2] Moreover, due to the catalyst recovery and reuse for several reaction cycles, cost-effective processes can be developed.

Valuable natural molecules such as aroma-compounds,[3] antioxidants,[4] as well as antimicrobials[5] have been successfully prepared merging the advantages of flow reactors with the specificity and benign conditions of biocatalysts. This strategy representing an alternative route for natural compound preparation and promoting a responsible care of natural resources, is particularly attractive for the food, pharma and cosmetic sectors.

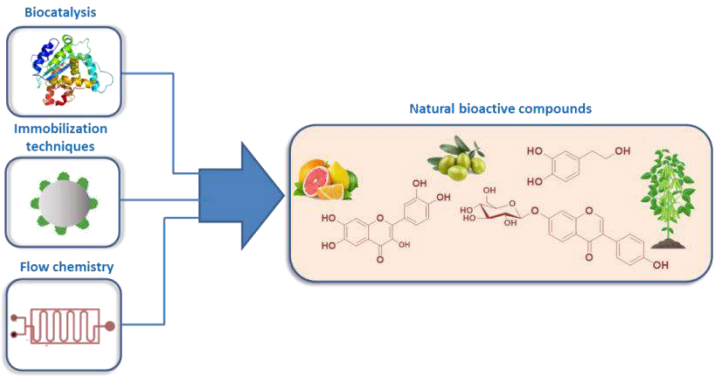

Figure 1: Merging biocatalysis, protein immobilization and flow facilities for natural compound preparation

cacciolaf@unime.it

Extra virgin olive oil (EVOO) is associated with the beneficial effects of a Mediterranean diet due to an "ideal" lipidic fraction and microconstituents with antioxidant activity. Among micronutrients, phenolic compounds did show important beneficial effects for human health. The majority of the research studies on the phenol content are carried out by liquid chromatography combined to photodiode array and/or mass spectrometry detection; however, because of matrix complexity, one-dimensional liquid chromatography cannot be sometimes sufficient to obtain satisfactory results. As a consequence, in this contribution, comprehensive two-dimensional liquid chromatography, incorporating RP-Amide and C18 stationary phases, in the first and second dimension, respectively, both under reversed phase conditions, was investigated for the determination of the phenolic fraction in EVOO and its by-products. As far as detection is concerned, triple quadrupole mass spectrometry was employed under multi reaction monitoring mode offering superior selectivity and sensitivity. The reduction of matrix effects, when using comprehensive two-dimensional liquid chromatography with respect to conventional one-dimensional liquid chromatography, was assessed by comparing the slopes of calibration curves built from standard solutions and spiked olive oil samples.

Acknowledgments

Food irradiation is an alternative technological process employed to preserve the hygienic quality of food and to extend its shelf life[1]. In this work, different types of dairy products were treated with X-rays and integrated omics approaches, a bottom-up proteomics and lipidomics, were used to evaluate their effect on protein and lipid fingerprints. Specifically, the matrices investigated were *mozzarella*, *robiola* and *primosale* as soft cheeses whereas *Camembert* and *Brie* as surface-ripened cheeses. Matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-ToF-MS) and ultra-high-performance liquid chromatography coupled with quadrupole Orbitrap mass spectrometry (UHPLC-Q-Orbitrap-MS) were adopted to analyse the peptide mixtures coming from the proteolytic digestion of irradiated soft cheese using both trypsin and chymotrypsin enzymes[2]. For lipid fingerprint, a first step of lipid extraction using four different techniques, Folch procedure, extractions with accelerated solvent[3], microwave assisted solvent[4] and supercritical fluid, were developed by appropriate design of experiments and successively the extracts were analysed by UHPLC-Q-Orbitrap-MS. Multivariate statistics, namely principal component analysis, partial least squares-discriminant analysis and linear discriminant analysis, allowed the discrimination of irradiated versus non-irradiated samples and the selection of potential markers of treatment, useful in food traceability plans. The outcomes confirm integrated omics approaches as a powerful tool for deepening knowledge of food irradiation, also suitable as a model for food quality and safety control.

This work was supported by the Italian Ministry of Health who funded the Project code GR-2018-12367064.

Keywords: traceability, food quality, food safety, metabolomic.

riccardo.zecchi@unifi.it

Rice (*Oryza sativa* L.) is an important cereal in human nutrition due to its richness in vitamins, minerals, and bioactive compounds. The processing steps to which paddy rice is subjected after harvesting, while on the one hand making it edible improving its sensory quality and cooking, on the other hand, from a nutritional point of view could result in the depletion of many micronutrients and phytonutrients that are concentrated in the germ and bran [1]. An effective processing technique to reduce cooking time of rice is parboiling, a hydro-thermal treatment that allows the water-soluble components of the germ and outer parts to diffuse within the caryopsis [2].

The aim of the work to define the best procedure for the application of MALDI-MSI [3] to investigate the localization and migration of two different classes of rice micro-components after industrial processing and domestic cooking: steryl ferulates and anthocyanins [4], which are known to provide positive physiological effects on human health [5]. Spectra acquisitions with IMS were conducted on a MALDI-LTQ-Orbitrap XL and the ionic intensity of the signal associated with the different distribution of the analyte in the tissue was evaluated. The *Oryza sativa* L. varieties studied were 'Carnaroli' (white rice), 'Oro' (white parboiled rice), 'Nerone', (black pigmented rice), and 'Venere', (black pigmented parboiled rice). About domestic cooking methods, all rice varieties were analyzed raw, after boiling in water and after steaming.

The sample preparation steps were optimized to obtain reproducible results by MSI. As regards steryl ferulates, the study allowed to verify their localization in the different rises, highlighting a negligible migration of these compounds towards the endosperm in the parboiled rice. Regarding anthocyanins, it was found that steaming or boiling the pigmented rice provides a consistent migration of these compounds in the endosperm.

The obtained results provide a solid basis for the definition of future experimental designs for the study of rice secondary metabolites in raw and cooked rice and for monitoring the effects of parboiling.

Insights into the Structure–Capacity of Food Antioxidant Compounds Assessed Using Coulometry

A. S. Sammarco,[a] G. Picariello,[b] E. Vasca,[a] F. Siano[b]

[a]*Dipartimento di Chimica e Biologia "A. Zambelli" Università degli Studi di Salerno, Fisciano - Italy*
[b]*Istituto di Scienze dell'Alimentazione – Consiglio Nazionale delle Ricerche, Avellino - Italy*
ansammarco@unisa.it

Antioxidant compounds assumed with food and plant extracts play relevant health-promoting roles. The antioxidant capacity is a key parameter for determining food quality as it affects product stability during preparation and storage. For this reason, antioxidants are often used for food preservation. In biological systems (e.g., cells, tissues, fluids), endogenous and exogenous antioxidants rule key physiological processes. Considering their relevance, an extraordinarily large number of chemical methods have been proposed for the determination of antioxidant capacity and radical scavenging properties. In general, these methods correlate poorly with each other, so that none of them has found universal applicability. The Coulometrically Determined Antioxidants Capacity (CDAC, expressed as $mmol_{electrons}\ g_{sample}^{-1}$) has been recently developed by our group to estimate the antioxidant capacity of individual compounds or their mixtures[1,2]. The CDAC measurements consist of a constant-current coulometric titration, in which the titrating agent is Br_2 (standard potential E^0=+1.05 V) electrogenerated *in situ* from a KBr solution. The Br_2 excess generated at the endpoint is determined with a biamperometric system. CDAC determines the micromoles of electrons delivered for oxidizing the target analyte(s) with high accuracy. The method is accurate, rapid, cheap and does not require the use of standards. Herein, 48 individual antioxidant compounds commonly found in food have been analysed by CDAC method.[3] Expressing the CDAC on a molar ratio scale ($mol_{electrons}\ mol_{sample}^{-1}$, $CDAC_\chi$) the antioxidant capacity of several representative compounds ranks as it follows: tannic acid > malvidin-3-*O*-glucoside ≅ curcumin > quercetin > catechin ≅ ellagic acid > gallic acid > tyrosol > BHT ≅ hydroxytyrosol > chlorogenic acid ≅ ascorbic acid ≅ Trolox®. The correlation of the $CDAC_\chi$ values with the chemical structure of the molecules investigated in the present study, underlines that the aptitude of compounds to electron and hydrogen atom transfers estimated through the Bors criteria[4] is often ineffective to account for the observed antioxidant capacity. Other factors like side- and down-stream reactions, pH, geometrical structure, chemical environment, metal chelating ability, are involved in determining the $CDAC_\chi$ values. In this context, the electrochemical ratio (ER), defined as the CDAC of the sample relative to ascorbic acid, is proposed as a new dimensionless index to describe the antioxidant power of any food.

[b]School of Biosciences and Veterinary Medicine, University of Camerino, Camerino (MC), Italy.

Abstract

Acorn flour resulted to be a promising alternative to the cereal flour for different applications thanks to its nutritional value, lack of gluten proteins and polyphenols content.

The aim of the study was to find possible differences in nutritional value, polyphenols, antioxidant properties and volatile profile of acorn flours obtained by acorns harvested at different times and to promote acorn flour as a rich source of nutrients and bioactive constituents. Indeed, two acorn flours have been studied: one was obtained from acorns harvested at the beginning of November 2023 (Spring 2023) and the other from those harvested in the late November 2023 (Fall 2023).

This study received funding from the European Union - Next-GenerationEU - National Recovery and Resilience Plan (NRRP) – MISSION 4 COMPONENT 2, INVESTMENT N. 1.1, CALL PRIN 2022 PNRR D.D. 1409 del 14-09-22 (CUP J53D23018470001). Results from nutritional analysis showed some differences, Flour Fall 2023 resulted to be richer in sugar content (glucose, fructose), total free aminoacids and most of the minerals (calcium, iron, phosphorous and magnesium) with respect to flour Spring 2023. An HPLC-MS/MS method was used for the determination of 38 polyphenols in flour samples (Mustafa et al., 2022) and their concentration resulted to be comparable between samples. However, the antioxidant activity, studied by DPPH free radical assay, Total Phenolic Content (TPC), Total Flavonoids Content (TFC) and Total Tannin Content (TTC), resulted to be different in acorn samples. In particular, TPC, TFC and TTP demonstrated a higher antioxidant activity in flour Spring 2023 with respect to flour Fall 2023. Finally, volatile profile was studied by HS-SPME-GC-MS and furanic compounds were quantified by HS-SPME-GC-MS (Acquaticci et al., 2024). This study demonstrated that acorn is a rich source of carbohydrates (50%), dietary fiber (25%), protein (10%) and macro-microelements such as potassium and calcium. Moreover, it has been assessed that flours obtained by acorns harvested at different times of the year showed differences in nutritional profile, antioxidant activity and volatiles. However, further studies are needed to understand if these differences will be maintained in food products to optimize the use of this flour to have a food product with the best possible properties.

Ulva sp. is a green algae associated with the so-called "green tides", caused by water eutrophication. The main biomolecule of interest this green algae is the sulfated polysaccharide ulvan. It has gelling properties and has shown anticoagulant, anti-hyperlipidemic, and immunomodulatory activities in *in vitro* and *in vivo* models[1] . Its biological and chemo-physical properties are directly related to its chemical structure, which strongly depends on the extraction conditions[1] . Particularly, *Ulva lactuca L.* has been found to grow spontaneously in aquaculture tanks in Orbetello lagoon (OL), Tuscany, Italy, and can be considered a by-product of fish farming. Thus, this study firstly focused on the optimization of ulvan extraction from *U. lactuca L.* collected in OL and its chemical characterization, which is crucial for understanding the biological activities of the ulvans and to define their future possible uses.

To do so, a Response Surface Methodology was applied to investigate the effect of pH, extractant/sample ratio and time of extraction on yield, purity and sulfation degree of ulvan. Purity was evaluated by quantitative ^{1}H-NMR as rhamnose percentage on dialyzed polysaccharides. Sulfate and neutral/acidic sugars were quantified by turbidimetric assay and HPAEC-PAD respectively. Then, the optimized extraction conditions based on the maximization of yield and purity were chosen and applied to produce ulvan for in *in vitro* test of prebiotic activity. To evaluate it, the isolated polysaccharide was subjected to an *in vitro* enzymatic digestion following the INFOGEST 2.0 protocol. The undigested ulvan underwent colonic microbial fermentation using an *in vitro* static fermentation system[2] . Slurries were collected at different time points (0, 12, 24, 48h). pH, short chain fatty acids, and tryptophan-related metabolites were quantified and untargeted metabolomics was performed.

Therefore, this comprehensive approach, integrating extraction optimization, chemical characterization and colonic microbial fermentation will provide insights on ulvan's impact on the function of microbial communities and its potential future applicability for upcycling *Ulva* biomass towards the development of functional food with prebiotic effects.

Carotenoids are biomolecules naturally produced by plants, algae, fungi, and bacteria as secondary metabolites[1]. The international market size for carotenoids in 2022 was 2.0 billion dollars and it is expected to reach 2.7 billion dollars by 2027, at a compound annual growth rate of 5.7% for the forecast period of 2022 to 2027. Currently, scientific interest in microbial carotenoids production, to be implemented as natural dyes in food industry, has come into the mainstream because of their economic sustainability and cost-effectiveness[2].

The aim of this study was to provide a first qualitative and quantitative profile of both carotenoids and fatty acids produced by the bacterium *Paracoccus* sp LL1[3]. With this purpose, the best growth conditions were investigated in order to identify the carotenoids produced by the strain, beside the fatty acid profile characterization. *Paracoccus* sp. LL1 batch cultivation was carried out in 5 L fermenter, in a final working volume of 3.5 L of minimal medium supplemented with 20 g L^{-1} of glucose, using an inoculum size of 10% (v/v). Fermentation parameters were temperatures 24 °C, air flow 2.0 L min^{-1}, rpm 300, dissolved oxygen maintained at 20%, pH controlled at 7.5±0.2 by using 4 N HCl and 4 N NaOH.

The carotenoids produced by *Paracoccus* sp LL1 have been identified by HPLC/MS. It was possible to identify 12 different carotenoids. Among these β-carotene was detected in the highest amount, reaching up a concentration of 0.3 mg g^{-1} of dry matter, after 72 h fermentation. Whereas the main fatty acids detected by GC-MS/FID were represented by: C12:1n7-(E), C16:0, C18:0, C18:1n9-(Z) and C18:1n7-(Z).

The production of microbial carotenoids and in particular β-carotene from *Paracoccus* sp LL1 could represents a matter of great interest and economic value from food industrial perspectives.

frigano@unime.it

Rapid Evaporative Ionization Mass Spectrometry (REIMS) is a relatively recent MS technique, dating back to 15 years ago, which was explored in many application fields demonstrating high versatility in the detection of a wide range of chemicals, from small molecules (phenols, amino acids, di- and tripeptides, organic acids, sugars) to larger biomolecules, i.e. phospholipids and triacylglycerols. In particular, it was coupled with different sampling devices and used in direct-MS approaches, without the need for laborious and time-consuming sample preparation procedures and chromatographic separations, according to the definition of Ambient MS which refers to the ionization of unprocessed or minimally modified samples in their native environment.

This innovative technique combines two complementary analytical approaches, that can be defined as a metabolomic profiling and a metabolic fingerprinting. The first deals with a complete and accurate characterization of the sample from both qualitative and semi-quantitative point of view. The second is a fingerprinting approach that aims to obtain characteristic profiles of various samples. In other terms, REIMS was successfully used to achieve a comprehensive sample profiling according to a metabolomics untargeted analysis. Moreover, when a multitude of samples were available, the combination with chemometric tools allowed a rapid differentiation of the samples and the identification of discriminant features.

The present talk aims to provide examples of the applicability of REIMS in two main fields, namely clinical diagnostics, covering both veterinary and human medicine areas, and food analysis, aiming both at the preservation of both food security and at the safeguard of food safety and quality.

More in details, the application to differentiation of brain tumors will be presented to demonstrate the potentiality of REIMS in the accurate identification of tumor grade and type, which can be exploited for an early cancer diagnosis. In the agri-food sector, the applicability against food fraud will be assessed through the building of statistical models aiming at differentiating between different fish species, spices and extra virgin olive oils in order to ensure to consumers safe and nutritious foods, as well as to protect the economy of local producers and the entire ecosystem.

Sustainability in Food Safety: Deep Eutectic Solvents for Aflatoxin Extraction in Pistachios

Andrea Schincaglia[a,b], Flavio Antonio Franchina[a], Alberto Cavazzini[a], Giorgia Purcaro[b], Marco Beccaria[a]

[a]*Università degli Studi di Ferrara, Via Luigi Borsari 46, Ferrara (Italy)*

andrea.schincaglia@unife.it

Aflatoxins, identified as carcinogenic mycotoxins belonging to Group 1 by the International Agency for Research on Cancer, pose a substantial risk to global food safety. These contaminants are present in diverse food sources such as wheat, rice, corn, milk, spices, and nuts. To address health concerns linked to aflatoxin exposure, global regulatory bodies have set maximum limits for aflatoxins in food products, necessitating thorough pre-trade analyses by producers. Existing official methods for aflatoxin analysis rely on organic mixtures, generating considerable waste[1]. In response to the increasing emphasis on sustainable analytical practices, especially in food chemistry and safety, this study suggests an innovative and environmentally friendly approach using Deep Eutectic Solvents (DES) for the extraction and quantification of aflatoxins from pistachios—an economically valuable commodity prone to contamination in hot and arid regions. DES, a recent class of alternative solvents, comprises a binary mixture with a hydrogen bond donor and acceptor in specific molar ratios, allowing their use at room temperature. Numerous DESs have exhibited non-toxicity, biodegradability, and effective extraction capabilities for various target compounds[2]. The extraction process was optimized using a Design of Experiment. Considering the complex nature of extracts from aflatoxin-contaminated pistachios, a necessary clean-up and concentration step involved dilution with water and passage through a C-18 solid phase extraction cartridge. The trapped aflatoxins were subsequently eluted with a minimal amount of methanol and analyzed using ultra-high performance liquid chromatography coupled to a fluorometer detector, equipped with a partially porous C18 column. This study illustrates the feasibility of utilizing DES as extraction media for aflatoxins in a complex matrix, diminishing dependence on conventional solvents and minimizing process waste. The developed method demonstrated robustness and reliability, achieving an inter-day repeatability lower than 6.4% (CV%) for each analyte, with limits of quantification below 0.71 ng/g. Recoveries for individual aflatoxins were as follows: 97.5% for AFB_1, 98.5% for AFB_2, 105.2% for AFG_1, and 92.9% for AFG_2. Additionally, the environmental sustainability of the method was quantified and evaluated using two distinct metrics. This inventive approach aligns with the ongoing trend towards more environmentally conscious analytical practices in the field of food safety.

tommaso.ugolini@unifi.it

Terpenes and pentene dimers are two less-studied classes of volatile organic compounds (VOCs), associated with characteristic sensorial attributes of extra virgin olive oils (EVOOs). This 3-years study aimed to characterize the mono- and sesquiterpene and pentene dimer profiles of monovarietal EVOOs from 14 Italian cultivars for their quality control and authentication. Quantitation of both classes of compounds was achieved with a recently validated HS-SPME-GC-MS method. A total of 225 monovarietal EVOOs collected over three harvest seasons were analyzed, and the quantitative data were used for the characterization of the cultivars. The cultivars were also classified in groups based on their terpene and pentene dimer profiles. Sesquiterpenes were the molecules that most differentiated the groups, ranging from a total content of 3.908 mg/kg for the Moraiolo variety to 38.215 mg/kg for the Nocellara variety. The chemical structure (e.g., acyclic, monocyclic, polycyclic) of the prevalent sesquiterpenes also played a role in the characterization of the cultivars. Pentene dimers (1.336-3.860 mg/kg) and monoterpenes (0.430-1.794 mg/kg) showed lower variability among cultivars and much lower content overall. Statistical methods such as Kruskall-Wallis test-PCA-LDA-AHC were applied to the experimental data and allowed dividing the cultivars into 4 clusters (cluster 1: Ascolana Tenera, Casaliva, Leccio del Corno, Moraiolo, Pendolino, Frantoio, Leccino; cluster 2: Coratina, Picholine, Tonda Iblea, Nocellara; Cluster 3: Bosana, Peranzana; cluster 4: Itrana). A predictive model to classify the monovarietal oils in the clusters was built and achieved a 94.3 % correct classification when used on the training group samples. The model was also tested on 33 additional monovarietal EVOOs, correctly classifying 91% of them.

Global climate change (GCC) has altered the frequency of climate change, determining much more severe environmental disruptions than occurred in the past. The presence of abiotic stresses, such as drought, heat, salt, or heavy metals and metalloids, like arsenic (As), exacerbates GCC effects. Flavonoids are a representative group of secondary metabolites with various functions in plants, protecting them from abiotic and biotic stresses through antioxidant activity[1]. However, flavonoid function remains to be determined experimentally in naturally tolerant wild plants living in stressful soils. Soils developed on the volcanic substrate, as a considerable part of the Campanian region and Etna surroundings, are rich in neo-formed amorphous alumino-silicates and organo-mineral compounds and have a high binding capacity for trace metals, such as As. The Brassicaceae family comprises several plant species with agronomic and economic significance, such as *Brassica rapa*, which was reported to show significant tolerance to As-rich soils[2]. However, the role of flavonoids in the oxidative stress tolerance of *B. rapa* remains to be addressed, although the tolerance mechanisms, as adaptive traits, evolved in this species can become a knowledge milestone for future phytoremediation. In the present project, through untargeted transcriptome and metabolome approaches, we aim to investigate the role of flavonoids as ROS scavengers within the tolerance strategy of wild *B. rapa* naturally growing in soils affected by arsenic, assessed through geochemical approaches, by performing transcriptome and metabolome profiling analyses.

In recent years, vitamin D has become increasingly important for human health due to its crucial role in maintaining bone and neuromuscular system homeostasis[1]. However, vitamin D deficiency is nowadays a concerning issue, with approximately 40% of the population estimated to have insufficient levels[2]. The ability of fish to store large quantities of Vitamin D_3 in their tissues, makes them an excellent dietary source of Vitamin D_3 for humans. Considering the activities related to the fishing sector, including fishery, aquaculture and the fish processing industry, significant amounts of fish waste are daily produced, leading to a significant environmental impact[3]. These precious wastes are often discarded because they do not meet market specifications, but they can serve as an excellent natural substrate for producing Vitamin D_3-rich extracts.

This research is part of the "VITADWASTE—Innovative and sustainable processes for the development of Vitamin D nutraceutical from fish waste: extraction, formulation and clinical study for the evaluation of its bioavailability and clinical equivalence" project, a PRIN (Research Projects of Significant National Interest) funded by Italian Ministry of University Education and Research (MIUR).

The final goal is to use fish production waste as a substrate for the extraction, enrichment, characterization and formulation of Vitamin D_3 nutraceuticals. An innovative approach is being tested to convert pure waste into a valuable resource for the pharmaceutical and food industries in accordance with the principles of the circular bioeconomy. For this purpose, a green and non-conventional technique, such as Supercritical Fluid Extraction (SFE), has been tested to obtain vitamin D_3-rich extracts. Extraction parameters were optimized using the Design of Experiment tool of XLSTAT software (2023.1.4.1408) in Box-Behnken design mode. Preliminary data showed the significant potential of supercritical carbon dioxide in extracting the lipophilic fraction from fish waste. The quantification of vitamin D_3 and its precursor, 7-dehydrocholesterol, which is highly concentrated in fish, was performed using a high-performance liquid chromatography coupled with a diode array detector, through a specifically developed method. After the optimization, a formulation study based on microencapsulation followed by a bio-accessibility study will be conducted to obtain a nutraceutical to be tested in pharmacokinetics and bioequivalence in comparison with a standard Vitamin D supplement.

antonella.buccafuri@unical.it

Palm oil (PO) derives from the palm tree fruit (*Elaeis guineensis*) and it is the most widely produced and consumed vegetable oil in the world. The palm tree accounts for the smallest percentage (5.5%) of all the cultivated land for oils and fats globally, but produces the largest percentage (32%) of total output. It is strongly debated due to environmental and nutritional issues, as it has a 1:1 ratio of saturated and unsaturated fatty acids. However, there are a number of studies in literature that do not support some of these assumptions.[1] Grapeseed oil (GSO) is extracted from grape seeds. The percentage of extractable oil varies according to the cultivar. It is particularly known for its beneficial properties, attributable to its high content of polyunsaturated fats and antioxidant compounds.[2] Herein, the phenolic fractions extracted from PO and GSO samples were investigated and their characterization is reported.

The extraction of the phenolic fraction from POs and GSOs was achieved in an ultrasonic bath by using a methanol/water solution (80/20, *v/v*) as the extraction solvent. Total phenolic content (TPC) was evaluated by using *Folin-Ciocalteu* method, and the results are expressed as mg GAE (gallic acid equivalents) / 100 g oil. The analyses for the determination of phenolics were carried out using an HPLC system, equipped with a Discovery C18 chromatographic column, coupled to an MSD API 4000 Q-Trap model mass spectrometer.

A higher amount of phenolics was observed in POs than in GSOs. In fact, TPC values were in the range 8.74 – 30.54 mg GAE / 100 g oil for PO samples and 0.21 – 0.90 mg GAE / 100 g oil for GSO samples.

Among the individual phenolics, simple phenols, phenolic acids and flavonoids were identified and quantified in both series of samples. The most abundant were: hydroxytyrosol, whose amount ranged 13.80 – 42.8 mg / kg oil for POs and 0.9 – 1.3 mg / kg oil for GSOs, while tyrosol ranged 2.74 – 8.12 mg / kg oil for POs and 1.25 – 1.4 mg / kg oil for GSOs; caffeic acid, whose amount ranged 11.08 – 45.58 mg / kg oil for POs and 1.013 – 1.3 mg / kg oil for GSOs (and it was lower than LOD in same GSO samples); apigenine, whose amount ranged 7.68 – 43.5 mg / kg oil for POs, while it was never found in GSOs; *m*-coumaric acid, whose amount ranged 7.82 – 45.20 mg / kg oil for POs (and it was lower than LOD in many PO samples) and 5 – 11 mg / kg oil for GSOs.

The added value of natural flavourings: characterization of bioactive compounds in Calabrian chili pepper flavourings obtained with different extraction techniques

S. Corsetti[a], L. Alessandroni[a], A. Casale[b], M. Floridi[b], G. Sagratini[a]

[a]*School of Pharmacy, Chemistry Interdisciplinary Project (ChIP), University of Camerino, 62032, Camerino, Italy*
[b]*New Flavours srl, Via Dell'Artigianato 7, 06010, Monte Santa Tiberina, Italy*
samanta.corsetti@unicam.it

Flavourings are defined as all those substances with a high impact on food flavour, while the term "natural flavourings" specifically refers to flavouring preparations of which at least 95% is obtained from a material of plant, animal or microbiological origin, by appropriate physical, enzymatic or microbiological processes, as described by the European Regulation 1334/2008. In particular, the aim of the present work is to compare natural flavourings obtained from Calabrian chili peppers by two extractive techniques and different parameters, both in terms of their volatile molecules, linked to specific sensorial properties, and through the characterization of their important bioactive compounds[1]. This research is part of a broader project aimed at the valorisation of natural flavourings from Calabrian chili pepper variety, considering the initiated procedure to obtain the PGI mark, and at the reuse of chili peppers, that are not suitable for a direct sale, for flavouring preparations, with a view to a circular economy. In this work Soxhlet extraction and Ultrasound Assisted Extraction (UAE) techniques were compared especially in terms of bioactive compounds recovery. Thus, hydroalcoholic solvents in different percentages were used, since they are environmentally friendly and permitted in food flavouring production. The extracts were then analysed in terms of pungency, related to the concentration of the two main capsaicinoids (capsaicin and dihydrocapsaicin), vitamin C, vitamin E, polyphenols, and carotenoids[2,3]. Analyses were performed using different methods and instruments such as HPLC-DAD and UHPLC-MS/MS. The volatile molecules were analysed by HS-SPME-GC-MS and compared to that of the original matrix. An accurate statistical analysis was then applied to compare all the obtained data. The most impactful parameter turned out to be the ethanol/water percentage of the extraction solvent, since, for example, capsaicinoids and vitamin E were more present in chili extracts from anhydrous ethanol, while polyphenols, vitamin C and antioxidant activity were more related to extractions with a higher water percentage, as expected. In particular, both for Soxhlet and UAE ethanol 70% was a good compromise, since it assured the most heterogeneous chemical composition of volatile extracted compounds, with a high similarity to the original matrix. Besides, in both the involved techniques, ethanol 70% extracted a high concentration of the analysed bioactive molecules, compared with the literature [4].

[b] *Research and Innovation Coffee Hub, Via Emilio Betti 1, Belforte del Chienti, Italy*

agnese.santanatoglia@unicam.it

Acidity in coffee is a crucial sensory characteristic mainly influenced by the roasting level and organic acid composition.[1,2] This research offers a comprehensive analysis of how eight coffee brewing methods (AeroPress, Chemex, Clever, FrenchPress, Moka, PureBrew, Ibrik and V60) affect the acidity profiles of both specialty and mainstream coffees across different types of coffee. For the first time, a systematic approach with chemical analysis and sensory evaluation has been applied to explore the relationship quantitatively and qualitatively between brewing methods and coffee acidity. Employing an innovative method, the study correlated the chemical composition comprising organic acids, chlorogenic acids, and caffeine [3], with sensory attributes like sourness and mouthfeel, alongside physicochemical acidity indicators such as titratable acidity, pH, and Total Dissolved Solids (TDS). Statistical analyses demonstrated that chlorogenic acids significantly affected the coffee's pH and titratable acidity (**Figure 1**), whereas the sensory perception of sourness was more closely correlated with the concentration of organic acids. Notably, non-filtered brewing methods like Ibrik and Moka showcased a higher total acids content, with Ibrik coffee registering the highest acid levels, reaching at 2500 mg/L for certain organic acids such as acetic and citric. In contrast, the Chemex method, which employs a specific paper filter, yielded the lowest acid extraction, underscoring the impact of filter type on acidity.

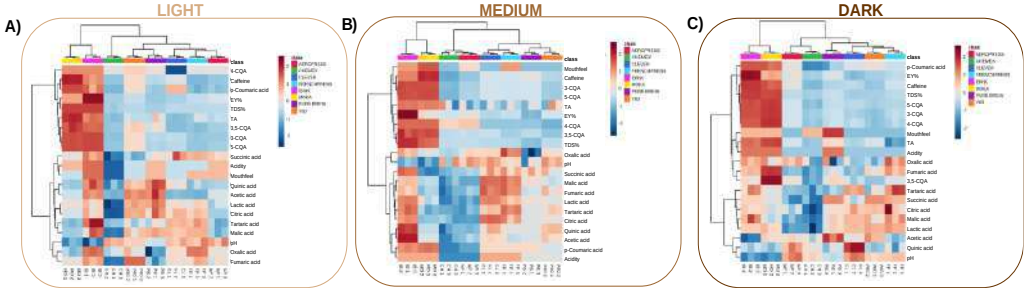

Figure 1. Hierarchical clustering and heatmaps of the three coffee varieties throughout the analyzed extraction methods.

These findings identified organic acids as likely predictors of perceived coffee acidity, providing new insights into how brewing techniques influence the sensory and chemical profiles of coffee. The study significantly advances our understanding of coffee brewing science and sets the stage for further research to improve coffee quality and consumer satisfaction with respect to acidity.

carla.buzzanca@unipa.it;

Moringa oleifera is a plant distributed in many tropical and subtropical countries and represents a precious source of bioactive molecules with numerous health benefits [1,2]. The experimental plan involved the production of a control cheese and two experimental fortified cheeses, obtained by adding commercial Moringa powder to the curd at a percentage of 1% and 2% (w/w). The samples (Moringa powder, freeze-dried ovine's milk, freeze-dried control and 1% - 2% fortified cheeses) were subjected to chemical characterizations on the lipid, phenolic, microbiological and sensorial profile. The microbiological analyses highlighted the absence of the main pathogens of dairy interest and the dominance of *Lactococcus lactis* added as starter cultures. Analyses carried out on samples, showed promising values of antioxidant activity, with a range of values equal to 0.82 – 1.35 mmol TEAC/100g for the ABTS test and 0.99 – 1.21 mmol TEAC/100g for the DPPH test, highly superior to cheese control (0.11 – 0.06 mmol TEAC/100g, respectively). Interesting values regarding the total phenolic content (TPC), equal to 2.01 and 2.72 mgGAE/g for the 1% and 2% fortified cheese, respectively, and higher than the control (1.19 mgGAE/g), were highlighted. GC/MS analyses did not reveal a particular increase in unsaturated fatty acids compared to the control cheese. The UHPLC-ESI MS/MS analyses involved the search for phenolic compounds in the freeze-dried cheese samples; cheese fortified with 2% Moringa powder was richer in polyphenols than the control; in particular, chlorogenic (23.62 mg/100g), caffeic (3.07 mg/100g), ferulic acid (14.38 mg/100g) and quercitrin (34.79 mg/100 g) were higher than cheese produced only with ovine's milk, which had lower concentrations of chlorogenic acid (0.51 mg/100g), caffeic acid (1.15 mg/100g), ferulic acid (0.254 mg/100g). Quercitrin was not detected in control cheese. The addition of Moringa powder did not negatively impact the judges' overall level of appreciation. This fortification therefore represents an optimal strategy to enhance Sicilian sheep's milk through the production of innovative dairy products, rich in bioactive molecules and with a longer shelf-life thanks to the presence of antioxidant compounds.

Chemical properties of hemp (*Cannabis sativa* L.) microgreens extract obtained with Natural Deep Eutectic Solvents (NADES)

L. Del Vecchio,[a] A. Agosti, [a] G. Galaverna,[a] B.Chiancone,[a] G. Campmajó, [a] C. Dall'Asta, [a] M. Cirlini [a]

[a] *Department of Food and Drug, University of Parma, Parco Area delle Scienze 17/A, 43124 Parma, Italy*
Lorenzo.delvecchio@unipr.it

Bioactive compounds have been regarded as desirable substances that naturally exist in plant and food items, which can promote benefits for human health thanks to biological properties including antioxidant, antimicrobial and anti-inflammatory. Natural Deep Eutectic Solvents (NADES) are used as solvent for bioactive compound recovery from different sources, such as agri-food residues and plant materials. Compared to common solvents, NADES present higher extractive capacities and are cheaper, readily prepared, safer for the environment, more biodegradable, and more sustainable alternative.[1]

Cannabis sativa L. is a versatile crop, whose industrial varieties can be cultivated in Europe provided they respect the 0.3 % Δ9-tetra-hydrocannabinol (THC) threshold set by the EU legislation. Consumption of food items containing hemp (such as seeds, oil extracts, and defatted flours) is rising up, particularly in Western countries, thanks to the its unique composition and significant nutritional and biological properties.[2] The production of an alternative to the mature plant, such as microgreen, young seedlings of plants grown from seeds, is becoming a great opportunity because they are harvested in two weeks since germination and the chemical composition is very attractive due to their richness in both phytochemical compounds and micro/macro elements.[3]

This work aimed to evaluate a green-extraction method based on the use of NADES to extract phytochemical compounds from hemp microgreens. Thus, the method was compared with a conventional one, performed with an ethanolic solution. Before selecting the NADES with the higher extraction yield, different eutectic solvents were tested. The extracts were characterized in terms of total polyphenolic content (TPC) and antioxidant activity (AO), applying FOLIN-CIOCALTEAU, DPPH and FRAP assays, respectively. Moreover, the molecular profile was obtained through UHPLC-MS/MS.

To the best of our knowledge this study investigates for the first time these types of plant materials applying a NADES extraction method.

Effects of feed supplementation of ewes with silages of prickly pear by-products (*Opuntia ficus-indica*) on the chemical-nutritional characteristics of their dairy products

A. D'Amico[1], C. Buzzanca[1], R. Gannuscio[2], M. Todaro[2], V. Di Stefano[1,3]

[1] *Department of Biological, Chemical and Pharmaceutical Science and Technology (STEBICEF), Università degli Studi di Palermo, Via Archirafi, 90123 Palermo, Italy;*

[3] *National Biodiversity Future Center (NBFC), 90133 Palermo, Italy.*

angela.damico02@unipa.it

Industrial and technological growth has led to an increase in waste and by-products, which requires green and circular economy approaches. The waste resulting from *Opuntia ficus-indica* can exceed 40% up to 55% of the total weight of the fruit. These by-products lend themselves well to ensiling[1] and are rich in bioactive substances such as proteins, vitamins, minerals, carbohydrates and polyphenols, and have multiple physiological activities such as antioxidant, anti-inflammatory and antimicrobial[2]. The aim of this study was to determine the chemical-nutritional characteristics of prickly pears by-products silages (PPS) (peels+12% of wheat bran and prickly pears peels, pulp, seeds + 12% of wheat bran), bulk milk and cheese samples from ewes fed with these PPS, in order to evaluate their effects on cheese quality. Milk, cheese and PPS samples were subjected to qualitative-quantitative chemical characterizations on the lipidic and phenolic fraction. Cheeses samples were subjected to triangular test. PPS, milk and cheese samples were freeze-dried before analysis. All the samples were analysed for their antioxidant activity by DPPH and ABTS tests, total phenolic content (TPC) by Folin-Ciocalteau test, phenolic profile by UHPLC-ESI/MS-MS analysis and fatty acid profile by GC- MS method. PPS showed considerable antioxidant activity, especially the PPS peels, which was reflected in the milk and cheese samples of the ewes fed with this by-product. In particular, cheese samples showed higher anti-radical values (0.375-0.710 mmol TEAC/100 g) respect to the control (0.122 mmol TEAC/100 g). Analyses carried out on TPC showed a higher value in milk and cheese samples (2.04-3.41 mg GAE/g), respect to the control samples (0.24 mg GAE/g). Supplementation of PPS in the sheep's diet, however, did not significantly influence the fatty acid profile of milk and cheese samples and the sensorial test ($P>0.10$). Therefore, the feed supplementation with PPS represents an optimal strategy to enhance Sicilian sheep's cheeses, through the production of innovative dairy products enriched with bioactive molecules and with a longer shelf-life, due to the presence of natural antioxidants without altering their sensorial aspects.

martina.bigliardi@unimi.it

Unlike lipases and esterases, the acyltransferase from *Mycobacterium smegmatis* (MsAcT) is able to catalyze acylation reactions of primary alcohols and amines in aqueous solutions at room temperature and with a high acyltransferase/hydrolase ratio.[1] Since nothing has been reported in literature on the use of MsAcT with amino alcohols, a screening with a collection of difunctionalized compounds was conducted for the development of a biocatalytic chemo-selective acylation tool.

In order to optimize reaction conditions, batch biotransformations were initially carried out with different substrates including amino alcohols, secondary alcohols and amines, using EtOAc as acyl donor. The enzymatic acylation of model amino alcohol substrates has been carried out to evaluate the chemo-, regio- and stereo-selectivity of the glyoxyl-immobilized MsAcT with the advantage of simplifying the downstream process by eliminating the work up step.[1] In all the cases studied, using EtOAc as acyl donor, a preference towards *N*-acetylation over the *O*-acetylation has been observed.

Finally, MsAcT has been tested for the synthesis of *N*-fatty acylalkanolamines starting from the ethyl esters of linoleic, arachidonic and oleic acids with various alkanolamines. MsAcT has been compared with *Candida antarctica B* (CAL B) lipase immobilized on an acrylic resin (Fig.1), the latter showing higher yields in the amidation steps.[2] Therefore, CAL B was applied as a biocatalyst in flow reactors for the development of a sustainable and continuous enzymatic preparation of the endocannabinoid anandamide (**1**) and a small collection of analogues.[3]

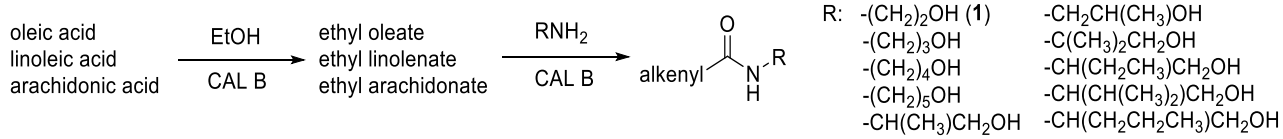

Figure 1: Scheme representing the CAL B-mediated reaction for the preparation of anandamide analogues.

Application of phenolic compounds from olive pomace in delaying flaxseed oil oxidation in model emulsions

D.V. Santisteban Soto,[a] M. Ciulu,[a] I. Fierri,[a] G. Zoccatelli,[a]

[a]*Department of Biotechnology, University of Verona, Strada Le Grazie 15, 37134 Verona, Italy.*
dianavanessa.santistebansoto@univr.it

Olive pomace (OP) represents the main by-product of olive oil production[1]. OP contains approximately 98% of olive phenolic compounds which are represented mostly by hydroxytyrosol (OH-tyr) and tyrosol (tyr), along with their precursors[2], whose antioxidant activity has been largely documented. Besides their health-promoting properties, these phenolic compounds could also be used as natural antioxidants. Hence, this research aimed at evaluating the capacity of OP antioxidant compounds to mitigate lipid oxidation of highly labile compounds like omega-3 fatty acids. A response surface methodology (RSM) was conducted to investigate the effect of three independent variables (temperature, 4-95 °C; time, 30-120 min; ethanol concentration, 0-50%) on the green extraction of free and total OH-tyr and tyr, measured by HPLC-DAD, and the radical scavenging capacity (RSC) assessed by DPPH assay. The conditions allowing for the higher yield of OH-tyr and tyr and RSC were 95°C, 40% ethanol and 30 minutes. The best-perfoming extract was incorporated at different concentrations into flaxseed oil model emulsions and incubated for 60 days at 40°C to induce oxidation. Primary and secondary oxidation products were assessed by peroxide value (PV) and thiobarbituric acid reactive substances (TBARS) tests, respectively. The degradation of OH-tyr and tyr was also monitored by HPLC. OP extract at the maximum concentration used (400 μM) provided a reduction of PV and TBARS of 97.8% and 78.0% respectively in the emulsions after 60 days. The 82.5% reduction of OH-tyr during the incubation time further proved its antioxidant capacity, differently from tyr that remained substantially stable. These results demonstrate the efficacy of OP OH-tyr in retarding the lipid oxidation of flaxseed oil, providing a valuable tool for future technological applications.

agostina.colacicco@unimi.it

As the global population is approaching 8 billion and lifestyles and dietary habits change, a significant rise in agri-food industrial waste is expected, posing both environmental and economic challenges. Many of these residues demonstrated to contain a plethora of bioactive compounds.

The recovery and processing of such molecules to generate value-added products for applications in the pharmaceutical, cosmetic, and food industries can represent a promising strategy for saving relevant resources and reducing bio-waste[1]. In this context, biocatalysis can offer important advantages over traditional synthetic methods in terms of efficiency and selectivity.

Extremophilic glycosidases, capable of cleaving glycosidic bonds, are essential tools due to their ability to withstand harsh reaction conditions. We particularly focused on rutin (RT) and hesperidin (HES), glycosides commonly found in citrus fruits and residues (Figure 1). By using a commercially available α-rhamnosidase (RN) and a homemade halo-thermophilic β-glycosidase (HOR), we aimed at obtaining their aglycones, hesperetin (HP) and quercetin (Q), which exhibit higherx bioavailability and membrane permeability. By developing a continuous process using flow reactors and enzyme immobilization techniques, we enhanced reaction yields and sustainability. Co-immobilizing both enzymes on the same matrix and employing a biphasic system with an unconventional green solvent, 2,2,5,5-tetramethyloxolane (TMO)[2], further reduced costs and addressed substrate solubility issues. By recovering and reusing all materials involved in the flow biotransformation, this approach can be claimed as a zero-waste procedure[3].

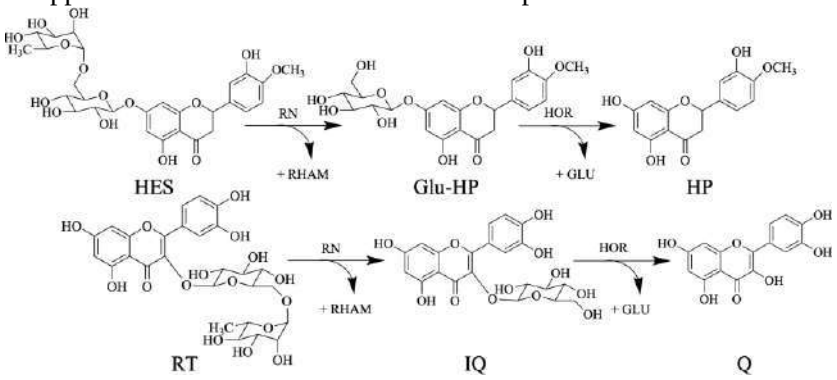

Figure 1: Obtainment of quercetin and hesperetin as aglycones from the corresponding natural glycosides.

stefania.pagliari@unimib.it

Diet is currently one of the most important exogenous factors in the prevention of chronic diseases. The increasing incidence of non-communicable diseases is driving the search for and use of functional foods that can actively contribute to the prevention of human disease [1].

Allium sativum L. is a plant known as a medicinal food since ancient times. To date, several beneficial properties have been demonstrated, such as anti-cancer, antibacterial, antiviral, anti-hypertensive, cardioprotective, hypolipidaemic and anti-diabetic effects, mainly associated with various organosulphur compounds [1,2]. However, the consumption of garlic is uncommon in Europe and America due to its pungent smell and taste, which is not very pleasant. To overcome this problem, it is common practice, especially in Asia, to ferment garlic at high humidity and temperature (around 70°C) for different days (30-40gg). Fermented black garlic becomes sweet and aromatic with a syrupy, gelatinous consistency. In addition, the fermentation process also seems to improve the beneficial properties, probably due to non-enzymatic browning reactions (phenol oxidation, Maillard reaction and degradation of organo-sulphur compounds) and enzymatic ones. Studies have shown that fermentation modifies the chemical composition of garlic, resulting in greater antioxidant power (mainly related to the formation of S-allylcysteine, Amadori products and melanoidins) and improved hypoglycaemic capacity [3].

In the present study, DOP garlic from Voghiera was fermented and several samples were taken throughout the process (30 days) to assess the changes in its chemical composition. For this purpose, the samples were extracted by hydroalcoholic sonication and, after purification, analysed by mass spectrometry. In addition, the antioxidant and hypoglycaemic properties were assessed using various spectrophotometric assays (ABTS, ORAC, DPPH, alpha-amylase and glucosidase), highlighting in particular an improvement in antioxidant capacity as the fermentation process progressed.

Finally, the chemical composition and bioactivities tested were correlated to identify the most bioactive classes of molecules.

lmondello@unime.it

In the last decades, lipidomics has emerged as a cutting-edge approach among omics- techniques, since lipids revealed to be essential molecules in the regulation of metabolic pathways. To this regard, the content of essential fatty acids (EFAs), as well as nutritional indices such as the levels of omega-3 and omega-6 FAs and their ratio are essential parameters to evaluate the beneficial properties of food products. In addition, the investigation of complex lipids in their native forms is proved to be crucial to obtain additional information about lipids role and on FA arrangement into each species.

For this reason, the present talk aims at a detailed elucidation of intact lipids in different functional foods, including marine organisms such as algae and the wastes of the fish industry, according to current trends in food science, such as the valorization of unconventional and sustainable food products and the minimization of food wastes and the promotion of recycle strategies (circular economy models).

From an analytical point of view, two parallel and complementary approaches are commonly used in the lipidomic field: gas chromatography-mass spectrometry (GC-MS) and high-performance liquid chromatography-mass spectrometry (HPLC-MS). The former is essential for the detailed characterization of the total FA composition, being able to reliably identify the position of the double bonds along the carbon chain (omega nomenclature) and/or the configuration of the double bond (cis/trans), while the latter is employed for the elucidation of intact lipids (e.g., triglycerides, diglycerides, phospholipids, free FAs) as they are originally present in the sample, thus adding important information about storage conditions and how they will be metabolized. In both cases, particular emphasis is paid on the miniaturization and automation of the entire analytical workflow by using robotic workstations able to perform the sample preparation in a fully automated manner and online with the chromatographic system.

In a second stage of a lipidomic workflow, biological samples could be analysed to investigate on nutritional aspects directly related to lipid metabolism. To this regard, lipid profiles of human blood can be obtained by using the same analytical platforms described above and can be correlated with different dietary regimes.

ptranchida@unime.it

This study presents a method based on dilute-and-inject liquid-gas chromatography-tandem mass spectrometry for the rapid determination of 16 polycyclic aromatic hydrocarbons (PAHs) in extra-virgin olive oil (EVOO). The sample preparation process was simple, involving only a dilution step, thereby eliminating the need for extraction, clean-up procedures, and reducing organic solvent usage significantly. A comparison between selected-ion-monitoring and pseudo multiple-reaction-monitoring (p-MRM) acquisition modes was conducted to assess specificity and analyte detectability. The results favored the p-MRM mode for its superior performance and was thus adopted for acquisition.

The method exhibited linearity within the concentration range of 1-200 µg kg^{-1} (and 5-200 µg kg^{-1} in three instances). Accuracy, tested at 2 µg kg^{-1} and 20 µg kg^{-1} concentration levels, fell within the range of 86.9-109.6%, with a relative standard deviation of less than 10%. Precision within the same concentration levels showed intra-day and inter-day variations ranging from 1.2% to 8.8% and 3.2% to 10.8%, respectively.

All PAHs showed a negative matrix effect. Among ten samples, three EVOOs exhibited traces of three out of the sixteen PAHs, albeit at low parts per billion levels.

micgalletta@unime.it

Olive oil production has expanded, resulting in a significant amount of solid and liquid by-products. From an economic and environmental perspective, the accumulation and management of residues represents a significant challenge. However, the valorisation of these by-products to recover and/or bio-transform their organic content is a significant potential, transforming the waste treatment process into one that produces high value products. In particular, olive leaves are one of the most important agricultural biomasses obtained from the pruning of olive trees, which can be considered as an available industrial by-product. They are known to be a rich source of various phytochemicals, including phenolic compounds, with high potential for their antioxidant properties.

The aim of this study was to characterise the main bioactive compounds from olive leaves of three different *Olea europaea* cultivars. Olive leaves are subject to solid-liquid extraction and then the analyses were carried out by high-performance liquid chromatography combined with photodiode array and mass spectrometry detection. The present analytical method has already successfully been employed by our research group in the drupes and olive oil and and wastes[1]. Method validation was performed in terms of limit of detection (LoD), limit of quantification (LoQ), linearity range, reproducibility and repeatability. Recovery of the method was performed achieving good results.

Determination of oxygen heterocyclic compounds content in cinnamon- and Citrus-flavoured foods using High Performance Liquid Chromatography-Tandem Mass Spectrometry

E. Irrera,[a] G. Cafeo,[a] M. Russo,[a] P. Dugo,[a,b] L. Mondello [a,b]

elisa.irrera@studenti.unime.it

A great number of plants, principally belonging to Apiaceae and Rutaceae families, contain high levels of oxygen heterocyclic compounds (OHCs), namely coumarins, furocoumarins and polymethoxyflavones[1]. These compounds are mainly present in *Citrus* fruits, cinnamon, carrot, parsnip, fennel, celery, parsley and turnip which are commonly used in several plant-based foods. Due to their numerous biological effects, coumarin and its derivatives are widely exploited as therapeutic agents but also as flavouring agents in foods[2]. The most important properties of these molecules are the antioxidant and anti-inflammatory effects[1]. Taking into account their significant role in several fields, special attention must be paid to the noteworthy drawback of their hepatotoxicity and skin phototoxicity. Among all the OHCs, the content of coumarin is the only one strictly regulated in foods. The Decision No 1334/2008 of the European Parliament and Council forbids the addition of coumarin to food as an additive, while the Annex III allows the maximum presence of 50 mg kg^{-1} for traditional bakery products and 5 mg kg^{-1} for desserts of coumarin in foods containing cinnamon as a flavor[3].

The aim of this research was to investigate the amount of coumarin and 35 OHCs in more than 30 foods flavoured with cinnamon and *Citrus* products to monitor the daily intake of coumarin by food. For this purpose, liquid chromatography coupled with triple-quadrupole mass spectrometry detector (RP-HPLC-QqQ/MS) was the approach of choice to determine the amount of OHCs in the samples of our interest and verify if coumarin content was in accordance with the limit of 0.1 mg kg^{-1} body weight as a tolerable daily intake imposed by EFSA[4]. Before the RP-HPLC-QqQ/MS analysis, each sample was subjected to solid-liquid extraction. The extraction method was validated in terms of recovery, varying the type and volume of solvent used, the extraction time and temperature, leaded by the objective of a more environmental friendly way to operate.

federica.vento1@studenti.unime.it

The Food and Agriculture Organisation of the United Nations has estimated that in order to cope with the continuous increase in world population, agricultural production should be increased by a 60% factor. For this reason, search for alternative food sources that can replace or complement existing ones are becoming widespread. In this context, seed oils are gaining an important role in food and nutraceutical market, as they are widely used both for direct consumption and as nutraceuticals for the high content in polyunsaturated fatty acids (PUFA). The present research focused on the investigation of unconventional eight cold pressed seed oils: blackcurrant, carrot, plum, pomegranate, radish, raspberry, rosehip, strawberry. The aim of the study was to demonstrate their beneficial properties related to the FA composition and/or volatile profile. Specifically, FAs were identified and quantified as FA methyl esters, obtained via a cold derivatization procedure[1], by using gas chromatography (GC) coupled with mass spectrometry (MS) and flame ionization detector (FID), respectively. The volatile fraction was elucidated by means of headspace solid-phase-microextraction (HS-SPME) coupled with GC-MS[2]. All the oils showed a content of UFAs, mainly consisting of oleic, linoleic and α-linolenic acid in the range 80-90%, potentially contributing to the prevention of cardiovascular diseases. Isomers of linolenic acid were also detected in significant amounts, such as α-linolenic and punicic acid in blackcurrant and pomegranate seed oils, respectively. Particularly, punicic acid is a conjugated isomers of linolenic acid, with possible antioxidant, anti-cancer, anti-obesity and anti-inflammatory activities.

Regarding the volatile compounds, aldehydes were the dominant molecules identified in plum, pomegranate and strawberry seed oils, while terpenes such as α-pinene, δ-3-carene and carotol were the main volatiles in blackcurrant, carrot and rosehip seed oils.

The results confirmed that these oils could be introduced into the food market for direct consumption or as nutraceutical products for the prevention of specific health conditions.

wamarchesiello@unime.it

The production of by-products from farming and food manufacturing poses a significant challenge to global environmental and food emergencies. Olive oil production employs a technological process that relies on physical operations without chemicals. However, the extraction process requires a large amount of water and produces a significant amount of solid waste and harmful liquids, which raises significant environmental concerns. Improper disposal of by-products of the olive oil mill industry can lead to environmental pollution and harm ecosystems. Olive mill wastewater (OMWW) is known for its dark color and high concentrations of organic carbon, potassium, nitrogen, phosphorus, calcium, magnesium, and iron, particularly phenols and polyphenols. Olive pomace (OP) is a solid waste consisting mainly of water, seed, and pulp with a high organic matter and carbon content, rich in potassium, low in phosphorus, with intermediate nitrogen levels. It may also contain phenolic and lipid compounds. Both matrices have a high pollution index due to their acidic nature and high concentrations of salts and phenolic compounds, making them potentially harmful by-products for the environment. Identifying and measuring bioactive compounds in complex matrices such as OMWW and OP after extraction and recovery is a challenging task. Accuracy and reliability are essential to promote new practical destinations for olive oil by-products, resulting in environmental and financial benefits.

In this study, a sensitive and robust analytical method for the quali-quantitative characterization of bioactive compounds (polyphenols and lipophenols) in samples of OMWW and OP based on high-performance liquid chromatography coupled with diode array detector and mass spectrometry with electrospray ionization interface (HPLC-PDA-ESI-MS) has been proposed and validated, by studying parameters such as repeatability, limit of detection (LOD), limit of quantitation (LOQ), linearity range, and recovery by analyzing standard phenolic and flavonoid compounds.

Preliminary investigations about protein insects bioaccessibility

M. Barberis,[a] V. Pellicorio, [a] R. Colombo, [a] A. Papetti[a]

[a] *Department of Drug Sciences, University of Pavia, Viale Taramelli 12,27100, Pavia*
marta.barberis01@universitadipavia.it

Edible insects are becoming a new protein source in order to feed a growing number of consumers, at the same time keeping environmental friendliness first[1]. Recently, after the positive safety evaluation by the European Food Safety Authority (EFSA) and their inclusion in the group of Novel Foods, it is mandatory to investigate their nutritional and toxicological profile that are generated during their intake. In this contest, the Italian National Recovery and Resilience Plan financially supported "OnFoods" which is a foundation including twenty-six public and private organizations taking sustainability, working on safety, security, and health actions. The University of Pavia is part of this foundation, and our research group aims to study the bioaccessibility, absorption, metabolism, and safety of selected components of novel foods, including *Locusta migratoria*, *Acheta domesticus*, and *Tenebrio molitor* proteins. Firstly, the proteins digestibility and amino acids bioaccessibility have been investigated using adapted Infogest 2.0 digestion protocol, a simulated *in-vitro* digestion process [2]. Digested fractions are being processed, according to protein precipitation and hydrolysis procedures under acid and basic conditions, to recovery macronutrients for subsequent investigations (e.i. protein content and digestible essential amino acid scores) [3,4]. In addition, changes occurring as a result of the digestion process will be monitored through Caco-2 cells biocompatibility tests. These preliminary investigations on insects underlines their potential nutritional value; in fact, they might be considered auspicious choices to overcome the future demands of new functional sources.

Biodiversity valorization through investigation of anti-glycative activity *of Diospyros kaki, Succisa pratensis, Aloysia citriodora*

G. Moretto,[a,b] R. Colombo,[a] A. Papetti[a,b]

[a]*Department of Drug Sciences, University of Pavia, Viale Taramelli 12, 27100, Pavia*
[b]*NBFC, National Biodiversity Future Center, Piazza Marina 61, 90133 Palermo, Italy*
giulia.moretto01@universitadipavia.it

Italy has one of the most significant biodiversity heritages in Europe, both in terms of the total number of plants and the high rate of endemism. Therefore, it is important to preserve and enhance it as a source of goods and resources to ensure the maintenance of healthy ecosystems and coexistence between humans and nature, which is sustainable in the long term and resilient to ongoing climate change. In this contest, the Italian National Recovery and Resilience Plan financially supported "National Biodiversity Future Center", dedicated to frontier research involving Italian institutions and companies, including the University of Pavia, which aims to monitor, preserve, restore, and enhance biodiversity. Therefore, our research group aims to investigate and identify biologically active edible plant species, focusing on their potential anti-glycative properties.

Glycation is a non-enzymatic reaction between a reducing sugar and the side-chain amino groups of protein lysine or arginine residues, followed by further rearrangements, leading to the formation of advanced glycation end-products (AGEs). In *vivo* AGEs accumulation is associated with many chronic disorders such as diabetes, retinopathy, nephropathy, cardiovascular, and neurodegenerative diseases.[1] In particular, the aim of the present study is to investigate the anti-glycative activity of *Diospyros kaki*, *Succisa pratensis*, and *Aloysia citriodora*, included in the Belfrit list, in order to identify and develop a new food ingredient with anti-glycative properties. Several in *vitro* assays were carried out to evaluate the ability to interfere with the glycation process at the initial, intermediate, and final stages of the reaction. In particular, model systems consisting of glycating agent, such as MGO, and a protein, such as bovine serum albumin (BSA), has been set up at physiological conditions (37 °C, pH 7.4) to evaluate the intermediate stage of glycation process.[2] With the help of NBT (blue nitrotetrazolium chloride), the capacity of the extracts to inhibit the formation of Amadori products (the initial products of the glycation process) has been evaluated.[2] In addition, MGO and GO trapping ability of the extracts has been investigated.[2] Then, the antiglycative activity at the final stage of the reaction was further investigated by several in *vitro* assays such as BSA-Glucose[3], BSA-Fructose[3], phthalaldehyde test[4], and thiol group test[5]. Overall, all three edible extracts had high anti-glycative properties at the intermediate stage of the reaction, efficiently inhibiting the formation of AGEs in the presence of MGO, which is also highly trapped. In addition, they inhibited the glycation reaction at the final stage of the reaction in presence of fructose and glucose, also increasing the percentage of free lysine amino groups; conversely, they had low anti-glycative properties at the initial stage of the reaction.

nada.baraldo@unife.it

Circular economy and recovery of mixtures of bioactive compounds from agri-food wastes and by-products is a well-known goal within UN Agenda 2030[1] for sustainable development. Many different strategies have been developed to achieve this task with attention also to other topics and targets, mainly that one known as Green Chemistry. Thus, aqueous buffers and solutions and strategies for enhancing the extraction of antioxidant compounds from vegetable matrices (i.e., microwaves, ultrasounds, pressurised liquid extraction, supercritical fluids, enzymes, or their practicable combinations)[2].

In this work, an enzyme mixture, made of mainly Pectolytic and Cellulolytic enzymes (known as Viscozyme[3]), was applied for the degradation of asparagus hard-stem (*Asparagus officinalis L.*) and red grape pomace (*Vitis vinifera L.*) samples and improve the extraction of phenolic substances. Asparagus hard-stem is the non-edible terminal part discarded after packaging asparagus edible stems with a given commercially defined length; red grape pomace is the most common by-product after grape pressing for must extraction and grape pomace is a mix between grape skin, seeds and green stem and it is also known as “marc”. Amount of enzymatic mixture (% w/w), incubation temperature and incubation time (hours) were the experimental variables studied for extraction optimization. Measured parameters in extracts were the antioxidant capacity (i.e., mM TE, trolox equivalents, by DPPH assay), total polyphenols content, TPC (i.e., mg CE, catechin equivalents, per g of dry sample, by Folin-Ciocalteu assay), total flavonoids content, TFC (i.e., mg CE, catechin equivalents, per g of dry sample, by $AlCl_3$ assay) and condensed tannins content, CTC (i.e., mg CE, catechin equivalents, per g of dry sample, by vanillin assay). A two-factors central composite design approach was used for finding the best extraction conditions and experimental data were fitted to a second order polynomial model with interactions between the independent variables. Results evidenced that the amount of antioxidants that can be recovered is quite different from the two waste matrices and optimum ranges for enzyme mixture quantity, temperature and incubation time can be identified in each case.

arenak@unime.it

Attaining comprehensive characterisation of complex food samples often requires the employment of advanced chromatographic platforms.

In this context, comprehensive two-dimensional liquid chromatography is one of the most widely used approaches to achieve high-quality data acquisition for unequivocal identification.

The characterization of polar compounds in food analysis is typically carried out by reversed-phase liquid chromatography (RP) and hydrophilic interaction liquid chromatography (HILIC) separation mode. The aim of this contribute is to compare different platforms (HILIC × RP, RP × HILIC, RP × RP) for the analysis of complex polyphenols samples.

Their performance was evaluated in terms of peak capacity, orthogonality and maximum number of identified compounds.

In particular, one of the most complex phenolic compounds mixtures is represented by herbal liqueurs, typically produced by macerating several herbs, roots, flowers, bark, and/or citrus peels in alcohol, either neutral spirits or wine, mixing the filtrate with sugar syrup, and allowing the mixture to age in barrels or bottles. The huge varieties of botanical families used in their production, make herbal liqueurs a perfect matrix to evaluate the different comprehensive set-ups, mentioned above, on several phenolic matrices at the same time. Moreover, hyphenation with PDA and MS/MS detectors and chemometric approaches allowed discriminating between the several isomers presents in the different botanical families.

Rhus coriaria L. (Anacardiaceae), commonly known as sumac, it is a typical plant of Mediterranean and Middle Eastern areas, whose ground fruits are nowadays mainly used as spice or for flavouring and garnishing food. However, has been also used, since ancient times, in traditional medicine for treating many diseases such as haemorrhoids, wound healing, diarrhea, ulcers, and eye inflammation.

Actually, sumac fruits and leaves are rich in antioxidant compounds, including several gallic acid derivatives and flavonoids, from which treatment of common oxidative stress diseases could benefit. However, while many studies are focused on fruits, really few were conducted on leaves composition; moreover, most of them about Middle Eastern area samples.

For this reason, conventional and advanced liquid chromatography techniques coupled with photodiode array and mass spectrometer detectors were employed to investigate the phenolic profile of *Rhus coriaria* L. fruits and leaves, coming from different Sicilian areas. More than 80 phenolic compounds, mainly represented by gallic acid and its derivatives were positively identified, with important qualitative difference between fruits and leaves extracts. The present work confirmed the nutraceutical value of this plant, highlighting sumac leaves as a rich source of gallic acid.

For extra virgin olive oils, it is crucial to ensure the authenticity of the declared and labelled commercial category. Olive oil companies, as well as quality control public and private laboratories, are often requested to rapidly assess the quality and purity of extra virgin olive oils. In this framework, a screening method based on gas chromatography coupled with ion mobility spectrometry (HS-GC-IMS) for the analysis of volatile compounds can be useful to support the virgin olive oils sensory analysis (Panel test). This instrumental approach can contribute to improve the overall efficiency of official quality and purity controls in the olive oil sector, thus protecting the consumer from the related common fraudulent practices.

In this research, around 80 commercial virgin olive oils were sensory assessed by five Italian panels, then classified, through the adoption of a decision tree based on the agreement among them, in a commercial category. Moreover, the volatile fraction of these oils was analysed in five laboratories by HS-GC-IMS. The results were elaborated towards the possible definition of a joint calibration based on a common dataset. In particular, the commercial categories of each oil were predicted based on volatile compounds data using PLS-DA models, with a focus on borderline samples between the extra virgin and virgin commercial categories.

This inter-laboratory study showed satisfactory results for such a prediction of the commercial category since most of the samples were correctly classified in the same quality grade with respect to the robust sensory classification.

Authors acknowledge the involved sensory panels, Federolio, and LabService Analytica.

cicafarella@unime.it

One of the most significant sources of "healthy" fats and bioactive compounds in the Mediterranean diet is extra virgin olive oil (EVOO). Due to its unique nutritional and sensory characteristics and high commercial value, it remains a primary target for fraudulent activities. Within this context, the present study aimed to establish a fast and reliable method to differentiate and valorize top-quality Italian EVOOs, thus preserving the national product against mislabeling practices. A cost-effective and user-friendly approach has been developed using an ambient mass spectrometry (AMS) ion source, specifically Direct Analysis in Real Time (DART) coupled with a compact single quadrupole MS analyzer, to characterize major and minor compounds in EVOOs. An untargeted approach based on the analysis of EVOOs in their native form and a targeted method involving a solid phase microextraction (SPME) of phenolic compounds prior of the analysis, were explored and evaluated in terms of rapidity of the analysis, cost-effectiveness, "greenness profile" and type of delivered information. Moreover, MS spectra were used to create a spectral database and statistical models useful to clusterize and classify EVOOs according to geographical origin and cultivar, as main factors determining their nutritional and sensory profiles. Targeted and untargeted strategies were also compared in terms of sample clusterization into the chemometric space and prediction capability of the statistical models as well as correctness of the real-time and playback identification of "unknown" samples. The targeted method provided the model with the highest correctness score, higher than 90%, despite the high intra-class variability (more than one olive cultivar, in different ratio, can be used for the production of the same PDO EVOO or the same PDO EVOO can come from different close territories) and low inter-class variance (all Italian top-quality EVOOs).

Fraudulent activities in food field are carried out principally for economic purposes and generated to improve perceived quality. In this contest, aromatic herbs and spices represent the most susceptible food matrices to those deceitful and illegal practices. The long and complex supply chain, the increasing in demand and prices make them vulnerable to economically motivated adulteration [5], which define the onset of issues related to the product quality and safety. Moreover, apart from their commercial value, herbs and spices or their extracts (or essential oils), contain functional compounds well-recognized for their biological activities, in particular phytochemicals (phenol compounds, terpenes and alkaloids), recognized for the anti-inflammatory and antioxidants properties. The authenticity and traceability of those samples are commonly evaluated according to ISO standards by using conventional analytical methods, that although provide high reproducibility and sensitivity, are time-consuming approaches in terms of sample preparation and analysis time. In order to deal such drawbacks and introduce more competitive approaches against food fraud, in the last decade fast fingerprinting methods have been employed for the reliable identification of "precious" foodstuffs. Ambient Mass Spectrometry (AMS) has attracted interest for the absent or minimal sample preparation, in line with green chemistry principles, and the capability of *in situ* analysis of samples in their native environment. The present study employed two innovative AMS techniques, REIMS-QTOF and DART-QDa, as fast and reliable methods to be used for preserving the biodiversity and local economies though the rapid screening of the total metabolome of different herbs and spices. The main goal was the obtaining of univocal fingerprinting for the different samples for the identification of discriminant features among the samples. In this regard, the coupling of these methods to chemometrics was essential, as starting point for finding similarities or dissimilarities across different groups of samples, based on the building of classification models capable to discriminate according to the according to the botanical species or varieties. The models were validated (correctness score higher than 90%) and used for the real-time identification of unknown samples, therefore distinguish genuine from adulterated products.

Food irradiation is a clean and safe non-thermal technology used worldwide for different purposes such as improving safety and extending the shelf-life of several foodstuffs, eliminating pathogenic and spoilage microorganisms, parasites, insects and/or viruses[1,2]. This process was regulated by the Community Directives 1999/2/EC and 1999/3/EC, according to which only Camembert can be irradiated, at a dose maximum of 2.5 kGy[3]. In this study, an optimized accelerated solvent extraction (ASE) procedure[4], employing the temperature of 60 °C, three extraction cycles and isopropanol/methyl-*tert*-butyl ether/cyclohexane (20:30:50 v/v/v) as solvent mixture, was applied to X-ray treated and non-treated samples of Camembert cheese produced from raw cow's milk. The recovered lipid fraction was analized by ultrahigh-performance liquid chromatography quadrupole Orbitrap high-resolution mass spectrometry (UHPLC-Q-Orbitrap-MS), to obtain the lipid fingerprints of the samples. Three different irradiation dose levels, namely 1.0, 3.0 and 4.0 kGy were chosen to investigate the variation of lipids in relation to the X-ray irradiation treatment. In particular, 1.0 kGy was within the range of authorized doses, while 3.0 and 4.0 kGy were considered to explore what type of lipid changes may occur when the cheese has been treated at unconventional levels. More than 400 lipids were identified and characterized, hence the collected data were studied using chemometric approaches, in particular principal component analysis and partial least square-discriminant analysis, to discriminate irradiated respect to non-irradiated samples. The results of our proposed ASE/UHPLC-Q-Orbitrap-MS-based lipidomic workflow confirm its effectiveness for deepening knowledge on the effects of X-ray irradiation on foods and for the evaluation of its safety aspects.

This work was supported by the Italian Ministry of Health who funded the Projects code GR-2018-12367064 and IZS PB 05/23 RC.

Protein content, fatty acid profile and antioxidant capacity of plant-based kefir milks

Alessia Fazio,[a] Chiara La Torre[a]

[a]*Department of Pharmacy, Health and Nutritional Sciences, University of Calabria, Via Alberto Savinio, 87036, Arcavacata di Rende (CS)*
a.fazio@unical.it

Kefir is widely known as an excellent source of probiotics with potential health benefits. Existing reports have suggested important bioactivities associated with kefir consumption, such as antimicrobial, anti-inflammatory and antioxidant activities. kefir is produced through a fermentation process using kefir grains as starter culture. They consist of a consortium of yeasts, lactic acid bacteria (LAB), and acetic acid bacteria (AAB) embedded in a branched galactoglucan matrix, named kefiran.[1]

Most of the reported kefir research has been focused on milk substrates from cow, sheep, goats or other type of milk.[2] An alternative way to intake beneficial health effects from kefir is through of its adaptation to non-dairy substrates for the production of new probiotic products to provide vegan, lactose intolerant, and dairy-product allergic consumers.[3] Thus, plant-based milks were used as medium of kefir fermentation.

Almond, coconut, hazelnut, oat, rice, soy, walnut milks were inoculated with 5% (w/v) milk kefir grains for 24 h at room temperature. Changes in protein content and fatty acid profile of the fermented samples were evaluated and compared with the starting milk values.

The fermentation led to an increase of protein content in all samples, except soy one where it was halved and walnut sample for which it remained unchanged. Beneficial fatty acids such as oleic and linoleic acid rose in all samples with the exception of soy and walnut ones. Phenolic content (TPC), determined by the Folin-Ciocalteu method, increased during fermentation in all samples: kefir from walnut milk showed the highest TPC (350.9 ± 3.0 µg GAE/mL) followed by soy sample (337.2 ± 8.4 µg GAE/mL). According to TPC results, antioxidant activity, evaluated by ferric reducing antioxidant power (FRAP) assay, showed improved activity in all probiotic fermented milks being highest in almond and walnut samples (536.0 ± 1.0 µM $FeSO_4$/mL) followed by the kefir from soy milk (207.8 ± 5.5 µM $FeSO_4$/mL).

The adaptation of milk kefir grains into different substrates such as plant-based milks has shown potential for the production of beverages with functional properties.

matteo.corti@unimi.it

Soybean is one of the most important crops worldwide, being placed 8th on the chart of the most cultivated species.[1] Its high level of production correlates with a huge amount of waste produced. These residues could be of great interest due to the presence of high value-added molecules. Among these compounds, glycosides (e.g., daidzin, genistin and glycitin) have been widely studied for their potent antioxidant properties.[2]

In the present work two parallel approaches have been followed: enzymatic hydrolysis to the corresponding aglycones and CaLB mediated glycoside lipophilization to obtain derivatives with increased bioavailability and/or stability for potential applications in food, nutraceutical and cosmetic sectors. Firstly, *Escherichia coli* strain BL21 (DE3) STAR was utilized to heterologously produce an extremophilic β-glucosidase from *Halothermotrix orenii* (HOR). This was then exploited for the production of aglycones starting from soybean glycosides. Subsequently, lipophilization reactions of daidzin with butanoic, hexanoic and octanoic acids have been carried out with *Candida anctarctica* lipase B under continuous flow conditions. This work contributes to evidence the possibility of using agri-food residues to produce high value-added compounds through eco-friendly biocatalytic methodologies.

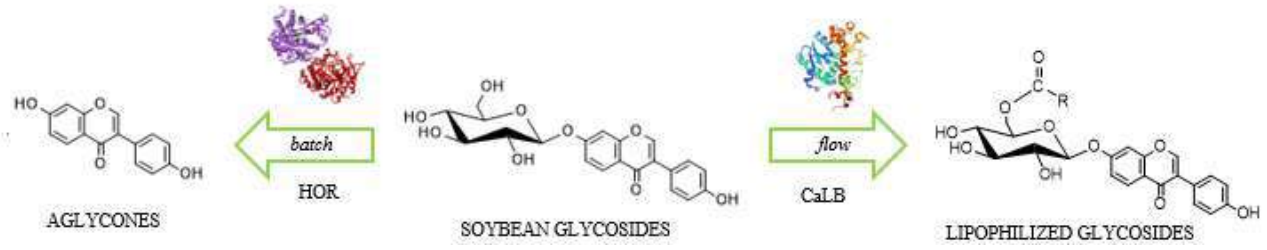

Figure 1: Schematic representation of the work-flow

This study was carried out within the Agritech National Research Center and received funding from the European Union Next-GenerationEU (PIANO NAZIONALE DI RIPRESA E RESILIENZA (PNRR) – MISSIONE 4 COMPONENTE 2, INVESTIMENTO 1.4 – D.D. 1032 17/06/2022, CN00000022).

Green Datterini tomatoes as a potential nutraceutical in the prevention of aging-related muscle diseases: proof of concept studies in mice

V. Piccolo,[a] A. Pastore,[a] A.G. Cicatiello,[b] M. Stornaiuolo,[a] M. Dentice,[b] G.C. Tenore,[a] V. Summa,[a]

[a] *Department of Pharmacy, School of Medicine and Surgery, University of Naples Federico II, via D. Montesano 49, 80131, Naples, Italy*
[b] *Department of Clinical Medicine and Surgery, University of Naples Federico II, via S. Pansini 5, 80131, Naples, Italy*

E-mail: vincenzo.piccolo3@unina.it

Sarcopenia is an aging-related muscle disease characterized by the loss of 50% of muscle mass, leading to several adverse effects as frailty and disability. In order to develop a nutraceutical formulation for sarcopenia prevention, our attention was focused on tomatidine, a natural compound able to act simultaneously on the mTORC1 and ATF4 factors, two targets involved in aging-related muscle disease.[1] Tomatidine represents the aglyconic moiety of α-tomatine, a glycoalkaloid identified in green tomatoes (*Solanum Lycopersicum* L.). α-tomatine is converted into tomatidine by an *in vivo* metabolic mechanism.[2] A matrix screening of seven tomato cultivars allowed to identify the green Datterini tomatoes (DT) as the cultivar with the most promising polyphenolic (chlorogenic acid: 1.41 ± 0.01 mg/g dry weight; rutin: 995.57 ± 3.46 µg/g dry weight) and glycoalkaloid content (α-tomatine: 34.70 ± 1.36 mg/g dry weight). Therefore, this cultivar was selected for further investigation through *in vitro* assays and *in vivo* proof of concept study in mice.[3] Tomatidine efficacy on C2C12 muscle cells confirmed tomatidine efficacy in the stimulation of protein synthesis and mitochondrial function. Therefore, an *in vivo* proof of concept study was performed to confirm the efficacy of green DT in sarcopenia prevention in elderly mice. A treadmill test showed the nutraceutical capacity to improve muscle performance in DT treated mice by increasing the time spent and the running distance on the treadmill and by reducing the number of interruptions during the speed. The histological analysis of gastrocnemius tissues showed a remodelling of the muscle profile of DT treated mice, with an increased number of young muscle fibers with high resistance to physical exercise. Moreover, metabolomic analysis confirmed the increment of metabolomic activity and protein synthesis. Therefore, these results suggested the potential use of green DT as a potential food matrix for the development of new nutraceuticals for the prevention of aging-related sarcopenia disease.

Optimized Extraction of Phenolics and Procyanidins from Seven Medicinal Herbs for Nutraceutical Development

N. Keivani[a], V. Piccolo[a], M. Maisto[a], G.C. Tenore[a], V. Summa[a]

[a] *Department of Pharmacy, School of Medicine and Surgery, University of Napoli Federico II, Via Domenico Montesano 49, 80131, Napoli*
niloufar.keivani@unina.it

The main objective of the study was the optimization of the procyanidin solid/solvent extraction process, using grape pomace, to ultimately determine the procyanidin profile and bioactivity of seven medicinal herbs to potentially use in nutraceutical products. Procyanidins, oligomeric forms of flavan-3-ols belonging to the flavonoids group, are (poly)phenolic compounds synthesized by plants as secondary metabolites[1]. Parameters influencing the extraction results have been evaluated singularly and the highest procyanidin yields were achieved by the following optimized conditions: extraction solvent 59.5% methanol, 1% formic acid, 10 min sonication, and 10 min shaking. The extraction method was validated by the evaluation of % recovery and % matrix effect. The HPLC-FLD method used for quantification of monomeric to trimeric procyanidins was validated by the ICH guidelines in which the low interday and intraday % bias and % CV values at all standards concentration levels were observed (% CV values not exceeding 20%)[2]. Quantification of 17 polyphenols has been performed by MS working in Multiple Reaction Monitoring (MRM) using a 4000 Qtrap spectrometer. Furthermore, HPLC-HESI-MS/MS analysis performed on the herbal extracts led to the qualitative identification of 27 further polyphenols. To have an insight into the potential bioactivity of the extracts, the *in vitro* antioxidant activity was evaluated by DPPH assay, resulting in 935.23 ± 169.85 µmol Trolox equivalent/g of dry weight in *Peumus boldus Molina* leaves extracts. Moreover, Pearson correlation analysis (PCA) results exhibited higher Pearson coefficient (R^2) and significance (p-value) values between total flavonoid content and DPPH in comparison with the total phenolic content and DPPH, indicating flavonoids as the most relevant active substances of the extracts. Finally, *Paullinia cupana Kunth*. seed extract contained the highest level of procyanidins among all the extracts evaluated and had an antioxidant activity of 693.63 ± 48.04 µmol Trolox equivalent/g of dry weight. In conclusion, the extraction and quantification analysis models proposed are considered valid to produce procyanidin-rich extracts, by which *Paullinia cupana Kunth*. seed (containing over 5000 µg/g of dry matrix of each dimeric and 2829.14 µg/g of dry matrix trimeric procyanidin) was the matrix that would serve better as the source containing a vast range of flavonoid-type antioxidant agents to be used in prospective nutraceutical products. It would also reduce inflammation rates by interfering with oxidative stress signaling and suppressing the pro-inflammatory signaling transductions, effective in the prevention of chronic inflammation and metabolic disorders.

Ulvan from *Ulva lactuca* L.: optimization of enzymatic hydrolysis by ulvan-lyase and characterization of the produced oligosaccharides

B. Zonfrillo,[a] M. Bellumori,[a] M. Khatib,[a] P. Faraoni,[b] M. Innocenti,[a] N. Mulinacci,[a] F. Ranaldi[b]

[a] *Department of NEUROFARBA, University of Florence, via Ugo Schiff 6, Sesto Fiorentino, Florence*
[b] *Department of Experimental and Clinical Medicine, University of Florence, viale Pieraccini 6, Florence*
maria.bellumori@unifi.it

Ulva lactuca L. is a green alga of the Ulvaceae family distributed worldwide, which has gained increased attention due to its high reproductive rate, which leads to the phenomenon known as "green tides", accelerated by water eutrophication. While algae from the Ulvaceae family are used for food and feed purposes, their biomass currently has limited applications. However, the cell wall of these algae is rich in polysaccharides, of which ulvan is the most peculiar and interesting. Ulvan is composed of disaccharides repeating units, constituting in rhamnose-3-sulfate (Rha3S) linked to *D*-glucuronic acid (GlcA), *L*-iduronic acid (IduA) or *D*-xylose (Xyl) by predominantly beta glycosidic bonds. Ulvan oligosaccharides has been associated with anti-cholesterolemic and antioxidant activities, making the production of these compounds a promising opportunity for biomass utilization[1]. Since these bonds are highly resistant to conventional acidic hydrolysis methods, enzymatic hydrolysis is preferred to ensure efficiency and the production of food-grade products. To this end, ulvan lyases (EC 4.2.2), found in marine bacteria, can be used for the catalysis of the endolithic cleavage between Rha3S and uronic acids, by a β-elimination reaction[2].

Aim of the present study was the optimization of the enzymatic hydrolysis of ulvan to obtain a pool of ulvan oligosaccharides to be testet for biological activities. Ulvan were extracted from *U. lactuca* collected in an aquaculture tank of Orbetello lagoon. A recombinant ulvan lyase of PL24 family commercially available was used for the hydrolysis. The enzyme was characterized kinetically and different concentrations of buffer medium (composed of NaCl and Trizma® base both from 0 to 100 nM) were tested to minimize the residual presence of salts in the final products. The activity of the enzyme was measured for 24 h as spectrophotometric absorbance at 235 nm (indication of double bonds formation after β-elimination), ^{1}H-NMR spectra were acquired to monitor the production of oligosaccharides, and Dynamic Light Scattering measurements were applied to evaluate the hydrodynamic volume of the hydrolyzed ulvan in solution.

In summary, ulvan lyase resulted a robust enzyme able to rapidly and extensively hydrolyze ulvan at different composition of the medium. To provide insights into the impact of ulvan on gut health and to promote future uses of *Ulva* biomass, the hydrolyzed ulvan will be tested *in vitro* for its prebiotic activity.

marina.russo@unime.it

Due to their pleasing scent, *Citrus* essential oils are widely used in flavouring foods and hydroalcoholic fragrance formulations. These oils contain a non-volatile fraction comprising approximately 10-20% of coumarins, furocoumarins, and polymethoxyflavones. Furocoumarins are known to cause photosensitization and possess potential carcinogenic and mutagenic properties. Therefore, regulatory bodies such as the International Fragrance Association closely monitor the levels of furocoumarins in cosmetic products. Supercritical fluid chromatography (SFC) has emerged as an innovative analytical technique for analyzing these molecules. SFC employs supercritical CO_2 as a mobile phase, offering characteristics between a liquid and a gas, resulting in faster analysis times and reduced solvent consumption compared to conventional liquid chromatography.

This research focuses on developing rapid analytical methods with minimal environmental impact using chromatographic techniques. Two validated methods were developed: the first utilizing SFC coupled with either a photodiode array detector (PDA) or a triple quadrupole mass spectrometry detector (QqQ-MS), enabling fast separation with minimal solvent usage in under 8 minutes; the second employing RP-HPLC-QqQ-MS for quick screening, completing analysis in about 4 minutes with less than 3 mL of ethanol per analysis. These methods aim to provide an environmentally friendly approach for quantifying coumarins, furocoumarins, and polymethoxyflavones in cold-pressed *Citrus* essential oils, flavoured foods and cosmetics. Calibration curves were constructed using distilled lemon essential oils to quantify these compounds in real samples, with satisfactory validation parameters allowing for quantification even at trace levels in finished products. Overall, these methods offer a green analytical approach for analyzing these compounds in *Citrus* essential oils, with the SFC-PDA method being particularly environmentally friendly compared to previously developed liquid chromatography methods. Thus, SFC is well-suited for quality control of these compounds in citrus essential oils and finished products.

Biocatalytic approaches to enhance exploitation of rice waste

D. A. Consolini,[a] A. Pellis[b], M. Gigli[c], F. Molinari[a], A. Pinto[a], M. L. Contente[a]

daniele.consolini@unimi.it

Rice production generates huge amounts of byproducts. It is estimated that around 80% of these residues are burnt *in situ* or incorporated in soil. These strategies not only fail to exploit the full potential of organic material, but also actively contribute to atmospheric pollution and GHG emissions.[1] Rice straw and husks, the primary components of non-food biomass deriving from rice production, contain a combination of cellulose, hemicellulose, and lignin, along with appreciable amounts of silica and other minor components.[2] Our research activities aim at boosting the valorization of rice waste streams, by developing a biocatalyst covalent immobilization strategy onto silica micro- or nanoparticles, obtained from rice husk with different chemical procedures, and pretreated with 3-aminopropyltriethoxysilane (APTES) and glutaraldehyde. The preliminary results of the immobilization of the lipase B from *Candida antarctica* (CaLB) are promising, as with two different enzymatic loadings (1 mg or 10 mg of enzyme/g of carrier) we obtained up to 100% immobilization yield with a recovered activity ranging from 50 to 100%, depending on the type of silica used as carrier.

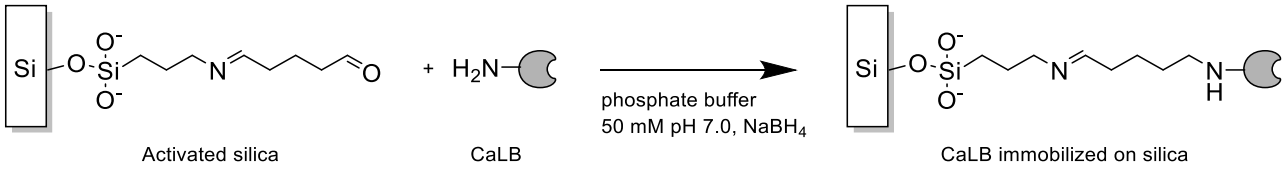

Figure 1: CaLB immobilization on silica pretreated with 3-aminopropyltriethoxysilane (APTES) and glutaraldehyde

The immobilized lipase will be used for the acylation of lignin-based low molecular weight species (LIMO), obtained by a laccase-catalyzed oxidative depolymerization of lignin from rice straw residues, to obtain molecules with enhanced antioxidant activity. These compounds will be ultimately used for the preparation of a bioactive packaging system, whose polymeric skeleton will be constituted by medium chain lignin oligomers containing OH functionalities (MCLO) and commercially available biobased building blocks.

Pomegranate peel fermented by *Saccharomyces cerevisiae*: a study on changes in tannin content and polysaccharide structure

M. Khatib[a], B. Zonfrillo[a], M. Bellumori[a], S. D'Agostino[b], L. Cecchi[b], D. Bertelli[c]; E. Truzzi[c], Nadia Mulinacci[a]

mohamad.khatib@unifi.it

The pomegranate fruit is highly appreciated for its nutritional properties and numerous uses in the food field. After processing pomegranate fruits to produce juice, significant quantities of waste are generated and the peel is the main by-product (approximately 50% of the total weight of the fruit). Peel contains several micronutrients, hydrolysable tannins and appreciable amount of polysaccharides, mainly pectin [1]. As regards the fermentation of the pomegranate fruit, the most widely described processes are those involving the juice through the use of lactic acid bacteria, namely *Saccharomyces c*. to obtain a sort of wine [2]. Among the procedures proposed in the literature, fermentation processes using only the peel of the pomegranate fruit have only been poorly explored and aimed at ethanol production [3]. Since there is a demand for simple and sustainable methods that can favor the obtaining of valuable products from pomegranate peel, the aim of the study was to evaluate the changes induced by fermentation with a common yeast such as *Saccharomices cerevisiae* on the tannins and polysaccharide of the peel (mesocarp and endocarp).

Two varieties (Wonderful and G1) were fermented applying 3 processes: i) fermentation in closed tubes (1N method); ii) fermentation in closed tubes after a blanching of few minutes of the peel at 100°C (2PbN method); iii) fermentation in open-air, with tubes closed only with a cotton cap (3Na method). The experiments were done in triplicate with and without the presence of yeast, to have for each method of fermentation a blank sample (B) characterized by the absence of the yeast (L). All the fermentations were carried out at 25°C adding water to reach a ratio of 1/10 w/v and the same amount of yeast (15 mg/g of dried peel); the samples were collected from 0 to 96 hrs of fermentation. The polysaccharides were recovered after decoction of the whole fermented samples and successive precipitation with ethanol.

HPLC-DAD profiles of tannins in blank samples and yeast samples were very similar or overlapping, within each fermentation method. From a quantitative point of view, the % yields in dry aqueous extracts from fermented samples, calculated on the dried skins, were decidedly higher for the white samples compared to the fermented ones. Interestingly, the concentration of total tannins in the dry extracts obtained from fermentation with *Saccharomices c*. after 48 and 96 hrs was found to be approximately 50% higher than in the corresponding blank samples.

As confirmed by DLS measurements and NMR-DOSY experiments, fermentation reduced the molecular weight of native peel pectin. Since polysaccharides from unfermented peels have previously shown prebiotic activity in vitro [4], an increase in their fermentability is expected as a consequence of the reduced molecular weight obtained after the fermentation processes.

marco.ciulu@univr.it

In this study, the occurrence of 73 pesticides residues in Italian honeydew honeys collected between 2022 and 2023 was investigated. Sample preparation was performed by a QuEChERS approach as previously described[1] . Sample analysis was performed by Orbitrap LC-MS. In only 6 of the 56 samples analysed (10.7%), no pesticide residues were found. As regards neonicotinoids, acetamiprid was detected in more than half of the samples with concentration ranging between 0.08 and 11.14 ng/g while imidacloprid was detected in one third of the samples with a content varying between 0.23 and 1.53 ng/g. Other relevant detected analytes include coumaphos (17 samples), 3-hydroxy carbofuran (14 samples), deisopropylatrazine (6 samples), propazine (6 samples) and chlorfenvinphos (5 samples).

The contribution of in-cell NMR to cellular structural biology

Lucia Banci

CERM and Department of Chemistry, University of Florence, Sesto Fiorentino, Italy

In-cell NMR, i.e. high-resolution NMR spectra of biomolecules in intact, living cells, allow the characterization of conformational and functional properties of biomolecules at atomic resolution in conditions as close as possible to the physiological ones. It also allows to monitor protein-protein interactions and to follow functional processes, as well as protein maturation and post-translational modifications. A further high-impact application is its use for drug screening in real time at cellular level, in human living cells.

A few examples of the striking power of this approach will be presented.

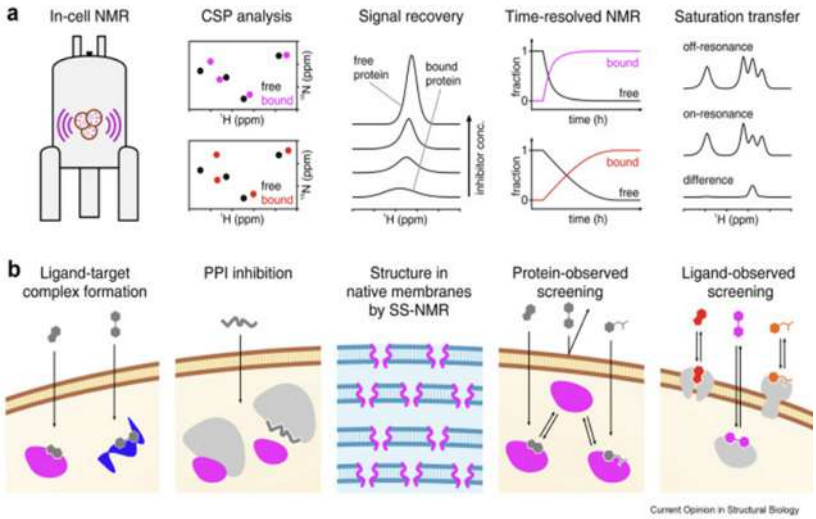

Figure 1: Examples of applications of in-cell NMR.

Multi-eGO: molecular modelling of biomolecular self-assembly processes

C. Camilloni[a]

[a]*Department of Biosciences, University of Milano, Via Celoria 26, 20133 Milano, Italy*
carlo.camilloni@unimi.it

Structure-based models have been instrumental in simulating protein folding and suggesting hypotheses about the mechanisms involved. Today, at least for fast folding proteins, folding in explicit solvent can be simulated using classical molecular dynamics. However, other self-assembly processes, such as protein aggregation, are still far from being accessible. With Multi-eGO [1,2], we have introduced a hybrid multistate structure-based model that could bridge the gap to the simulation of out-of-equilibrium, concentration-dependent self-assembly processes. By learning from the dynamics of a few minima of a system simulated by conventional molecular dynamics simulations, Multi-eGO can enable the comprehensive simulation of processes such as protein aggregation, the folding of complex multi-domain proteins, and the binding/unbinding of ligands. In this talk I will present the current state of the model and some recent applications.

Chemokines heterodimer activate or dampen their cognate receptors during inflammation. CXCL12 chemokine forms with the fully reduced (fr) alarmin HMGB1 a relevant heterocomplex (frHMGB1•CXCL12) that synergically promotes the inflammatory response elicited by the G-protein coupled receptor CXCR4. The molecular details of complex formation were still elusive. Here, by an integrated structural approach we show that frHMGB1•CXCL12 is a fuzzy heterocomplex, the first reported for chemokines. Unlike previous assumptions, frHMGB1 and CXCL12 form a dynamic equimolar assembly, with structured and unstructured frHMGB1 regions recognizing the CXCL12 dimerization surface. We uncover an unexpected role of the acidic intrinsically disordered region (IDR) of HMGB1 in heterocomplex formation and its binding to CXCR4 on the cell surface. Our work shows that the interaction of frHMGB1 with CXCL12 diverges from the classical rigid heterophilic chemokines dimerization. Simultaneous interference with multiple interactions within frHMGB1•CXCL12 might offer novel pharmacological strategies against inflammatory conditions[1].

Advanced extracellular matrix mimics with controlled mechanics for the study of cell mechanosensing

Pasquale Sacco

Department of Life Sciences, University of Trieste, Via L. Giorgieri 5, I-34127 Trieste, Italy
psacco@units.it

Natural tissues and extracellular matrices (ECMs) are not purely elastic biomaterials but exhibit dissipative (viscoelastic) properties. Although it has recently emerged as a novel regulator of cellular responses, the contribution of material dissipation to controlling cell fate decisions is still in its infancy. In this talk, I will present an unprecedented strategy to tune the dissipation rate of viscoelastic substrates suitable for 2D cell culture while precisely regulating linear elasticity. In particular, I will present recent findings on viscoelastic hydrogels with varying degrees of linear elasticity that can modulate cellular functions.[1-4] By introducing specific sugar sequences or weak physical entanglements that act as stress dampers, a novel approach to precisely extend the linear stress-strain range is described. Our results show a crucial link between this material property and cell response in 2D cultures. They influence the type and speed of cell migration, the geometry and size of vinculin-dependent focal adhesion, F-actin organization, force transmission and YAP nuclear translocation. I will show that cells require a common actomyosin contractility and microtubule tension to probe the substrate and decide whether to adhere or not. This reveals a clear correlation between force transmission, biomaterial dissipation rate and number of anchoring points. Overall, these results introduce linear elasticity as a new design parameter for the construction of tunable dissipative biomaterials to study the mechanosensing of cells in 2D and possibly also in 3D cultures.

Is proteins structural stability challenged by lipid peroxidation?

C. Honisch,[a] M. Rotondo,[b] E. Galluppo,[a] S. Tartaggia,[a] R. Hussain,[c] G. Siligardi,[c] P. Ruzza[a]

c.honisch@icb.cnr.it

Lipid oxidation can arise in vivo during oxidative stress and redox imbalance situations. This process involves the generation of reactive oxygen species (ROS) within the cells, which can readily attack unsaturated fatty acids in membranes through non-enzymatic mechanisms, triggering a chain reaction that generates various oxygenated small molecules. These molecules often contain reactive electrophilic carbonyl groups, including α,β-unsaturated aldehydes, which can interact with nucleophilic moieties on protein surfaces, inducing misfolding and aggregation.[1]

Lipid peroxidation significantly affects membrane organization and can modify proteins and DNA, leading to functional alterations. Consequently, it was suggested to be implicated in aging and the pathogenesis of various diseases, including atherosclerosis, neurodegenerative disorders, autoimmune diseases, and type 2 diabetes.[2]

To investigate the effects of lipid peroxidation on the conformational stability of model proteins, bovine serum albumin (BSA), hen egg white lysozyme (HEWL), ubiquitin and rabbit IgG were solubilised in phosphate buffer and studied alone or in the presence of DMPG-DOPC (at 1:1 molar ratio) small unilamellar vesicles (SUVs) at either 20° or 40°C.

Oxidative conditions were performed by collecting 30 consecutive repeated synchrotron radiation circular dichroism (SRCD) spectra at beamline B23 of the Diamond Light Source synchrotron. We have previously demonstrated that the high photon flux and brilliance of the synchrotron radiation induces water photolysis and production of ROS that can denature protein/peptide folding and is used to quantify the UV photostability of proteins/peptides with and without ligands and a as a function of environment.[3]

For HEWL in phosphate buffer (PB) and SUV at 20 °C and 40 °C, respectively, the normalised spectral changes at 192 nm reported against the number of scans revealed that the ROS damage and the effects of lipoxidation of protein was less pronounced in SUVs than in PB at higher temperature suggesting a protective property of SUVs against ROS damage on protein.

DEVELOPING NEW TOLL-LIKE RECEPTOR 4 (TLR4) MODULATORS AS INNOVATIVE AND INEXPENSIVE VACCINE ADJUVANTS

Alessio Romerio[a], Mohammed M. Shaik[a], Alice Italia[a], Federico Lami[a], Francesco Peri[a]
[a] *Università degli Studi di Milano-Bicocca, Department of Biotechnology and Biosciences, Milano*

Vaccines have been a breakthrough in medicine: they saved millions, reduced the incidence and morbidity of diseases such as polio, measles and tetanus and caused smallpox eradication. [1]
Modern subunit-based and nucleic acid-based vaccines are safer and easier to produce than inactivated pathogen-based ones, but require vaccine adjuvants to achieve a proper immunization.[2]

A vaccine adjuvant is any entity that enhances a vaccine efficacy. For more than 70 years Alum® has been the only adjuvant licensed for human use: only recently few new adjuvants have been approved.[3] The most prominent example is Monophosphoryl lipid A (MPLA), an agonist of Toll-like receptor 4 (TLR4). MPLA is commercialized by Croda International PLC and is employed in several vaccine formulation vaccines (Fendrix®; Cervarix®; Shingrix®; Mosquirix®; and Pollinex-Quattro).[3] However, MPLA is a complex molecule with a long synthesis (>25 reactions), resulting in high final cost (~230 USD/mg).[4]

We present here a series of simplified, rationally designed MPLA analogues called FP compounds. FPs show a similar or better TLR4 agonists activity than MPLA, thus being promising vaccine adjuvant. As FPs are much easier to synthesize, they are currently being preclinically developed in collaboration with Croda International PLC as innovative and inexpensive vaccine adjuvants.[5–7]

Monovalent metal ions promote pre-mRNA splicing

J. Aupič,[a] J. Borišek,[b] S. M. Fica,[c] W. P. Galej,[d] A. Magistrato[a]

jana.aupic@sissa.it

Nucleic acid processing enzymes, composed of both protein and RNA molecules, rely on a two-metal (M^{2+})-ion motif to enact phosphodiester bond breakage and formation. However, structure comparisons revealed that many of them contain highly spatially conserved second-shell monovalent cations, whose precise function remains elusive. A recent cryo-EM structure showed that the spliceosome, a massive ribonucleoprotein complex responsible for excising intron regions from pre-mRNA, also contains an additional K^+ ion in the catalytic site. To decipher its role, we employed hybrid quantum-classical molecular dynamics (QM/MM MD) simulations. We discovered that the K^+ ion promotes the branching reaction by rigidifying the active site and stabilizing the substrate in pre- and post-catalytic state via formation of key hydrogen bonds. This results in the reduction of both the reaction free energy and activation barrier. Our findings highlight the so far overlooked role of monovalent metal ions in RNA processing and provide a mechanistic hypothesis that may be broadly shared by other RNA/DNA-processing engines.

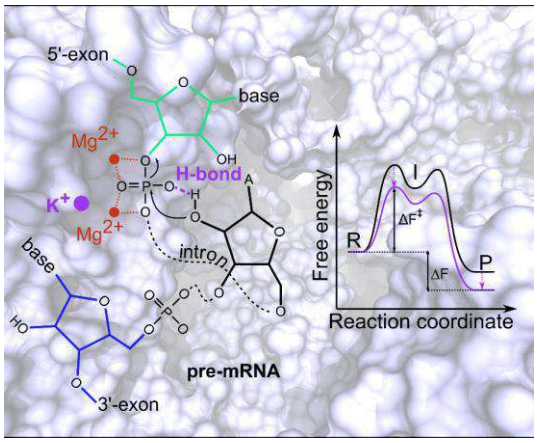

Figure 1: Potassium ion enhances the efficiency of the branching reaction by rigidifying the spliceosome active site, thus facilitating optimal positioning of the attacking hydroxyl group of the branch point adenosine.

Integrated metabolomics and proteomics of symptomatic and early pre-symptomatic states of colitis

E. Shimshoni,[a] I. Solomonov,[a] I. Sagi,[a] V. Ghini[b]

[a]*Department of Biological Regulation, Weizmann Institute of Science, 7610001, Rehovot, Israel*
[b]*Department of Chemistry, University of Florence, 50019, Sesto Fiorentino, Florence, Italy*
ghini@cerm.unifi.it

Colitis has a multifactorial pathogenesis with a strong cross-talk among microbiota, hypoxia and tissue metabolism. We aimed to characterize the molecular signature of the disease in symptomatic and pre-symptomatic stages of the inflammatory process at the tissue and fecal level. The study is based on two different murine models for colitis; High-Resolution Magic Angle Spinning (HR-MAS) NMR on cryopreserved "intact" colon tissues and LC-MS/MS on colon tissue extracts were used to derive untargeted metabolomics[1] and proteomics information, respectively. Solution NMR was used to derive metabolomic profiles of fecal extracts. By combining metabolomic and proteomic analyses of the tissues, we found increased anaerobic glycolysis, accompanied by altered citric acid cycle and oxidative phosphorylation in inflamed colons; these changes associate with inflammation-induced hypoxia taking place in colon tissues[2]. Different colitis states are also characterized by significantly different metabolomic profiles of fecal extracts, attributable to both the dysbiosis characteristic of colitis, as well as the dysregulated tissue metabolism. Strong and distinctive tissue and fecal metabolomic signatures can be detected before onset of symptoms[2]. Therefore, untargeted metabolomics of tissues and fecal extracts provides a comprehensive picture of the changes accompanying the disease onset already at pre-clinical stages, highlighting the diagnostic potential of global metabolomics for inflammatory diseases.

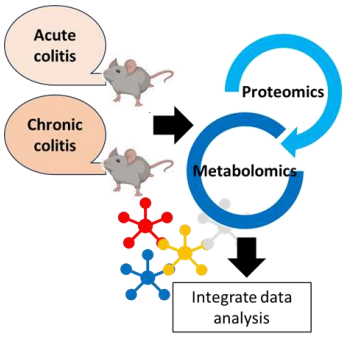

Figure 1: Experimental scheme.

Potential relationship between secondary structure and biological functionality of Micro-RNAs

A. D'Urso,[a]

[a] *Chemical Science Departmento, Catania University, Viale A. Doria 6, Catania*
adurso@unict.it

It has been recently discovered that mature miRNAs, a class of highly conserved, short (18-24 nucleotides) and non-coding RNAs [1], could form highly ordered structures similar to aptamers and their structural versatility may determine a variety of functions other than the well-known mechanism of mRNA recognition and degradation [2].Therefore, in addition to sequence even the structure adopted by miRNAs might play an important role to reach the target. However, the biological role of these conformations is still unknown. As a result, identifying the various structures of miRNAs using functional probes capable of interfering with processes governing the biological functions might lead to a better understanding of the mechanisms behind some diseases and the development of new therapies. Indeed in our previous paper we have reported that two endogenous miRNA sequences (miR-15a and miR-15b), having different biological activity (pathogenesis of chronic lymphocytic leukemia and progression of metastasis respectively),[3] can arrange in distinct secondary structures suggesting potential relationship between secondary structure and biological functionality. Then we decide to characterize another fascinating sequence, miR-337-3p, involved in tumor progression and cognitive processes. The miR-337-3p differs only for two basis located in the external portion of the seed region in human and in bat. We think that these differences induce different arrangements of the sequences, which might justify the distinct biological targets.

Finally, in order to investigate if porphyrins can be used as chiroptical probes and/or modulate the stability of miRNA secondary structures, we studied the interactions between another endogenous miRNA, miR-26b-5p, and two porphyrins, having different functional groups and their metallo derivatives.[4] To characterize porphyrin/miRNA interactions, we have used several spectroscopic techniques, namely, absorption, fluorescence, resonance light scattering (RLS), circular dichroism (CD) and CD-melting.

Combined chemical tools to tackle a challenging mitochondrial target with therapeutic relevance: synergic use of NMR, SAXS and MS unveils the structural properties of the protein OSCP

S. Fabbian,[b] G. Giachin,[a] A. Sosic,[b] M. De Zotti[a], R. Battistutta[a] and M. Bellanda[a]

simone.fabbian@unipd.it

Proteins structural characterisation at the atomic level is a key purpose for all chemists working at the interface of chemistry of biological systems and medicinal chemistry. X-ray diffraction, cryo-EM and NMR spectroscopy represent the three most powerful techniques to analyse protein structure, but each of them has specific requirements: the first one needs protein crystallisation, the second one provides high resolution structure only for very large proteins (e.g. MW > 50-60kDa) and the last one works well for small proteins in solution (e.g. MW < 40-30kDa). But what if a protein that cannot crystallise and whose molecular weight is large for NMR spectroscopy and tiny for Cryo-EM must be characterised? This is the case of the ATP synthase subunit OSCP (Oligomycin Sensitivity Conferral Protein), a protein we found to be a dimer of 40kDa in solution, highly dynamics and not suitable for crystallization. OSCP represents an emerging therapeutic target for its connection with the Permeability Transition Pore (PTP), a mitochondrial channel whose dysregulated activity is related to ageing and several human diseases such as Alzheimer's and cancer[1]. Importantly, OSCP subunit is indicated as the molecular site for the regulation of the pore[2]. Targeting OSCP to achieve drug-based control of the PTP opening represents an interesting therapeutic perspective. In this context, a strong limit is the characterization of the isolated OSCP in solution: in fact, this protein, as well as its C-terminal domain (OSCP-CT)[3], is described to be aggregated when disconnected from the rest of the ATP synthase.

Here, we present the first structural characterisation of human OSCP, by the synergic use of NMR, Small Angle X-ray Scattering (SAXS), and native mass spectrometry (MS). Unlike that reported in literature, we obtained the recombinant C-terminal domain and the full protein through pET SUMO expression strategy. We found that both protein constructs do not aggregate but are involved in an unexpected oligomerization equilibrium in which the monomeric state is poorly populated. We therefore designed and synthetized a peptide for stabilizing the monomeric OSCP-CT as well as the full protein. Our results make OSCP suitable for future drug discovery processes, in the field of PTP related diseases. We also show a strategy to characterise the structural features of a protein when it is a challenging candidate for being studied from X-ray diffraction, cryo-EM, or NMR alone.

Targeting METTL3-14 degradation via "hijacking" of the ubiquitin-proteasome system by medicinal chemistry design and synthesis of a promising library of PROTACs[1]

Recent studies of the ''epitranscriptome'' reveal important roles of different RNA modifications in cancer.[2] Methylation of adenine N6 (m6A) is the most frequent RNA modification, and it has been first associated with tumorigenesis in Acute Myeloid Leukemia (AML) and with other types of blood cancers and solid tumors. On mRNA, it is catalyzed by the core writer complex formed by two methyltransferase-like proteins, METTL3 and METTL14. Here, we disclose the first PROteolysis TArgeting Chimeras (PROTACs) for an epitranscriptomics protein harnessing the ubiquitin–proteasome system to degrade a target protein. Based on the crystal structure of the METTL3−14 complex with a potent and selective small-molecule inhibitor (UZH2), here, we report the design, synthesis, and biological evaluation of new PROTACs.[3] To modulate the physicochemical properties of resulting PROTACs, a variety of linkers and functional groups has been investigated featuring PEG- or alkyl-based linkers of different lengths and rigidity. The formation of the ternary complex was validated by a FRET-based biochemical assay and an in vitro ubiquitination assay. The PROTACs that promote a more significant degradation of METTL3-METTL14 measured by Western blot in MOLM-13 cells are characterized by a rigid "handle" and a longer linker.

In the last decade, the bioconjugation of small molecules to biocompatible carriers has emerged as an efficient approach for targeted drug delivery, controlled release, and distribution in cancer therapy. Amongst the biomolecules exploitable as carriers, bile acids (BAs) have been intensively explored, due to their peculiar physicochemical properties and biocompatibility.[1] The cellular trafficking of BAs is regulated by intracellular Lipid-Binding Proteins (iLBPs). Notably, chicken liver Bile Acid-Binding Proteins (cL-BABPs), a sub-family of iLBPs, provide a valuable model to investigate the transport of bioactive molecules within the liver, due to the higher similarity with the human counterpart.[2] A recent strategy to treat cancer has focused on the development of molecules capable of interfering with the DNA repair mechanism, mainly the MRN complex. Inhibitors of the activity of this complex, such as Mirin, have shown potential in sensitizing cancer cells to chemotherapy and radiotherapy, although their clinical utility is limited by selectivity and pharmacokinetic issues.[3] This underlines the need for efficient bioconjugation strategies to renew its therapeutic potential. In this investigation, a multidisciplinary approach has allowed us to develop and characterize, both structurally and biologically, a novel cholic acid (CA)-Mirin conjugate (CA-M11), as a potential adjuvant in liver cancer treatment. We conducted *in-silico* analysis on various BAs and identified CA as the optimal candidate for developing the bioconjugate. The results have been confirmed through X-ray crystallography. Following the analysis of CA, we performed similar *in-silico* assessments on CA-M11, specifically designed and synthesized. By examining the crystal structure of the complex, we confirmed the successful accommodation of CA-M11 in the ligand-binding pocket of cL-BABP, providing robust evidence of its transportability by the protein. Subsequently, CA-M11 was extensively studied to characterize the first ADME properties and its possible antitumor activity on Hep G2 cells, used as an *in vitro* model of liver cancer. These promising preliminary findings demonstrate the potential of our strategy to develop novel conjugates as adjuvant treatments for liver cancer. In addition, being the cytotoxic agent and an MRN inhibitor, this also represents a valid opportunity to find renewed applications for such agents in cancer therapy.

Giant dsDNA viruses are gaining interest in the field of Glycobiology because, and differently from other viruses, they can glycosylate their own proteins by a host independent process. Giant dsDNA viruses include different species, and this contribute will focus on the prototype chlorovirus, PBCV-1,[1] whose capsid protein, Vp54, is glycosylated by an unusual and complex oligosaccharide (Figure 1).[2] This glycan is N-linked and the substituted asparagine residues always occur in non-canonical protein sequences, NIPG, NTAT, NTET and NTGT. The main glycoform is a nonasaccharide with a fucose unit fully substituted at all available positions instead of being terminal as typically occurs in most N-linked glycans. The Vp54 N-glycan contains both D- and L-Rha residues, a feature that is rare and only found in bacteria. Interestingly, the comparative study of the N-glycan of PBCV-1 with those of other chloroviruses has evidenced that all share a common oligosaccharide core made of four sugar units, which comprehends the glucose unit linked to the capsid protein, its two substituents (xylose and fucose), and the galactose unit linked on the fucose (Figure 1).[3] To date, several spontaneous mutants of PBCV-1 are available and the study of their glycans has enabled the structure-to-function assignment of the mutated genes.[4] This contribute will focus on the activity of the protein encoded by PBCV-1 gene *a111/114r* involved in the biosynthesis of the conserved core region, as determined by a combination of bioinformatics and preliminary biochemical studies.

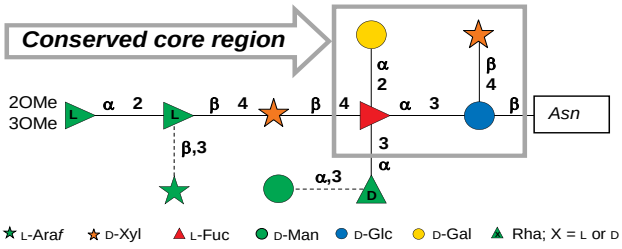

Figure 1: Structure of the Vp54 N-glycan.

The accumulation of aggregates and fibrils of tau protein is a pathological hallmark of many neurological diseases such as Alzheimer's disease. Tau filaments are subjected to a large variety of post-translational modification which reflect disease progression[1].

Ubiquitination is involved in many cellular functions and requires the action of a series of enzymes for the covalent attachment of one or multiple ubiquitin molecules to substrates to regulate the cell signaling under physiological conditions. Many evidences suggest that ubiquitination may also be a key player in the transition of tau towards toxic species[2]. Therefore, the tau-ubiquitin pathway has been proposed as a target for the development of novel treatments to alleviate tau pathology.

In this context, the elucidation of the structural determinants for specific protein-protein interactions at the basis of ubiquitin signaling is crucial. We employed site-resolved solution NMR spectroscopy to characterize the interaction of tau with the deubiquitinating enzyme Otub1, which has been proposed to be involved in the formation of pathological Tau forms[3]. Using enzymatic reaction, we produced samples of ubiquitinated tau with segmentally isotope-labeled units and exploited chemical shift perturbation to map protein-protein interfaces, gaining significant insights into the molecular recognition of tau with Otub1, a regulator of tau ubiquitination.

Termination of G protein-coupled receptor (GPCR) signaling is driven by arrestin (Arr), which acquires a binding competent, active state by interacting with the phosphorylated activated receptor through its phosphate and activation sensors[1]. Despite having a well-conserved structural fold and high sequence similarity, the four Arr subtypes display remarkable differences in their preferences towards the phosphorylation state of the receptor. Cytoplasmic unbound Arr3 is flexible and can sample pre-activated states, which are described by structural parameters at the N-C domain interface, and the inter-domain rotation angle[2]. In this work, we aim at stabilizing those pre-activated conformations by means of small molecules targeting activation hotspots at the N-/C-domain interface. Towards this end, we i) performed molecular dynamics simulations to sample pre-activated conformational states of Arr3, ii) performed virtual screening on multiple structures by targeting the selected pockets emerging from dynamics, and iii) computationally examined the impact of ligands on Arr3-ligand complexes. The successful ligands, computationally predicted to bind Arr3 and stabilize the domain rotation angle required for activation, were tested for their effect in driving recruitment of Arr3 to phosphorylation-deficient beta2-adrenergic receptor (beta$_2$AR) in N2a and H9C2 cells. One small molecule showed activity in increasing the interaction between phosphorylation-deficient beta$_2$AR and Arr3 *in vitro* studies performed by FRET and functional cAMP assay. A nanoBIT assay confirms the activity on unphosphorylated, WT beta$_2$AR, and shows that the molecule is not active on WT muscarinic M2R. This study opens new avenues for the development of small molecule tools that target GPCR signaling termination independent of receptor phosphorylation and support the discovery of therapeutics to selectively modulate phosphorylation-deficient receptors.

Exploring mesothelin-Fn3 interaction by computational modeling and epitope mapping

M. Piccardi[a,b*], A. Spinello[c*], V. Butera[c], S. Landi[b], F. Gemignani[b], G. Barone[c], S. J. Moore[a]

Mesothelin (MSLN) is 40 kDa surface glycoprotein overexpressed in many solid tumors. In addition, MSLN is known to interact with CA125/MUC16, promoting cancer progression and metastasis. For these reasons, MSLN has been studied as a target for therapeutic and diagnostic purposes. In the last decades, multiple antibody-based strategies were developed to target MSLN, but their therapeutic efficacy remains limited, potentially due to antibodies' large size (~140 kDa). To overcome this limitation, we engineered a small peptide derived from the tenth type III domain of human fibronectin (Fn3, 12.8 kDa, Figure 1A) to bind MSLN with high affinity in ovarian cancer and mesothelioma cell lines ($K_D = 12 \pm 4$ nM). The engineered Fn3 variants were observed to internalize into MSLN-expressing cancer cells and induce apoptosis[1,2]. Here, we explored the Fn3-MSLN interaction site through computational modeling and experimental validation.

Fn3-MSLN binding was predicted by a consensus strategy using three protein-protein docking algorithms (HDOCK, pydock, and ClusPro). A homology model of Fn3 and the published MSLN structure (pdb ID 8CX3) were used[3]. In addition, MD simulations were carried out using GROMACS 2021.2 software package and the Amber ff99SB-ILDN force field. To validate the models, full-length MSLN, combinations or single MSLN domains (named A, B, C, and D as in Zhan *et al.*, 2023)[3] were expressed on the yeast surface. Cells were treated with fluorescently labelled Fn3 and binding was analysed through flow cytometry (Figure 1B).

The three docking algorithms predicted a similar binding of Fn3 to MSLN: the binding site includes domain A, B, and partially C. The models showed that the Fn3 loops are interacting with MSLN and that Fn3 residues mostly contributing to the binding are in Fn3 BC and DE loops (Figure 1C). Overall, domain-level epitope mapping confirmed the docking prediction. In addition, experimental validation revealed that MSLN domain B predominantly binds to MSLN. Interestingly, the Fn3 binds a minimal domain on MSLN that interacts with CA125/MUC16, highlighting that Fn3 potentially competes with MUC16, possibly affecting MSLN-positive cancer development. Further experiments are necessary to validate the Fn3/MSLN interacting residues and to explore Fn3/MUC16 competition.

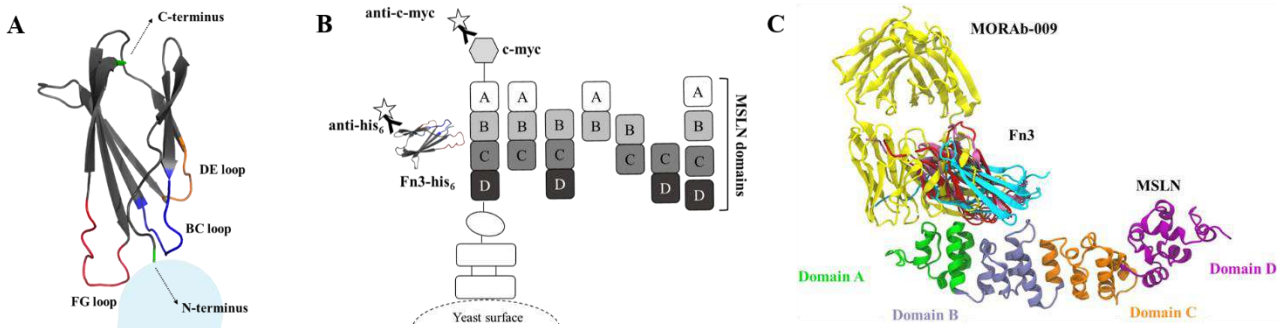

Figure 1: (A) Fn3 structure consists of a hydrophobic core (grey), C-terminus bound to a His_6-tag (green), variable regions or loops (blue, orange, red); (B) MSLN expressed on yeast surface. MSLN domains expression was evaluated through c-myc epitope labelling. Fn3-MSLN binding was analysed using an anti-His_6-tag antibody; (C) Superposition of the top ranking models (pink, red, and cyan ribbons). These models were superposed with the X-ray structure of the complex between MSLN and Fab of MORAb-009 (yellow ribbons, pdb ID 7UED)[3].

Proteins as biomolecular carriers of photosensitizing agents for application in nanomedicine

M. Di Giosia,[a] A. Marconi,[a] E.J. Mattioli,[a] F. Zerbetto,[a] M. Calvaresi[a]

[a] *NanoBio Interface Lab, Dipartimento di Chimica "Giacomo Ciamician", Alma Mater Studiorum—Università di Bologna, via Francesco Selmi 2, Bologna 40126, Italy*
matteo.digiosia2@unibo.it

Photodynamic therapy (PDT) and photothermal therapy (PTT) are innovative approaches to treating various medical conditions, such as cancer or infections. Both therapies utilize harmless VIS-NIR light to activate a photosensitizing agent (PS) and achieve therapeutic effects, but they differ in their mechanisms of action. PDT is based on the local generation of reactive oxygen species (ROS) while PTT induces localized hyperthermia.

Photosensitizers may either be a single molecule species or a nanomaterial. Due to their hydrophobicity, most photosensitizers lack solubility and biocompatibility in the physiological environment, hampering the full exploitation of their potential in nanomedicine.

To address this issue, protein-based theranostics nanoplatforms were recently proposed for transporting hydrophobic photosensitizers. Due to their biocompatibility, physiological stability, structural diversity, and abundance from natural sources, proteins meet the strict requirements for biomedical usage.1

Human serum albumin (HSA) is the natural carrier of many hydrophobic endogenous and exogenous compounds. We demonstrated the possibility of using albumins and other proteins as versatile carriers for photosensitizers, both via covalent conjugation and supramolecular interactions, for PDT (i.e., Chlorin e6, Temoporfin, fullerenes)2-5 and PTT (gold nanoparticles, carbon nanotubes) applications. We also developed alternative protein-based formulations, synthesizing protein nanoparticles. Spectroscopic and thermometric analysis showed that the photophysical properties of PSs were preserved upon protein binding. In addition, the functionality of the proteins can be improved with the bioconjugation of imaging tags and targeting agents.

The PSs-protein hybrids were tested in vitro and in vivo, evaluating their performances in cancer, antimicrobial, and regenerative medicine applications.

A paradigmatic example of multidomain protein studied by NMR spectroscopy: The nucleoprotein of SARS-CoV-2

M. Schiavina,[a] T. Bolognesi,[a] A.S. Tino,[a] I.C. Felli,[a] R. Pierattelli[a]

schiavina@cerm.unifi.it

Multi-domain proteins are composed of folded domains connected by disordered regions, each with a distinct function. The presence of these components is crucial for the protein's overall function.

This is the case of the Nucleocapsid protein of SARS-CoV-2 (N). N is a modular protein composed of 419 amino acids divided into an N-terminal RNA-binding domain (NTD), a C-terminal dimerization domain (CTD), and three intrinsically disordered regions (IDRs) (Figure 1a)[1].

Nuclear magnetic resonance (NMR) spectroscopy represents a powerful and versatile tool for studying the structural and dynamic features of multi-domain proteins, providing a wealth of information at the atomic level. Despite its versatility, NMR spectroscopy must face several challenges when applied to modular proteins. These challenges stem from the size, conformational heterogeneity, and structural complexity of these proteins. Here, I will present how N, a paradigmatic example of a multidomain protein, was characterized through NMR exploiting diverse NMR strategies[2,3]. By studying various N constructs (NTD, NTR, N), each possessing specific structural and dynamic features, we were able to shed light on the importance of the various modules of N in defining its characteristics. Moreover, the importance of IDRs in the interaction of N with different partners was elucidated by exploiting NMR in conjunction with other biophysical techniques[4,5].

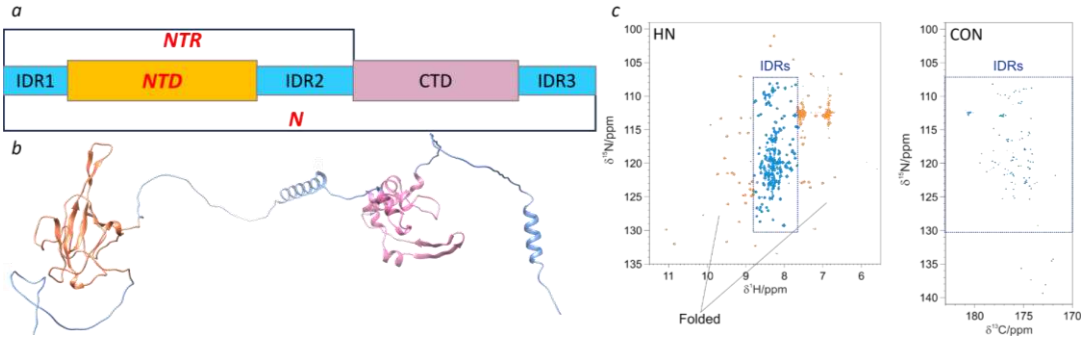

Figure 1: Panel *a* reports schematically the domains of N protein and the names of the three studied constructs in red (N, NTR, NTD). A structure of N, obtained with Alpha Fold software, is reported in *b*. Some of the spectra obtained with our proposed strategy to study multi-domain proteins are reported in *c*.

Enhancing Vaccine Efficacy through TLR4-based Adjuvant systems

Shaik, Mohammed Monsoor,[a] Romerio, Alessio,[a] Pasco, Samuel Tanner,[b] Italia, Alice,[a] Anguita, Juan,[b] Lami, Federico,[a] Fernández-Tejada, Alberto,[b] Re, Francesca,[a] Peri, Francesco[a]

mohammed.shaik@unimib.it

Our study delves into the innovative realm of vaccine enhancement by leveraging the synergistic capabilities of co-formulated Toll-like receptor 4 (TLR4) modulators. We systematically explore two pivotal approaches: firstly, the strategic combination of distinct TLR4 agonists targeting different downstream pathways; and secondly, the integration of TLR4 modulators with saponin based QS-21 variants.

In our initial investigation, we focused on the co-formulation of TLR4 modulators FP18 and FP20, which uniquely activate the MyD88 and TRAM-TRIF pathways, respectively[1,2]. A meticulous exploration of varying ratios led us to identify an optimal blend (60% FP18, 40% FP20) that remarkably amplified cytokine response in THP1 derived macrophages, surpassing the baseline set by conventional MPLA and LPS controls. This breakthrough, evidenced by SEAP assay results followed by *in vivo* experiments, underscores the potential of TLR4 modulators' combination in augmenting immune responses.

Further, we ventured into formulating FP20 in tandem with saponin variants, drawing inspiration from the FDA-approved AS-01 (MPLA and QS-21) adjuvant system[3]. Utilizing synthetic counterparts - FP20[2] for MPLA and QS-21 Echinocystic acid for QS-21[4], we crafted novel co-formulations. These were characterized via differential scanning calorimetry, dynamic light scattering, zeta potential, and TEM analyses. The *in vivo* studies revealed that these co-formulations substantially bolstered the immune response beyond the scope of individual compounds.

The synergistic effects of the adjuvant systems can offer a promising foundation for the development of advanced vaccine adjuvants, marking a significant stride in immunological research.

Revealing the regulatory mechanisms of Rac1 small GTPases through all-atom simulations

A.Parise,[a] S. Cresca,[a] , A. Magistrato[a]

[a] *Consiglio Nazionale delle ricerche (CNR)-IOM c/o International School for Advanced Studies (SISSA/ISAS), via Bonomea 265, 34136 Trieste, Italy*
aparise@sissa.it

The Rac1 (Ras-related C3 botulinum toxin substrate 1), member of the Rho-GTPase family, regulates cell adhesion, morphology, and movement, and it is over-expressed in various types of cancers. [1] An elegant and intricate system of protein-protein interaction network regulates the function of Rho-GTPases. GTPase-activating proteins (GAPs) and guanine exchange factors (GEFs) repeatedly promote the exchange between GTP and GDP thereby allowing to switch between an active to and inactive form of the Rho GTPase protein.

The crystal structures of DOCK proteins and their small-GTPase complexes provided insights into the GEF activity mechanism. However, the regulation mechanism of DOCKs by partner proteins and the signal transduction events responsible for Rho-GTPases regulation in larger macromolecular assemblies remains elusive. Due to their key regulatory role, Rho GTPases are the object of cancer associated mutations, and, following the recent approval of Sotorasib, they are emerging as amenable target for the discovery of small molecule covalent inhibitors.

In this contribution, we apply all-atom simulations to uncover the regulatory mechanisms of Rac1. Several model systems are compared, starting with the homodimeric cryo-structure (Figure 1) of ELMO1-DOCK5-Rac1 [2], the monomer and only the DOCK5-Rac1 complex bound to a GDP and in the apo form, are investigated. Additionally, a comparison between the different wild-type systems, the most frequent Rac1P29 mutations and the Rac1b splice variant was done.[3]

A drug-repurposing strategy to target DNA G-quadruplexes in breast cancer

V. Arciuolo,[a] S. Marzano,[a] F. Moraca,[a] A. M. Malfitano,[b] B. Pagano,[a] J. Amato[a]

valentina.arciuolo@unina.it

Breast cancer is the most common type of cancer diagnosed among women.[1] Notably, advanced breast cancer is characterized by an unstable genome and aberrant gene expression patterns, in which noncanonical DNA conformations play an important role by regulating gene expression and influencing disease progression.

Among the noncanonical nucleic acid structures, G-quadruplex (G4), a transient structure formed by guanine-rich DNA and RNA sequences, is gaining increasing interest due to its involvement in key biological processes, like DNA replication, gene regulation, and telomere protection.[2] In the context of breast cancer, of significant interest are the regulatory G4s that are within or near the promoter regions of some key oncogenes, including *c-MYC*, *HER2*, *NRAS*, and *YY1*.[3] These genes confer increased proliferative capacity and invasive properties in breast cancer, making them critical areas of research.[4]

In this study, a drug repurposing approach was used to rapidly identify drug-like compounds targeting G4s in some key oncogenes involved in breast cancer. Starting from a library of 3000 FDA-approved compounds, we performed a ligand-based pharmacophore virtual screening and identified 50 potential G4 ligands. From these, taking advantage of the pharmacophore hypotheses generated, 22 drugs were selected. To assess their affinity for *c-MYC*, *HER2*, *NRAS*, and *YY1* G4s, various biophysical techniques such as circular dichroism, nuclear magnetic resonance, and isothermal titration calorimetry were used. 10 of the 22 selected drugs were found to be promising G4 ligands. Therefore, they were evaluated for their ability to inhibit the proliferation of three different breast cancer cell lines. Only 3 drugs, raloxifene, belotecan and irinotecan, showed interesting antiproliferative activity. In particular, irinotecan demonstrated ability to bind and stabilize G4 structures in cells, leading to a decrease of the G1 phase of the cell cycle, preventing the M phase of mitosis and duplication, ultimately resulting in inhibition of tumour growth. Our results suggest that already existing drugs could be used as G4-targeting anticancer agents in breast cancer treatment, being able to interact with such noncanonical structures present in the promoters of overexpressed oncogenes, interfering with their functionality.

New Curcumin Mimics based on Ethyl Phosphonates: Neuroprotective or Anticancer Activity depending on Aromatic Moiety[1]

R. Pagano,[a] V. Romanucci,[a] S. Koeberle,[b] S. Di Gaetano,[c] D. Capasso,[d] M.F.M. Sciacca,[e] V. Lanza,[e] A. Zarrelli,[a] A. Koeberle,[b] D. Milardi,[e] G. Di Fabio.[a]

Curcumin, a well-known polyphenol extracted from *Curcuma longa*, is one of the most studied natural products. Its pharmacological action has been mainly attributed to its antioxidant, anticancer, and neuroprotective activities.[2] Despite such potential, curcumin suffers from low bioavailability and poor chemical stability, features that limit its pharmacological applications.[3]

To overcome these relevant limitations, here we reported the design, synthesis, and biological evaluation of new tyrosol-based Ethyl Phosphonates curcumin mimics (EP, Figure 1). The new mimics present the phenolic moieties based on tyrosol, homovanillyl and 3-hydroxytyrosol alcohols, in addition to the 5-methoxy tryptophol. The substitution of β-diketone moiety with an ethyl phosphonate, keeping a seven atoms linker, confers at all the mimics better stability in biological media.

By our investigations, the two mimics EP2 and EP4 result very interesting in different manner. EP2 represents a potential candidate for neurodegenerative disorders, displaying a strong antioxidant activity, a potent inhibitory effect on ferroptosis, and an anti-aggregating effect on Aβ amyloids. Conversely, EP4 presents a strong anticancer activity against different human cancer cell lines (HeLa, A375, WM266, MDA-MB-231) with an apoptotic mechanism of cell death and with a high selectivity for tumor cells. This potency was also confirmed by ubiquitination assays were emerged an inhibitory action comparable to that of curcumin.

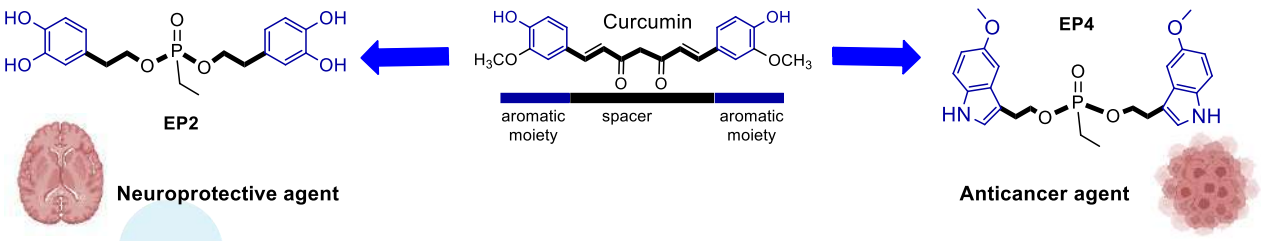

Figure 1: Ethyl Phosphonates: new curcumin mimics.

Not only vinegar: Acetic Acid Bacteria as versatile biocatalysts for selective oxidation

L. Nespoli,[a] E. Ribul Moro,[a] S. Donzella,[a] F. Molinari,[a] M.L. Contente,[a] D. Romano,[a]

[a] *Department of Food, Environmental and Nutritional Sciences, Via Celoria 2, Milan*
luca.nespoli@unimi.it

Acetic acid bacteria (**AAB**) are aerobic, Gram-negative microorganisms able to oxidise a wide variety of sugars, alcohols, and polyols with high stereo- and regio-specificity, thanks to the presence of dehydrogenases located in their membrane and periplasmic space[1]. Moreover, several strains of AABs are also able to produce bacterial cellulose (**BC**), a natural polymer with high crystallinity and purity, which of particular relevance not only for its mechanical properties but also as an innovative support for enzymatic immobilization[2].
Our research group kept an all-round view on the synthetic potentialities of AAB as biocatalysts for oxidations. *Acetobacter malorum*, isolated from the mother of vinegar, demonstrated good to excellent conversions (60-100%) in the oxidation of different aryl-aliphatic alcohols to their corresponding acids (**Figure 1**). This result was obtained either using resting cells or immobilised cells into barium alginate beads, thus allowing to maximize the productivity by using continuous-flow reactors. Among the tested compounds, regiospecific desymmetrization of 1,4-benzenedimethanol to 4-(hydroxymethyl) benzoic acid (m.c. 90%) is particularly noteworthy, since the only available procedures show low conversion (40%) and require heavy metals and harsh conditions[3].

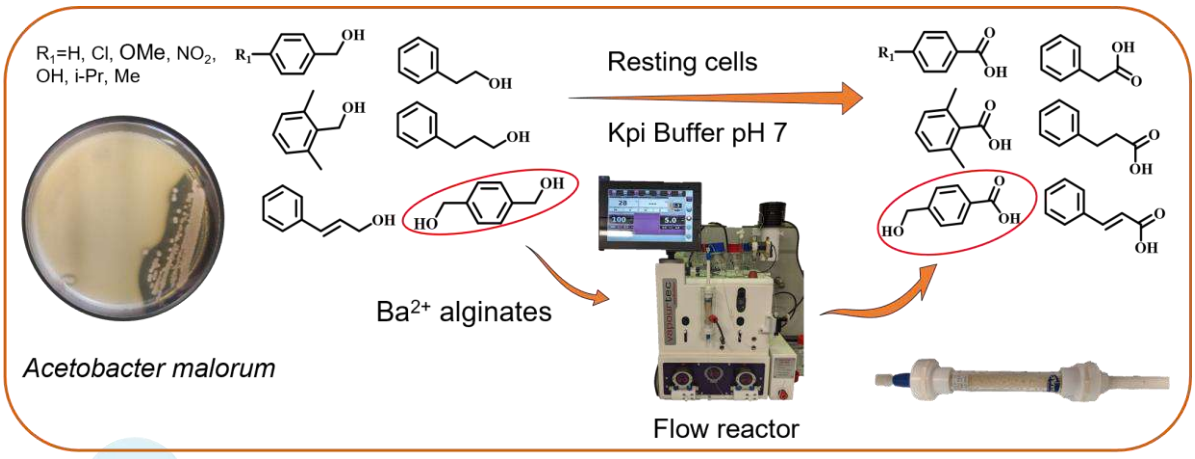

Figure 1: Oxidative versatility of *A. malorum* as biocatalysts.

maria.perina@phd.unict.it

Alterations on protein conformation and aggregation state are at the basis of the pathogenesis of different pathologies, such as neurodegenerative diseases, characterized by the formation of misfolded and/or aggregated proteins. Understanding the biomolecular mechanisms involved in this process is of paramount importance for tackling many diseases, such as Diabetes and Alzheimer's Disease.

In this presentation, I will show a novel Surface Plasmon Resonance (SPR)-based method[1] to monitor the diffusion coefficient (D) of proteins with a different oligomerization/conformation state. This is possible because D is sensitive to any differences in the hydrodynamic radius of molecules, either due to an unfolding or an aggregation process. In particular, through this method, we have been able to study the oligomerization of Insulin at different experimental conditions, such as pH or the presence of metal ions (zinc and copper)[2]. In addition we report the D value of Bovine Serum Albumin in native and denatured conditions, demonstrating the possibility to obtain conformational information from D measurements.

Furthermore, we have coupled the SPR-based investigation with a Photo-Induced Crosslinking of Unmodified Proteins (PICUP) technique, which allowed us to monitor and identify specific oligomeric species present in solution. In particular, the method was used to obtain more information about Insulin oligomerization at different experimental conditions.

The new way of applying SPR represents an innovation in the bio-sensing field which permits to expand the applicability of the technique. Moreover, the synergy between SPR and PICUP will permit us to obtain a deeper insight into the biomolecular mechanism involved in protein aggregation pathways.

giada.ciardullo@unical.it

The hydrolysis of the β-lactam core, typical of some antibiotics such as penicilins, cephalosporins and carbopenemes, is caused by the presence in bacteria of enzymes belonging to β-lactamases family[1]. Specifically, the New-Dehli metallo-β-lactamase (NDM-1) is able to hydrolyze the four-membered structure of the β-lactam ring[2] assisted by two zinc ions that share the coordination of a bridge water molecule. A recently published experimental study proposed the ebselen molecule as promising NDM-1 inhibitor.[3] Spectroscopic analyses evidenced that ebselen is covalently bound to NDM-1 by a S-Se bond with the Cys-166 residue coordinated with a zinc ion 2 at the active site. The aim of this work by using a multiscale methodology that combined dynamic simulations and computational modeling, is to examine the molecular mechanisms governing substrate(inhibitor) affinity, enzyme activity such as the final product release. At this purpose, starting from crystallographic structure (PDB=3SPU)[4] 1 μs of molecular dynamics (MD) simulation was performed on the apo-form of NDM-1 protein and 100 ns on its non-covalent complex (enzyme-ebselen). Aiming to gain insights on zinc ions of the active site when the Se-S is formed, a further MD of 1 μs was done on NDM-1 with ebselen in covalent interaction. Results evidence the role played by the amino acid residues inside the active site during the recognition, the chemical reaction and final product release.

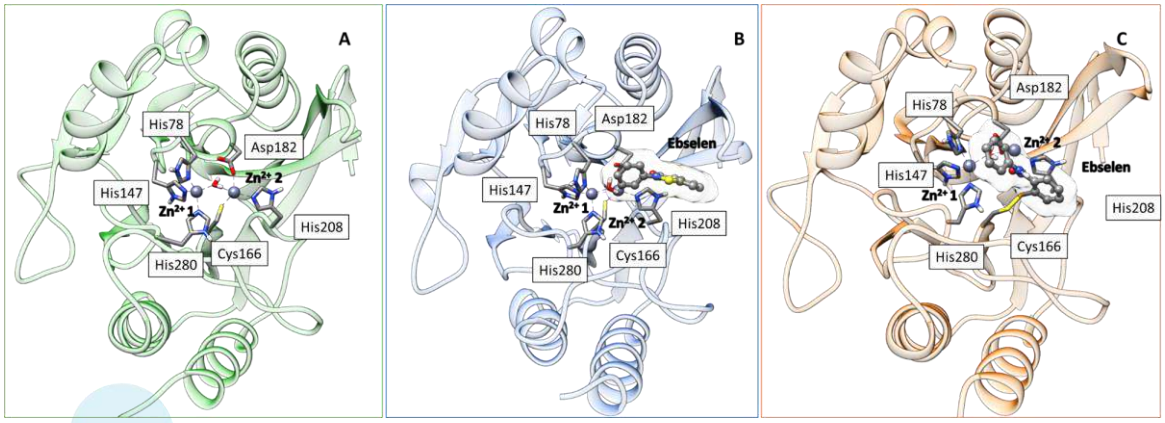

Figure 1: The NDM-1 enzyme without substrate (A), with ebselen bound non-covalently (B) and with ebselen bound covalently (C) with evidence of the coordination of the two Zn^{2+} ions.

martina.dragone@unicampania.it

Prokaryotic zinc finger Ros is a protein involved in the horizontal transfer of genes from *A. tumefaciens* to a host plant infected by it. It acts as transcriptional repressor and was identified in 1998 by Chou et al[1]. Ros belongs to a family of proteins, namely Ros/MucR, whose members have been recognized in different bacteria, mostly α-proteobacteria, symbionts, and pathogens of mammals and plants[2]. The Ros/ MucR gene is very conserved in proteobacteria and is central for host-bacterium interactions[3].

The protein contains a single Cys_2-His_2 zinc finger domain and assumes a βββαα fold stabilized by the presence of a metal cofactor and by a 15 amino acids hydrophobic core. It was intensely studied as suitable model domain to unveil the effect of the metal ion replacement in metallo-proteins and appeared to tolerate the Zn to Cd substitution but not the replacement of the wild type metal by Ni(II), Pb(II) and Hg(II)[4].

Interestingly, the sequence alignment of the prokaryotic Ros homologs, it shows that the second cysteine residue is frequently replaced by an aspartate residue, raising questions about the role of this amino acid in metal coordination. Previous research, carried out on RosC27D, a Ros mutant in which the second cysteine is replaced by an aspartate, has shown that the presence of this residue has only a slight effect on the functional structure of the protein, but it does influence its thermodynamic properties[5].

Here, we report the binding affinities of RosC27D to cadmium and cobalt and compare the geometrical characteristics, obtained by using computational methods, of both the wild type and mutated coordination sphere in the presence of different metal ions.

Amino Acid Chirality to Design Functional Superstructures

S. Marchesan[a]

[a]*University of Trieste, Via Giorgieri 1, Trieste*
smarchesan@units.it

Nature's choice for homochiral biopolymers (*i.e.*, L-peptides, D-polysaccharides) has inspired our scientific journey, as we question it through the design and characterization of heterochiral minimalistic peptides, composed of L- and D-amino acids at specific positions along the sequence. We found how and why heterochiral short peptides behave differently from the homochiral analogs at supramolecular level, by monitoring their self-assembly *in continuo* from the nanoscale to the macroscale.[1] In particular, amphipathic conformations play a key role to stabilize superstructures,[2] to enable various functions, such as catalytic activity,[3] antimicrobial activity,[4] or coordination with metals for their subsequent reduction to nanoparticles.[1] Alternatively, the conjugation of amino acids that are prone to self-assembly with those that favor disassembly, can be used to yield stereoisomers that inhibit amyloid fibrillation, and with different selectivities depending on their stereoconfiguration, for instance binding Alzheimer's Abeta[5] or insulin,[6] thus giving scope for their future use as stabilizers for protein biotherapeutics.

Figure 1: Two supramolecular structures emerging from the self-assembly of dipeptides in water.[5]

maria.dellavalle@unicampania.it

The increasing global issue of micro- and nano-plastics (MPs/NPs) arises from their wide distribution and complicated effects on living organisms.[1] Plastic particles easily fragment in smaller pieces so they can enter our body through inhalation, food, skin[2] or blood[3]. Given the limited understanding of the causes and effects, it's crucial to understand how they interact with biological systems and (bio)macromolecules within them.
Proteins associate with nano-plastics, forming a complex which shields the nanoparticle's surface and largely determines its biological identity, thereby influencing the *in vivo* response.
Here, a structural and dynamic characterization of the human Ubiquitin (Ubq), in presence of 23 nm polystyrene nano-plastics (PS-NPs), was performed by using Circular Dichroism (CD) and Transmission Electron Microscopy (TEM) integrated with high-resolution homo- and hetero-nuclear NMR (Nuclear Magnetic Resonance) methodologies. The ability of NPs to induce protein conformational rearrangement may represent one of the mechanisms through which nanoparticles exert nanotoxicity on humans. Furthermore, we examined the impact of these polymers on ubiquitin functions by studying ubiquitination both *in vitro* and *in cell*. Our findings confirm that NPs lead to a sensible reduction of ubiquitination mis-function that underlies many neurodegenerative and oncogenic diseases.[4]
In addition, according to numerous studies, the nano-plastics can also affect human health via the gastrointestinal tract, interfering the tolerance and immune response of the intestine through bioaccumulation. In this context, the influence of NPs on the intestinal microbial community was tested by analysing the survival of bacteria, their ability to form biofilms and metabolism.

Mastering proteostasis as a promising therapeutic avenue in Alzheimer's Disease

D. Milardi

Istituto di Cristallografia, Consiglio Nazionale delle Ricerche, Via P. Gaifami 9, 95125, Catania, Italy
danilo.milardi@cnr.it

Alzheimer's Disease (AD) arises from the aberrant accumulation of toxic amyloid Aβ peptides in neuronal tissues, prompting the exploration of the "Amyloid Hypothesis" targeting Aβ misfolding to thwart disease progression. Yet, the setbacks of anti-aggregating drug trials underscore the necessity for a better understanding of proteome maintenance mechanisms (proteostasis)[1]. In our interdisciplinary research, we delve into the intricate biochemical pathways governing Aβ homeostasis, employing a multi-target approach to screen diverse small molecules for their potential to restore physiological Aβ balance. Furthermore, we also explore the molecular mechanisms through which amyloid aggregates exert their toxicity, such as their ability to penetrate lipid membranes,[2] and examine how small molecules can inhibit this process.

In this contribution, our focus is on presenting a comprehensive overview of our studies, with a primary emphasis on exploring the effectiveness of small natural molecules, in halting toxic amyloid aggregation[3]. We also investigate their potential to revive natural degradation mechanisms, such as the ubiquitin proteasome system (UPS) and proteases. Furthermore, we delve into synthetic compounds, assessing their ability to modulate proteasome activity based on their structural characteristics[4]. Finally, we consider repurposing "old" drugs, formerly potent antipyretics, as potential regulators of proteasome function[5]. Our research spans from fundamental inquiries into protein/lipid membrane stability to medicinal chemistry pursuits bridging the gap between basic science and therapeutic applications, and potentially opening new avenues in AD treatment.

Screening of Inhibitors of ALR Protein–Protein Interaction Pathway using NMR spectroscopy

A. Gallo,[a], R. Muzzioli[b]

angelo.gallo@unito.it

MIA40 and ALR of the MIA pathway mediate the import of protein precursors that form disulfides into the mitochondrial intermembrane space. This import pathway is suggested to be a linear pathway in which MIA40 first binds to the precursor via a disulfide linkage and oxidizes it[1,2]. Subsequently, ALR re-oxidizes MIA40 and then ALR transfers electrons to terminal electron acceptors. With a collection of small molecule modulators (MB-5 to MB-9 and MB-13) that inhibit ALR activity, we characterized the import mechanism in mitochondria. NMR studies show that most of the compounds bind to a similar region in ALR.

Here NMR spectroscopy provided a method to investigate protein–ligand interactions in solution, mimicking, even though not fully reproducing, the physiological flexibility of a protein target present in the cell compartment. Appropriate protein preparation protocols coupled with sensitive NMR experiments and systematic data analysing schemes were applied for a drug discovery investigation that clearly showed that the integration of several techniques is needed. Characterization was carried out mainly in vitro and in silico with some information on the inhibitory activity in cellulo by Koehler and coworkers[3,4].

Mechanistic studies with small molecules demonstrate that treatment with compound MB-6 locks the precursor in a state bound to MIA40, blocking re-oxidation of MIA40 by ALR. Thus, small molecules that target a similar region in ALR alter the dynamics of the MIA import pathway differently, resulting in a set of probes that are useful for studying the catalysis of the redox-regulated import pathway in model systems.

The prototype of the neurotrophin family, Nerve Growth Factor (NGF), is essential for the development and maintenance of neurons and is crucial in immune and endocrine systems and in the pain pathway. NGF precursor, proNGF, whose pro-peptide is an intrinsically unstructured domain (IUD), is endowed with different biological properties. The binding to TrkA, $p75^{NTR}$ and sortilin receptors activates the NGF/proNGF signaling pathways. Much is known about NGF in neuronal physiology. However few reports described essential endogenous ligands as modulators of NGF biology.

Recently, the binding of ATP to NGF was identified. To determine the molecular elements of this binding, we used integrative structural biology to unveil for the first time the binding cartography of ATP to NGF [1]. Isothermal Titration Calorimetry (ITC), ^{1}H Saturation Transfer Difference NMR (^{1}H STD-NMR), 2D ^{1}H-^{15}N HSQC, coupled to the determination of the 3D solution NMR structure of NGF and MD simulations, helped identifying the likely binding mode of ATP on NGF. ATP/NGF binding to the receptors was investigated through Surface Plasmon Resonance (SPR).

We also undertook a complementary biophysical study on the binding of ATP to proNGF. Our results reveal a different binding profile for mature and precursor proteins. A combination of Small Angle X-ray Scattering (SAXS), Hydrogen-Deuterium Exchange Mass Spectrometry (HDX-MS) and limited proteolysis showed that ATP binding induces a change in the conformation and/or dynamics of proNGF, predominantly in the IUD pro-peptide [2].

Combined, these results suggest a functional role for ATP in modulating the biological role of proNGF/NGF in health and disease states.

Nucleopeptides represent a novel class of biomolecules where the peptide backbone incorporates nucleobases in the side chains (Fig. 1)[1]. The inherent versatility of nucleopeptides arises from the potential to manipulate both the peptide and nucleobase constituents, modulating favorable characteristics such as biostability, biocompatibility, multifunctionality, and the ability to spontaneously self-assemble in aqueous solutions[2]. Herein, we present an ongoing investigation into the US-assisted[3] synthesis of tailored nucleopeptides aimed at identifying novel binders for ATP and GTP (Fig. 2). While these nucleopeptides feature diverse amino acid sequences, they share distinctive functional moieties: a nucleobase-bearing amino acid (NBA) in the C-terminus (Lys) to bind Adenine or Guanine of the ATP or GTP, respectively; aromatic L-Phe and hydrophobic L-Leu, to enhance aggregation processes after target sequestration; three L-Arg residues to interact with the phosphate groups of ATP/GTP in cell and facilitate cell penetration through electrostatic interactions with negatively charged molecules on the cell surface; L-Ser as a hydrophilic spacer to balance the hydrophobic component and improve the solubility of the nucleopeptides in aqueous environments. Preliminary CD studies reveal nucleopeptide-ATP/GTP interactions by adopting distinct binding modes. NMR studies are in progress to gain further insights into their local conformational peculiarities and structural changes driving the target recognition process. Remarkably, some of these nucleopeptides, except for those bearing an acetyl group that replaced nucleobase on the side chain of Lys, also exhibited gel-forming abilities, highlighting the involvement of the nucleobase in sol-gel transition and opening new perspectives for drug delivery applications.

TLR4 is an inflammatory receptor belonging to the class of Pattern Recognition Receptor (PRRs), whose function is to sense Pathogens or Damages Associated Molecular Patterns (PAMPs, DAMPs) and start the innate immune response.[1] The natural ligand of TLR4 is Lipopolysaccharide (LPS), an essential component of Gram-negative bacteria outer membrane.[1,2] The minimal portion of LPS required for immunogenicity is a glycolipid called Lipid A.[2] Through molecular simplification starting from Lipid A, our group developed two new compounds which showed promising TLR4 antagonism: FP7 (Fig. 1, **a**) and FP12 (Fig.1, **b**) (HEK-Blue hTLR4 IC_{50} = 2.0 and 0.63 µM; RAW-Blue TLR4 IC_{50} = 7.7 and 1.7 µM).[3,4]

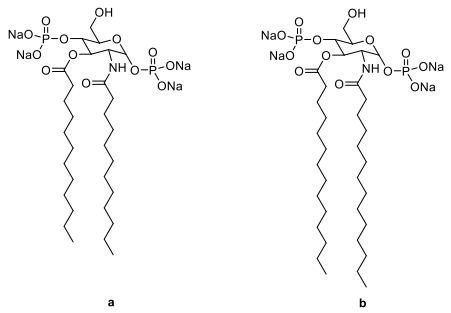

Figure 1: TLR4 antagonists developed by our group.

The aim of this work is to produce novel TLR4 antagonists. This goal will be achieved modifying the substituent on the anomeric position of FP7 and FP12 to increase stability for further functionalization of the C6 position. Furthermore, starting form promising natural compounds active as TLR4 antagonists, computer assisted docking will be applied to select new scaffolds to be synthetized and chemically modified.

Study on the impact of Toll-like Receptor 4 (TLR4) modulation in rare inflammatory-fibrotic diseases

A. Italia [a], *A.R. Franco* [a], *M. M. Shaik* [a], *A. Romerio*[a], *F. Lami* [a], *S. Lovisa* [b], *F. Peri* [a], *B.S. Costa* [a]

a.italia@campus.unimib.it

The project focuses on the modulation of fibrotic phenotype up-set in rare diseases through a Toll-like Receptor 4 (TLR4) antagonist.
In particular, in this work, we started to test the possible impact on fibrosis progression of FP7 and FP12 that showed inhibition activity against TRL4 activation by LPS in a dose-dependent way in both human and murine cells [1].
Fibrosis is an outcome of the repair response to tissue damage caused by inflammation. When the fibrotic process is excessive or dysregulated it leads to a pathological condition that can affect different organs and functions. Here, it is now clear that inflammation, which however is not the only trigger, plays a key role in the critical cellular process of fibroblast activation that leads to fibrosis up-set [2].
The recent discovery of complex crosstalk between fibrosis progression and inflammatory pathways underlines the central role of TRL4 and its potential as a new drug target[3]. Here it is proposed an in vitro screening on cellular models of fibrosis with TLR4 antagonists to identify new potential drugs targeting Idiopathic Pulmonary Fibrosis (IPF), a rare fibrotic pathology where a pivotal role of TLR4-mediated inflammation has been observed [4 5].

paola.alletto@phd.units.it

The ability of some peptide sequences to self-assemble into functional nanostructures is an appealing alternative to the industrial use of natural enzymes, such as hydrolases.[1] Common designs incorporate sequences with a β-sheet conformation, and, in this regard, L-His-D-Phe-D-Phe is the first example of an unprotected tripeptide that gels at physiological conditions and catalyses ester hydrolysis.[2] C-terminal amidation yields L-His-D-Phe-D-Phe-$CONH_2$, which displays an improved catalytic ability.[3]

Our aim is to further enhance the catalyst performance through co-assembly with other sequences bearing residues commonly found in enzyme catalytic sites, such as L-Asp-D-Phe-D-Phe-$CONH_2$. The resulting nanostructured materials are being characterized by several techniques and will be tested for catalytic hydrolysis of chromogenic substrates, also under suitable conditions to apply the Michaelis-Menten model.

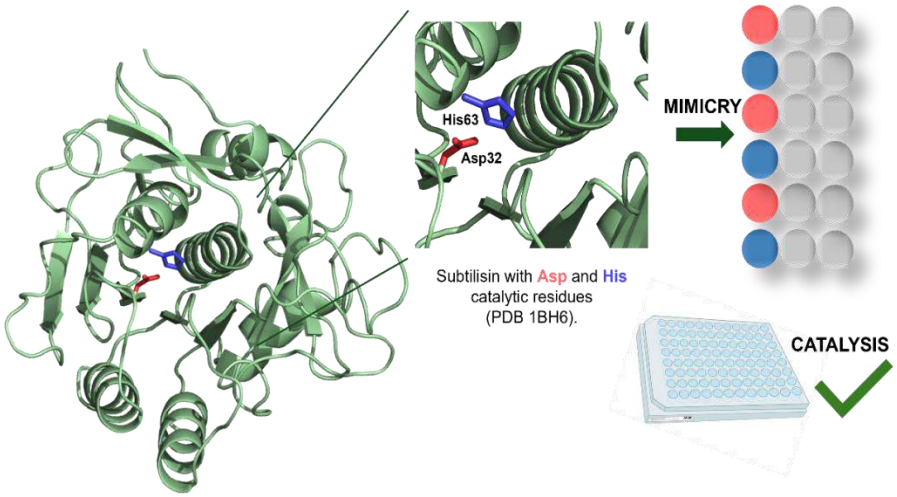

Figure 1: Hydrolase active site features Asp and His residues, which are used for the design of catalytic tripeptide co-assemblies.

anna.gambini@unimore.it

PIN1 is a ubiquitous enzyme involved in the control of myofibers metabolic behaviour the roles of which in skeletal muscle is still to be defined.[1] We investigated the metabolic consequences of *Pin1* depletion in mammalian skeletal muscles using a murine model. In particular, a metabolomic study on slow-twitch soleus (SO) and fast-twitch tibialis anterior (TA) muscles, from *Pin1* knock out (KO, N=10) and wild type (WT, N=10) mice, was carried out using high-resolution magic angle spinning nuclear magnetic resonance (HR-MAS NMR) spectroscopy, directly applied on tissue samples, without any pre-treatment.[2]

Multivariate statistical analysis highlighted metabolic differences between SO and TA muscles. The SO samples are richer in lipids, fumarate, succinate, glutamate and glutamine, instead TA samples show higher content of creatine, glucose, lactate and pyruvate. These results agree with the notion that slow-twitching SO have an oxidative metabolism, whereas fast-twitching TA are characterized by glycolytic metabolism.

We detected metabolic changes in *Pin1* depleted muscles that suggest a tendency of TA to become more oxidative, whereas those observed on SO are more nuanced.

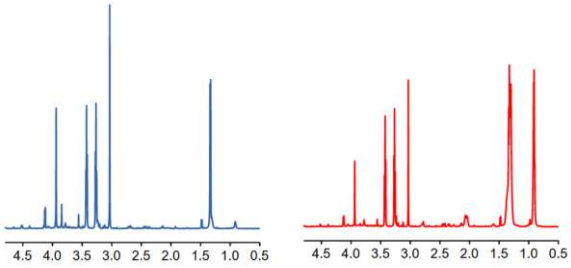

Figure 1: ^{1}H HR-MAS NMR spectra of TA (blue) and SO (red) muscles.

Proteins' misfolding and the formation of their aggregates is a common event to several human pathologies (Protein Misfolding Diseases – PMDs) and neurodegenerative disorders, as Alzheimer's Disease (AD). Recently, it has been observed that a decreased activity of Ubiquitin Proteasome System (UPS),[2] fundamental pathway of misfolded or damaged proteins, leads to an accumulation of the proteins that plays a key role in Protein Conformational Diseases (PCDs). Starting from the selected lead-metabolite Curcumin (**Cur**),[3] reported to have an unprecedented therapeutic potential in the pathophysiology of AD, but poor pharmacokinetics (PK), different approaches of drug discovery[4] have been pursuing for the development of novel molecules capable both to interfere with protein misfolding processes and to enhance the activity of UPS. To create derivatives with better drug-like properties and inspired by the presence of common structural elements among small-ligand proteasome activators, we have designed, synthesized, and characterized a mini-library of novel Curcumin mimics by varying the two aromatic moieties and modulating the length and rigidity of the newly settled diamide spacers. (**Figure 1**). These compounds will be functionally probed for their antiaggregating ability and to stimulate h20S proteasome, both crucial capabilities in restoring cellular proteostasis. Resulting structure-activity relationships will be used to implement the pharmacophore model to drive future structure optimization.

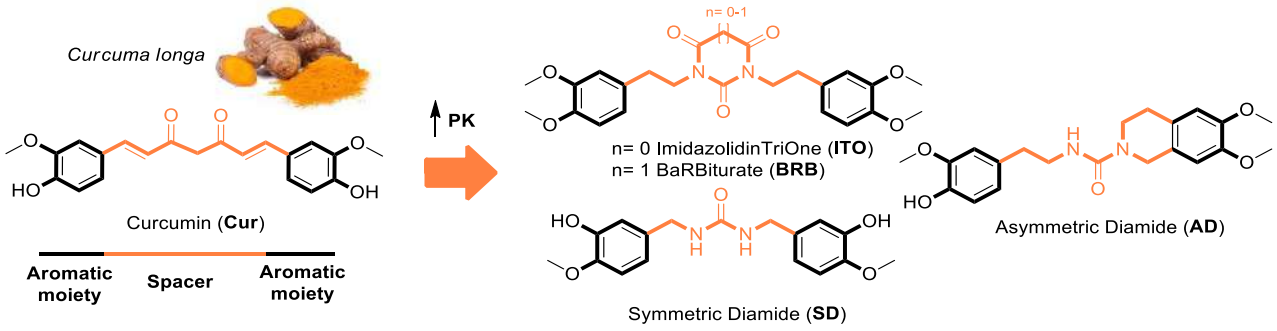

Figure 1: Curcumin and its synthetized mimics.

Development of NIRF probes for FAP imaging

R. Rizzo [a], M. Capozza [a], L. Avalle [a], V. Poli[a], E. Terreno[a]

Department of Molecular Biotechnology and Health Sciences, University of Turin, Via Nizza, 52, 10126 Torino

Fibroblast Activation Protein is a pan-cancer target[1], thus the development of diagnostic approaches by targeting FAP would be impactful. Besides diagnostic imaging techniques, optical imaging guides the clinician's decision making in real-time, thus the development of novel tumour-targeted dyes has been increasing interest. This work aims at synthesizing, and *in vitro/in vivo* testing two novel FAP-targeting probes for Near Infrared-fluorescence imaging applications based on IRDye800CW and FNIRTag fluorophores. The FAP targeting fluorescent conjugates were synthesized through amidic bond (Fig 1A). The absorption, emission and excitation spectra were recorded at different concentrations both in PBS pH=7.4 and in PBS:MeOH (1:1). Stability in human serum and photobleaching were investigated by UPLC-MS and fluorescence emission decrement measurements respectively. Albumin binding was evaluated incubating the two molecules (0.5 μM) in human serum albumin (0-30 μM) for 1h at room temperature. The uptake on FAP-expressing cells (293T-FAP$^+$) was evaluated by flow cytometry measurements. Preliminary *ex vivo* experiments were conducted to assess the FAP expression, by inoculating subcutaneously TUBO cells in female *Balb-C* mice through flow cytometry analysis and immunohistochemical evaluation. *In vivo* fluorescence imaging studies were performed on TUBO tumor-bearing athymic mice by *i.v.* administration of 5 nmol of dyes. Biodistribution studies at 24h post injection were performed to quantify the fluorescence in the main organs. Photophysical properties investigation revealed a linear relationship in the range 0-2 μM and a 3-fold higher fluorescence for FAPI-FNIRTag (fluorescence measurements and phantom imaging). FAPI-IRDye800CW and FAPI-FNIRTag showed no degradation in serum and exhibited remarkable stability to photobleaching after 2h-irradiation, higher for FAPI-FNIRTag (92% vs 68%). Albumin binding data showed a comparable affinity, as shown from the K_D values obtained from the fitting of the binding isotherm (10^{-7}). Flow cytometry analysis revealed that the conjugation of FAP-inhibitor mojety to the fluorescent dyes did not affect the FAP specificity (Fig.1B). IHC staining and FACS analysis proved that TUBO tumor-bearing mice is a suitable model for the preclinical validation of imaging probes based on FAP-inhibitors. *In vivo* imaging studies (Fig. 1C) revealed a good tumor-to-background ratio for both of the dyes but competition experiments are needed to confirm the specificity of the signal. Biodistribution studies showed a liver uptake of the dyes and a kidney clearance. IRDye800CW and FNIRTag dyes are used for the first time to develop FAP-targeting NIRF probes with FAPI-46 FAP inhibitor.

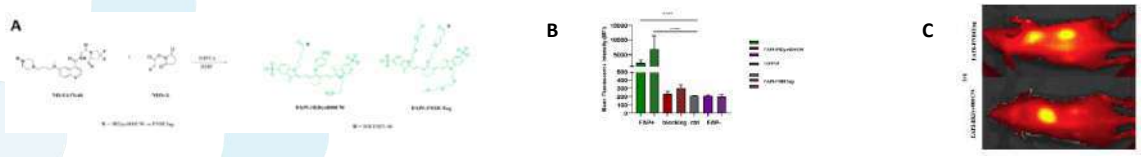

Figure 1 (A) Synthetic procedure. (B) Uptake on FAP-expressing cells. (C) *In vivo* imaging 24h p.i.

It is well established that antibiotic resistant bacteria have the genetics to specifically target and disarm an antibiotic's mode of action. The more obscure phenotypic resistance, i.e. *temporarily* antibiotic tolerant, has yet remained relatively unexplored. These elusive sub-populations called persisters, are in a transient pseudo-reduced metabolic state, sometimes occurring without environmental pressure. They can be multidrug tolerant and often contribute to chronic and recurring infections. Furthermore, persisters have been credited as an evolutionary stepping stone to antibiotic resistance.[1]

The downregulation of metabolism displayed by persisters is interconnected with activation of the stringent response and thus is believed to also be initiated by the accumulation of the intracellular signalling alarmone, guanosine penta- or tetra-phosphate, (p)ppGpp.[2] The intracellular concentration of (p)ppGpp is controlled by the superfamily of RSH (RelA/ SpoT Homologue) proteins (Fig.1), making them potential targets for drug development to reduce chronic infections and help restrict antibiotic resistance.

The main objective of this study is to design small molecules to selectively inhibit the synthetase domain of Rel proteins, from which we have chosen Rel$_{Seq}$ (*S. equisimilis)* as our model protein. Among the chemotypes identified through in silico screening,[3,4] we present the growth of the amino benzoic acid fragment into the first family of synthetase selective Rel inhibitors.[5]

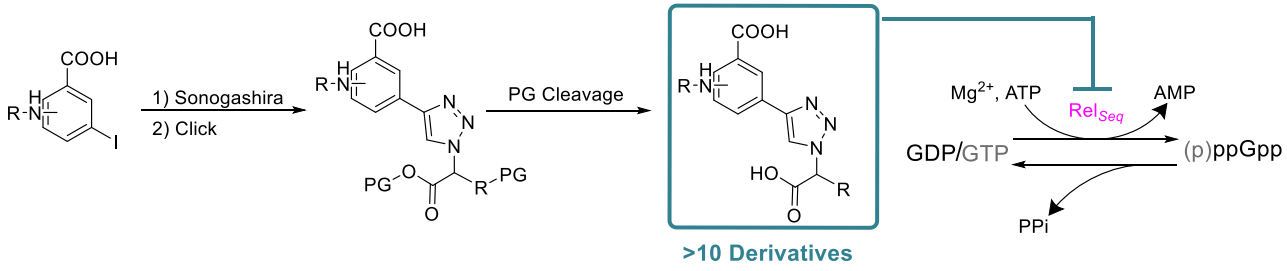

Figure 1: The general synthetic scheme of inhibitors designed around amino benzoic acid to inhibit the forward enzymatic reaction catalysed by the synthetase domain of RSH protein Rel$_{Seq}$. PG: protecting group.

Metabolic profiling of solid matrices under HR-MAS NMR and ASAP HR-MS conditions

L. Molteni, A. Palmioli, C. Ciaramelli, M. Brioschi, L. Moretti, C. Airoldi

University of Milano-Bicocca, Department of Biotechnology and Biosciences, P.zza della Scienza 2, 20126 Milano
linda.molteni@unimib.it

The NMR- and LC-MS-based metabolic profiling of complex matrices, such as whole cells, biopsies, or food flours, are usually carried out in the liquid state, after metabolite extraction.

Such approaches involve time-consuming sample manipulation that also prevents both relative and absolute quantification of matrix components since extraction efficiencies for the different metabolites strictly depend on the experimental conditions.

NMR analysis under High-Resolution Magic Angle Spinning (HR-MAS) conditions and High-Resolution Mass Spectrometry (HR-MS) with the Atmospheric Solids Analysis Probe (ASAP) allow the analysis of semi-solid and solid samples, respectively, the latter through desorption of compounds by heated nitrogen gas flow and ionization by corona discharge[1].

Here we report the application of both techniques to the analysis of the metabolites contained in five different food flour samples (rice, quinoa, chickpeas, faba beans, and lentils). We compared the data collected by extraction and analysis in the liquid state with the data provided under HR-MAS NMR and ASAP HR-MS conditions from both a qualitative and quantitative point of view.

Once validated, this approach will be very useful for rapid anti-fraud checks of foodstuffs but will also increase the versatility and speed of NMR and MS techniques in resolving complex mixtures of organic compounds in a wide range of applications, minimizing solvent usage and environmental impact.

CHEAP BUT RICH: Yeasts containing carotenoids and lipids as sustainable feed additives

S. Donzella,[a] F. Molinari,[a] C. Compagno,[a] D. Romano[a]

[a]*Department of Food, Environmental and Nutritional Sciences (DeFENS), University of Milan, Via L. Mangiagalli 25, Milan, 20133, Italy*
silvia.donzella@unimi.it

The global market of carotenoids, commonly included in animal feed as colorants and sources of antioxidants and vitamin A, is growing significantly together with the attention in their sustainable and green synthesis. The biotechnological production of carotenoids by yeasts emerges as a valuable strategy, also fitting the circular economy pillars when low-cost feedstocks are used as main components of culture media [1]. In the context of OnFOODS-PNRR, bioprocesses employing red yeasts were set up starting from agro-industrial residues such as potato waste, threshers, and soy okara. The enzymatic pre-treatment of waste residues was optimized to obtain a balanced and effective fermentation medium in terms of carbo and nitrogen sources. The HPLC screening of red yeast collections (including *Rhodosporidium* or *Rhodotorula* genera) revealed strains naturally rich in β-carotene but also in torulene and torularhodin, uncommon but potent carotenoids not yet commercially available [2]. The carotenoid production process on waste-derived medium was optimized in 2L bioreactor and stress conditions were applied to boost the production of carotenoid-rich biomass, reaching more then 100 mg/L of total carotenoids in 90h process, corresponding to 20 mg/g_{dw}. In addition, some of these strains are also oleaginous, meaning that they are able to accumulate intracellular triglycerides into vesicles called lipid bodies [3]. Notably, carotenoids produced by oleaginous yeasts are stored within these lipid bodies, enhancing their stability against oxygen and light exposure and preserving their nutritional and biological properties. Therefore, this product can be introduced in animal nutrition as lyophilised whole cells, thus serving as a multifunctional feed additive source of several valuable nutrients as carotenoids, lipids, and proteins.

Computational Study of a Metamorphic Protein

Massimiliano Meli,[a] Alessandro Pandini[b]

[a]*Istituto di Scienze e Tecnologie Chimiche 'Giulio Natta' (SCITEC-CNR), Via Mario Bianco n°9 20131, Milan*
[b]*Departement of Computer Science, Brunel University, UB8 3PH, London*
massimiliano.meli@cnr.it

Metamorphic proteins, also known as fold-switchers, are capable of interconverting their structure between two or more stable native states to perform different functions in response to changes in the environment. The origin and purpose of fold-switchers in protein evolution have been the subject of an exciting literature debate[1,2,3]. The selective access of different folds and functions suggests potential applications in drug discovery and molecular target treatment. A small molecule that interferes with the fold switch could directly control the biological process, offering a new avenue for function modulators. Known fold-switchers are present in both eukaryotic and prokaryotic cells and are involved in essential biological processes such as chemotaxis, cell cycle regulation, ion transport, and regulation of transcription and translation[4,5,6]. A metamorphic protein has also been discovered in the SARS-Cov-2 genome. The study examines the viral protein ORF9b13 and its interaction with the human mitochondrial protein Tom70. When co-expressed, ORF9b13 adopts an all-alpha conformation, whereas in isolation, it dimerizes as a beta-sheet protein[7]. The study of ORF9b revealed that two residues (S50 and S53) are the driving force for the conformational switch from alpha helix monomer to beta-sheet dimer[7].

Here we show a computational study of the metamorphic Collagen Binding Domain (CBD) from bacterial Collagenase. This enzyme degrades collagen tissue in cases of gangrene. The metamorphic properties of CBD are induced by changes in calcium concentration, as demonstrated by X-Ray, NMR, and SAXS. We simulated both metamorphic states of the CBD and identified atomistic details of the pseudo-transitions in metamorphic regions of the domain.

Unraveling the molecular basis for G-quadruplex-binders targeting ALS/FTD-associated G4C2 repeats of the *C9orf72* gene

A. Spinello[a]

[a] Department of Biological, Chemical and Pharmaceutical Sciences, University of Palermo, Palermo, Italy
angelo.spinello@unipa.it

The present work is part of the "HEAL ITALIA" project in the general context of the Italian National Recovery and Resilience Plan. The main goal of this extended partnership is the development of novel, inexpensive, and noninvasive diagnostic routes for more efficient prediction, detection, and monitoring of complex diseases. In this context, many research projects are currently being performed, and one of those will be the subject of the present communication.

Intronic G4C2 expanded hexanucleotide repeats in the *C9orf72* gene were identified as the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD), two devastating neurodegenerative disorders. It was shown that these repeating sequences can fold into distinct G-quadruplex (G4) structures, which were recently solved using NMR techniques.[1] Small molecules, able to selectively target RNA G4C2 G4-forming repeats, showing promising therapeutical activities, were reported.[2] Unfortunately, to date, insights into the mechanism of action at the atomistic level for these compounds are still missing. For these reasons, considering the absence of any structural data, we have applied distinct computational tools to unravel the structural basis for the selectivity of these small molecules. Finally, we have tested the activity of the recently reported Au(I)/N-heterocyclic carbene G4-binder, $AuTMX_2$,[3] and we have rationally designed novel Cu(II) metal complexes able to strongly and selectively bind G4C2 repeats forming RNA G4 motifs. Thus, our findings could help to shed light on this novel potential therapeutic strategy to tackle neurodegenerative disorders.

Breast cancer is one of the most commonly diagnosed cancers in females globally [1]. Type 1 interferons (IFNα and β) are known to have a considerable inhibitory impact on cancer cells' survival and growth. IFN1 induction stimulates cell intrinsic apoptotic pathways while simultaneously priming the immune cells to exert their cytotoxic effects on cells producing the IFN1 by activating the immune cells including the natural killer (NK) cells [2,3]. Further, IFN1 induction also suppresses oxidative stress and inhibits the release of tumor-promoting pro-inflammatory cytokines [4]. Also, the presence of a repressed IFN/STAT1 signature is correlated with the progression of breast cancer characterised by an increased epithelial to mesenchymal (E-M)/cancer stem cells (CSC) plasticity [5]. Tilorone dihydrochloride (Tilorone) is an orally active interferon-inducing agent that is used as an over-the-counter broad-spectrum antiviral agent [6]. Apart from its antiviral effects, tilorone has been shown to have anticancer effects that are mediated by multiple mechanisms including DNA intercalation and promotion of anticancer immunity mediated by interferon induction and activation of NK cells and cytotoxic lymphocytes [7]. On account of its interferon-inducing effects, we hypothesized that tilorone can have tumor suppressing effects on breast cancer by virtue of its opposing effects on tumor promoting pro inflammatory cytokines and oxidative stress. Therefore in the current studies, the relationship between oxidative stress, pro-inflammatory cytokines and tumor growth in response to treatment with tilorone in cell and animal model of breast cancer will be presented.

Emerging evidence suggests transition metal ions accelerate pathological protein aggregation. Imbalances in metal levels, notably copper, impact brain, tissue function and can worsen amyloidosis, leading to toxic protein build-up, oxidative stress, and inflammation. [1,2]

Tolcapone (3,4-dihydroxy-4′-methyl-5-nitrobenzophenone, Tol), an inhibitor of COMT, stands out as one of the most commonly prescribed FDA-approved medications for Parkinson's disease (PD) demonstrating remarkable potency as an adjunct to levodopa and carbidopa for the treatment of PD patients with motor fluctuations.[3] Additionally, Tol inhibits amyloidogenic protein aggregation, including Aβ and Syn, protecting against the cytotoxicity caused by their oligomers and aggregates.[4]

Despite the widespread use of Tol in PD treatment, its interaction with Cu^{2+} and Zn^{2+} has not been explored. To address this gap, we investigated the Cu^{2+} and Zn^{2+} complexes of Tol using various analytical techniques. Furthermore, we evaluated the ability of Tol to scavenge free radicals in the presence of metal ions and to affect the metal-induced aggregation of amyloidogenic proteins.

Our findings underscore the ability of Tolcapone to interact with metal ions and affect metal ion-triggered processes. This phenomenon offers potential to restore metal balance in amyloid diseases.

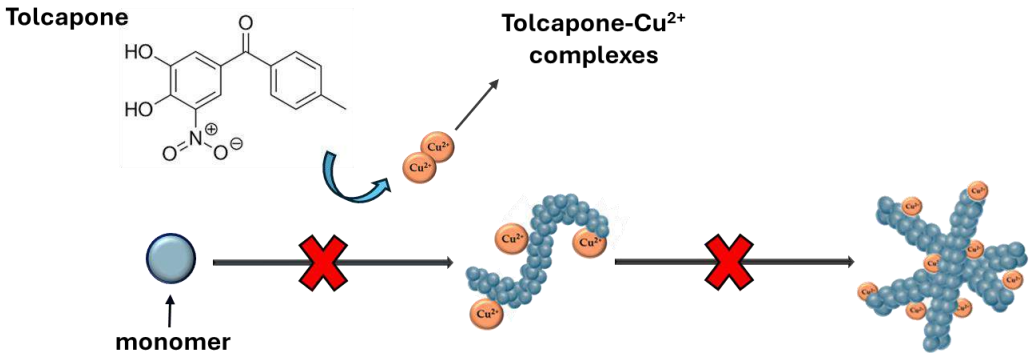

Figure 1: Schematic representation of the protein aggregation pathway promoted by Cu^{2+}.

Funicones and structurally related compounds represent a homogeneous group of fungal polyketides that were initially characterized as determinants of the antagonistic abilities by the producers against other microorganisms but were later found to possess remarkable biological properties that have promoted their consideration as drug prospects[1]. Furthermore, their low toxicity, high bioavailability, low molecular weight, and chemical structures make them compatible for designing various pharmaceutical formulations. Within our recent activity aimed at studying the antiviral properties of 3-O-methylfunicone (OMF), a member of this group of secondary metabolites obtained from Talaromyces pinophilus, were studied. The results showed that OMF is able to reduce the infectivity of bovine herpesvirus and canine coronavirus. (CCoV), in addition two additional funicon-like compounds, penimplicixin and vermistatin, were also tested in CCoV[2]. Cyclodextrins (CDs) are used in pharmaceutical formulations for their ability to improve the pharmacokinetic characteristics of the species included[3]. In particular, OMF has a low solubility, therefore the formation of inclusion complexes between CDs and OMF can improve this aspect, also increasing its bioavailability, allowing for better administration in animal organisms. In view of their potential application as novel drugs against coronaviruses (CoV), inclusion complexes involving the use of β-cyclodextrin (β-CD) as a complexing agent have been designed. The affinity that funicons have towards β-CD was evaluated by Molecular Docking. UV-Vis analysis of the complex was used to determine the stoichiometry of the complex and binding affinity. Finally, following CoVs (Bovine, Canine, and Feline CoVs) infection *in vitro*, cytotoxicity analysis and antiviral activity of inclusion complexes will be performed.

Magnetic Resonance Spectroscopy (MRS) is a very powerful and non-invasive technique for the study of biological systems *in vitro.* MRS may provide information on cultured tumour cell metabolism, aiming to an increased knowledge of cell response to anti-cancer therapies.[1] In particular, once identified the most relevant metabolic signals (spectroscopic markers), their variations can give insight on the response of tumour cells to different treatments, including drug delivery systems based on gold nanorods (AuNRs).[2] AuNRs are arousing great interest in the biomedical field, thanks to their peculiar physicochemical properties, and the possibility of differentiated surface functionalization, allowing the transport of drugs.[3,4] This study focused on the synthesis and characterization of AuNRs stabilized with cetyltrimethylammonium bromide (AuNRs-CTAB) and their effects on the metabolism of a glioblastoma cell line (namely, T98G). ^{1}H MRS characterization of the metabolic profile of T98G cells was performed to identify the main observable metabolic pathways. Then, ^{1}H MR cell spectra were acquired at different times after T98G incubation with AuNRs-CTAB at different concentrations. Both one-dimensional (1D) and two-dimensional COrrelation SpectroscopY (2D COSY) spectra were acquired.

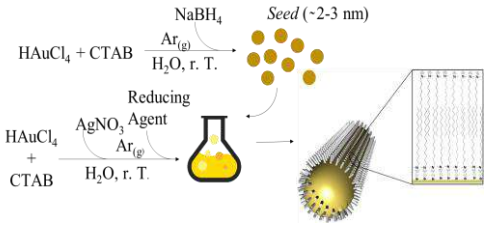

Figure 1. Schematic steps of AuNRs-CTAB synthesis.

The following abstract is based on a recently published paper:
S.N. Agrò, et al. "Molecular Dynamics Simulations Elucidate the Molecular Basis of Pre-mRNA Translocation by the Prp2 Spliceosomal Helicase." J. Chem. Inf. Model. (2023) 63(13), 4180-4189.

The spliceosome is a dynamic molecular machinery essential for precursor-messenger RNA (pre-mRNA) splicing, orchestrated by specific RNA-dependent ATPases/helicases. In the study cited above, we delve into the functional dynamics of Prp2, a member of the DExH-box ATPase/helicase family, which harnesses the energy of ATP hydrolysis to translocate a single pre-mRNA strand in the 5′ to 3′ direction, thus promoting spliceosome remodeling to its catalytic-competent state[1].

Through extensive molecular dynamics simulations, we uncovered the functional coupling between ATPase and helicase activities of Prp2. Our findings reveal a typewriter-like rotation of the Prp2 C-terminal domain, driven by pre-mRNA selection, ATP binding, hydrolysis, and dissociation. This rotational movement is facilitated by the swing of interactions between Prp2 residues and nucleobases at the 5′- and 3′-ends of pre-mRNA, ultimately driving the translocation of pre-mRNA. Moreover, our results suggest a conserved translocation mechanism across the DExH-box helicase family, with implications for understanding splicing regulation in diverse cellular contexts.

Dysregulation of DExH-box ATPase helicases can often be associated with tumorigenesis and genetic diseases, as they are involved in vital biological functions[2]. The molecular mechanism of Prp2 described in this study provides a basis for the therapeutic development of RNA helicase inhibitors for the treatment of several human diseases.

The assessment of enzyme activity is a critical factor in the early diagnosis of many diseases. In this study, we propose the use of the Ultra-Low field Overhauser MRI (OMRI) as an alternative diagnostic approach for the detection of enzymatic activity.[1] OMRI is a double resonance imaging technique that combines the advantages of MRI with the use of stable radicals as polarizing agents to enhance the NMR proton signal.[2] For this purpose, a "off/on" radical probe in micellar form was investigated to target esterase enzymes over-expressed in pathological tissues. We synthesized an Oxo-TEMPO radical derivative containing an ester group and an aliphatic chain, namely Tempo-2-C_{12} ($T2C_{12}$).[3] A new formulation with Tween 80 (T80) (20 mol %) was also investigated and in aqueous solution the two compounds self-aggregate to form EPR-silent micelles ($T2C_{12}$-T80) with an enhanced stability and reduced size. But in presence of esterases, the radical becomes free in solution showing an intense EPR signal, that is correlated to the enzyme activity. Thank to this change in the EPR signal, allows the probe to act as a reporter of enzymatic activity with OMRI. The enzymatic activity was well detected with ultra-low field OMRI system at 206 μT using this OFF/ON system displaying any signal when the probe is in micellar form. On the other hand, after the hydrolysis an increase of the Overhauser enhancement is observed, giving bright images. Furthermore, preliminary tests were performed by incubating the $T2C_{12}$-T80 probe with human pancreatic cancer (HS776t), human hepatocarcinoma (HepG2) and fibroblast (3T3) cytosolic cells extracts to evaluate the expression of esterases. The results confirmed a higher expression of esterases in tumour cells compared to healthy fibroblast 3T3. In summary, $T2C_{12}$-T80 probes provide an excellent technique for detecting enzymatic activity in diseases characterized by esterase overexpression. For the first time, an in vitro esterase kinetic were monitored with an OMRI system that operates almost at earth field, revealing an enormous off-on change of the signal caused solely by probe hydrolysis. The results proved the technique's great potential and its possible translation to in vivo OMRI.

Detergent Screening for Membrane Protein Purification

M. De Conto,[a] R. De Zorzi,[a]

[A]*University of trieste, Via A. Valerio, 1, Trieste*
marco.deconto@phd.units.it

Gram-negative bacteria build a cell wall that functions as a protective envelope around their cell membrane. Lipopolysaccharide (LPS) units are among the primary components of this wall. A collection of membrane proteins, very unique to each bacterial strain, controls the synthesis of the LPS[1]. This project aims at characterizing two of these proteins, WZX and WZY, to understand their structure and function. In the long term, the goal of this research is to hamper the construction of the protective wall of Gram-negative bacteria, thus weakening their defenses.

We developed a good purification protocol that allows the isolation of significant amounts of WZX in detergent solution, a crucial step in the characterization of the protein through structural techniques. However, initial results from light scattering and circular dichroism indicate a short-term protein stability in detergent micelles.

In membrane protein (MP) structural studies, the identification of a detergent able to preserve the native conformation of the target is often a challenging process[2]. For this reason, we started working on the development of an in-silico approach to detergent screening. A library of detergent models has to be established by building micelles of various surfactants. These systems will be examined along time utilizing molecular dynamics. However, as traditional approaches to molecular dynamics of single proteins are not suitable for large micelles held together by hydrophobic interactions, a new protocol for relaxing the system has already been evaluated and optimized to improve the stability of the models.

The behavior of the in silico system is compared with experimental data to validate the protocol. Testing with different detergents highlights the best detergent, or detergent mixture, to stabilize the native structure of WZX and WZY.

Furthermore, mutations can enhance membrane protein stability outside of the cell membrane. We apply computational techniques to identify single-point mutations able to stabilize the protein folding. The best mutants of WZX and WZY will be expressed as recombinant proteins.

marco.leusciatti@unipd.it

In 2020, we took a leap back in time, from the era of modern medicine to the great flu of 1918. The recent pandemic caught us off guard, with the same defence tools as the last century. As one group, several researchers from all over the world have turned their attention to the discovery of new antivirals. The research line based on the chemistry of nitrosocarbonyls generated from nitriloxides has been active in Pavia since 1997. Through the use of computational methods we wanted to investigate which molecules potentially active as antivirals could be accessed via these two synthetic routes.[1,2] Two different enzymatic targets have been studied: RNA polymerase and protease. Docking experiments of nucleotide derivatives were conducted on the first target, characterized by different modifications of the scaffold and the heterobase, obtained through the 1,3-dipolar cycloaddition of different nitriloxides to N-benzoyl-2,3-oxazanorborn-5-ene, in the crystal structures of SARS-CoV-2 RdRp in the pre- and post-catalytic state. The docking poses were classified and compared, the best ones were subjected to molecular dynamics simulations and the trajectories analyzed focusing on the requirements necessary for catalysis. With these tools, structural modifications have been proposed to improve the affinity of compounds to the catalytic pocket.[3] As regards the second target, M^{Pro}, following the analyzes performed on the most representative structures identified through molecular dynamics of the dimer, two allosteric sites with good druggability characteristics were identified. By characterizing the allosteric pockets thus identified with a clustering approach, a docking screening of a database containing compounds obtainable via the chemical pathways studied in this research unit was performed on the representative structures. Then, MDs simulations of the complexes gave us clues regarding allosteric effects of the designed nitrosocarbonyl derived compounds. This allowed the selection of candidate molecules to synthesize. Antiviral activity tests are ongoing to evaluate the agreement between computational predictions and the biological systems studied. Initial biological testing has shown that, at present, one compound stands out in terms of activity compared to others, with the ability to reach an IC_{50} of 22 µM.

edoardojun.mattioli2@unibo.it

Photochemotherapy (PCT) is an emerging cancer treatment that combines phototherapy and chemotherapy.[1] This kind of combination therapy can provide a more potent treatment than using either treatment alone, leading to additive and synergistic antitumor effects. Since PCT is based on the administration of two different compounds, a photosensitizer (PS) and a chemotherapeutic drug, many problems can arise due to the different pharmacokinetic and/or pharmacodynamic profiles of the two molecules.[1]

Here we propose two innovative approaches to develop novel solutions for PCT:

i) Use of proteins or protein nanoparticles to simultaneously transport both the photosensitizer and the chemotherapeutic drug. We have previously showed the ability of human serum albumin (HSA) to disperse temoporfin (mTHPC), an approved photosensitizer. This protein-based formulation improves the phototoxicity of mTHPC, when compared to its clinical formulation.[2] Through a virtual screening approach we now identified chemotherapeutic drugs capable of binding to HSA in a different pocket than the PS, creating an efficient protein-based delivery systems loaded with both the chemotherapeutic agent and the PS.

ii) Exploitation of the intrinsic photosensitizing properties of some chemotherapeutic drugs, like doxorubicin,[3] to enhance their anticancer activity upon light irradiation. We built a structural database of approved anticancer drugs, and we calculated all the photophysical properties of these molecules. We identified 17 promising molecules (i.e. mitoxantrone, pixantrone, daunorubicin, dactinomycin, sunitinib) with the photochemical characteristics to be also a PS. In principle, these chemotherapeutic drugs *per se* can be also used as a PS in phototherapy.

For both the approaches we selected the most promising candidates for *in vitro* testing. We observed excellent results, validating the new developed PCT protocols, through the i) simultaneous transport of the PS and the chemotherapeutic drug with a protein-based formulation and ii) light-enhanced cytotoxicity by photoactivation of selected approved drugs.

E-mail: tessa.bolognesi@unifi.it

The Nucleocapsid protein (N) of SARS-CoV-2 is a complex protein with 419 amino acids, including an N-terminal RNA binding domain (NTD), a C-terminal dimerization domain (CTD), and three intrinsically disordered regions (IDRs)[1]. N is highly expressed, and during viral infection plays a crucial role in organizing the RiboNucleoProtein complex, essential for viral replication. Our central aim is to characterize the Full-Length (FL) N protein and study its interaction with RNA. We want to understand how this interaction evolves with increasing system complexity, from NTD (44-180) to FL (1-419), including a construct comprising the NTD and the two flanking IDRs (NTR 1-248). Studies on NTR have highlighted that the NTD's affinity for nucleic acids is augmented by the presence of the two positively charged disordered regions[2]. The FL protein, which forms a dimer through its CTD domain, is expected to further increase N's affinity for RNA due to synergistic effect. Therefore, we have chosen to enlarge our focus moving our attention from the smaller NTR construct to the more complex and interesting FL protein. Here I will present the latest results on FL protein, starting from its challenging expression and purification. Its structural and dynamic features are obtained through Nuclear Magnetic Resonance (NMR) and compared with those of smaller constructs.

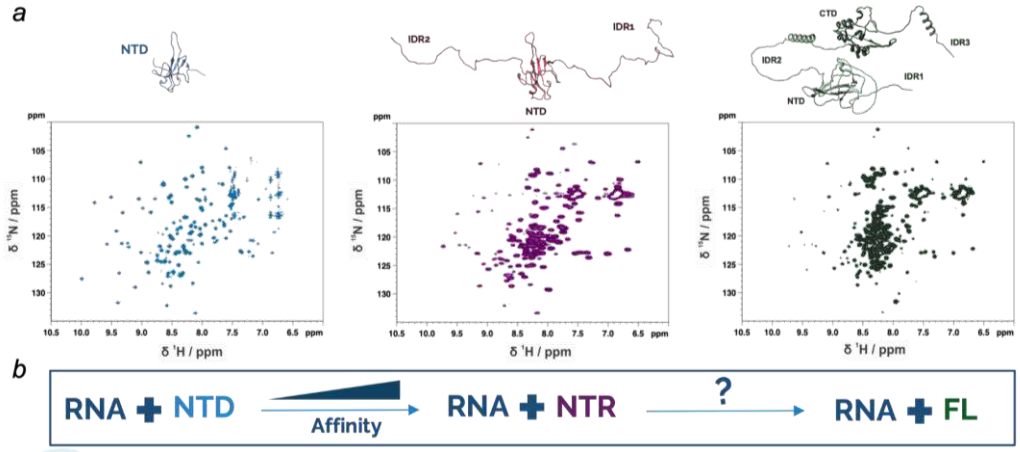

Figure 1: Panel *a* reports a possible conformation for each of the three *in-studio* constructs (NTD blue, NTR purple, FL green) with their corresponding HN-HSQC spectra; Panel *b* shows schematically the increased affinity for RNA moving from NTD to NTR and our upcoming subject of study.

beatrice.debonis@student.unisi.it

Natural photosynthesis inspired the development of artificial devices aiming to convert solar energy into chemical energy. In this scenario, artificial photosynthesis (AP) might lead to more sustainable ways for energy production based on light-driven water splitting, with not-polluting gases as side-products (e.g., O_2 and H_2).[1] The present work aims to develop and optimise novel biological catalysts for their application in AP. Human carbonic anhydrase II (hCAII) is a ubiquitous enzyme catalysing the reversible hydration/dehydration of carbon dioxide/bicarbonate.[2] The Zn^{2+} metal ion is an essential cofactor for hCAII, being located in the protein active site where it tetrahedrally coordinated by three histidine residues. As reported in previous works, the replacement of zinc with different metal ions (e.g., Co^{2+}, Ni^{2+}, Cu^{2+}, Mn^{2+}) can modify the catalytic activity of hCAII, opening new interesting perspectives for biotechnological application.[3]

To this end, we focused on the development of metal-substituted hCAII to explore their role in modulating the catalytic activity of the enzyme. In particular, we focused on Ir^{3+}-substituted hCAII, because it was formerly reported to acquire peculiar water-splitting properties.[4] In this work, hCAII was expressed as recombinant enzyme in *E. Coli,* and the active protein was attained from multiple chromatographic stages (direct and reverse affinity, and size exclusion). Following the removal of zinc via chelation, the apo-protein was used to obtain various metal substitutions. The metal-substituted enzymes were then characterized through Isothermal Titration Calorimetry and X-ray crystallographic analysis. Furthermore, we also characterized the water-splitting capabilities of metal-substituted hCAIIs for AP applications. The structures of the metal-adducts revealed the pivotal contribution in metal binding of different His-residues. Their role in metal binding and catalysis has been recently investigated by the generation of mutants, obtained through site-directed mutagenesis. Our studies aim to obtain engineered enzymes, having increased turnover rates of oxygen production and long-term stability, exploitable for large-scale implementation in AP.

Impact of aberrant N-glycosylation on GRP94 functionality: insights from Molecular Dynamics simulations

Elisabetta Moroni[a] , Matteo Castelli[b], Giorgio Colombo[b]

elisabetta.moroni@cnr.it

The glucose-regulated protein 94 (GRP94), a member of the Hsp90 family, acts as a chaperone in the endoplasmic reticulum, aiding in the folding and activation of client proteins. Structurally, GRP94 is a homodimer with three globular domains per chain: the N-terminal, middle, and C-terminal. Mechanistically, ATP binding at the N-terminal domain induces conformational changes in GRP94, facilitating client protein binding and folding. Upon ATP hydrolysis, rearrangement of client-binding-site residues occurs, inducing conformational changes in the bound client protein.

Recently, a glycosylation-dependent disease specific variant of the chaperone GRP94 has been identified[1]. Aberrant glycosylation at specific asparagine residues triggers a structural shift in GRP94, leading to its relocation to the plasma membrane and stable interactions with the membrane proteins. This altered state transforms GRP94 from a folding to a scaffolding protein, resulting in the reorganization of protein assembly and connectivity, ultimately leading to widespread proteome dysfunction and disruption of normal cellular pathways.

In this study, we use molecular dynamics simulations to elucidate, at an atomistic level, the mechanism by which N-glycans at different protein sites modulate the conformational dynamics of GRP94, affecting both its interaction mode with clients and nucleotide processing, and ultimately GRP94's function. More specifically, our findings reveal a crucial structural role of N-glycans in regulating the internal dynamics of the protein, which is associated with its functional motions. Furthermore, we demonstrate that N-glycosylation promotes specific protein states, ultimately influencing interactions with different partners involved in the assembly of complexes determining cell phenotypes. Finally, we used these insights to rationalize the engagement of GRP94's conformational states by both active and inactive ligands, providing guidance for designing molecules targeting disease-specific, aberrantly glycosylated variants of GRP94.

Global food security is constantly threatened by plant pathogens that cause crop diseases. This is mainly due to the ability of pathogens to develop new invasion strategies through their effective co-evolution with hosts. Microbial plant pathogens secrete a wide range of effector proteins to facilitate infection. Necrosis- and ethylene-inducing peptide 1 (Nep1)–like proteins (NLPs) form a large family of microbial proteins produced by bacteria, fungi and oomycetes. NLP-producing pathogens infect a variety of important crops, including potatoes, tomatoes, soybeans, grapevines and tobacco[1].

NLPs are the only known cytolytic pathogen effectors that can permeabilize plasma membranes of eudicot plants by forming transient small pores. Recently, major plant membrane components, glycosylinositol phosphorylceramides (GIPCs), have been identified as targets of NLP binding to plant plasma membranes. NLP has been shown to oligomerize on plant membrane, but the molecular mechanism of oligomerization and pore formation of NLPs remains elusive[2].

This research aims to improve our understanding of the interaction between NLP toxins and plant plasma membranes. In particular, we aim at unravelling the molecular mechanism of membrane pore formation as induced by NLP monomers and oligomers and the behaviour of protein/lipid complexes during membrane attachment. In doing so, we employed AI-based modelling tools and all-atom computer simulations, which provide well-established support for experimental methods by allowing the determination of key interactions at the atomic level and the time-dependent monitoring of the accessible conformational space of protein-lipid complexes. These findings are expected to support the development of innovative and efficient strategies to control plant diseases caused by NLP-producing pathogens.

In 2020, with the spread of Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) infection, the PROteolysis TArgeting Chimeras (PROTACs) strategy to defeat coronaviruses (CoV) disease was also investigated[1]. Indeed, PROTAC degraders acting against the major viral protease 3-chymotrypsin-like protease ($3CL^{Pro}$) were hypothesized to be next-generation anti-CoV drugs[2]. $3CL^{Pro}$ (also named nsp5 or main protease) is shared by all coronavirus genera as well as by members of the large genus Enterovirus in the Picornavirus family[3]. Combining NMR spectroscopy and X-ray crystallography, we characterize the interaction between the α, β-unsaturated peptidomimetic-based PROTAC (FT235) with $3CL^{Pro}$ from SARS-COV-2 and $3C^{Pro}$ from Coxsackievirus B3 (CVB3), the latter being a cardiotropic virus belonging to enterovirus genus[4]. The results are compared with those obtained with the precursor molecule (FT234). We demonstrate that PROTAC molecule bind to the active site of both enzymes and the residues involved in the interaction are identified by solution NMR experiments. Furthermore, the crystal structures of SARS-CoV-2 $3CL^{Pro}$ in complex with both FT234 and FT235 molecules are obtained. For both ligands the Cβ carbon of the α, β-unsaturated amide moiety forms a covalent bond with the catalytic Cys145. Moreover, we obtain the crystal structure of $3C^{Pro}$ from CVB3 in complex with FT234 molecule, revealing the covalent binding with Cys147. Finally, preliminary cellular studies show that the synthetized PROTAC molecule drastically reduces protein levels of SARS-CoV-2 $3CL^{Pro}$ in cultured cells. In the future the interaction of PROTAC molecule with both proteases and Cereblon, the substrate receptor of the CRL4 E3 ubiquitin ligase responsible for the polyubiquitination of the target proteins, will be investigated to verify the formation of a stable ternary complex.

cristina.airoldi@unimib.it

Spinocerebellar ataxia type 3 (SCA3) is a neurodegenerative disorder characterized by ataxia and other neurological manifestations, with a poor prognosis and a lack of effective therapies. The amyloid aggregation of the ataxin-3 protein is a hallmark of SCA3 and one of the main biochemical events prompting its onset, making it a prominent target for the development of preventive and therapeutic interventions.

Here, we tested the efficacy of an aqueous Lavado cocoa extract and its polyphenolic components against ataxin-3 aggregation and neurotoxicity. The combination of biochemical assays and atomic force microscopy morphological analysis provided clear evidence of cocoa flavanols' ability to hinder ATX3 amyloid aggregation through direct physical interaction, as assessed by NMR spectroscopy. The chemical identity of the flavanols was investigated by NMR spectroscopy and ultraperformance liquid chromatography-high-resolution mass spectrometry. The use of the preclinical model Caenorhabditis elegans allowed us to demonstrate cocoa flavanols' ability to ameliorate ataxic phenotypes in vivo.[1]

To the best of our knowledge, Lavado cocoa is the first natural source whose extract can directly interfere with ATX3 aggregation, leading to the formation of off-pathway species.

alessandro.gigli@unifi.it

The multifunctional non-structural protein nsp13 is an helicase encoded on the ORF1b and consists of 601 amino acids. It belongs to the superfamily 1B and exhibits a high degree of conservation across all Coronaviruses. Nsp13 plays a crucial role in viral replication, initiating the first step of RNA cap synthesis. This capping process is essential for shielding the viral RNA from cellular innate immune responses, stabilising it, and facilitating its translation[1,2]. The installation of the type 1 cap (m7GpppNm-RNA) involves several enzymes: nsp13, nsp14, nsp16, and nsp10. Nsp13 functions as an RNA 5'-triphosphatase, catalyzing the hydrolysis of the 5' γ-phosphate of the pppN-RNA as the initial step of capping. In addition to its role in RNA capping, nsp13 exhibits NTP-dependent unwinding of RNA duplexes with a 5' to 3' polarity. This activity is enhanced by its interaction with nsp12, the RNA-dependent RNA polymerase (RdRp). Nsp13 consists of five domains: the N-terminal Zinc binding domain (ZBD) (amino acids 1-100), the stalk domain (101-150), 1B (151-261), 1A (262-442), and the 2A domain (443-601). Research indicates that the latter three domains are responsible for nucleic acid binding and NTPase activity[2].

In an effort to better elucidate the molecular behaviour of the enzyme and explore potential therapeutics for COVID-19, my project involved the production of the SARS-CoV-2 nsp13 protein. To enhance existing protocols, particularly those detailed by Chen et al. 2020, adjustments were implemented, primarily focusing on the choice of expression system and the timing of zinc administration to the Rosetta PlysS strain, before induction in the protein production process. These adjustments were found to be crucial for both the quantity and stability of helicase production, a task that posed inherent challenges.

Following protocol refinement, our focus shifted to conducting a drug screening of various in-house small molecules libraries to assess their interaction with nsp13. This screening aimed to identify potential direct antiviral agents against SARS-CoV-2. Through a comprehensive approach involving both computational and experimental methods, we aimed to pinpoint promising candidates for enzyme inhibition.

Vaults are large ribonucleoprotein (RNP) particles with a size of 70 nm × 40 nm × 40 nm. Initially reported in 1986, vaults have a distinct ovoidal architecture made of two symmetric 39-meric shells composed of the major vault protein (MVP). Despite its large size and the high levels of conservation of the vault components, the precise role of this complex in the cell is not yet fully understood.
Here, we report the first cryoelectron microscopy (cryoEM) reconstruction of the human vault complex at 3.3 Å and provide a comparison to the previously published structures of its murine counterpart. Additionally, we investigated the interaction and binding site to the human onco-suppressor protein PTEN with Grating-Coupled Interferometry (GCI) and Small Angle X-ray scattering (SAXS), which showed a strong affinity (kd of 1 μM) in presence of 10 mM of Ca(II), this supports the role of the vault as molecular scaffold and transport of the onco-suppressor protein.

Sustainability, Circular Economy and Chemistry

Fabrizio Passarini [a b]

[a] *Department of Industrial Chemistry "Toso Montanari", University of Bologna, via Piero Gobetti 85, 40129 Bologna*

fabrizio.passarini@unibo.it

The paradigm of circular economy has become a vital way to develop the future social and production system, considering that the so named "linear" model has proven its inherent failure, due to the so many impacts on the environment, on human health, on Earth resources[1]. However, the concept of circular economy has taken a certain time to be accepted and introduced in European strategic documents and legislation.

But an important question is: how circular economy and sustainability could move forward together?

It must be born in mind that sustainability is the final goal of human activities, it can be measured through different approaches, among which the Life Cycle Assessment is the most common and widely used, with an important application also in the chemical industry[2]. Conversely, circularity is a tool, which is usually the best way to reach that aim, even though it cannot be defined sustainable "by default".

Chemistry could play a crucial role in the comprehension and in the development of these concepts. D. Meadows was the first author of the world famous book *The limits to growth*, a pivotal document describing the necessity of a change in human behaviour, to avoid the exceedance of the physical boundaries of our planet[3]. Another chemist, M. Braungart, was one of the main inspirers of the principle "cradle to cradle", which represents a concept strictly related to the circular economy[4].

There are some specific flows which require a diversion from some practices that in principle could be considered the more sustainable, such as reuse or recycling, to preserve the priority guideline of environmental sustainability (e.g., in the case of highly energy-consuming old appliances, or when substances of very high concern are present in the end-of-life materials). This is also in line with the European Waste Framework Directive[5], which states that specific waste streams may depart from the hierarchy where this is justified by life-cycle thinking on the overall impacts of the generation and management of such waste.

The challenging role of chromatography in environmental analysis: unveiling the polyhedrality of separation sciences

M.C. Bruzzoniti[a]

[a]*Department of Chemistry, Via P. Giuria, 5, 10125 Turin*
mariaconcetta.bruzzoniti@unito.it

This talk aims to highlight how separation science, and mainly liquid chromatography, is a strategic approach to address the challenges of environmental analysis in all its key phases. The quantitative recovery of pollutants from difficult matrices, that hinder their correct quantification, through high selectivity separations, also based on the modelization of the equilibria involved, can be achieved ensuring their accurate identification and quantification in various environmental matrices. These requirements are the basis for a correct interpretation of the data obtained, for a reliable risk assessment[1,2], and for issuing recommendations for policy actions[3]. Environmental analysis faces analytical challenges due to achieving low detection limits and high selectivity and specificity in agreement with regulatory and standardization issues. Chromatographic approaches based on selective interactions between analytes-stationary phase and eluent represent the only possible answer to solve the mentioned problems as well as to implement technologies for the removal of pollutants. Examples of how the elucidation of analyte-adsorbent interactions can be exploited in environmental analysis[4] and remediation will be provided[5].

Ancient Alchemies: Analytical Identification of Psychotropic Substances in Archaeology

E. Greco [a], D. Tanasi [b], G. Samorini [c], P. Barbieri [a]

[a]*Department of Chemical and Pharmaceutical Sciences, University of Trieste, via Giorgieri 1, Trieste, Italy*

[c]*Indipendent Researcher, Bologna, Italy*
enrico.greco@units.it

In this presentation, we would explore the intersection of ancient rituals and the use of psychotropic substances, unveiling the sophisticated chemical knowledge of past civilizations through the lens of modern analytical science. Our journey delves into the methodological innovations and interdisciplinary approaches that have enabled the identification of psychoactive compounds in archaeological finds, shedding light on the cultural, medicinal, and ritualistic contexts of their use. The core of our exploration is centered on a comprehensive study that employs state-of-the-art analytical techniques—including proteomics [1], metabolomics by using Liquid Chromatography coupled with Mass Spectrometry in tandem with Orbitrap analysers (LC-MS/MS), genetics, synchrotron radiation-based Fourier Transformed Infrared microSpectroscopy (SR μ-FTIR)—to decode the chemical signatures preserved in ancient artifacts. This approach has unveiled the complex concoctions used in rituals, revealing a rich palette of nutraceutical, psychotropic, and medicinal substances that underline the advanced understanding ancient cultures had of their natural environment. Particular emphasis is placed on the discovery of substances from plants such as Peganum harmala, Nymphaea nouchali var. caerulea, within a 2nd-century BCE Egyptian ritual vase, showcasing the diverse pharmacopeia that was available to ancient Egyptians. The identification of these compounds, alongside traces of human fluids and fermented fruit-based liquids, provides unprecedented insights into the ritualistic practices of Ptolemaic Egypt [2]. Furthermore, we address the challenges and controversies surrounding the identification of the same molecules in traditional Amazonian hallucinogenic brews, such as ayahuasca, in archaeological contexts. The speculative detection of harmine and harmaline in Andean finds raises intriguing questions about the historical use of Banisteriopsis caapi and the origins of its psychoactive use. Through critical examination of archaeological, ethnobotanical, and analytical data, we highlight the complexities of confirming the ancient use of ayahuasca and the importance of a cautious, evidence-based approach to interpreting archaeological findings [3]. This presentation aims not only to showcase the groundbreaking discoveries in the field but also to encourage a discussion on the implications of these findings for our understanding of ancient cultures. By bridging the gap between the past and present through the analytical identification of psychotropic substances, we gain a deeper appreciation for the sophisticated ways in which ancient societies interacted with their natural world. The insights gained from this research enhance our knowledge of historical belief systems, cultural practices, and the potential therapeutic uses of these substances, offering a unique perspective on the ancient alchemies that have shaped human history.

ZIFs (Zeolitic Imidazolate Frameworks) are recently developed materials belonging to the MOF (Metal Organic Framework) family. They are composed of transition metal cations (Fe, Co, Cu, Zn) coordinated with imidazolate ligands in a tetrahedral structure. These materials are attractive as they combine the advantages of both MOFs and zeolites, such as crystallinity, porosity, as well as high chemical and thermal stability[1]. Recent interest from the scientific community has been attributed to ZIF-8, consisting of zinc clusters linked to 2-methylimidazole units. The most studied method for the synthesis of this material is the solvothermal one: currently the best performing solvent in terms of crystallinity is *N,N*-Dimethylformamide[2], followed by water which gives ZIF-8 with excellent yield and crystallinity. In both cases, a huge excess of organic linker is requested[3]. In this work we described the use of glycerol carbonate as green and alternative solvent in the synthesis of ZIF-8 starting from 2-methylimidazole and zinc acetate. The reaction conditions were optimized in terms of temperature, reagents molar ratio, amount of solvent and reaction time. Glycerol carbonate, a glycerol derivative, shows several advantages such as (a) its preparation from glycerol (5 billion liters in 2021)[4], obtained as the main byproduct of the bio-diesel production; (b) polar as the *N,N*- Dimethylformamide and, above all, (c) it's atoxic and biodegradable. In this work we also tested the feasibility of recycling the reaction mixture after each reaction cycle with encouraging results regarding the crystallinity of the product. It turned out that glycerol carbonate seems to be able to carry out the ZIF-8 preparation for five consecutive cycles in the optimized conditions. In terms of simple E-Factor the use of glycerol carbonate shows the best results in comparison to the other systems (contemplating respectively DMF and water as solvents). As a support of the current work, we elaborated a "cradle to gate" life cycle assessment (LCA) to counterpose the results obtained in glycerol carbonate with those reported in literature for ZIF-8 preparation (water and DMF). The comparative study shows promising results and paves the way for perspectives and improvements in order to overcome the impacts associated with the synthesis of glycerol carbonate.

Marine biota as an environmental indicator: determination of heavy metals and rare earth elements.

Claudia Cucolo[a], A. Marano[a], R. Topa[a]., C. Salvi[a], A.Belletti[a] , S. Sbriglia[a] , M. Toscanesi[a], G.Di Natale[b], M.Trifuoggi[ab]

[b]*CeSMA (Metrological and Advanced Technological Services Center), University of Naples Federico II, 80146 Napoli*
claudia.cucolo@unina.it

The increasing anthropogenic pressure on the marine ecosystem is a growing concern, as the health of the oceans is closely linked to the health of the planet and humanity. This crucial connection is highlighted by the incessant increase in pollutants discharged into the seas, a direct consequence of human activities such as industry and natural resource extraction.[1]

In this context, a study of considerable importance was conducted in the Sicilian area of Gela, with the main objective of assessing the effects of direct discharge of wastewaters resulting from hydrocarbons and metals extraction on the health of waters and aquatic ecosystems. The study focused on the quantification of trace elements such as heavy metals and rare earth elements (REEs), which can have devastating effects on the marine ecosystem. The heavy metals studied include mercury (Hg), lead (Pb), and cadmium (Cd), known for their toxicity even at low concentrations. REEs, on the other hand, are a group of metals including the 15 lanthanides together with Yttrium and Scandium, which are also subject to release into the environment during industrial processes[3]. The technique used for analysis was inductively coupled plasma mass spectrometry (ICP-MS), a sensitive and precise methodology that allows for the accurate determination of the concentrations of these elements in the analyzed samples[2]. The processing of the data obtained using this technique allowed the evaluation of bioaccumulation and biomagnification indices, providing crucial information on the accumulation of pollutants along the marine food chain. The results obtained from this study revealed the persistence of pollution in the Gela area and its potential threat to marine biodiversity and human health.

The results highlight prevalent concentrations of essential metals such as aluminium, iron, copper, and zinc. The concentrations of heavy metals and REEs detected in 28 fish species analyzed indicate a significant accumulation of pollutants, with the risk of transfer to predatory organisms along the food chain. Specifically, for metals like mercury, cadmium, and lead, the obtained values exceed the limit values established by European regulations regarding the treatment of fishery products.

Street art materials: characterisation by analytical pyrolysis coupled with gas chromatography and mass spectrometry

S.Pizzimenti,[a,b] J. La Nasa,[b] I. Degano,[b] F. Modugno[b]

[a]*Department of Pharmacy, University of Pisa, Via Bonanno Pisano 33, Pisa*
[b]*Department of Chemistry and Industrial Chemistry, University of Pisa, Via Giuseppe Moruzzi 13, Pisa*
silvia.pizzimenti@unipi.it

Analytical pyrolysis coupled with gas chromatography and mass spectrometry (Py-GC-MS) is a versatile analytical tool that is currently applied in different fields including heritage science. This technique can be used to characterise the organic fraction of paint materials at the molecular scale. Besides the Py-GC-MS set-up, the same instrument can be exploited to directly analyse the evolved volatile fraction by mass spectrometry during controlled heating of the sample in an inert environment (EGA-MS mode).

Both Py-GC-MS and EGA-MS are successfully exploited in the analytical work package of the PRIN project Sustainable Preservation Strategies for Street Art – SUPERSTAR SUPERSTAR sets as a goal the definition of innovative guidelines for the preservation strategy of street art, aimed at safeguarding its powerful social and cultural message in the urban context. Py-GC-MS have been used to study the composition of street art materials of relevant murals in different cities in Italy (Milano, Torino, Bari, Bologna and Collelongo) and in Europe: the Graffiti Alley (Ghent, Belgium) and Galeria del Arte Urbana (Lisbon, Portugal). For the last two urban art sites, which have undergone up to 25 years of repaintings on the same surfaces, providing a unique perspective on material evolution within a specific time frame, our investigation was enhanced by experiments conducted at the European facility IPANEMA Employing a combination of multiscale and multispectral methods alongside micro-destructive Py-GC-MS analysis, we gained chemical insights into the various layers of paint. This approach allowed us to discern the stratigraphy of paint binders, distinguishing between different classes of organic polymers such as alkyds, acrylics, and nitrocellulose resins present in each layer, and provided valuable information on the evolution of these materials' formulations over time. The information obtained will be crucial for the definition of the best preservation and conservation strategies, and to guide the choice of the materials and methods for the conservation of street art murals.

Sustainable biodeterioration prevention for Built Heritage stone surfaces: increasing essential oils antimicrobial features through encapsulation with SiO_2-based NPs

A. Campostrini,[a,b] A. Sala-Luis,[b] P. Bosch-Roig,[b] E. Ghedini,[a] M. Signoretto,[a] F. Menegazzo[a]

[a] *CATMAT Lab, Department of Molecular Sciences and Nanosystems, Ca' Foscari University of Venice and INSTM RUVe, Via Torino 155, 30172 Venice, Italy*
[b] *Instituto Universitario de Restauración del Patrimonio, Universitat Politècnica de València, Camí de Vera s/n, 46022 Valencia, Spain*
andrea.campostrini@unive.it

When dealing with Cultural Heritage stone artifacts, biodeterioration is considered one of the main threats to maintaining an adequate conservation state. Biodeterioration can begin with the colonization of microorganisms, which could then favor the establishment of larger organisms.[1] These microorganisms can damage the material, leading to other physical and chemical degradation phenomena. Therefore, to avoid such degradation phenomena, preventive actions must be employed, such as the application of protective coatings.[2]

Currently, most antimicrobial products used to contrast microbiological growth are highly toxic not only for the target organisms but also for the operators and the environment. For this reason, attention must be given to employing sustainable alternatives. In this regard, the use of essential oils (EOs) has emerged. EOs have a high antimicrobial power; however, their action is often time-limited and regulated by the evaporation time of the active molecules.[3]

In this work, two essential oils (*i.e.*, *Origanum Compactum* and *Thymus Vulgaris*) were encapsulated in MCM-41 silica porous nanoparticles (SiO_2 NPs). The proposed method ensures that the antimicrobial features of EOs are maintained for a longer duration, reducing the evaporation rate and also diminishing the quantity required: the amount necessary to achieve the minimum inhibitory concentration (MIC) and the minimum fungicidal concentration (MFC) was halved. Moreover, since the NPs can host a higher quantity of product than is necessary to exert the antimicrobial effect, the duration of activity is further prolonged, releasing the EOs over time.

This combination of the mesoporous SiO_2 NPs and EOs was also tested as the principal component of a protective coating for stone surfaces. The promising synergic results show that this system could be of interest for inhibiting and preventing microbiological growth on stone surfaces, while also avoiding visible aesthetic impacts or color changes, being non-toxic for the environment or the operator, and preventing the EOs from evaporating holding them for gradual release.

anfaggiano@unisa.it

Addressing the urgent environmental challenge of contaminants of emerging concern (CECs) in wastewater, this study introduces a pioneering approach by employing the solar photo-Fenton process within raceway pond reactor (RPR), utilizing iron-functionalized biochar (FeBC) as a catalyst. This novel method aligns with stringent European regulations and the global commitment to Sustainable Development Goal 6, emphasizing the importance of clean water and effective sanitation for all [1]. The choice of RPR for this application is innovative, marking the first time such a system has been optimized with iron-functionalized biochar for the degradation of CECs like acetamiprid in municipal wastewater. The research focuses on optimizing operational parameters, including the precise concentration of hydrogen peroxide (H_2O_2) and the quantity of FeBC, to maximize the degradation efficiency of targeted pollutants. This setup leverages the generation of hydroxyl radicals under UV-A radiation, crucial for oxidizing complex organic molecules effectively [2]. By conducting both batch and continuous flow experiments in RPR, the study evaluates the process's scalability and its potential for integration into existing wastewater treatment frameworks. Continuous flow experiments are particularly valuable, providing insights into the system's performance under variable conditions typical of municipal wastewater treatment, thereby demonstrating its real-time applicability. This groundbreaking application of RPRs with iron-functionalized biochar for the solar photo-Fenton process offers a promising solution for enhancing reclaimed water quality. It not only meets environmental and regulatory demands but also paves the way for sustainable water management practices, particularly in the context of agricultural irrigation. Through this innovative approach, the study makes a significant contribution to the field, potentially setting a new standard for the treatment of CECs in wastewater. Remarkably, the application of this process in both batch and continuous flow configurations within an RPR has led to the removal of up to 99% of acetamiprid (with an initial concentration of 100 µg/L) from secondary effluent sourced from the El Toyo wastewater treatment plant in Almeria, Spain. These results underscore the efficacy of the optimized process in significantly reducing acetamiprid concentrations, showcasing its potential as a highly effective method for the treatment of wastewater containing CECs.

Biogeochemistry and bioaccumulation of toxic elements in freshwater ecosystems of Bosnia and Herzegovina

C. Petroselli,[a] G. Placidi,[a] R. Selvaggi,[a] F. Lorenzoni,[a] A. Carosi,[a] M. Lorenzoni,[a] D. Cappelletti[a]

[a]*Dipartimento di Chimica, Biologia e Biotecnologie, Università degli Studi di Perugia, via Elce di Sotto 8, 06123, Perugia (Italy)*
chiara.petroselli@unipg.it

Metals and metalloids are ubiquitous in the environment due to both natural and anthropogenic sources. As some of them can exert toxic effects on living organisms, their presence can hinder the environmental quality and determine bioaccumulation and damage in living tissues. Bioindicators are a very effective tool for assessing the environmental quality of an ecosystem, as these organisms tend to bioaccumulate contaminants in their tissues. The bioaccumulation in a living organism depends on its exposure and contact mechanisms with pollutants, but also on the specific interaction between the studied pollutant and the target organs.

Bosnia and Herzegovina is characterised by one of the widest variety of plants and animal species in the European continent, and this country is currently working towards the re-evaluation of its protected areas and species in line with European Union standards, to improve its biodiversity protection strategy.

This project focuses on the characterisation of aquatic habitats and protection of freshwater biodiversity, and the specific aim of the presented work is to assess the environmental quality and bioaccumulation in freshwater ecosystems located in the two target areas of the "NatureBosniaErzegovina: aree protette e sviluppo sostenibile" project (AID 012003), namely the Blidinje Natural Park and the Sutjeska National Park.

In particular, we determined the concentrations of essential and toxic elements in water and sediment samples, and we evaluated the bioaccumulation in selected animal (fish, crayfish) and plant (reed) species by means of Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Moreover, target organs were identified for both plant (roots, stem, leaves) and animal (muscle, liver/hepatopancreas, gills) species. Results show that contamination levels is variable between the studied ecosystems, and that bioaccumulation within the same habitat is both species-specific and organ-specific.

NANO-STRUCTURED EMULSIONS LOADED GEL FOR REMOVING UNDESIRED MATERIALS FROM STONE ARTIFACTS

Maduka L. Weththimuni[a], *Matteo Ferretti*[a], *Maurizio Licchelli*[a,b]

[a]*Department of Chemistry, University of Pavia, via T. Taramelli 12, 27100, Pavia, Italy*
[b]*CISRiC, University of Pavia, via A. Ferrata 3, 27100 Pavia, Italy*
madukalankani.weththimuni@unipv.it

The conservation of the Cultural Heritage items is a common operation to maintain their original structure against degradation processes. Removing undesired and/or decayed products from the artworks represents an important and delicate step in the conservation process. There are many possible undesired materials (aged coatings, degraded materials, deposits of pollutants, grime or dirt, soil materials) to be removed from the surfaces of artifacts, and the challenge is to remove them without damaging their properties and affecting their original aspect[1]. Highly selective techniques must be applied for this purpose, in order to preserve the original nature and properties of the substrates. Hence, the present research study was mainly focused on studying the removing process of different undesired materials (e.g. decayed polymer coatings, graffiti, organic pollutants) from the stone surface by different cleaning tools. In particular, the effectiveness of nano-structured emulsions (NSE; surfactant with limited amount of organic solvents) supported on gels was investigated for the removal of an acrylic polymer (Paraloid B-72), common soil, and graffiti from a stone substrate (Marble, M).

For this purpose, three different gel materials were synthesized and characterized in the laboratory: (i) a synthetic gel[2] (HEMA-MBA/PVP copolymer: 2-hydroxyethyl methacrylate/N,N-methylenebisacrylamide with polyvinylpyrrolidone), (ii) a new bio-degradable gel: Xylan (X) treated with Polyvinyl alcohol (PVA), PVP, and sodium borate (SB), and (iii) Starch (S) treated with PVA, PVP and SB. All the considered gel materials were characterized using different techniques to comparatively assess their properties that are relevant for cleaning purpose: gel content, equilibrium water content, retention capability, morphology, and durability. The results indicated that both gels prepared by natural polymer (Xylan and Starch) have higher equilibrium water content (EWC ~93%) than the synthetic gel (HEMA-MBA/PVP, EWC ~81%). Consequently, the retention capacity has the same trend. NSE-loaded gels were applied in the cleaning of marble surface[1], and the results were comparatively evaluated to find out the gel materials more appropriate for removing the different undesired compounds.

Life Cycle Assessment of a Catalytic Process for Methane Conversion to Hydrogen and Carbon Nanotubes using a Co-Precipitation Catalyst

E. Rossi[a,b], L. Canuti,[a] L. Ciacci[a,b] I. Giarnieri[a], P. Benito[a], F. Passarini[a,b]

The rising cost and decreasing supply of fossil fuels have spurred the search for clean, alternative energy sources. Hydrogen holds promise as a clean fuel, but current production methods often generate significant CO_2 emissions[1]. The STORMING project, funded by the European Union's Horizon Europe program, aims to tackle this challenge. The project's team is developing a novel catalytic technology that converts methane gas (CH_4) into two valuable products: clean-burning hydrogen fuel (H_2) and carbon nanomaterials for batteries. Researchers from the University of Bologna, participating in the STORMING project, developed a catalytic process to convert methane using a catalyst obtained by co-precipitation.

In this study, a life cycle assessment[2] (LCA) is conducted to evaluate the environmental impact of the process. The analysis focused on two highly efficient catalysts, one containing copper (Cat 2) and one without it (Cat1), with and without a reduction step (NR) of the catalyst. For each of the 4 cases, environmental impacts were analyzed for the synthesis of 0.5g of catalyst and then for the production of 1g of carbon nanotubes considering their productivity. H_2 is credited as an avoided impact.

The assessment revealed that energy consumption, particularly during the laboratory-scale catalyst synthesis phase, mainly contributes to the process's environmental impact. However, this aspect can be significantly reduced during large-scale production. The study found that considering the catalyst production scenarios without the reduction during the pre-treatment step had a slightly lower environmental impact.

While the pre-treatment step seems to have a minimal impact on catalyst synthesis, it becomes more significant when considering the overall reaction with methane. This is because the pre-treatment also affects the catalyst efficiency. The study found that catalysts without the reduction step have the lowest environmental impact thanks to their higher productivity in converting methane to hydrogen and carbon nanomaterials.

The study has some limitations. Since it was based on a laboratory-scale process, energy consumption estimates might not reflect a fully optimized, large-scale production scenario. Additionally, some assumptions are made for some data and certain values related to productivity have been only predicted.

Overall, this LCA study provides valuable insights into the environmental impact of the methane conversion process and offers useful indications to develop a technology that is as sustainable as possible.

Acknowledgments:
This project has received funding from the European Union's Horizon Europe Research and Innovation Programme, under Grant Agreement n° 101069690.

Ozone is one of the most important greenhouse gases and a very hazardous atmospheric pollutant. In the troposphere, ozone is a secondary species produced by complex reaction mechanisms involving nitrogen oxides and VOCs. However, there is another source of ozone, which is the stratosphere to troposphere exchange whose mechanisms are not yet well understood especially in Antarctica.

In order to deepen the knowledge about such transports, their frequency and their intensities, an experimental facility was set up in Concordia Station, on the Antarctic plateau at Dome C, within the framework of STEAR (Stratosphere-to-Troposphere Exchange in the Antarctic Region) project. While greater attention is focused on stratospheric ozone, due to the recurrent ozone hole occurrence and its alarming fluctuations causing a globally recognized threat, tropospheric ozone, though well-known among scientists, is less popular than the former. The comprehension of ozone-related issues relies on the possibility of defining an accurate tropospheric budget of this gas, starting from the identification and subsequent quantification of stratospheric ozone contribution.

Beside direct observations of ozone, STEAR project is focused on the sampling and analysis of beryllium-7 (^{7}Be), a natural cosmogenic radionuclide[1] produced by spallation reactions of nitrogen and oxygen nuclei induced by cosmic rays in the stratosphere. Its presence in the troposphere is an established marker of stratosphere-to-troposphere exchange events[2]. While ^{7}Be data at coastal sites in Antarctica have been often object of research, this contribution aims to present the first high-resolution ^{7}Be time series in aerosol samples from the Antarctic plateau from January 2022 to date. The main novelties are not only the data time resolution (2–4 days) but mainly the coverage of winter-over periods, so far unprecedented, and the deployment at Dome C of a dedicated high-resolution γ-ray spectrometer, to allow the determination of the short-lived radiotracers on-site. This contribution will be therefore focused on the first results obtained, considering the two years-time series, the correlations found between ^{7}Be concentration and meteorological variables, and the evaluation of the source points by back-trajectory analysis.

e-mail elena.badetti@unive.it

The recovery of starch grains from ground stone tools (GSTs) dating to the Late Pleistocene have provided evidence that *Homo sapiens* (HS) was mechanically grinding plant organs during its dispersal into Eurasia.[1] Starch is the reserve of polysaccharides accumulated in the amyloplasts of plants, and its high energetic value might have played a vital role for HS to survive a new environment (the Northern latitudes) and the harshening of the climate that occurred in the late Marine Isotopic Stage 3 (MIS 3, 60-25 ka BP). Starch grains are conventionally analyzed by means of optical microscopy with bright and polarized light after washing/sampling archaeological materials either by pipetting or sonicating the selected portion of the GST surface, or by mechanical remotion. Indeed, the identification and recognition of starch grains is challenging because on the one hand their removal from GSTs requires invasive procedures that can invalidate a proper physical-chemical characterization, and on the other, necessitate a comparative reference collection.

Within SMarT4BioArCH project[2] we propose an integrated methodology: from the extraction to the characterization of starch grains (but also of other biogenic residues) adhering to the archaeological GST surfaces, to testing different approaches for their extraction. Our approach relies on the combination of morphological and chemoprofiling analyses, and by comparing the archaeological data to a tailored reference collection that includes aged starch granules from relevant plants potentially available during the MIS 3. We aim to enhance the narrative on the exploitation of available resources by hominins thriving in a given territory through a multi-disciplinary approach.

e-mail: antonio.medici@unina.it

The investigation of Nimesulide (NIM) degradation, recognized as an emerging pollutant[2], was conducted through a hybrid approach combining free chlorine (Cl_2) and UVA irradiation (UVA/Cl_2)[3]. The primary objective was to elucidate the kinetics, generation of reactive species, and transformation mechanism implicated in the degradation process. Furthermore, the feasibility of utilizing natural sunlight as an illumination source was explored. Our findings unveiled NIM's limited reactivity towards hypochlorite (OCl^-) alone, necessitating complementary methods to expedite degradation. UVA irradiation facilitated the activation of the oxidizing agent, resulting in the degradation of 88% of NIM in 180 minutes (Figure 1).

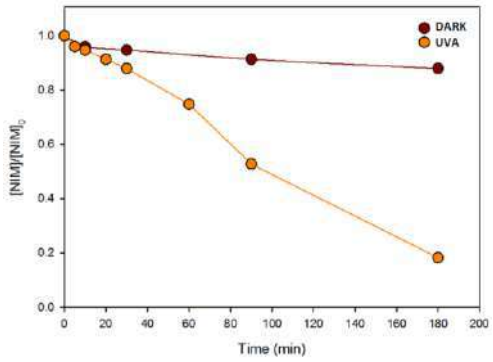

Figure 1: Nimesulide degradation in the presence of 0.5 mM of Cl_2 under dark and UVA.

Chemical probes were employed to assess the radical species generated during the process. High-performance liquid chromatography-mass spectrometry (HPLC-MS) analysis disclosed the presence of novel oxidation by-products, previously unreported.

Total organic carbon (TOC) analysis confirmed the substantial degradation of NIM during the UVA/ Cl_2 process, indicating efficient mineralization up to 60%. Additionally, the feasibility of employing natural sunlight as an alternative light source and application of the process to real wastewater was validated.

Motion picture films made of cellulose acetate (CA) are subjected to chemical degradation mainly due to the "vinegar syndrome". It concerns the cleavage of the ester bonds between the acetate group and the cellulose chain through ester hydrolysis (deacetylation), with the release of acetic acid, which acts as a catalyst for the reaction. By-products of deacetylation can promote, also, the hydrolysis of the glycosidic bonds of the cellulosic backbone. The consequent deformation and embrittlement of the films can strictly compromise their usability [1,2]. The most important goal of this project is to set up innovative, cheap, easy-to-produce and handle and possibly reusable chemical inhibitors. We proposed and characterized several systems based on two strategies: the use of sponge-like systems (1) made of polyethyleneimine (PEI) and/or (2) uploaded with metal oxide nanoparticles. The intent was to use free amino groups, in the first case, and inorganic nanoparticles, in the second case, to convert acetic acid into ammonium carboxylate and acetate salt, respectively, through an acid/base reaction. The evaluation of the efficacy of the above-mentioned systems in inhibiting the vinegar syndrome was performed both on real motion picture films on which the deacetylation process has been artificially induced with an innovative degradation protocol and on films naturally affected by the "vinegar syndrome". The different behaviors of untreated and treated films have been evaluated through an innovative multi-analytical protocol able to monitor the chemical alterations of the supports connected with the occurrence and the evolution of the "vinegar syndrome".

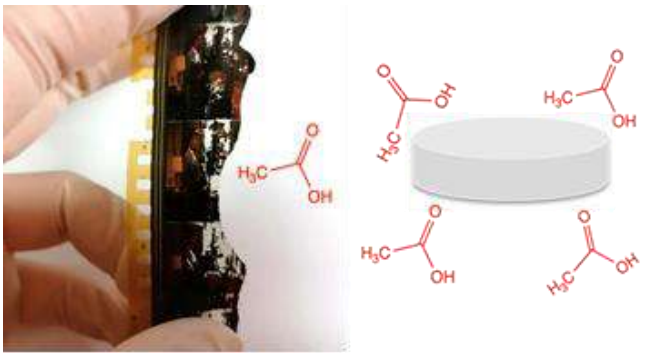

Figure 1: sponge-like inhibitor for the "vinegar syndrome" of CA-based motion picture films.

The production of farmed fish from aquaculture is significantly increasing, due to the raise of seafood demand from a growing world population and because of overfishing of world fish stocks. The expansion of aquaculture production is accompanied by an augmented use of veterinary medicinal products (VMPs), such as parasiticides and antibiotics, the application of which in aquaculture prevents and reduces the outbreak of fish diseases. However, this poses a potential environmental risk since VMPs can be released in water bodies from aquaculture effluents, despite the adoption of wastewater treatment procedures.[1] The presence of pharmaceuticals in water bodies is a worldwide environmental problem because, although their concentration values are very low, these contaminants of emerging concern (CECs) can have adverse effects on aquatic ecosystems, including the spread of antimicrobial resistance.

In water bodies, abiotic photochemical reactions play a role in the attenuation of the ecotoxicological risk posed by CECs, because the latter are usually photodegraded into compounds of lower environmental concern; however, photoproducts are sometimes formed that are more toxic than the parent contaminant.[2]

Oxolinic acid (OxA) is a quinolone antibiotic used in both fresh- and saltwater aquaculture, and is thus released in aquatic environments. The few studies published so far about the fate of OxA in natural waters showed that photoreactions would be important degradation processes.[3] However, the photoreactivity of OxA in surface waters has not been systematically investigated.

In this work, the photochemistry of the basic form of OxA (pK_a ~ 6) was studied. The direct photolysis quantum yield and the bimolecular reaction rate constants of OxA with relevant reactive transient species ($HO^\bullet$, $CO_3^{\bullet-}$, $Br_2^{\bullet-}$, $^1O_2$, and triplet states of dissolved organic matter) were determined by means of steady-state irradiation experiments and laser flash photolysis measurements. Despite high OxA photoreactivity, we observed that some photodegradation pathways are inhibited by phenol, here used as representative of antioxidant dissolved organic matter (AODOM). By considering measured reaction kinetics together with inhibition by AODOM, we could model the photochemical half-life time of OxA in surface waters.

Influence of the chemical environment on CO_2-sequestration by clathrate hydrates: a Raman study

M. Zannotti[a] and R. Giovannetti[a]

[a]*School of Science and Technology, Chemistry Division, University of Camerino, Camerino, 62032, Italy*
marco.zannotti@unicam.it

Clathrate hydrates (CHs) are nonstoichiometric solid compounds formed by cage-like crystalline structure of water molecules where a guest molecule is entrapped under proper conditions of temperature and pressure. CHs offers a solution for the sequestration of Carbon Dioxide (CO_2) in its structure as trapped molecule both in seawater and under the seafloor.[1] The formation conditions and a deeply investigation about the chemical properties of seawater, sediments and the environmental parameters are fundamental to understand the process and help the know-how for a technological solution for the CO_2 sequestration as CO_2-CHs.

Whitin the PRIN2022 project CO_2-RESTO, the water hydrates features were deeply investigated by Raman spectroscopy, since important information can be obtained from the observation of the -OH stretching bands of water that are present in CO_2-CHs. The Raman study has been performed by using lab-reproduction CHs with and without CO_2, in presence or in absence of salts and sediments. The in-depth analysis of Raman shifts showed that the presence of salt, as NaCl, influences the water structure decreasing the hydrogen bonds, but in the same conditions, in presence of sand, the latter limiting the inhibition effect of salts. Moving towards the CO_2-CHs test, using Raman spectroscopy the characteristic two peaks of CO_2, in the region 1200-1400 cm^{-1}, can be easily detected. Also in this case, the Raman bands of the water -OH stretching in the CO_2-CHs, showed useful information. At different temperature, the CO_2 hydrates showed a less ordered structure in the presence of sand but however, thanks to the interaction between water and silanol groups of sand particles, their stability was maintained with the variation of temperature, favoring the expansion of the cages that was highlighted by the Raman shifts of the CO_2 Fermi diad.[2] All the obtained experimental results will be used to the devolpment of a theoretical model applicable to the CO_2-CHs formation for their reproduction in lab-scale and for the technological solution as the CO_2-injection.

antonio.manco@unisalento.it

Introduction: Increase in human activities within urban centers in recent years has resulted in an increase in the number of individuals exposed to progressively higher levels of atmospheric pollutants such as particulate matter. An increasing number of studies demonstrates the significance, for public health scopes, of characterizing not only the total mass of particulate matter but also studying the size distribution of particles and attributing their sources. Although there have been efforts to normalize the particulate emissions in PM10 and PM2.5 fractions, little has been done for the ultrafine fraction, which constitutes the majority of total particle number concentrations (PNCs). The aim of this study is to characterize the emission sources affecting the urban center of Lecce (Italy), which is representative of medium-sized cities in terms of urban planning and climate, during the summer period.

Metodh: The sampling site is located at "Piazza Ludovico Ariosto"-Lecce, where the main sources of airborne particulate matter are vehicular traffic, biomass combustion from human activities, regional background, and dust transport from the saharan region. A total of 39 days were sampled using a real-time AQ-SMART 1000 (PALAS) station, which analyzes particles using an optical analyzer based on the Light Scattering principle (spectral analysis), wich can provide real-time particle number and size class distribution. Continuous 1-minute observations were obtained for each of the 64 size classes, covering a range from 0.175 µm to 20 µm, and mass concentrations of PM1, PM2.5, and PM10.

Results: The data were then processed to obtain daily averages of PM1, PM2.5, and PM10 masses and their respective ratios PM2.5/PM10, PM1/PM10, and PM1/PM2.5, which allowed us to identify a Saharan Dust event confirmed by back trajectories and satellite images, and some days characterized mainly by ultrafine particulate matter attributable to anthropogenic sources such as vehicular traffic. Next, data on the number of particles for different size classes were considered, and Positive Matrix Factorization (PMF)[1] was applied to confirm the emissive sources impacting the urban center of Lecce, including vehicular traffic, regional background, and Saharan dust.

Conclusion: Assigning a size range of atmospheric particulate matter to a specific source provides a helpful tool for decision makers, enabling them to implement effective and sustainable solutions to improve air quality and the health of urban residents.

Recycling of construction and demolition waste in the European Union: an environmental and economic assessment

Dario Caro[a]

[a]*University of Siena, Piazzetta Enzo Tiezzi 1, SienaAddress, City*
caro2@unisi.it

Although the recovery rate of construction and demolition waste in the European Union is at 89 %, it does not correspond to high-value material recovery but rather "poor" levels of circularity. The environmental impacts and costs of 12 construction and demolition waste material fractions relying on alternative pathways and treatment technologies are assessed by using a life cycle assessment. Important trade-offs in the transition towards the circular economy are found. Recycling of concrete, bricks, gypsum, and ceramics and tiles is the best environmental performance but also the most expensive pathway. Overall, recycling construction and demolition waste in the European Union with advanced technologies could save about 264 kg CO^2eq t^{-1} with a cost of 25 EUR t^{-1}. The maximum potential for recycling would correspond to a total reduction of about 33 Mt of CO_2eq in 2020. Concrete and bricks result as the fractions with the highest potential for improving current waste management practices in environmental terms. Economic and non-economic barriers for realising this potential at EU level are discussed in relation to the European Green Deal and the EU's circular economy objectives.

The increasing prevalence of organic micropollutants (OMPs) from both industrial and domestic sources has significantly affected the quality of surface water and treated wastewater for reuse. Among these, pharmaceutical compounds pose a significant concern due to their widespread distribution and biological activity. Specifically, steroid hormones (SHs) have drawn growing interest in the scientific community for their disruptive effects on the endocrine system in aquatic organisms.[1] Wastewater treatment plants (WWTPs) are recognized as sources of these pollutants,[2] since they are not designed for their removal. Therefore, as recently remarked in a Proposal for an European Directive concerning urban wastewater treatment,[3] it is urgently needing to address the issue of OMPs in urban wastewater, especially for larger WWTPs. Among the technologies developed to remove OMPs from wastewater, physicochemical processes such as adsorption offer promising solutions due to their simplicity, eco-friendliness, and relatively low cost. As a potential adsorbent, biochar could represent a cost-effective and efficient solution. Furthermore, the biochar production from sewage sludge pyrolysis could represent a promising strategy to manage hazardous residues from WWTPs.

Based on the aforementioned considerations, this work used a two-step pyrolysis methodology to produce biochar on a bench-scale with improved adsorption stability by removing tar produced during pyrolysis and mineral components, that are intrinsic to this waste, so as to reach the highest removal of different categories of SHs. For this purpose, physicochemical properties of various biochars produced in our laboratory were investigated. The best material, subjected to a chemical and subsequent thermal treatment, provided a remarkable surface area (436 m^2 g^{-1}), together with a high environmental compatibility in terms of water leachable impurities. Maximum adsorption capacity (Q_m) for SHs were assessed in real wastewater matrices through kinetic and isotherm tests, using a commercial activated carbon (AC) as reference. Q_m values 2.5-1.1 lower than those of AC were observed, (except for Estrone for which Q_m values 1.5 higher). Additionally, different regeneration processes were evaluated to prolong the lifetime of sorbent reusability.

andrea.bergomi@unimi.it

Exposure to atmospheric particulate matter (PM) has been linked to various adverse health effects such as respiratory, cardiovascular, and neurological disorders[1]. In most studies, the effects are linked to mass concentrations of PM or particle dimensions. An emerging hypothesis is that these toxic effects are caused by the oxidising activity of specific chemical components of PM, which lead to the formation of reactive oxygen species (ROS) that are harmful to our bodies[2]. The overall oxidative capacity has been proposed as a metric that is more closely related to the biological responses caused by PM exposure and thus may be more informative than particulate mass alone.

The oxidative potential (OP) of particulate matter is defined as the ability of PM to oxidise target molecules by generating ROS. Many methods have been developed to measure OP including cell-free in vitro assays, which have the advantage of being fast, inexpensive, and easier than cell-based assays[3]. Two popular acellular ones are the dithiothreitol (DTT) and the ascorbic acid (AA) assays. In both tests, the redox-active species present in the PM (heavy metals and quinones) oxidise the reagents and the oxidative potential is determined as the rate of reagent depletion; respectively, OP^{DTT} and OP^{AA}.

DTT and AA assays were performed on particulate matter samples of different origins: urban PM filters from the city of Milan collected during a one-year sampling campaign, indoor PM samples from the *Santuario della Beata Vergine dei Miracoli* in Saronno (VA), and PM deriving from fixed-source emissions, namely wood-fired pizza ovens. The results from the one-year sampling campaign on urban PM filters show that the samples are more responsive towards the AA assays than the DTT assay. The yearly trends are also different between the two: OP^{DTT} does not change significantly between the different seasons, whereas OP^{AA} is higher during summer. Results also show a similar oxidative capacity of indoor PM with respect to outdoors. Finally, compared to the other two types of samples, particles emitted from wood-fired pizza ovens are more responsive towards the DTT assays than the AA assays probably due to the lower metal-content and higher contribution of the organic fraction.

Antibiotics are compounds, either natural or synthetic, with bactericidal or bacteriostatic properties widely used in human and veterinary medicine. The massive use of such drugs has resulted in environmental contamination both through diffuse sources (intensive agricultural areas, industrial districts) and through point sources (livestock facilities, aquaculture, urban and hospital sewage discharges). Urban sewage discharges are considered among the main sources of antibiotic entry into the aquatic environment as wastewater treatment plants, as currently designed, are inefficient or barely efficient in their removal[1].

Currently, antibiotics are recognized as emerging pollutants, as they can represent dangerous contaminants for the ecosystems in which they are introduced and play a crucial role in the development of resistant bacteria and resistance genes (Antibiotic Resistant Gene, ARG)[2].

In this study, real samples of wastewater, both incoming and outgoing from the Servola treatment plant, and samples of seawater taken along the submarine discharge pipeline in the Gulf of Trieste were analyzed. Samples were taken at various depths to assess contamination along the water column, allowing for the evaluation of anthropogenic impact along the "water pathway," from the WWTP inlet to the coastal areas of the Adriatic Sea.

The contamination assessment was updated by integrating investigations on the contribution of some commonly used antibiotics (Fluoroquinolones, Sulfonamides, Macrolides) and their respective prototypes. Simultaneously, to assess ecological impact, the presence of antibiotic-resistant bacteria is investigated. Antibiotic resistance assays involve the search for three specific genes that determine resistance to sulfonamides, fluoroquinolones and macrolides (respectively sul2, qnrS, and ermB).

The results obtained from the first year of the campaign show a reduction effect attributed to the wastewater treatment plant for both the targeted antibiotics and antibiotic-resistant genes, as well as a significant seasonal effect.

Quantification of Plastic Particles in Sewage Sludge via Py-GC-MS Analysis

I. Coralli,[1] I. Vassura,[2] T. Baldelli,[2] D. Fabbri[1]

[1]Dep. of Chemistry, University of Bologna, Tecnopolo di Rimini, Via Dario Campana 71, 47922, Rimini

[2]Dep.of Industrial Chemistry, University of Bologna, Tecnopolo di Rimini, Via Dario Campana 71, 47922, Rimini

In recent decades, micro- and nanoplastics (MPs and NPs) have emerged as persistent contaminants of increasing concern to the environment. Nowadays, they have been found almost everywhere.[1,2]

While identification method for MPs has been optimized for different analytical techniques (e.g. spectroscopical and thermal), quantification remains challenging, mostly because of the heterogeneity of the matrices from which this class of contaminants must be separated.[3] Some methods have been validated for the quantification of MPs in water thanks to the simplicity of the matrix, but dealing with environment, it is not possible to overlook on its complexity. Moreover, not all the plastic particles (PPs) in the environment are categorised as MPs; fragments smaller than 1 µm generate even more concern due to their potential to interact at cellular level.[4]

In this study, sewage sludges (SS) were selected as complex matrices of environmental interest. Domestic and industrial activities generate N-MPs which can be collected in wastewater, then treated at the wastewater treatment plant (WWTP). Despite these plants are not designed for the abatement of emerging contaminants, MPs can be satisfactorily reduced probably accumulating in SS.[1] Subsequently, SS can be used in agriculture as soil conditioners, posing an indirect contamination source of MPs in soil. Therefore, the analysis of MPs in SS is of environmental significance to understand the extent of this contamination.

The present study proposes a method for the identification and quantification of PPs in the 0.3 µm – 0.3 mm size range (large NPs and small MPs) in SS. The organic and inorganic carbon content of the matrix was utilised as a criterion for both characterising the SS and optimising of the method for the separation of PPs. The proposed method involved the use of Fenton reagent to minimise the organic load, enabling the analysis by pyrolysis-gas chromatography-mass spectrometry (Py-GC-MS), to detect PPs. After confirming the detection and chemical assignment of PP polymers, the study aimed to assess the matrix effect on the quantification of polymers. The standard addition method was used for the quantification of PPs and the results were compared with external calibration-based quantification. Findings revealed that the presence of the remaining organic matter differently affected polymer quantification. Finally, according to the previous outcomes, PPs were quantified in SS collected from WWTPs, to provide insight into the extent of N-MP contamination in agricultural soils resulting from the use of SS as soil improver.

Testing the EU Safe and Sustainable by Design (SSbD) framework for chemicals and materials in specific fields: an example on innovative solutions for art restoration

E. Semenzin,[a] M. Menegaldo,[a] E. Giubilato, [b] L. Pizzol,[b] E. Badetti[a]

semenzin@unive.it

On December 2022 the EC recommended the Safe and Sustainable by Design (SSbD) framework, developed by JRC[1], as a voluntary approach to guide the innovation process for chemicals and materials. It is composed of five steps encompassing hazard assessment, risk assessment for human health and the environment as well as environmental, social and economic sustainability assessment. Currently, the framework is in a testing phase, with the aim to refine it and make it applicable to a wide variety of substances.

The HEU GREENART (GREen ENdeavor in Art ResToration) project has been included among the case studies for such testing phase as it aims to propose new materials and chemicals (i.e., cleaning systems, protective coatings and consolidants, packaging and sensors) for the conservation of Cultural Heritage (CH), which are demonstrated to be safe and sustainable. As initial step, EU REACH and CLP regulations were used to look at the intrinsic properties of the chemical or material in order to understand its hazard profile. All formulation ingredients were assessed for Human Health, Environmental and Physical Hazards, by consulting SDSs and/or the ECHA dossier. Then, they were classified (Levels 0 to 3) according to the SSbD criteria for assessing intrinsic hazard properties. These initial results were communicated to the formulation developers along with observations for each SSbD hazard level. Finally, a self-classification of the mixture in accordance with CLP guidance was performed. Based on the outcomes of this initial phase, developers had the option to modify the original formulation in order to minimize any potential risks, or they could choose to eliminate it altogether, if functionality could not be preserved. Steps 2 and 3 of the SSbD framework were then performed to evaluate human health, safety and environmental aspects in both production and final application phases. Finally, a semi-quantitative screening sustainability assessment was performed by integrating environmental, socio-economic and functionality aspects, which will be complemented, for the most promising solutions only, by Life Cycle Assessment (LCA) and Life Cycle Cost (LCC). Building on the results of the previous H2020 NANORESTART project[2], this work is expected to contribute to the development of criteria to support the application of the SSbD framework to the CH sector and beyond (e.g., cleaning systems in cosmetics).

maria.labate@unito.it

The characterisation of degraded artefacts has specific complexity and needs, to be duly faced with a multi-analysis approach. Obtaining information about the alloys and corrosion products is very relevant to the study of Cultural Heritage both in terms of documentation and conservation. Corrosion products can consist of a great variety in composition and appearance of mineral phases, which must be investigated to define the most suitable restoration intervention. In particular, for copper-based artefacts, easy detection of active corrosion is a priority: also known as bronze disease, it is a dangerous form of corrosion disease caused by copper trihydroxychlorides. Several studies on this subject have recently been published using different analytical techniques[1] and also adopting spectroscopic methods and machine learning models[2 3].

This study employs colorimetry, Fiber Optics UV-Vis-NIR diffuse Reflectance Spectroscopy (FORS), Portable X-ray fluorescence Spectrometry (pXRF), μ-Raman Spectroscopy (μ-RS) and X-ray Powder Diffraction Analysis (XRPD). Machine learning clustering and classification models were adopted, trained using datasets comprising hundreds of measuring points from degraded copper-based artefacts from various museum collections. Non-invasive techniques results were integrated and re-interpreted in light of results also obtained by micro-invasive analyses to characterise the corrosion products and to classify different kinds of alloys.

The study identifies the colorimetric space regions that are most affected by certain types of corrosion and the spectral reflectance features of several mineral phases occurring in corrosion products. Furthermore, a method of easy identification of chlorine-based phases by Machine Learning classification of reflectance spectra is proposed. Finally, the study develops a classification model that accurately distinguishes between degraded Ptolemaic-era bronze coins according to their minting period. This model can accurately predict the periods of coins that are no longer legible and, therefore, cannot be studied numismatically.

jolanda.palmisani@uniba.it

The exploration of indoor plants' role in the abatement of airborne pollutants concentration and, as a result, in improving indoor air quality (IAQ) has recently become a matter of interest within the international scientific community [1-3]. Formaldehyde (FA) is a priority pollutant for the proven potential adverse effects on human health; it is an ubiquitous chemical compound inside indoor environments, emitted by building materials and products or generated by human activities (e.g., smoking cigarettes). Epiphytic Tillandsia species show to uptake compounds directly from the gas phase via their leaf trichomes for sustainment and growth, therefore they may play a key role in the removal of airborne pollutants including FA. The present study was performed with the main objective to investigate whether two Tillandsia species e.g., *Tillandsia Velutina* and *Tillandsia Ionantha* can efficiently adsorb FA and remove it from the gas phase. Static experiments with and without plants were carried out inside a test chamber under controlled micro-environmental conditions and lighting (natural or artificial). Temporal variation of gas-phase FA concentration was monitored by means of FA-selective high-temporal resolution detector (*Formaldemeter Htv-M, PPM Tecnologies*). In order to deepen the effect of FA absorption on plant cellular metabolism, investigations onto Tillandsia leaves, e.g., glutathione and soluble protein contents measurements, pre- and post- exposure to FA were additionally carried out. Experimental outcomes demonstrated that Tillandsia species were able to remove FA with a high efficiency. FA removal was promoted when artificial lighting was applied, suggesting that a controlled lighting in a selected spectral range result in a stimulated plant metabolism. The extent of FA removal was shown to be related with plant dimensions: the removal capacity increased with the increase in leaf surface and number of absorbing trichomes. FA, probably due to a fast metabolism and reutilization, was not accumulated in the leaves as the glutathione content significantly decreased (suggesting the occurrence of oxidative stress) and the content of soluble proteins simultaneously increased.

In conclusion, the experimental outcomes obtained in the present study combining test chamber investigations, e.g., monitoring of FA concentration into the gas-phase, with foliage investigations suggested that *Tillandsia Velutina* and *Tillandsia Ionantha* were both capable of absorbing FA via the specialized trichomes located onto the leaves' surface. Moreover, the absorbed FA is likely to be quickly metabolized and used for plant growth.

Near-infrared hyperspectral imaging to map collagen content in prehistoric bones for radiocarbon dating

Cristina Malegori[a], Giorgia Sciutto[b], Paolo Oliveri[a], Silvia Prati[b], Lucrezia Gatti[b], Emilio Catelli[b], Stefano Benazzi[c], Silvia Cercatillo[d], Dragana Paleček[d], Rocco Mazzeo[b] & Sahra Talamo[d]

lucrezia.gatti2@unibo.it

Many of the rarest prehistoric bones found by archaeologists are enormously precious and are considered to be part of our cultural and historical patrimony. Preserving the integrity of rare prehistoric bones while accurately determining their age is crucial for cultural and historical studies. Traditional radiocarbon dating, although effective, poses limitations due to its destructive nature[1]. Recently, NIR-HSI has been applied to obtain spectral maps that reveal the collagen distribution in large bones[2]. However, this method offers only an estimation of the distribution of collagen. Moreover, the pretreatment used in this study was not the same as the one used in radiocarbon laboratories.

In this study, we propose a non-destructive approach utilizing near-infrared spectroscopy (NIR) coupled with a camera with hyperspectral imaging (HSI) to quantify collagen presence in ancient bones and to localize its distribution. Combining the acquisition non-invasive approach with a multivariate partial least squares (PLS) regression model, we obtained chemical maps of the collagen distribution. This model quantifies the collagen at every pixel and thus provides a chemical mapping of collagen content, correlating the relative collagen amount and NIR absorptions. The proposed approach allows for precise collagen quantification and localization within bone samples, facilitating the selection of optimal regions for subsequent radiocarbon dating analysis.

Our findings promise significant contributions to the study of human evolution by minimizing bone material destruction, thereby safeguarding our cultural heritage and providing accurate chronological context to valuable artifacts.

ilaria.serafini@uniroma1.it

Archaeological textiles are invaluable relics from ancient cultures, cherished for their historical and cultural significance. However, their high delicate state of preservation and the degradation processes they have been subjected to require the use of highly sensitive analytical tools to conduct thorough studies.

The PARCA project is dedicated to examining both components of ancient wool textiles, dyes, particularly anthraquinone ones, and keratins (IFs) and keratin-associated proteins (KAPs), devising an innovative protocol that combines dye and protein analysis in a single extraction, thereby minimizing the number of samples while maximizing the information obtained.

Beginning with madder-dyed wool mock-ups, proteins and dyes were simultaneously extracted using either the recent TCEP/CAA method or a modified urea method. Following extraction, various clean-up methods, such as µ-SPE, stage tips, dLLME[1] or paramagnetic beads (such as SP3[2]), were employed to isolate both components, assessing their application wouldn't result in losing the analytical sensitivity for both. Proteins were digested with trypsin, either in-solution or on beads, and subsequently desalted using C18 SPE/C18 stage tips. Peptides were separated using ThermoScientific Acclaim PepMap 100 trap and analytical columns at 300 nL/min, while dyes were separated using a Waters BEH Shield RP18 column with an Ultimate 3000 system at 200 uL/min. Both were detected on an Orbitrap Elite mass spectrometer. The methodology was further tested on laboratory samples subjected to a progressive thermal ramp, from 200°C to 300°C at different times, thus trying to simulate the conditions of charred archaeological samples to determine the survival threshold of proteins and dyes at the various thermal aging steps. These data are correlated to FTIR and SEM information, to establish a correspondence between non-destructive and proteomics analyses. Preliminary results of the application of such methodologies on wool samples from Vesuvian area are presented.

We will present a technology for fabricating sustainable Surface-Enhanced Raman Spectroscopy (SERS) sensors based on paper substrates, for Cultural Heritage (CH) applications. Silver nanostructured thin films were deposited via pulsed laser ablation[1] onto flexible cellulose fiber substrates reclaimed from waste sources. Several typologies of paper structures were tested. By optimizing deposition conditions, SERS efficiency was maximized for the rough, porous paper textures. Samples were characterized by UV-Vis absorption spectroscopy and SEM to evaluate deposited films morphologies. SERS performance was evaluated for model analyte Rhodamine 6G at concentrations from $10^{\wedge -2}$ to $10^{\wedge -10}$ M using a portable Raman system with 785 and 835 nm lasers. The lowest detectable concentration achieved for Rhodamine 6G was $10^{\wedge -10}$ M (Fig. 1).

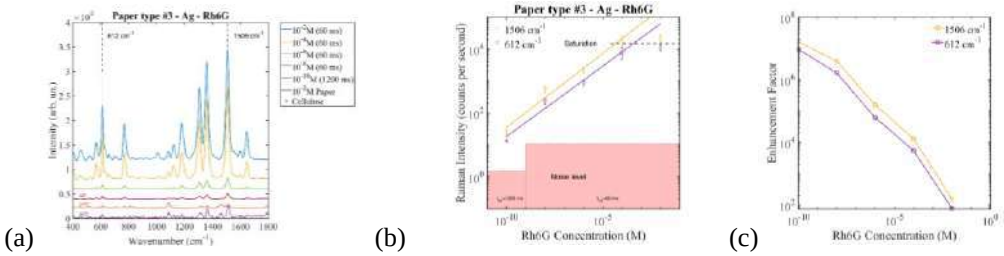

Figure 1: (a) Spectra acquired on Paper#3 at different Rh6G concentration; (b) Calibration curves obtained from the intensities of the 612 and 1506 cm^{-1} Raman peaks vs Rh6G concentration. (c) Behaviour of the Enhancement Factor.

This procedure demonstrates strong performance for CH materials characterization, diagnostics, and preservation applications, through trace chemical detection. Some real-world case studies will be presented, involving materials from archaeological sites and museum. This work has been funded by NextGeneration EU, through the MUR-PNRR project SAMOTHRACE (ECS00000022).

In recent years, the development of eco-friendly composites using biodegradable polymers and natural materials has gained significant attention to mitigate environmental pollution effects.

Here, we explore diatomaceous earth (Diat) as a filler for polycaprolactone (PCL) to obtain composites useful for environmental applications. Both components are biocompatible materials with relevant adsorption capacities towards inorganic and organic pollutants. Diat, well known for its non-toxicity and eco-friendliness, possesses high absorption capacity, low thermal conductivity, and low density due to its high porosity. Derived from the amorphous silica cell walls of dead diatoms deposited on marine sediment, Diat is composed of silicon dioxide (>90%), alumina and trace iron oxides, with particle sizes ranging from 3 to 200 μm[1]. Its unique structure makes Diat suitable for diverse applications, including drug delivery systems, environmental remediation, and polymer reinforcement[2].

In this study, composites were prepared by blending different Diat amounts (5, 15 and 50 wt%) with molten PCL. We present here the promising viscoelastic and thermal properties of these composites.

Dynamic Mechanical Analysis (DMA) was employed to assess the viscoelastic characteristics of PCL/Diat hybrids, while Differential Scanning Calorimetry (DSC) and Thermogravimetric Analysis (TGA) were used to determine the thermal properties. Incorporating Diat within the polymeric matrix improved PCL elasticity at temperatures below its melting point, with a more evident effect in composites with higher Diat content. DSC results showed that Diat can act as a nucleating site for PCL crystallization, resulting in enhanced melting and crystallization enthalpies. On the other hand, the melting and crystallization temperatures of the polymer were slightly affected by the filler concentration. Notably, mixing with Diat generated relevant effects on the PCL thermal stability, as evidenced by TGA data, due to the filler's barrier effect.[3]

Overall, the results obtained by thermal analysis methods highlighted the interfacial compatibility between PCL and diatomaceous earth. Melt blending of PCL with Diat emerges as an easy and efficient strategy to obtain biocompatible composites with enhanced properties, compared to the pure polymer. Such composites hold promise for various applications, including air pollutant remediation in museum environments.

Natural Clays for the Removal of Inorganic and Organic Pollutants from Leachate of Waste Collection Centers

V. Canaletti[a], A. Bonetto[a], A. Brunelli[a], E. Semenzin[a], A. Marcomini[a], E. Badetti[a]

vanessa.canaletti@unive.it

Billion metric tons of municipal solid waste (MSW) are annually generated worldwide, raising concerns about potential exposure to human health and the environment from hazardous substances that may result during their storage. Indeed, MSW are often stored in waste collection centers in open-top containers placed in open-air yards, being exposed to various weather conditions, including rainfall, which can lead to the release of high concentrations of pollutant. To decrease the exposure towards these hazardous substances, according to the corresponding Italian legislation, wastewater must be collected, routinely monitored through periodic sampling, and treated before the final discharge. Among the different methods for removing pollutants from wastewater, clays have garnered increasing attention worldwide due to their availability, low cost, and excellent adsorbent properties. In wastewater resulted from waste collection centers, metals, in particular iron, aluminium, and zinc, are among the primary pollutants. In this context, this work aims to identify the most suitable type of clay, or a combination of them, that allows the best removal capacity of Fe^{3+}, Al^{+3}, Zn^{2+}, Cd^{2+} and Pb^{2+} in aqueous medium. The capability of bentonite, chabazite, kaolinite, and clinoptilolite in adsorbing the single metals and the competition for the adsorption sites given by their simultaneous presence were evaluated. The effects of the experimental conditions - initial concentrations, contact time, adsorbent mass, solution pH, and ionic strength - were investigated in the study. Moreover, considering that these metals are commonly employed for intercalation into the interlayers of clay minerals[1] to create new adsorption sites that enhance the adsorption of organic molecules[2], the adsorption capacity of an emerging organic pollutant was also studied. This involves evaluating if the co-adsorption of organic and inorganic pollutants could increase the removal efficiency of the different tested clays compared to their starting materials.

vittoria.guglielmi@unimi.it

This research's main concern is the characterisation of findings from one of the most important prehistoric sites in mediterranean Europe, i.e. Riparo Mochi in Ventimiglia (Imperia - Italy), with the final goal of obtaining a reliable representation of the original combustion structures at the site. The results of the study will allow the researchers to go deeper in the understanding of the use and management of fire by humans in the Upper Palaeolithic period. Archaeological materials from the site (heated stones and soils, ashes, bones, reddened earths, and possibly pigments) have been characterised using a wide range of analytical techniques, both in laboratory and in-situ. Specifically, electron microscopy coupled to X-ray micro-probe (SEM-EDXS), X-ray Diffraction (XRD), porosimetry, Fourier Transform Infrared (FTIR) and Raman spectroscopies, colorimetric and visible reflectance techniques, in addition to density measurements [1] have been employed. The use of portable instruments, e.g. systems for Raman, FTIR and visible-NIR spectroscopies, which are acknowledged to be suitable for the characterisation of these materials, made it possible to perform the analyses of the archaeological finds effectively and in a totally non-destructive manner on the site. The results emerging from the chemical analyses have been post-processed through Artificial Intelligence (AI) strategies. In particular, the results from the different chemical characterisation techniques will be brought together to enhance both the sensitivity and selectivity of predictive models. Specific parameters/markers, hereafter named as ARchaeological Markers (ARMs), have been identified to determine the concentration of the studied materials. For example, the presence of natural or artificially made hematite, specific silicates or botanical and biological residues were significant. Neural network-based algorithms have been trained through a set of selected datasets coming from reference chemical species' mixtures with known compositions of ARMs and their efficacy have been tested by the outcomes' validation sets. Both training and validation sets have initially been made up exploiting single-ARM and, thereafter, multiple-ARM samples, encompassing, therefore, the effects of possible cross-sensitivities in the model-identification step. The identification and validation path also considered the inherent uncertainty of input data, particularly focusing on the contributions due to repeatability/reproducibility of the chemical analyses and calibration methods.

Modelling the photodegradation of acetaminophen, carbamazepine, bentazone and clofibric acid in a river under water scarcity conditions

silvia.bertolotti@unito.it

Wastewater treatment plants (WWTPs) are known to behave as point sources of pollution for surface waters as rivers, introducing a) extra amounts of nutrients and b) contaminants of emerging concern (CECs) that are not completely removed by the wastewater treatment processes. After reaching the water body, CECs can undergo a range of transformations. These include photochemical reactions triggered by sunlight, which may either achieve the degradation of the compounds into products with lower ecotoxicity, either generate more harmful intermediates that threaten the health of the aquatic ecosystems.[1]

During drought periods, the frequency and the duration of which is expected to increase in the near future, the impact of WWTPs on riverines ecosystems may be exacerbated due to the decreased dilution capacity of the watercourse.[2] Beside this, the photochemical reactions occurring in water may be affected, as the alterations of water flow and flow velocity may reflect on the photochemical fate of pollutants released by the WWTPs.[3]

In this work, the photochemical transformations of four contaminants (acetaminophen, carbamazepine, bentazone and clofibric acid) were modelled as a function of water chemistry and hydrological conditions (water depth and flow velocity) measured in a one-year sampling campaign on the Stura di Lanzo river, a 3rd order stream belonging to the Po basin and located in Piedmont, NW Italy. The samplings were carried out upstream (U), at the discharge point (W) and downstream (D) of a local WWTP during the year 2022, which was characterised by a severe drought provoking water scarcity conditions in many Italian basins. Using the software Apex (*Aqueous Photochemistry of Environmentally-occurring Xenobiotics*), the steady-state concentrations of the photochemically produced reactive intermediates (PPRIs; i.e., $^{\cdot}OH$, $CO_3^{\cdot-}$, $^1O_2$ and triplet states of dissolved organic matter) were predicted, along with the kinetics of direct and indirect photolysis of the investigated compounds. The results showed that, beside the expected seasonal trends (lowest phototransformation during winter months), the effluent discharge from the WWTP in the Stura di Lanzo river affected the photochemistry of the contaminants in terms of PPRIs involved in their photodegradation.

A urgent issue in cultural heritage investigation consists of the need for acquiring information regarding the in-depth distribution of organic and inorganic components, without any invasive sampling. To address this requirement, a new analytical set-up, able co-register VNIR, SWIR, and XRF spectral data, was exploited in combination with a multivariate and multiblock data processing strategy, for the analysis of multilayered paintings.

The instrument simultaneously records X-ray fluorescence (XRF,1.4-40 keV) data, together with visible & near-infrared (VNIR, 380–1100 nm) and short-wave infrared reflectance (SWIR, 1100–2500 nm) spectra, obtaining elemental and molecular information from superficial to subsurface layers across the investigated area. Data from these three spectral ranges were co-registered, thus inherently saved with high spatial coherence.

The chemometric strategy applied efficiently reduced data and extracted valuable information from the three different spectroscopies. For an effective data visualization and inter-correlation assessment, the approach combined principal component analysis (PCA), brushing, correlation diagrams, and maps within and between spectral blocks, using both low-level and mid-level data fusion. Correlation diagrams and maps are particularly useful for reconstructing a stratigraphic structure without sample collection. They account for inter-correlations among data variables, characterizing possible component combinations at the same depth level. The strategy was applied for the multi-level characterization of a complex painting reproduction study and of the painting of San Sebastiano attributed to Raffaello Sanzio (1483-1520) and exhibited at the Accademia Carrara (Bergamo, Italy).

Outdoor public art and painted murals, in particular, can improve the city's environment, bring communities together and deepen public understanding of community identity and culture[1]. Due to this important social role, murals are subjected to conservative actions through various and still under discussion methodologies since these artworks are not juridically defined as cultural heritage and, therefore, subjected to the current guidelines for traditional mural paintings. These interventions lead to different results regarding many variables: the painting techniques, the substrate layer typology, the environmental conditions, the materials used for the interventions, etc. This research aims to investigate the durability of conservative interventions, particularly for surface protection and consolidation, carried out with different materials and applied methods on murals located in urban, rural and mountain environments and prepared with various painting materials and techniques. Crossing these data allows us to individuate the best procedures for the different scenarios and, eventually, to modify the properties of already used materials to make them more suitable for specific situations. Non-invasive *in situ* surveys and analyses, such as optical microscope, Raman spectroscopy and multi-spectral analyses, are used [2] to evaluate the current state of conservation of the murals and a database has been built to collect all the information, including the climatic conditions after the interventions in each case study analyzed.

Thanks to the collaboration of municipalities, foundations, and restorers involved in the maintenance and valorization of modern murals, it has been possible to collect a lot of information and access numerous case studies in very different environmental conditions[3,4,5] and contribute to the suitable and durable preservation of this most important kind of art.

alessandra.marano@unina.it

The Rare Earth Elements (REEs) hold promise as tracers in geothermal systems, yet progress has been hindered by the scarcity of data on REE behavior in thermal waters, as well as on REE mineral solubility and complex stability under high temperatures and pressures. Major and trace element geochemistry of geothermal waters is crucial for sample classification and for comprehending subsurface mass transport during groundwater circulation.[1]

A better understanding of the behavior of REEs in thermal waters could have significant implications for geothermal resource exploration and the investigation of water–rock interactions in geothermal systems. Consequently, the main objective of this study is an evaluation of REEs concentrations in waters sourced from different continental geothermal systems.[2]

The matrices under investigation are analytically complex, requiring pre-treatments to eliminate interferences resulting from high saline content before instrumental analysis via inductively coupled plasma-mass spectrometry (ICP-MS). Each sample, after acidification with high-purity grade HNO_3, was divided into two aliquots: one underwent filtration while the other was analyzed as is. Corrections for isobaric oxide interferences were implemented for BaO on Eu and Sm, PrO on Gd, and NdO on Tb, with In serving as an internal standard. A comparison between filtered and unfiltered aliquots was conducted to discern the form in which REEs are present within the sample, both in solution and as suspended particulates.

Approximately 70 samples of thermal waters from two Italian regions, Campania, and Veneto, were analyzed, with temperatures at the source ranging from 22.7°C to 86.4°C. In addition to REEs, minor and major elements such as Ag, Al, As, B, Ba, Ca, Cd, Cr, Cu, Fe, Li, Mn, Mo, Ni, Pb, Sb, Se, Sr, Rb, Tl, V, and Zn were analyzed using ICP-MS with Y and In serving as internal standards. Fluoride, chloride, bromide, nitrate, sulfate, and phosphate were determined using ion chromatography.

In both fields, trace element concentrations are higher in the geothermal waters than in the cold waters. Rb/Cs ratio in the geothermal waters was evaluated, as an indicator of water–rock interaction.

The REE concentration distributions were normalized to chondrite and to the European shale composition, with particular attention to Ce and Eu, whose anomalies in the patterns may be used as an indicator of rocks in the water circulation environment.

rosanna.topa@unina.it

The determination of essential and toxic chemical elements in environmental, biological and food matrices is nowadays of considerable importance as an indispensable tool for the assessment of risk factors for human health, as well as for the drafting of consequent standards and legislation.

The living environment substantially determines an individual's state of well-being or illness, and the environment-health pair is now considered inseparable. Water, food, air, and soil are examples of pathways through which individuals are exposed to pollutants that may affect their health. Men and their state of health can be considered essential indicators of the environmental state, evaluating the presence of contaminants within biological matrices[1]. Each biological matrix retains a different pollution trace capable of being conserved for variable times[2]. Urine, in particular, matrix represents the biological matrices of choice for clinical and forensic investigations. This is 'stable' matrix since it has less variability than other matrices, for example, nails and hair, which are subject to sources of external contamination. Main objective of this work is the evaluation of the environmental exposure of subjects residing in two different areas of the Campania region: Land of Fires and Sele Valley. The volunteers recruited for this purpose are, in fact, healthy boys and girls aged between 18 and 22, with body mass indexes and homogeneous lifestyles. To evaluate the environmental exposure of the subjects of interest, the concentrations of trace elements (Hg, Li, Be, Al, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Rb, Sr, Cd, Sn, Sb, Te, Ba, Pb, U) and alkali and alkaline-earth elements (Na, K, Ca, Mg) have been evaluated in different biological fluids in order to evaluate the bioaccumulation of these elements in the human body. For the determination and quantification of these trace elements, analytical methods have been implemented and validated for the different biological matrices using the ISTISAN 15/30[3]. report as a starting point and the subsequent instrumental determination by inductively coupled plasma mass spectrometry (ICP-MS) and microwave-generated plasma-coupled atomic emission spectrometry (MP-AES).

Presenting author e-mail: agiannattasio@unisa.it

Contamination of water with polymer micro- and nano-metric debris (PDs) is an emerging issue in environmental chemistry and public health. Polyolefins (such as polyethylene (PE) and polypropylene (PP)) and polydimethylsiloxane (PDMS) find a wide range of practical applications in everyday life and are thus the most abundant PDs in wastewater (WW). They have densities lower than water and are typically isolated by flotation. A novel procedure to recover and quantify PE and PDMS in wastewater treatment plants (WWTPs) has been developed and herein described.[1] The analytical protocol, based on quantitative NMR analysis, has been applied to a real case study (50 samples) from two campaigns of sampling in WWTPs located at Tavernola (Battipaglia (SA), Italy) and Punta Gradelle (Vico Equense, (NA), Italy) where different approaches to the WW treatment are used, namely the bed adhered biomass (MBBR) and membrane bioreactor (MBR) technologies[2], respectively. Samples of influent, intermediate stage and effluent WW were collected, the PDs isolated by flotation, filtration and finally analyzed by solution ^{1}H nuclear magnetic resonance spectroscopy (^{1}H NMR) in 1,1,2,2-tetrachloroethane-d_2 solution. Assessment of the PDs concentration at a limit of quantification (LOQ) of 1 mg/m^3 level has been successfully obtained, whereas their presence is typically reported in the current literature as a number of microparticles per volume of water. As expected, PDs of PE are the most abundant, and PE concentrations of 1.80 ± 1.10 g/m^3 (Tavernola Plant) and 3.48 ± 2.70 g/m^3 (Punta Gradella Plant) were actually determined with this novel method after sampling the effluent water twice a week. In the same samples, PDMS concentrations of 257 ± 236 mg/m^3 and 498 ± 613 mg/m^3 were found in the Tavernola Plant and Punta Gradella Plant, respectively. The abatement of PE in both plants was also investigated. Higher removal yields and greater efficiency were found in the Punta Gradelle plant equipped with the MBR technology. The Punta Gradella Plant showed filtration efficiency of 97.5± 2.5% for PE and 87.8 ± 7.9 % for PDMS; by contrast, the Tavernola Plant showed values of 94.9 ± 0.7 % for PE and 67.3 ± 17.8% for PDMS. The proposed method has achieved unprecedented simplicity, rapidity and sensibility of analysis. Moreover the study of microstructure and molecular weights of the PDs allowed drawing some hypothesis of the origin of these pollutants.

The role of hydrogen peroxide and thermally activated persulfate in phenol removal

Antonino Fiorentino[a,b]*, Antonio Faggiano[a,b], Ana B. Martínez-Piernas[c], Maria Ricciardi[a,b], Oriana Motta[b,d]*, Antonio Proto[a,b]

This study investigates the effectiveness of a novel approach that combines hydrogen peroxide (H_2O_2) with thermally activated persulfate (T-PDS) for the removal of phenolic contaminants from wastewater. Diverging from previous research, this investigation adopts a comprehensive chemometric strategy, utilizing both Response Surface Methodology (RSM) and Principal Component Analysis (PCA) to fine-tune the treatment process parameters, including temperature, pH levels, and the concentrations of H_2O_2 and $S_2O_8^{2-}$. The investigation pinpointed the most effective conditions for the degradation process: a temperature of 70°C, a pH level of 5, and a molar ratio of H_2O_2 to $S_2O_8^{2-}$ at 1:6, with concentrations set at 50 mg/L for each compound. Under these parameters, the degradation efficiency of phenol (PhOH) was observed to be around 89%, reducing its concentration to 1.2 mg/L (initial concentration 10 mg/L). Kinetic studies illustrated a nonlinear reduction in PhOH levels, suggesting a multifaceted reaction mechanism. A significant drop of approximately 38% in PhOH levels was recorded within the initial 15 minutes, followed by an additional 15% decrease over the next quarter-hour, indicating a brisk pace of reaction. The reaction rate then slowed, with PhOH levels plateauing between 75 and 120 minutes, potentially due to the depletion of oxidants or the accumulation of intermediates. The consumption and reactivity patterns of $S_2O_8^{2-}$ and H_2O_2 were found to differ, underscoring their distinct roles in the reaction mechanism. The accuracy of the model was confirmed by high R^2 values of 0.99 for both PhOH and $S_2O_8^{2-}$, and RMSE (Root Mean Square Error) values of 0.017 and 0.033, respectively. Hydrogen peroxide exhibited a slightly lower R2 value of 0.98 and a higher RMSE of 0.046. These results highlight the potential of the H2O2/T-PDS system for efficient and scalable phenol removal from wastewater, providing a solid foundation for its application in industrial settings. The findings underscore the significance of employing H_2O_2/T-PDS in broader pollutant management strategies, advocating for environmentally sustainable treatment solutions.

Worldwide water pollution has become one of the most prominent problems over the past decades. The so-called contaminants of emerging concern (CECs) are a broad group of anthropogenic pollutants detected in the environment, that cannot be properly removed by conventional wastewater treatment plants and tend to accumulate ubiquitously in ground and surface water, causing damage to the ecosystems and human health[1]. The use of zero valent iron (Fe^0) has been proposed to remove a wide range of recalcitrant pollutants[2]. In this work, the removal of two CECs, a chlorinated nitroaromatic antibiotic (chloramphenicol succinate sodium salt, CAP) and an azo dye (Acid Orange 7, AO7) by Fe^0 has been investigated, also evaluating the effect of initial pH on degradation. Additionally, ecotoxicity surveys were carried out on samples after the treatment using *Artemia franciscana*, as indicated by the Italian regulatory authorities for wastewater monitoring[3].

In each test, 100 mL of CAP or AO7 solution (20 mg/L) were treated with a certain amount of Fe^0 (0.1125 g/L, 0.225 g/L,0.45 g/L, and 1 g/L). Each test lasted 80 minutes and samples were collected at regular intervals. CAP or AO7 residual concentration was monitored through UV-Vis spectroscopy, by following the intensity of their characteristic peaks at 275 nm and 484 nm, respectively. The degradation of both contaminants improved with increasing Fe^0 dosage, allowing to reach removal rates up to 50%, 75%, 93%, and 95% for CAP and 25%, 43%, 65%, and 96% for AO7. In both cases, the degradation kinetic can be divided in two stages: a rapid discoloration happened in the first 10-15 minutes of treatment, then the reaction slowed, reaching a plateau. The efficiency of the contaminants' removal was also evaluated adjusting the starting pH to ≈3 or ≈9, using 0.225 g/L of Fe^0. In both cases Fe^0 efficiency was higher at acidic pH, achieving up to 87% and 84% removal of CAP and AO7, respectively. In alkaline conditions, the reactions yielded similar results to natural (≈7) pH. Untreated CAP and AO7 solution caused 100% of mortality in all life stages of *A. franciscana*. The treatment with Fe^0 greatly reduced the toxicity of the starting solutions, decreasing the mortality of ~65-85%. The residual toxicity observed can be ascribed to the Fe^0 that remained in the effluents.

Photochemical fate of benzene and phenol as polystyrene degradation products, in a surface water – atmosphere two-phase compartment

D. Vione, L. Carena, M. Minella

Dipartimento di Chimica, Università di Torino, Via P. Giuria 5, 10125 Torino
davide.vione@unito.it

Micro- and nanoplastic particles are a considerable emerging problem in the environment, because their small size facilitates interaction with living organisms with harmful effects. Exposure of water-suspended plastics to sunlight may cause fragmentation, which is a source of microplastics and nanoplastics, but it may also induce formation of dissolved compounds [1]. The latter phenomenon is interesting because it could end up in eventual removal of plastic particles from environmental waters, thus its details deserve investigation. We have previously shown that exposure of polystyrene aqueous suspensions to sunlight produces a range of aromatic and aliphatic compounds that could derive either from the polymer skeleton, or from additives and plasticisers [2]. This presentation will introduce an approach to predict the fate of two toxic/carcinogenic photodegradation products of polystyrene, i.e., benzene and phenol, using a two-compartment model that considers both surface waters and the atmosphere.

Most benzene produced by irradiation of aqueous polystyrene would end up in the gas phase, where it would react with the hydroxyl radical ($^{\bullet}OH$); phenol is the main product of the reaction between benzene and $^{\bullet}OH$ in both water and air. In water, phenol would mainly react with the triplet states of chromophoric dissolved organic matter ($^{3}CDOM^{*}$) [3]. In the gas phase, the main removal pathways of phenol would be reaction with $^{\bullet}OH$ in daytime and with the nitrate radical ($^{\bullet}NO_3$) during the night [4].

The reaction between phenol and $^{\bullet}NO_3$ yields nitrophenols, which can undergo partitioning to atmospheric waters (e.g., cloud water), whence they could reach surface-water environments by precipitation (especially, 4-nitrophenol and 2,4-dinitrophenol). This scenario was modelled by considering a gas-water partitioning equilibrium, as described by the Henry's law constants (K_H) and by the volume fraction of liquid water in the atmosphere ($f_W = 5\times10^{-7}$) [4]. We could thus model the time evolution of aqueous phenol from benzene + $^{\bullet}OH_{(w)}$, followed by phenol degradation with $^{3}CDOM^{*}_{(w)}$, as well as phenol formation in the gas phase followed by liquid-water partitioning and precipitation of its transformation products.

Polydimethylsiloxane (PDMS) organogel sponges were prepared and studied in order to understand the role of pore size in an elastomeric network on the ability to uptake and release organic solvents. PDMS organogels sponges have been produced according to sugar leaching techniques by adding two sugar templates of different forms and grain sizes (a sugar cube template and a powdered sugar template), in order to obtain materials differing in porosity, pore size distribution, solvent absorption and liquid retention capability. These materials were compared to PDMS organogel slabs that do not contain pores. The sponges were characterized by Fourier Transformed Infrared spectroscopy in the Attenuated Total Reflectance mode (FTIR-ATR) and compared with PDMS slabs that do not contain pores. Scanning Electron Microscopy (SEM) provided information about their morphology. X-ray Micro-Tomography (XMT) allowed us to ascertain how the form of the sugar templating agent influences the porosity of the systems: when it was in the form of cubes, the porosity was 77% and the mean size of the pores was ca. 300 μm; when it was in the form of powder, the porosity decreased to ca. 10% and the mean pore size was reduced to ca. 75 μm. These materials, porous organic polymers (POPs), are able to absorb many solvents in different proportions as a function of their polarity. The absorption capacity, as measured by swelling of eight solvents, covering a wide range of polarities, was investigated. Rheology data established that solvent absorption did not have an appreciable impact on the gel-like properties of the sponges, suggesting their potential for applications in cultural heritage conservation. Application tests were conducted on the surfaces of two different lab mock-ups that simulate real painted works of art. They demonstrated further that PDMS sponges are a potential innovative support for controlled and selective cleaning of works of art surfaces.

In the field of cultural heritage conservation, the cleaning of artworks has become an essential practice as part of preservation processes, because artefacts are often affected by different unwanted materials. Cleaning of cultural heritage items usually concerns the removal of substances deriving from natural pollution (e.g., surface dirt, grime, and soil) as well as from past non-original treatments (e.g., polishing treatments, adhesives, and decayed varnishes).

Following previous research works, we focused our attention on gel materials as cleaning tools for the cultural heritage. Gels were introduced by the pioneering works of Wolbers at the end of 1980s as cleaning systems to remove dirt and degraded materials from different substrates such as metals, stones, and paper.[1]

Generally, the gels were prepared from different polymers loaded with solvents, including water, or organic solvent/water mixtures (e.g. emulsions). More recently, "green" gels have been prepared from natural polymers, although the rather complicated structure and composition of these matrixes may induce a more difficult control of some gel properties such as mechanical features and water content. Commonly used water-containing natural gels (hydrogels) are based on agar, gellan gum, xanthan gum, and chitosan. The hydrogels based on these natural polymers have been considered as cleaning tools by conservators over the last few decades.[2, 3]

The present study is focused on the preparation and characterization of new gels based on the natural polysaccharide alginate, whose structure was chemically modified in order to control the properties of the resulting hydrogels. In particular, different crosslinking materials were used to prepare a series of hydrogel characterised by different mechanical properties and water content values. The control of water content (and water release) of hydrogel is expecially important when the cleaning of potentially water-sensitive substrates is considered. Functionalization of alginate was performed by using as much as possible "green conditions", aiming to develop highly sustainable materials. A multi-analytical approach was used to characterize the structure and the properties of hydrogels. The tuning of alginate properties by its chemical modification opens the opportunity to use the corresponding gels for the surface treatment of different substrates like wood, stones, and paper.

The anthropic impact on Antarctica: a biennial study on emerging contaminants' occurrence

M. Baglietto[a], H. MacKeown[a], B. Benedetti[a], C. Scapuzzi[a], B. Cossu[a], M. Di Carro[a], E. Magi[a].

matteo.baglietto@edu.unige.it

Human activities influence (often negatively) the environmental processes. The most visible consequences occur in highly-impacted regions, where industries and residences are more abundant. Still, even small settlements in remote areas can have an impact on the surroundings, like the Mario Zucchelli Italian research Station (MZS) in Terra Nova Bay (Antarctica). The PNRA (National Research Program in Antarctica) project called 'MATISSE' (Emerging contaminants in the Ross Sea: occurrence, sources and ecotoxicological risks) is devoted to assess such an impact[1]. In this work, the results of the samplings performed in the outlet of the MZS's wastewater treatment plant (WWTP) and the surrounding Road Bay seawaters (where the WWTP discharges) during two consecutives campaigns (37th and 38th Italian expedition in Antarctica) were compared. Samplings were carried out by following two approaches: (i) spot sampling and consequent solid-phase extraction and (ii) passive sampling (exploited by the first deployments of Polar Organic Chemicals Integrative Samplers – POCIS –in this remote region for 2-3 weeks), which encompasses an in-situ pre-concentration during the sampling itself. The final extract of each sample processed was properly diluted and analysed by LC-MS/MS, targeting approximately 40 emerging contaminants, belonging to various classes and presenting different physico-chemical properties. The first campaign involved an intensive sampling, which was reorganized during the second one according to the obtained results[1]: the processing method was slightly modified to increase the recovery of the most polar analytes, and the sampling point at Road Bay was moved closer to the WWTP outlet to reduce the seawaters' dilution effect. This allowed to double the number of compounds detected in marine samples, while the analytes within the WWTP effluent were more or less the same from one year to the following one. Detected substances included food- and recreational activities-related compounds (methylxanthines, artificial sweeteners, taurine, nicotine), pharmaceuticals (non-steroidal anti-inflammatory drugs, β-blockers, β-agonists…), hormones, UV-filters and industrial additives (like PerFluoroAlkyl Substances and BisPhenol-A) at concentrations ranging from dozens of ng L^{-1} to dozens of µg L^{-1}. During the two campaigns, most of these analytes were quantified at comparable levels. In order to get a more comprehensive evaluation and interpretation of the results, both principal components analyses and correlation matrices were implemented, highlighting the relations among the compounds and those with the number of personnel in the base, as well as between the two sampling approaches, whose quantifications resulted correlated for many compounds[1].

Life cycle assessment (LCA) is applied in this study to evaluate the Global Warming Potential (GWP) of a system[1] that use advanced oxidation processes (AOPs), such as photo-Fenton enhanced by UVC light[2], for the degradation of 1 mgL^{-1} of acetaminophen, as an example of contaminant of emerging concern (CEC), under different conditions[3]. Results showed in Figure 1 depicts the GWP of acetaminophen removal under different scenarios. This indicate that energy is the most important factor to be taken into account in order to reduce the overall greenhouse gases emission. This analysis confirmed the results obtained in the previous study since photo-Fenton process is the best as it is the fastest and emits the least kg CO_2-eq. Finally, in future works the study will be extended to treat larger volumes in order to approach a WWTP.

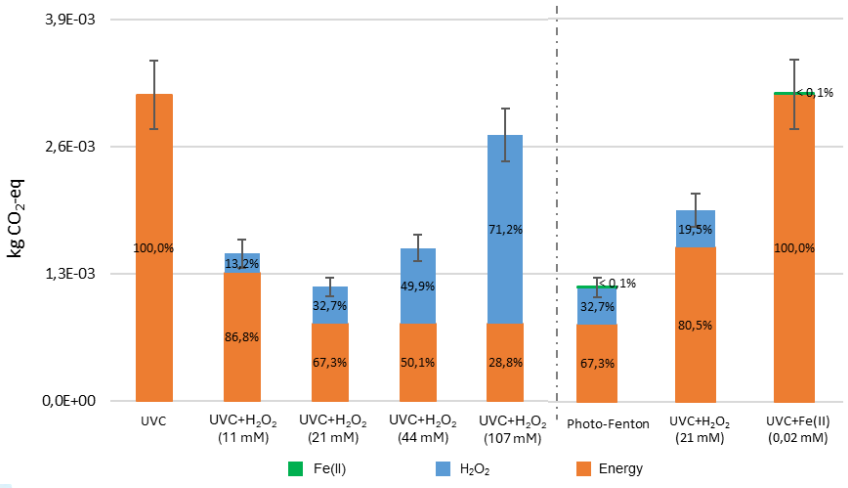

Figure 1: GWP of acetaminophen removal under different conditions.

Nowadays, outdoor built cultural heritage is particularly affected by degradation phenomena threatening the conservation of the stone elements because of the changes in environmental conditions (e.g. increase in the air pollution, climate changes) along with predisposing factors linked to the intrinsic characteristics of the material (porosity, composition, etc.). These changes have resulted in an acceleration of degradation processes, including those of biological origin. The Baroque monuments of eastern Sicily, built in local limestones, represent a significant conservation challenge since physical, chemical decay and biodeterioration are easily observable. In this context the attention to the environmental issue encourages the definition of more sustainable conservative strategies[1] focused on safer and cheaper alternatives to traditional chemical biocides. The objective of this research is to synthesize biopolymeric membranes as controlled-release systems for natural biocides, to test on Modica, Ragusa and Comiso stones widely used in the Sicilian Baroque. The main compositional and physical features of the limestones were previously and opportunely determined to assess the efficacy of the developed polymeric systems.

In this study, a biopolymeric membrane based on Polylactic acid (PLA) and combined with limonene was synthesized and characterized using analytical techniques[2] such as Fourier-transform infrared spectroscopy (FTIR) and nuclear magnetic resonance spectroscopy (NMR). FTIR analysis enabled the identification and interpretation of molecular interactions between limonene and the PLA matrix through vibrational band analysis, while NMR highlighted the presence of limonene in the membrane. The next steps foresee to prepare membranes with different amounts of limonene and to evaluate their biocidal efficiency in biological tests conducted on limestone samples undergone biocolonization in laboratory-controlled environment.

Neural Network Modeling of Nanobubble Characteristics in Venturi Tube-Assisted Hydrodynamic Cavitation for Organic Chemicals Degradation

S. Moftakhari Anasori Movahed,[a] L. Calgaro,[a] A. Marcomini [a]

a Department of Environmental Sciences, Informatics, and Statistics, University Ca' Foscari of Venice, Via Torino 155, 30172 Mestre Venice Italy

saman.movahed@unive.it

Hydrodynamic cavitation has been shown as a suitable technology to remove organic contaminants from water, especially in the presence of nanobubbles. Nanobubble generation has been investigated using devices, including Venturi tubes, showing a strong correlation between nanobubble characteristics (e.g., diameter, Zeta potential, and size distribution) and the Venturi tube's geometry. However, building and testing different designs can be resource and time-consuming; therefore, three neural network models were developed to estimate nanobubble characteristics from Venturi tube configuration parameters in this study.

A design of experiment (DoE) approach was employed to select the most relevant Venturi tube configurations considering throat diameter (Dt), throat length (L1), divergence length (L2), and divergence angle (α°). In detail, 10 out of the 30 considered designs were built and tested in a cavitation system to obtain the data needed to train and validate the neural networks. Dynamic light scattering (DLS) analysis was used to measure the size and zeta potential of the produced nanobubbles. The neural networks were trained and tested to estimate nanobubbles' diameter, zeta potential, and size distribution. Considering the limited range of each design factor (L1, L2, Dt) caused by technical limitations, the model shows good prediction efficiency based on the regression coefficient (R-value), error histogram, and goodness-of-it. The Venturi tube showing the best results regarding nanobubble generation was manufactured from steel and tested inside a semi-pilot cavitation system (4 bar pressure, 13.6 liters of water) to degrade Methylene Blue dye (96% of degradation in 20 min at pH = 3.3). The neural networks developed in this study will facilitate the advancement of Venturi tubes by accommodating various design factor configurations and enabling thorough investigations into their performance.

Within the European Green Deal, the Chemicals Strategy for Sustainability (CSS) identified several actions to reduce negative impacts to human health and the environment related to chemicals, materials, products and services in the European Union (EU). The EU CSS action plan envisions the development of a framework to define Safe and Sustainable by design (SSbD) criteria for chemicals and materials with the aim to reduce greenhouse gas emissions by 55% by 2030 from 1990 levels. Therefore, according to a SSbD framework developed by the Joint Research Centre, the safety assessment of the SiO_2@ZnO multi-component nanomaterial (MCNM) embedded into a cement mortar for NO_x degradation was performed, defining specific safety criteria highlighted here below. First, in line with step 1 of the framework, the hazard assessment of the MCNM was carried out by i) investigating the physico-chemical identity of both the individual NMs and the MCNM, ii) assessing the hazard of the precursors for the MCNM synthesis and iii) evaluating the cytotoxicity of both the individual components and the MCNM through *in vitro* testing. Physico-chemical characterization showed that the mesoporous SiO_2 core present an incomplete coating of a thin layer of ZnO, did not impacting on the overall SiO_2 size, but reducing the surface area covering the surface pores. As far as the hazard assessment of MCNM precursors is concerned, while SiO_2 NM powder was considered a non-hazardous substance according to the present classification, $ZnAc_2 \cdot 2H_2O$ showed both health and environmental hazards, (i.e., acute toxicity, serious eye damage and long-term chronic aquatic hazard). Moreover, the *in vitro* hazard screening using THP-1 cells to inform the early innovation stages suggested the hazard of the MCNM was comparable to ZnO NM. Afterwards, according to step 2 of the framework, human health and safety aspects of the MCNM-based material were also investigated. Starting from the very early stage of the design phase, a questionnaire-based standard industrial hygiene survey showed that a release of nanoscale particles into the workplace air could not be excluded during synthesis. This required an occupational exposure assessment of three different exposure scenarios selected through the survey, i.e., material synthesis, calcination and MCNM-based mortar formulation. The results showed that particles concentration was always lower than the recommended limit values (Recommended Benchmark Level – RBL, or nano reference values – NRV) proposed by international bodies. Lastly, as proposed in the final application/use phase of step 3 of the framework, an environmental exposure assessment was carried out, investigating the potential release of inorganic elements constituting the MCNM-based mortars in ultrapure water, following ISO 2812:2018 for mortars' immersion conditions and EN 12457-3:2004 for leaching evaluation. No or negligible release of Zn and Si was recorded, indicating that their potential exposure is unlikely once the MCNM is embedded into the mortars. In conclusion, the safety assessment of this MCNM through the SSbD framework helped in identifying safety criteria, providing useful information on their risk profile for future assessment of their sustainability.

New materials with low environmental impact for the protection of Cultural Heritage

L. Vespignani,[a] A. Salvini,[a]

[a] *Chemistry Department 'Ugo Schiff', University of Florence, Via della Lastruccia 3-13, 50019, Sesto Fiorentino (FI)*
laura.vespignani@unifi.it

In recent years it has become increasingly important to identify new materials to be used for the protection of Cultural Heritage in place of long-chain perfluoroalkyl compounds (PFAS), highly efficient products[1] but with a high environmental impact, and therefore currently under restriction in EU. In the last decade, new materials have been designed for the protection of degraded, non-varnishable wooden artifacts, but also applicable in other cases, for instance stone based items, where the maintenance of the aesthetic characteristics of the treated object is essential.

Recently, interesting results have been obtained on wood using various fluorinated products, prepared by reacting different oligoamides and a diethylenetriamine with a C6 fluorinated chain epoxide[2]. All these compounds have low molecular weights and therefore non-film forming properties, the presence of polar groups makes them similar to polar materials such as wood while the fluorinated chain gives hydrophobicity and stability to light, but above all they are soluble or easily mixable in eco-sustainable solvents such as 2-propanol. In view of a further probable extension of the restriction to the use of C6 fluorinated chemicals, other products with a shorter fluorinated chain (C4) have been also synthetized.

Systematic tests on wood samples have been done to evaluate and compare these products using a diagnostic protocol developed for this specific application field. The optimal application method has been evaluated for each product. To verify the actual variation in surface wettability with no or minimal alterations to the surface color, contact angle and colorimetric measurements have been carried out. Furthermore, the second part of the diagnostic protocol has been developed to test the resistance of these protective materials to natural and artificial photoinduced aging, as well as the resistance to mild abrasion, both on fresh and aged samples, to simulate the effects of manipulating the artefacts. Tests on stone samples have confirmed the potential of these new materials as protective agents.

Best results both in terms of protective efficacy and stability to various types of stress were obtained with the C6 derivatives, demonstrating the criticality in the use of products with a too low fluorine content.

Fluorine-free derivatives are being also studied as alternative protective agents for Cultural Heritage.

Acknowledgments: We thank Maflon S.p.A., partner of the PhD project 'Study of new materials with low environmental impact and their use in the protection of wooden artifacts' (Dottorato PON - Bando 2021 - Ciclo 37, DM 1061).

Pollution by polycyclic aromatic hydrocarbons in the Mediterranean Sea: the *Caretta Caretta* turtle as a bioindicator

M. Toscanesi [a], M. Annetta [a], G. Di Natale [b], A. Giarra [a], M. Trifuoggi [a,b]

maria.toscanesi@unina.it

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous pollutants that can be detected quite often in marine and coastal environments. PAHs are highly toxic, mutagenic, carcinogenic, teratogenic, and immunotoxicogenic to various life forms. One of the main targets of PAHs in marine environments is sea turtles. They are at the top of the marine food chain and, despite being migratory, are good indicators of marine contamination. The loggerhead turtle C. caretta (Linnaeus, Cheloniidae) is the most common sea turtle species in the Mediterranean Sea and it often uses the Italian coasts for nesting and feeding ground. The Mediterranean Sea represents an area where conservation efforts are of paramount relevance due to historic release from former industrial sites, and current commercial release from cargo, tanker, and passenger transportation. Caretta caretta, diving into deep and cold water and returning in surface for breathing, rest or rewarm are highly exposed to hydrocarbon pollution from both seabed and surface [1].

This study aimed to determine the 16 priority PAHs, in different organs and tissues of loggerhead turtles, stranded along the coasts of the southern Tyrrhenian Sea, Italy, from 2019 to 2021. The 16 EPA's priority PAHs were determined by gas chromatography coupled with mass spectrometry (GC-MS).

The first results showed the prevalent presence of naphthalene and represented 90.0% and 93.7% of the ΣPAHs in the different organs. A very interesting and little-studied thing is the presence of PAHs in the salt gland, whose concentrations are sometimes higher than in other organs. Furthermore, an overall higher bioaccumulation of NAP is observed in the salt glands of female and adult individuals. Data of PAHs richness highlighted a potential risk of neoplastic disease development and that anthropogenic activities may seriously impair healthy state conditions of C. caretta. populations in southern Tyrrhenian Sea [2].

raffaella.lamuraglia@iit.it

Microbial colonization poses a significant challenge to the longevity of mural paintings[1, 2]. Despite efforts to combat microorganisms using various biocides, their long-term effectiveness remains limited, accompanied by high toxicity and corrosive side effects[3]. The recent advances in nanotechnology are opening great opportunities for the conservation of cultural heritage, changing the approach paradigm. This study centres on developing ground-breaking nano-engineered formulations, merging noble metal nanoparticles with natural biopolymers, to assess their potential as microbial inhibitors on frescoes. Tailored synthesis of nanoparticles with specific physical-chemical attributes enhances antimicrobial efficacy. Upon achieving desired properties, mock-ups are meticulously crafted for preliminary performance evaluations. The formulations exhibit minimal colour variation, non-glossy surfaces, favourable hydrophobicity, water vapour permeability, and chemical stability post-artificial and natural aging.

Testing various concentrations screens the in vitro antimicrobial activity to identify the most promising formulation. Remarkably, these formulations substantially limit fungal colonization of frescoes and reduce bacterial growth by up to 99%. Further assessment involves observing biofilm formation and evolution on chitosan-nanoparticle-treated frescoes mock-ups post-aging in climatic chambers, supported by electron microscopy and XPS analyses.

These experiments underscore the efficacy of highly innovative composite formulations in inhibiting microbial growth on mural paintings, signalling their readiness for application to Cultural Heritage materials.

francesca.perra4@unica.it

Introduction

In recent years, the concerns surrounding heavy metal pollution and the increasing CO_2 levels contributing to global warming have intensified. This study focuses on the synthesis and functionalization with aminosilanes of mesostructured silicas (MCM-41, MCM-48) for the development of amine-silica sorbents with potential applications in Cd^{2+} removal from aqueous solutions and in Carbon Capture and Utilization (CCU) technologies. Thanks to their highly ordered mesoporous structure, the donation of lone pairs by amines to Cd^{2+} and the amines' high affinity for CO_2, amine-silica sorbents are suitable for such applications. Moreover, mesostructured silica-based composites have been developed by impregnating MCM-41 with oxidic phases of copper, zinc, and zirconium (CZZ), for a prospective application in the catalytic hydrogenation of CO_2 to methanol.

Materials and Methods

Mesostructured silica was synthesized via the sol-gel technique employing a templating agent, a siliceous alkoxide precursor and two distinct solvent systems: water alone (yielding MCM-41) and a combination of water and ethanol (yielding MCM-48). Various amine-silica sorbents were obtained from post-synthesis grafting with aminopropyltriethoxysilane and tested for Cd^{2+} removal and CO_2 capture. To lower both environmental and economic impact of the grafting procedure, an eco-friendly solvent (*i.e.* butanol instead of toluene) was used. The CZZ@MCM-41 composites were prepared through auto-combustion. Moreover, for the development of cadmium sorbents and CZZ-based catalysts, mesostructured silica from an industrial waste (hexafluorosilicic acid, FSA) was also tested. All sorbents were characterized by XRD, TEM-EDX, TEM, N_2-physisorption, thermogravimetric-analysis and ATR-FTIR.

Results and discussion

MCM-48 was obtained by adding ethanol as co-solvent, keeping all the other experimental conditions equal to the MCM-41's synthesis, confirming its key role among others synthesis parameters in tuning the mesophase. The replacement of the alkoxide precursor with FSA allowed the production of MCM-41 with comparable textural properties, reducing environmental and economic impacts for CZZ-catalysts' support. The same amino groups' concentration (~2 mmol/g) was obtained for MCM-41 functionalized with either toluene or butanol. Amino-silica sorbents were tested for Cd^{2+} sorption showing a removal percentage of 99% and adsorbed amount of cadmium q_e=46 $mg_{Cd(II)}/g_{sorb}$ at pH 5. This preliminary study suggest that amine-silica sorbents have the potential to remove significant amounts of cadmium ions from aqueous solutions.

The use of butanol instead of toluene in the grafting procedure led to a decline in CO_2 adsorption performances (968 $\mu molCO_{2ads}/g_{sorb}$ *vs.* 480 $\mu molCO_{2ads}/g_{sorb}$), indicating the need to improve functionalization process. Nevertheless, a comparison revealed that toluene-functionalized MCM-41 is more efficient than SBA-15, emphasizing the crucial role of the support's surface area.

pierpaolo.guolo@unive.it

The implementation of Water Safety Plans (WSPs) promoted by World Health Organization (WHO) aims to ensure safe drinking water supplies by identifying and assessing potential site-specific risks as well as developing mitigation strategies to prevent and minimize impacts on human health and the environment. One of the crucial steps in applying the WSP approach is the identification of chemicals of concern, especially those not regulated or monitored. In this study, we developed and tested an integrated approach applying on both desk-based and experimental methodologies to identify such chemicals in the deeply industrialized Province of Vicenza (Veneto Region, Italy) where significant aquifers historically subjected to severe contamination are used for water supply. The first methodology involved the use of publicly available databases (e.g., European CHemical Agency (ECHA) database) and information on the geographical distribution of the industrial plants present in the study area. We obtained a list of 46 non-regulated chemicals of concern that were further prioritized based on their Persistence, Mobility, and Toxicity (PMT) characteristics, and the quantity of wastewater associated with their use based on information retrieved from the local water utility. The second methodology involved the sampling of surface and wastewater collected within the study area followed by analysis using liquid chromatography coupled with high resolution mass spectrometry (LC-HRSM, qTOF Bruker Compact) to qualitatively assess the presence of chemical of concern. The mass spectroscopy data and retention time was compared with libraries containing information (e.g., parent ion exact mass, isotopic pattern) on more than 2000 substances including pesticides, pharmaceuticals, and illicit drugs. The analytical results showed that the highest number of chemicals was detected at the outlet of wastewater treatment plants, with pharmaceuticals being the most present class of compounds. Moreover, several of the 46 substances identified through the first methodology, including venlafaxine, diclofenac, and valsartan, were also detected during the screening analysis. The proposed approach effectively identified site-specific chemicals of concern highlighting the importance of integrating information on industrial activity with experimental data. In fact, all substances identified in this work will be further investigated through quantitative analysis to better understand their occurrence in the examined water supply area.

Exposure assessment of plant protection products in the Northern Adriatic Sea: emission inventory and environmental modelling

L. Calgaro[a], E. Giubilato,[a] P.P. Guolo[a], A. Bonetto[a], E. Semenzin[a], A. Marcomini[a]

[a] *Department of Environmental Sciences, Informatics, and Statistics, University Ca' Foscari of Venice, Via Torino 155, 30172 Mestre Venice Italy*
loris.calgaro@unive.it

Plant protection products (PPPs) are formulations mainly used to keep crops healthy and prevent them and their products from being destroyed by diseases and/or infestations, thus contributing maintain high levels of food production. These products include fungicides, herbicides, insecticides, plant growth regulators, and pest repellents. The toxicity of these chemicals towards humans and animals is quite lower with respect to that against target organisms, but there are still direct and indirect toxic effects on non-target organisms that are not fully understood yet. Moreover, the monitoring of the most recently developed PPPs in the environment is still limited, especially for coastal waterbodies. The use of predictive exposure models has been identified as a complementary, cost-efficient tool to support the investigation of the behaviour and environmental fate of these contaminants and the assessment of associated risks.

The Northern Adriatic is a narrow and shallow sea, where the variety of temperature, salinity, and sedimentation patterns leads to the presence of different and unique habitats for marine species. This area is also subjected to pollution loads from both point and diffuse source. In particular, agricultural activities can affect water and sediments quality due to both nutrients and chemical pollutants loads.

The aims of this work, developed within the iNEST project, are: (i) to develop an emission inventory of several PPPs in the study area, (ii) to use state-of-the-art modelling tools to investigate the environmental distribution and fate of these contaminants in the Northern Adriatic Sea, with particular attention to the processes involved in their natural attenuation, and (iii) to define a risk-based priority list of contaminants specific to the case study area, taking into consideration the overall mass balance of the target pollutants.

The emission inventory was developed by integrating PPPs sales data obtained from Regional authorities within the Northern Adriatic drainage basin with river flow, land-use and geographical information through statistical data treatment and GIS-based spatial analysis. In addition, a preliminary modelling exercise was carried out by applying the newly-developed ChemicalDrift model[1], a chemical transport module part of the open-source Lagrangian framework OpenDrift.

costanza.scopetani@unifi.it

Mulching, a widely practiced technique in agriculture, involves laying a protective layer of material over the soil's surface [1]. This is typically achieved using films derived from polyethylene (PE), known for containing additives such as phthalates. These additives are recognized for their ability to disrupt endocrine functions, thereby posing environmental and health risks through the potential transfer of chemicals to the soil and crops.

Biodegradable plastic mulches could represent an alternative to reduce plastic waste and the costs associated to the PE films removal. However, concerns exist regarding the release of substances from these mulches, impacting biodiversity and human health. To assess contaminants transport, a field experiment was conducted with strawberries by mulching the soil with four different film materials: PE, biodegradable PE (PE-BIO), polypropylene (PP) and polybutylene adipate terephthalate (PBAT)/starch. Soil and strawberry samples were analysed by GC-MS for phthalates and other plastic additives such as acetyl tributyl citrate, di-n-butyl sebacate and tris(2-ethylhexyl) phosphate.

The Kruskal-Wallis test showed significant differences in the total concentration of phthalates between the control soil and soils mulched with PE-BIO ($p=0.033$) and PP ($p=0.002$). Furthermore, a significant difference was also observed between the soil mulched with PE and that mulched with PP ($p=0.048$). However, no statistically significant differences were found between the controls and the soil mulched with PBAT-starch and PE ($p=1$). Regarding dibutyl sebacate and acetyl tributyl citrate, the statistical tests did not show any significant differences among the treatments ($p>0.143$).

Data from strawberry samples are currently being analysed and will be presented at the conference.

The results will help determine the risks posed by mulches to agricultural soils and whether differences exist in contaminant transport among different mulching materials.

giulia.pellis@unito.it

Outdoor bronze statues face daily exposure to weathering and reactive compounds present in the atmosphere which can interact with the surfaces of the artworks. To avoid these phenomena, one of the most exploited methods is the application of coatings including corrosion inhibitors. However, the most employed acrylic coating, Incralac®, contains benzotriazole (BTA) which is toxic and considered a suspected carcinogen.[1] The development of safe and reliable long-term methods and strategies for the conservation of these artworks is nowadays a mandatory prerequisite, since the currently exploited hazardous materials need to be replaced.[2] The idea behind this work arose from the attempt to improve the poor permanence over time of two corrosion inhibitors chosen to formulate new acrylic coatings for outdoor bronzes.[3] Cyclodextrins were selected to host corrosion inhibitors, due to their capability of giving rise to complexes embedding small organic molecules. Cyclodextrins are water-soluble macrocyclic oligosaccharides, made of at least six α-D-glucopyranose units linked via α-(1–4)-glycosidic bonds. CDs are among the most widely used host molecules thanks to their unique structure that creates an internal cavity less hydrophilic than the external aqueous environment and therefore able to accommodate a large variety of hydrophobic molecules inside it.[4]

In this work, Methyl β-Cyclodextrins (Me-β-CD) were investigated as nanocontainer of 5-ethyl-1,3,4-thiadiazol-2-amine (AEDTA) for enhancing its permanence inside acrylic coatings. First, the compatibility of the nanocarriers inside the acrylic systems was assessed. Then complexes of Methyl β-Cyclodextrin and AEDTA were prepared and the formation of the inclusion complex was proved by FTIR and XRD. Three types of acrylic coatings were prepared at different concentration of Me-β-CD/AEDTA system. The coatings were applied on both inert supports and bronze polished mock ups. The so-prepared samples were aged inside an oven at 80 °C and monitored every 24 hours by Fourier Transformed Infrared Spectroscopy, either in transmission or in reflection mode according to the support. During the first 72 hours, SPME-GC/MS and py-GC/MS analyses were also performed to assess the volatilization of the corrosion inhibitor. The obtained results were compared with the corresponding data for pure AEDTA films and Incralac®. The outcomes from the experiments are encouraging, highlighting that Me-β-CD/AEDTA complexes might be considered as serious candidates for the formulation of novel coatings, exhibiting increased stability and longer retention of AEDTA over time.

a.criscuoli@itm.cnr.it

The presence of toxic elements in water is becoming a serious concern, also when it is not due to pollution related to human activities, but to the natural interactions occurring between water and rocks. In fact, this type of water contamination is usually underestimated with respect to that linked to industrial productions; however, its impact on human health is also significant, since the concentration of toxic species in groundwater is often higher than the imposed limits. In last years, an increase of the awareness for natural contaminated groundwaters has grown. In particular, in this work, the approach followed within the PNNR project (CUP B83C22003980006) to manage groundwaters contaminated by arsenic and hexavalent chromium is reported and discussed. Starting from a map of geochemical characteristics of groundwaters present in the Sila and Pollino massif areas (Southern Italy), it was possible to obtain information useful to identify the most suitable technology to treat the water, in order to obtain a stream which meets the threshold values (25 µg/L and 10 µg/L for chromium and arsenic, respectively). In this respect, membrane operations, like nanofiltration, showed interesting performance in terms of removal efficiency and purified water production.

annalaura.tassi@unimi.it

Biological air contamination inside cultural heritage indoor spaces is a frequent problem that needs to be solved since microbial deposition on artistic surfaces causes mechanical biodeterioration and the impossibility of a complete appreciation of the artwork. To prevent those mechanisms, it is helpful to reduce the microorganisms present in the air by introducing an air-cleaning system. The starting point of this project is the work of a research group from the *Universitat Politècnica de Valencia* that has already applied tea tree essential oil cold diffusion as an active air cleaning system for this purpose at a small space in *Los Santos Juanes* Church in Valencia [1]. In this research work, the tea tree essential oil has been encapsulated inside the pores of mesoporous silica support to elongate the period of activity of the oil and enhance its performance. To obtain the simplest device, it has been designed to be a part of a passive-release air cleaning system.

The silica mesoporous support has been characterized through diffuse/specular reflectance, attenuated total reflectance infrared (ATR-IR) and Raman spectroscopies, electron scanning microscopy coupled with X-ray microprobe (SEM-EDX), porosimetry and X-ray diffraction (XRD) whereas the amount of the charged essential oil has been evaluated through thermogravimetric analysis (TGA) [2].

In addition, this innovative air cleaning system has been tested in test rooms and compared with the free-oil system. The complete air monitoring control (temperature, relative humidity, microbial assay, and particulate matter) performed in these rooms showed that the essential oil encapsulated in the microparticles (as a passive release system) keeps its biocidal activity for a longer time than the oil-free one, especially after the third week for the bacteria and after the fourth for the fungi. The new cleaning system has also been applied in vitro [3].

These promising results are the beginning of future research projects that will focus on combining the microparticles and the essential oil to have a high immediate and long-term biocidal effect, for example, applied in an air filtration system.

Drinking water purification from Emerging Contaminants (ECs), which include pharmaceuticals, personal care products, additives, and dyes, in a current main global challenge. To this aim, the development of innovative, sustainable, cheap, versatile and efficient technologies is urgently needed.[1]

In this communication, I will report innovative materials deriving from industrial scraps of polysulfone (PSU) and polysulfone-graphene oxide (PSU-GO) hollow fiber membranes industrial production, and their validation as sorbent materials for ECs in tap water.[2-3]Mechanical grinding was employed to convert scraps into PSU and PSUGO granules and cartridges filled with these materials exhibited superior adsorption capacities than Granular activated carbon (GAC), the industrial benchmark sorbent.[3] Notably, PSU-GO granules showed over 2 times higher adsorption capacities for diclofenac (DCF), a drug, and perfluorooctanoic acid (PFOA), and over 10 times higher on lead (Pb).[4] Molecular dynamics simulations provide insights on adsorption mechanisms, revealing the key role of graphene oxide (GO) in enhancing the adsorption performance.[5] The obtained materials were exploited under tap operational conditions (4 L/min, 2 bar) and the leaching of GO was excluded by Surface-enhanced Raman spectroscopy analysis of treated water.

Figure 1. a) Hot wire industrial membrane processing for commercial ultrafiltration modules, b) granular sorbent materials and cartridges obtained by scraps grinding , c) adsorption capacity of granules on lead, compared to GAC.

francescaboccaccini@cnr.it

Metal objects of cultural and artistic values are detrimentally affected by corrosion processes, which induce changes in the aesthetic and structural properties of precious surfaces. To hinder degradation and to preserve the artefacts, protective coatings are usually applied on metal objects. Traditional protective coatings are based on petroleum-derived materials and require harmful solvents for their application, representing a serious threat for both conservators' health and the environment. Recently, an increasing research interest has been addressed to the development of sustainable and effective protective materials for cultural heritage applications[1].

In the framework of the European GREENART project, research activities, aimed at the development of new solutions for the sustainable conservation of cultural objects, are currently ongoing. One of the main goals is the formulation and validation of polymeric coatings, starting from renewable sources and waste materials, to ensure a reliable and long-term protection of metal surfaces.

To achieve these challenges, we focused on coatings based on chitosan, an eco-friendly biopolymer derived from crustacean shells (as waste of fishing industry). Chitosan was used to prepare and optimize highly transparent and removable anticorrosive coatings. Water-based formulations were produced and applied on different metal surfaces, such as polished and patinated bronze and silver substrates, with the aim of studying the coating/metal interactions. To this purpose, both accelerated corrosion tests and long-term treatments reproducing natural indoor environments were performed and the structural and chemical properties of the coatings before and after the tests were deeply investigated. Results pointed out that chitosan show excellent protective properties toward different metal substrates. The coatings behaviour during the tests strictly depends on the composition of the metal surfaces and on the duration of the aging, proving that both accelerated and long-term treatments are required to evaluate the polymer/metal interactions as they provide complementary information[2]. The alteration of the films observed after a prolonged exposure to uncontrolled environmental conditions was used to optimize the formulation and enhance the long-term stability of the coatings.

The research activities were carried out within the GREENART project (GREen ENdeavor in Art ResToration, grant agreement n. 101060941) which is kindly acknowledged for financial support.

Bronze disease: synthesis and characterization of new recycled polystyrene-based coatings

D. Porcu,[a, b] D. Bandelli,[a] E. Carretti,[a, b] R. Fontana[b]

[a]*Departement of Chemistry "Ugo Schiff" and CSGI Consortium, University of Florence, Via della Lastruccia 3-13, 50019, Sesto Fiorentino, FI, Italy*

daniela.porcu@unifi.it

Polystyrene (PS) is one of the most used and worthwhile plastic materials: millions of tons of PS are produced every year for applications in several aspects of modern life, from packaging to construction and automotive. However, high production volumes imply high procession costs, making recycling a central goal for end-life PS plastics. Hence, the development of low-cost strategies aimed at converting waste plastics into new valuable materials is of paramount importance to minimize the environmental and health impact of this kind of waste. In particular, the PS conversion can match the need to develop new materials suitable for protecting outdoor bronze artifacts, also complying with circular economics goals (*e.g.* the European Green Deal).

To this aim, a new protocol for PS upcycling was developed, based on a study by Kurbanova.[1] Expanded PS was functionalized with an increasing feed of maleic anhydride (MA, 5 to 25% mol) *via* Friedel-Craft acylation reaction. The functionalization results in the formation of carboxylic pendant moieties, which could both (i) improve PS performances as a coating due to the interactions of the newly formed moieties with the bronze surface and (ii) act as a protecting group for the copper alloy.

The library of newly established materials (PS-MA) was analyzed by proton nuclear magnetic resonance (^{1}H NMR), attenuated total reflection Fourier transform infrared (ATR-FTIR), size exclusion chromatography (SEC), and differential thermogravimetry (DTG).

Application tests were carried out by laying PS-MA on bronze substrates. Coating thickness was measured by Optical Coherence Tomography (SD-OCT) before and after artificial aging treatment.[2] The tested samples have shown promising performance in terms of corrosion resistance, color, thickness, and adhesion.

Overall, the PS-MA library represents optimum candidates for the development of new and effective coating materials. Moreover, this novel class of end-life polystyrene materials could be further modified with target molecules to introduce additional anti-corrosive agents for cultural heritage aims and scopes.

Iron oxi(hydroxi)des are known to be efficient sorbents toward arsenic species, thanks to the formation of complexes of the inner sphere, through ligand exchange of surface -OH_2 and -OH^- with the arsenic species in the coordination sphere of the structural Fe atoms.[1] Recently, we compared the sorption ability of different iron oxi(hydroxi)des, namely akaganeite (β-FeOOH), ferrihydrite (referred to as $Fe_5HO_8{\cdot}4H_2O$), and maghemite (γ-Fe_2O_3, as bare and silica-based composite) toward arsenate/arsenite species in spiked aqueous solutions.[2] Akaganeite was proved to be the best sorbent for arsenate anions (89 mg g^{-1} at pH_0 3, 52 mg g^{-1} at pH_0 8) and also an efficient one for arsenite species (91 mg g^{-1} at pH_0 3–8), thanks to its high positive surface charge (measured by Electrophoretic Light Scattering, ELS, ≈30 mV) and high surface area (determined by N_2 physisorption, ≈200 m^2 g^{-1}). To investigate the adsorption process and the interaction between arsenate/arsenite and akageneite, different methods, such as powder X-ray diffraction (PXRD), infrared spectroscopy (FTIR-ATR), transmission electron microscopy also in high resolution (HRTEM) and coupled with chemical probes (EDX-EELS), X-ray photoelectron spectroscopy (XPS), X-ray absorption (XAS), and DC magnetometry were adopted. None of these techniques were able to detect any changes in the sorbent properties upon adsorption, but FTIR-ATR and DC magnetometry. In particular, the interaction between akageneite and arsenate species was found to produce a distinctive change in the magnetism of the sorbent, with the appearance of a second band in the temperature profile of the magnetisation, whose associated intensity increased with increasing adsorbate amount. This work demonstrates the high sensitivity of DC magnetometry in exploring surface phenomena in iron-bearing materials.

Green nanostructured composites for the consolidation and protection of Street Art: formulation, characterization, and application

C. Cianci,[a] R. Giorgi [a]

[a]*Department of Chemistry "Ugo Schiff" and CSGI, University of Florence, Via della Lastruccia 3, 50019 Sesto Fiorentino, Florence, Italy*
chiara.cianci@unifi.it

Street art is increasingly influencing world artistic production, but its conservation is challenging due to constant exposure to environmental conditions such as light, pollution, temperature, and relative humidity fluctuations. Furthermore, biological agents are non-negligible in urban art degradation[1]. Unlike traditional wall paintings, graffiti are made with synthetic organic paints on inorganic substrates such as concrete, brick walls, and mortars. Therefore, it is necessary to study the degradation processes and develop appropriate conservation products and methods.

Organic-Inorganic Hybrid Materials (OIHM) can be an effective strategy for the formulation of protective coatings that can act both as a barrier layer and a consolidating product, considering the physicochemical properties of urban art materials.

Chitosan (Chs) is an abundant, and sustainable biopolymer obtained by partial deacetylation of chitin from the industrial waste processing of marine shells and crustaceans. It has been selected as the organic component for its good film properties as it forms mechanically resistant and semi-permeable films. Additionally, it shows good optical, and antimicrobial properties, it is non-toxic, and it has already been studied as a new biopolymeric treatment on porous limestones in historic architecture to inhibit the crystallization of hazardous salts[2].

The main objective of this project is to develop a hybrid coating that combines Chs and nano-silica (NS) to improve the compatibility and the adhesion of the coating to the inorganic substrate. The new formulation would act as a barrier layer and a consolidating product by introducing innovative green materials that can best mitigate the degradation effects on Street art. The hybrid formulation was designed and investigated by ATR-FTIR, SEM, DLS, and zeta potential analysis. Alkyd and acrylic spray-painted concrete mockups were prepared to mimic street art techniques.

Chemical stability, color and gloss variations, water vapor permeability, and hydrophobicity are evaluated on the mockups before and after the application of the Chs-NS-based coating, and its long-term stability is assessed through accelerated aging tests.

HIGH TEMPORAL AND SPATIAL RESOLUTION MONITORING OF INDOOR AIR QUALITY IN AN ITALIAN BASILICA

A. Di Gilio[1]*, L. Pastore[1], A. Marzocca1, J. Palmisan[1], V.Pizzillo[1], M. Nisi[1], and G. de Gennaro[1]

alessia.digilio@uniba.it

In recent years, people spend most of their time in indoor environments as working places, public or private transportations, homes and schools which are frequently more contaminated than outdoors one[1, 2]. In fact, in addition to outdoor pollutants penetrating through windows and doors and affecting the indoor air quality (IAQ), indoor pollutants sources as building materials, furniture, cleaning and combustion processes (heating, cooking and incense or candles burning) can deeply worsen the air quality in closed environments. Among indoor sources linked to combustion processes, cooking or cigarettes smoking has been deeply characterized in contrast to incense burning emissions [3]. Anyway, over recent years, incense burning is attracting ever more interest because it was found to be the significant source of large amounts of particulates, heavy metals, polycyclic aromatic hydrocarbons (PAHs) and volatile organic compounds (VOCs) [4]. In a poorly ventilated environments as the churches where a large number of people gathers and incense is commonly burned, high concentrations of harmful chemical pollutants could affect IAQ and, thus, the human heath of exposed people. Therefore, this study aims to investigate the time profiles of pollutants concentration in an Italian basilica during the liturgical celebrations. An high-time and spatial resolved monitoring campaign was carried out from 1st November 2023 to 2nd April 2024 inside an basilica that covers an area of about 23000 m^2. The real time measurements of PM, TVOCs, CO_2 and microclimatic parameters as temperature and humidity were provided by integrated systems consisting of low-cost sensors named NOSE (Beefrest srl) located in eight different points inside the basilica. In addition, the real time concentrations of total polycyclic aromatic hydrocarbons (TPAHs) were monitored by a photoionization analyzer (PAS2000 - EcoChem Analytics) installed bottom of the church altar in a beeline with the first lines of pews.

The preliminary results highlighted relevant increments of PM10 (maximum value: 216 $\mu g/m^3$), PM2.5 (maximum value: 184 $\mu g/m^3$), TVOCs (maximum value: 3.9 ppm) and TPAHs (173 ng/m^3) concentrations, especially, at the sites nearest the altars and during liturgical celebrations linked to Christmas, Lent and Easter when incense was burned. These peak concentrations as well as PM10 and PM2.5 daily mean concentration values registered during Christmas and Easter days were significantly higher than the daily limit value established by Italian law for the PM10 outdoors concentrations (Legislative Decree 155/10).

The aquatic environment is a reservoir of pollutants of natural or anthropogenic origin. Pollution and the invasion of exotic species are recognised as major factors in the loss of biodiversity[1] and are known to have a negative impact on ecosystems and trophic networks. Monitoring is therefore necessary, including chemical investigations to assess contamination of environmental and biological matrices. *Procambarus clarkii* is one of the most widely introduced freshwater animal species in the world, raising concerns about its impact on native aquatic biota[2]. Despite the important nutritional properties of freshwater decapods and their potential use as a source of bioactive molecules, there are potential health risks associated with their consumption due to their ability to accumulate contaminants[2]. In the present work, three representative Sicilian aquatic ecosystems were selected for the collection of *P. clarkii* specimens and environmental samples (water and sediment). The analytes selected for determination in the muscle and exoskeleton of *P. clarkii*, as well as in water and sediment, were trace elements (TEs), pesticides, per- and polyfluoroalkyl substances, phthalates, antibiotics and cyanotoxins. Except for TEs, all samples showed concentrations below the detection limit for all contaminant classes. Bioaccumulative potentials and TEs contamination profiles differed significantly between sites and matrices, confirming the suitability of *P. clarkii* as a biomonitor of environmental contamination. The levels of TEs found in the biological matrices were similar or lower than those reported for other sites in different parts of the world[3] and below the limits set by current European environmental and food safety legislation. However, these results should be contextualised to the selected sites, time of sampling collection and contaminants, and desirably confirmed by further periodic sampling and analysis.

A conservation project that aims to preserve an artwork in the best possible way must adopt an analytical approach, developing methodological strategies to gain exhaustive knowledge of the object and the environment that hosts it.
Identifying the composition of materials not only enhances understanding of an artist's technique and may provide evidence of authenticity, but it is crucial for directing restoration interventions and identifying past ones, shedding light on the conservation history of the object. In fact, the study of the state of conservation of historical and artistic heritage assets also takes into account the composition of alteration products and the processes leading to their formation. It is therefore necessary to consider environmental factors such as temperature, humidity and air quality, as they can lead to alterations and chemical, mechanical and biological degradation.[1]
In the King's Apartment of the Royal Palace of Turin, monitoring of microclimatic conditions, air quality and aerobiological particulates is currently underway with the aim of identifying the environmental risks in the apartment in its current state of disuse and in view of its possible future use for exhibition purposes. Moreover, the study aims to identify possible sources of pollution, external or internal to the apartment, and any correlations between air quality and the state of conservation of the artworks currently present in the apartment.
The contribution presented here reports some preliminary results on air quality emerging from the processing of data collected in the first five months of monitoring. In particular, the monitoring involves the continuous detection of particulate matter (PM1.0, PM2.5 and PM10) and volatile organic compounds (TVOC), measurements of formaldehyde concentration and detailed analysis of organic emissions through solid phase microextraction coupled to gas chromatography/mass spectrometry (SPME-GC/MS).

In the framework of a conservation intervention -promoted and supported by the Superintendence of Cultural Heritage of Ragusa, the Prefecture of Ragusa and the Diocese of Ragusa-, the opening of a 15th Century sandstone sarcophagus, conserved in the Church of San Francesco all'Immacolata in Comiso, revealed a set of precious findings: several bones were found, belonging to twelve human bodies, among adults and children, along with various textiles. These were likely part of the grave goods of deceased members of Naselli nobles; however, they have been dated to the 16th Century, one hundred years after the sarcophagus.

Among these, several textile fragments showed technical features of luxurious goods, representing important evidence for the history of costume. In particular, three textile fragments, likely representative of a gown and a pair of trousers, captured the attention of the anthropologists for the preciousness of both fabric and colours. The brown and the black of these silk samples evidenced a refined manufacturing, while the complexity of dyeing processes for obtaining dark shades[1] and the issues related to their conservation[2] pushed the conservators to investigate the composition of these ancient matrices by means of an empowering collaboration with scientists and anthropologists, aimed to reconstruct the history of the ancient Naselli sarcophagus.

In this study, we present the results of an extended diagnostic campaign on these textiles, which exploited a multi-analytical approach covering dating, microscopic and spectrometric techniques. A particular focus was dedicated to Raman scattering, through the combination of the most solid and the newest strategies of this spectroscopy[3]. The achieved data allowed for an insight, helpful in unveiling the palette of ancient dyes used to colour the garments of this ancient Sicilian family in the darkest shades.

Innovative, eco-friendly coatings allow to implement sustainable treatments with low impact on the environment and operators[1]. Their efficacy can be assessed via accelerated ageing tests that simulate outdoor exposure conditions. In order to decrease discrepancies between the predicted behaviour of protective treatments and their performance in real conditions, the chosen environmental parameters should reflect current environmental conditions.

Two sets of bronze coupons, coated and uncoated, underwent artificial ageing in order to assess the anti-corrosion properties of an innovative cutin-based polyurethane coating. The cutin used in its production is extracted from tomato peels and reused, consistently with a circular economy approach[2].

The quaternary bronze G-85 or UNSC83600 was chosen to produce the coupons, as this alloy is commonly used in cultural heritage for artistic casting. Two kinds of substrates were considered: unaltered i.e. the new, non-degraded material, and pre-aged i.e. patinated bronze. The second substrate was used to test the coating on an oxidized metal surface, with chemical and morphological features similar to those met during a realistic conservation treatment. Patinated bronze was obtained by cyclical immersion of the bronze coupons in a synthetic rain solution with pH = 4,2 for 30 days.

The artificial ageing phase was carried out in two subsequent steps to systematically observe the effects of rainwater, both in stagnant[3] and runoff[4] conditions, and then of other environmental parameters such as temperature, relative humidity and solar radiation. In order to recreate conditions as representative as possible of real ones, the chosen environmental parameters were based on environmental monitoring data. Specifically, pH and ionic concentration values for the synthetic rain solution reflect rainwater composition data gathered in various locations in southern Europe and northern Italy in the last decade[5]. Moreover, T, RH and UV parameters chosen for the climatic chamber aimed to simulate combined day-night and seasonal conditions, alongside average irradiance on a clear day in southern European regions.

Following a multi-analytical approach, the coupons were characterized by scanning electron microscopy coupled with energy-dispersive X-ray spectroscopy (SEM-EDS), infrared spectroscopy, micro-Raman spectroscopy, UV-Vis spectrophotometry for colour analysis, and electrochemical impedance spectroscopy (EIS). The analyses were performed before ageing and were repeated after each step of the ageing procedure in order to observe the evolution of the degradation processes. Moreover, the solutions in contact with the coupons were sampled throughout the ageing period and later analysed by microwave plasma atomic emission spectroscopy (MP-AES) in order to know the concentrations of ions coming from the substrates, whose presence is diagnostic for the corrosion process.

After the first step of the ageing procedure, colour changes were characterized by $\Delta E<5$ (i.e. the threshold for acceptable colour change in cultural heritage) for coated coupons and uncoated patinated bronze, while pristine bronze showed $\Delta E>20$ as it underwent oxidation. Raman analyses indeed showed cuprite in various stages of formation. SEM-EDS analyses on pristine bronze after ageing also showed, as expected, a decrease of Cu due to the decuprification process occurred, alongside a relative enrichment of Sn at surface level. This

Studying the degradation of egg proteins in polychrome layers by MS-based proteomics

Elena C. L. Rigante[a], Cosima D. Calvano[a], Simona A. Riganti[a], Tommaso R. I. Cataldi[a]

[a] *University of Bari Aldo Moro, Department of Chemistry, via E. Orabona 4, 70125, Bari (Italy)*
elena.rigante@uniba.it

Egg was widely used in the tempera technique thanks to its good resistance and stability to aging[1]. The present study aimed to investigate the effect of artificial aging on egg white proteins to better explore the process of protein degradation in polychrome artworks. According to the literature, the most common protein events in historical samples are the oxidation of serine, phenylalanine, and cysteine as well as the deamidation of asparagine and glutamine[2]. In many cases, inorganic pigments may accelerate the binder's degradation as several studies claim[3,4].

Mock-up samples made of beaten egg white, egg white each mixed with hematite and calcium carbonate, applied, and dried on glass microscope slides, were analyzed as such and after artificial aging with a solar lamp (300 W, 230 V, 280-2000 nm) at 50 °C for a maximum of 864 hours and relative humidity between 60 and 75%. Three types of enzymes (trypsin, GluC and AspN) were employed to enzymatically digest the freshly prepared samples as well as the ones subjected to 30, 72, 144, 288, 576 and 864 hours of aging. Trypsin was chosen as the conventional enzyme for bottom-up proteomics while AspN and GluC were selected for a middle-down approach. ATR-FTIR (attenuated total reflectance – Fourier-transform infrared spectroscopy) analysis was performed on microscope slides, while reversed-phase liquid chromatography with electrospray ionization-mass spectrometry (RPLC-ESI-MS) and matrix-assisted laser desorption/ionization-time of flight MS (MALDI-TOF-MS) were used to investigate the enzymatically digested samples. Regardless of the enzyme employed, the number of no specific peptides increased with artificial aging time, suggesting a protein structural degradation. This was also confirmed by the peptide mass fingerprinting (PMF) in MALDI-MS showing a progressive decrease of the S/N ratio with aging especially for heavier peptides. In this communication, the main results will be presented and discussed.

This work was supported by Progetto di Ricerca di Interesse Nazionale—PRIN 2022CNNRWZ- REActive GEl for orgaNic bindERs recognition in Artworks (REAGENERA), financed by the Italian Ministero per l'Istruzione, l'Università e la Ricerca (MIUR).

Photo-/Electro-chemical CO_2-recycling: from disposal to resource

M. Agnes,[a] A. Saavedra Moncada,[a] A. Barbero,[b] C. Nervi,[b] C. Damiano,[c] E. Gallo,[c] and N. Armaroli[a]

The most distressing task of Anthropocene is to find an effective process to convert renewable feedstocks of otherwise disposable materials into exploitable, cheap fuels and chemicals via sunlight-driven processes. This project targets the production of small, transportable molecules with high energy content, starting from CO_2 as raw material. The overarching goal is to simultaneously target the mitigation of climate change and the principles of circular economy.

The strategy is based on the synergistic action of orthogonal photo- and electro-catalysts able to drive the photoelectrochemical (PEC) conversion of CO_2. In particular, an array of metal-coordinating porphyrin-derivatives with appended amine groups has been synthesized and tested in homogeneous phase as plausible electrochemical (EC) catalyst,[1] whereas organometallic Mo-/Mn-based complexes bearing terminal amino moieties have been tested as photosensitizers (PS).[2]

A screening of the selected porphyrins showed a promising EC behaviour. Cyclic voltammetry data exhibit values of standard reduction potential (E°) for these molecules between -1.155 and -0.097 eV, i.e., compatible with CO_2 reduction. Further, the photochemical and photophysical characterization of the substrates suggests the possibility to exploit both catalysts simultaneously without facing electron transfer (ET) processes.

These preliminary results suggest the possibility to covalently link the tested molecules on an inert matrix in order to perform heterogeneous catalysis in view of a further optimization and scalability of the system.

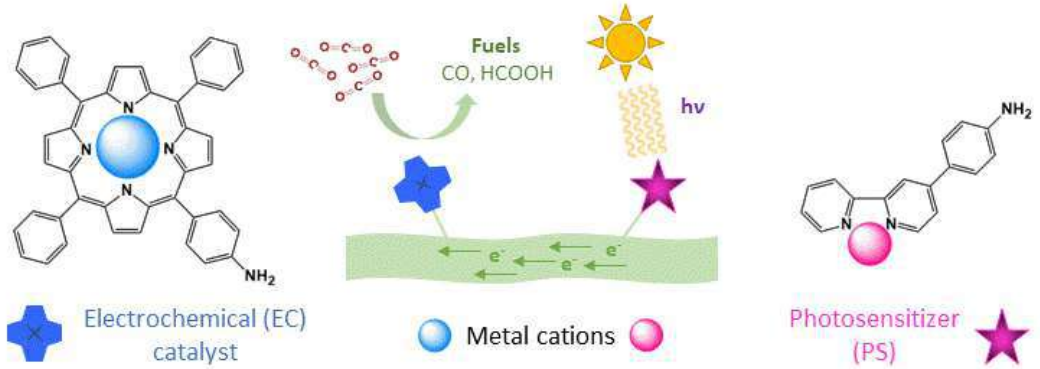

Figure 1: schematic representation of the selected molecules envisaged for targeting CO_2 reduction.

Ecclesiastic heritage safeguarding: a monitoring campaign in the Saronno Sanctuary

M. Borelli[a], A. Bergomi[a], C. A. Lombardi[a], V. Comite[a], A. Spagnuolo[b], C. Lubritto[b], C. Trigona[c], A. Gueli[d], R. Galvagno[d], P. Fermo[a]

Ecclesiastic heritage is a tangible testimony of artistic vocations among history. Despite hosting such masterpieces, churches' purpose differs from museums' one; thus, controlling microclimatic and pollutant levels can be challenging. Monitoring is essential to possibly suggest improvement measures[1].

Here is presented a monitoring campaign in the "Beata Vergine dei Miracoli" Sanctuary in Saronno (VA), which hosts frescoes and wood works from some of the most relevant 1500's artists of northern Italy. Temperature and relative humidity were measured by a 6 low energy Bluetooth nodes network, innovative in the power supply systems, ranging from vibrations to light. Particulate Matter (PM) was measured with a custom start-go-stop energy-saving GPRS system placed near the "Last Supper" woodwork. The application of innovative sensors allowed to guarantee the less-invasive setup, from the visual, acoustical and operator-dependent point of view. The monitoring campaign was performed between February and October, 2023.

Temperature and RH followed seasonal trends, and, comparing results with the normative suggestions[2], the values were in conformity mainly in spring and autumn. Besides absolute values, source of concern rises from the variation from the "historical microclimate" of the artworks[3]. There weren't problems with temperature, while, regarding RH, a mechanical-stressing 10% 24-hours variation (more than doubling the limit) was frequently observed during all the seasons, yet variations up to 35% were observed in summer. PM showed a season-dependent baseline with significant peaks related not only to worshippers' presence but rather to specific indoor sources as the use of incense, which acutely exposes the artworks to soiling and future chemical stress, as PM2.5 and PM1 were 90 and 70% of PM10 mass. Interestingly, peak correlation could be observed between RH and PM values all along the year. RH peaks could be thus linked to people presence, and it was possible to distinguish between celebrations with a lot of or a few people and with or without the use of incense.

This study will be crucial for the Sanctuary to better understand its point of weakness, to adopt corrective actions and to cut future restoration costs. It contributes to the awareness of the safeguarding theme, also by underlining the respectfully approach the scientific research has towards churches purpose.

Amelogenins are structural proteins of the dental enamel matrix, playing a key role in archaeological and forensic fields due to their relative abundance and relevance for sex determination. Currently, the detection of amelogenins mainly relies on liquid chromatography (LC) and tandem mass spectrometry (MS/MS)[1] and only few studies have involved immunoassays based on antibodies[2], but the application of fast, reusable and cost-effective biomimetic systems has not yet been explored. We present an innovative biosensor based on Molecularly Imprinted Bio-Polymers (MIBPs) coupled with Surface Plasmon Resonance (SPR), capable of detecting and binding amelogenins from standard solutions and protein extracts from human teeth samples. The protein sequence was studied by machine learning methods to select suitable peptide sequences to be used to molecularly imprint polynorepinephrine (PNE). The imprinting efficiency of the PNE-based biosensor was evaluated by performing single cycle kinetic (SCK) analyses, allowing the characterisation of the system in terms of kinetic rates and binding affinity parameters, towards both the peptide template and protein. The demonstration of the applicability in real cases was achieved optimising a suitable extraction protocol and performing measurements of extracts from human dental enamel. The results prove the effectiveness of the biosensor, which was specifically tailored on the target protein sequence and requires a quick and simple preparation process involving natural, 100% green, and biodegradable reagents. The application of state-of-the-art MIBPs offers a low-cost, highly effective, and environmentally friendly alternative to the use of antibodies in the development of label-free detection systems that allows the possibility to select and design the epitope to be printed with high precision, therefore deciding the protein capture target.

The interest in the ancient pigment Egyptian blue $CaCuSi_4O_{10}$ (cuprorivaite) increased dramatically after its discovery in frescoes of Raphael in the Villa Farnesina by non-invasive mapping [1]. This pigment has also been shown to have luminescent properties. In order to study the effect of possible impurities on the color and luminescent properties of the cuprorivaite phase, we prepared two series of samples corresponding to (1) isovalent substitution of Ca by Ba, (2) heterovalent substitution of Ca by La and Si by Al (Fig. 1). The samples were obtained by liquid sintering method in the presence of Na_2CO_3 (2%) at 1000ºC. Solid solutions based on cuprorivaite containing Ba are characterized by a monotonic increase in lattice parameters. The substitution of Ba by Ca in $BaCuSi_4O_{10}$ doesn't occur. The formation of solid solutions with successively increasing parameters has been proven in the case of heterovalent substitution. In both cases, the formation of solid solutions leads to a change in color from blue to violet in (1) and to steel bluish-green in (2). The effect of dispersion on the color is studied. A change in IR luminescence upon substitution in series (1) and (2) is shown.

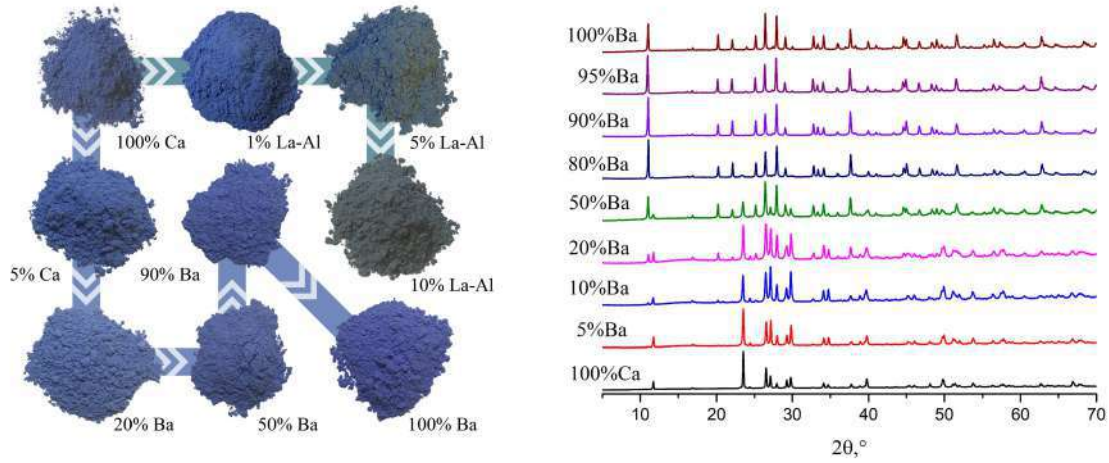

Figure 1. The color changes in series (1) and (2) (left) and powder XRD diffraction data for series (1) (right)

Dye analysis represents an invaluable repository of historical knowledge, while also shaping future strategies for cultural heritage conservation. However, characterizing dyes within complex matrices presents challenges, particularly when aiming for minimal or non-invasive analyses, due to potential interferences. Optimal techniques in this regard include high-performance liquid chromatography coupled with mass spectrometry (HPLC-MS), capable of separating components in mixtures and identifying them individually, and surface-enhanced Raman spectroscopy, providing ultrasensitive high-throughput vibrational information[1,2]. Nevertheless, achieving fingerprint characterization requires the removal of paint or thread fragments. Moreover, traditional approaches often involve high temperatures, strong acids, and significant amounts of organic solvents to extract various dye classes with varying solubility from the sample.

In the proposed methodology, a direct hydrogel extraction technique is introduced, tailored for minimal dye quantities, able to facilitate SERS and HPLC-MS characterization while preserving artifacts integrity. This approach utilizes agar, a green polysaccharidic compound forming a hydrogel upon interaction with water. Agar gel loaded with an ammonia aqueous solution was employed to gently extract dyes without the need for organic solvents[3].

To maximize the use of minimal analyte quantities extracted for multi-technique characterization, a clean-up strategy, known as dispersive liquid-liquid microextraction (dLLME), was tailored. DLLME purifies and preconcentrates low concentrated analytes, reducing organic solvent volumes while maintaining effectiveness.

Following successful results on laboratory mock-up, the gel was rescaled until it could be applied using a Pasteur pipette tip, to prevent any visible markings. The methodology was applied to real study cases in collaboration with the Berlin National Museums. The results highlight the effectiveness of the developed workflow in enabling fingerprint dye characterization using minimal analyte quantities while minimizing visible impacts on artifact surfaces.

Performic acid pre-treatment of poplar biomasses from green remediation to obtain fine-products

A. Angelini,[a] E. Scelsi,[a] V. Ancona,[a] G. Aimola[a], P. Pastore[a]

[a]*Italian National Research Council, Water Research Institute (IRSA-CNR), Italy*

Lignocellulosic biomass is the most abundant and cheap carbon-based feedstock on earth and is the main candidate for the purchasing of bioderived added value compounds namely biofuels and biochemicals. The valorisation of the lignocellulosic biomasses generally occurs through bio-chemical transformations of polysaccharides (cellulose) into simple soluble sugars (glucose). The use of enzymes (cellulases)[1] has proven to be more advantageous, thanks to the higher specificity towards the substrate which leads to the selective production of glucose. To make the enzymatic processes more efficient a pretreatment is necessary to destroy the complex structure of hemicellulose and lignin that act as shields for cellulose by preventing its hydrolysis[2].

In this research work a sustainable pre-treatment for the valorisation of a poplar matrix (pruning residues) recovered with Plant-Assisted BioRemediation (PABR) technology was studied[3]. Pre-treatment was carried out using mixtures of formic acid and hydrogen peroxide to make the lignocellulosic structure simpler to make cellulose more available for the consequent enzymatic process. The synergic action of formic acid and hydrogen peroxide was greatly efficient and yields a solid phase enriched in cellulose (56% of cellulose) with a total recovery equal to 70–80% of the starting cellulose. The recalcitrant molecules such as hemicelluloses and lignin, potential platform molecules for biorefinery[4], were almost completely recovered in the liquid phase.

The resulting biomass was subjected to enzymatic hydrolysis through a commercial cellulase (from Trichoderma reesei): the enzymatic digestibility was proven to be already effective on samples pre-treated with 3.5 M performic acid at 55 ◦C since the cellulose in the residual biomasses was completely hydrolysed in glucose. The produced monosaccharide was then used as feedstocks to produce levulinic acid in presence of $AlCl_3 \cdot 6H_2O$ (1%) and sulphuric acid (0.5%) at 150 ◦C for 45 min. A final yield of 68.2% of levulinic acid and 4.8% of HMF was obtained. These results are comparable to those obtained with other heterogeneous[5] and homogeneous catalytic systems[6] reported in more extreme operative conditions.

Technological and compositional characterisation of Chinese Tang-style pottery

B. Vitale [a], E. Diana [a] , A. Agostino [a], T. Poli [a], M. C. Valsania [a]

[a] *Department of Chemistry, University of Turin, Via Giuria 7, Turin 10125*
benedetta.vitale@unito.it

The so-called *mingqi* figurines are Chinese funerary glazed or painted pottery statuettes. They became highly popular during the Tang dynasty (618-907 AD), a golden age of Chinese art, depicting peculiar characters such as coloured horses, foreign servants, and Bactrian camels [1]. Then, from around the 1910s, *mingqi* figurines began to attract Western collectors, and modern reproductions began to proliferate in the art market [2,3]. However, little provenance information is available, and authenticity is often uncertain. In addition, Tang-style finds have never been subject to systematic investigation.

As part of the PhD research project in *Technologies for Cultural Heritage*, 30 figurines from the Museo delle Civiltà in Rome, Museo di Arte Orientale in Venice, and Museo delle Culture in Milan have been analysed using non- and micro-invasive methods. In this study, the focus was set on the first chemical examination of their ceramic bodies. The comprehensive chemical characterisation of 30 pottery fragments from the inner cavities of the statues was carried out. More specifically, the samples were examined by colourimetry (Munsell colour system), μ-Raman/μ-FTIR spectroscopies and X-ray powder diffraction (XRPD) to assess the mineralogical patterns, Backscattered (BS) Scanning Electron Microscopy (SEM) to characterise the shape of the inclusions, SEM coupled with Energy Dispersive X-ray Spectrometry (SEM-EDS) to verify possible classifications based on the compositional analysis.

The employed multi-technique approach provided compositional, morphological, and structural information, with a possible comparison and cross-checking of the results. The early results allowed us to check for a first classification of modern Tang-style production from the major Chinese collections in Italy, and a comparison of the technological features with those of authentic Tang figurines from Chinese archaeological sites. The systematic investigation using the illustrated methodology might offer valuable information for further authentication and provenance studies of all the Tang-style artefacts stored in Western contexts.

Based on the framework developed by Rockstrom et al. [1], planetary boundaries (PBs) are defined as biogeochemical and physical thresholds that could have severe consequences for the Earth System (ES) if crossed. Chemical pollution has been included in the list of PBs since the first release of the PBs framework, and has recently been renamed to novel entities (NEs) to encompass "new substances, new forms of existing substances and modified life forms" [2]. At present, the assessment of the amount of NEs that can be tolerated by ES before irreversible shifts remains a challenge. Coral reefs are a hotspot of the current ecological crisis and human-driven ES changes: reef-like structures have existed on Earth for over 500 million years, but now their existence appears threatened by a combination of anthropogenic stressors such as higher water temperatures, ocean acidification, and chemical pollution. To collect data in these delicate environments and establish the contribution of NEs to large-scale bleaching events, we are currently developing new monitoring strategies based on the application *in vivo* of solid-phase microextraction and advanced mass spectrometry techniques [3]. Our work focuses on detecting different classes of contaminants including persistent organic pollutants (POPs), contaminants of emerging concern (CECs) [4], heavy metals and radionuclides, micro and nanoplastic (MPs and NPs) [5], and at the same time secondary metabolites to be used as markers of ecological system integrity [6]. By identifying the primary stressors that lead to irreversible changes, the marine pollution mitigation actions are then correctly prioritized, and the effectiveness of restoration plans is accurately evaluated.

The extensive use of synthetic pesticides in agriculture has a significant environmental impacts and poses severe health risks to living organisms, including the human population. Hence, exploring effective alternatives to current pesticide practices is one of the main research goals in agrifood chemistry. A potential solution lies in the controlled release (CR) of bioactive compounds. In the frame of the Profood-IV Project (PON ARS01:0755), the use of two biocompatible and biodegradable polymers, i.e. sodium alginate and sodium carboxymethylcellulose (CMC), was investigated to synthesize crosslinked hydrogel beads for encapsulating and releasing glucosinolates-rich extracts from Brassicaceae. Glucosinolates are secondary metabolites of plants, which can be hydrolyzed by the mirosinase enzyme to isothiocyanates, a class of compounds with a renowned biocide activity towards fungi, bacteria and insects. The physicochemical properties of the developed CR systems was performed using several analytical techniques, including Attenuated Total Reflectance-Fourier Transform Infrared (ATR-FTIR) spectroscopy, thermogravimetry (TGA), Differential Scanning Calorimetry (DSC), and rheometry. The encapsulation efficiency was assessed and the release kinetics was analyzed both in water and in a model soil. Preliminary microbiological tests were conducted to evaluate the efficacy of this approach, both in laboratory and on field. These systems represent a cost-valuable, sustainable and scalable alternative solution to the use of traditional pesticides, which exploits the by-products of the agrifood industry in agricultural practices.

Atmospheric depositions are the process by which particulate matter, aerosols, and atmospheric gases from both anthropogenic and natural sources reach the ground in the form of precipitation and dry deposition. The combination of these two components is referred to as BULK depositions. In this study, two sampling sites were chosen: one representing an area in the urban center of Lecce affected by vehicular traffic (Arpa site, DAP Lecce), and one representing a suburban area influenced primarily by regional background (Ecotekne site within the university campus).

Sampling and determination of pollutants in BULK depositions were carried out on a monthly basis in accordance with Legislative Decree no. 155/2010, following UNIEN standards 15980:2011 for the determination of organic micro-pollutants and UNI EN 15841:2010 for the determination of inorganic parameters. Specifically, water-soluble inorganic species were analyzed using HPIC, heavy metals in the filtered aqueous sample were determined with ICP-MS, and the filters used for filtration were analyzed with ICP-AES. Additionally, PAHs were analyzed using GC-MS.

Applying source apportionment techniques such as multivariate statistics and PMF (positive matrix factorization), common sources between the two sites were identified. It was observed that the urban site had more samples characterized by exhaust emissions from traffic, while in the suburban site, samples showed a greater contribution from crustal sources.

This study suggests the application of source apportionment techniques on samples of atmospheric depositions to identify differences between sites impacted by anthropogenic activities compared to less impacted suburban sites, in order to provide useful information for decision-makers regarding public health management and air quality in cities.

angelo.agostino@unito.it

The conservation of archival and librarian objects represents a continuous challenge especially for what concerns the protection of paper and parchment from bacterial and fungal biological attacks.

The development of biocidal materials produced using green techniques or associated with circular-economy processes represent a unique opportunity to safeguard these goods.

The synthesis of MgB_2 nanostructured through microwave techniques has shown the possibility of exploiting this material as a biocide in biomedical and, in this case, cultural heritage contexts.

The use of inorganic nanomaterials is definitely an advantage over traditional antibiotics, due to the low cost of production and the chemical inertia towards organic media to be preserved [1, 2].

The advantage resides in their different mode of action comparatively to antibiotics, therefore, the chemotherapeutic effect of NM is driven by processes that take place at the interface and two major lethal groups of interdependent mechanisms are presented in literature [3]: (i) disruption/damage of membrane integrity and potential [4]; (ii) production of Reactive Oxygen Species (ROS) [5], far away from an optimum level reached during the cellular metabolism. At low doses, ROS can cause severe DNA damage and mutations, while at higher concentration, ROS lead to the imminent cell death, caused by the severe oxidative stress and macromolecules modification via lipid peroxidation, alteration of proteins, inhibition of enzymes, and RNA and DNA damage

The results of in vitro, in vivo and in situ application of MgB_2 and MgB_2 - fulleren doped nanocompounds in the contrast of mycetes and cellulositic bacteria or that attack collagen fibers in parchment will be presented here.

Porcelain and Magnesian Mortars: an update on the traditional mortar formulations

M. Destefani,[a] E.Balliana [a], L.Falchi [a], E. Zendri,[a]

[a]*Ca'Foscari University of Venice, Italy, Venice*
858827@stud.unive.it

The preservation and restoration of architectural heritage has recently re-evaluated the role of traditional mortars due to their high compatibility with ancient masonry. Their use has therefore increased in recent years, as has the research and development of new formulations in improving their durability and resistance to deterioration. The focus of this research relies on the study of two past mortar formulations, called "porcelain mortars" and "magnesian mortars" whose documentation, even if lacking in numbers, still highlights their noticeable setting and hardening properties even in high humidity environments. Porcelain mortars are characterized by a mixture of sand and natural lime with metakaolin, nowadays known as a supplementary cementitious material (SCM) used often by the Portland cement industry as an additive to enhance the compressive strength and pozzolanic properties of cement[1,2,3,4,5]. Magnesian mortars are based on magnesian lime, composed by $CaCO_3$ and $MgCO_3$ (~30% in volume), able to produce a rather durable material capable to harden even within 2 or 3 days while immersed in water[6]. This project wants to deepen the knowledge about the aforementioned mortar formulations mixed with different percentages of metakaolin to evaluate its influence on both physical and mechanical properties as well as their freeze-thaw and salt decay resistance. Two sets of samples were produced, traditional and magnesian lime-based mortars with variable lime/sand ratios and variable quantities of metakaolin. The study paid particular attention to the rheological aspect of fresh mock-ups and the consequent influence of the different binder/inert ratio and additive on properties such as spreading, specific weight and workability. From the analysis of fresh mortars, no noticeable differences were found between the different percentages of added metakaolin, but magnesian lime appeared more useful for the application on inclined surfaces than the traditional ones due to its texture and thixotropy. The formulations were studied in their behavior with water through the analysis of capillary absorption and water vapor permeability. The presence of metakaolin seems to not modify in an evident way the behavior of these mortars, even though, for what concerns the compression test, good results were obtained for mortar formulations containing metakaolin. Research is ongoing to test the influence of traditional and innovative additives on these mortars.

The influence of pigment-medium interactions in the manifestation of selective degradation phenomena on modern white oil paints

M. Gnemmi[a,b], M.Á. Herrero-Cortell[c], A.M. García-Castillo[c], M.T. Martínez-López[d], L. Fuster-López[c], F. C. Izzo[b]

[d]*IVAM, Institut Valencià d'Art Modern, Valencia, Spain*
margherita.gnemmi@unive.it

The presence of selective degradation patterns in modern oil paintings, depending on the colored area considered, has been the starting point of this research: indeed, random, unconnected cracks, sharper edges, and protrusions, can be found beside vertical cracks of a semi-connected network within the same painting. The aim of this study was to understand the causes that led to such differential degradation phenomena by understanding the physical, chemical, and mechanical mechanisms involved in the damage patterns.

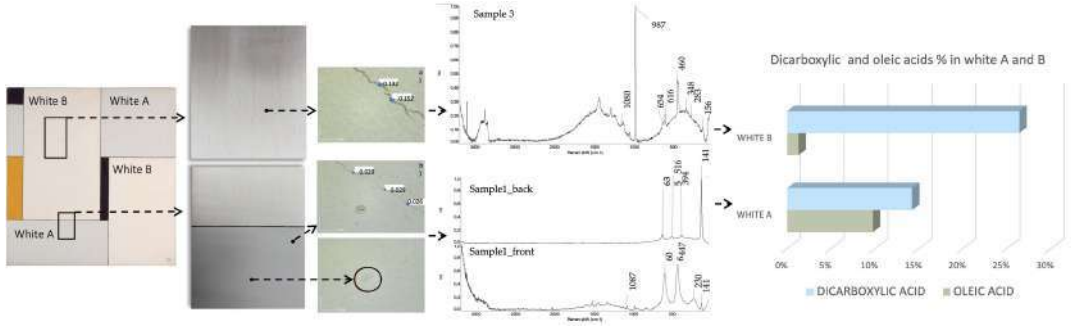

Figure 1: Multi-analytical approach carried out on *Composition dans le cône avec couleur orange* by G. Vantongerloo.

The case study (Fig.1) allowed to understand that the interactions between the composition of pigments, the nature of the binding media and the products resulting from the film formation processes were the mainly responsible for the ongoing degradation phenomena. A hybrid experimental approach based on non-invasive analysis (such as OM and multiband imaging analyses) were coupled with μ-Raman, ATR-FTIR and GC–MS analysis. The results highlighted that: random cracking and protrusions in white A areas were due to zinc soaps migrated from the preparatory layer; in white B areas, semi-combined cracking network was related to the interaction between lithopone and the lipidic binder causing the significant formation of dicarboxylic acids. This research bridges the gap between the chemical knowledge of artist's material choices and their degradation processes: it does not merely describe the morphology of cracks, but focuses on the role played by the pigment-medium interaction in the film formation processes of XX century commercial oil paints.

The GoGreen project, funded by Horizon Europe (2022-2026), aims at introducing a green revolution in conservation by implementing both preventive and remedial strategies anchored in sustainable principles.

In the field of preventive conservation, we are developing new damage assessment tools for a variety of materials including glass, metal, ceramic, oil paintings, limestone, and lime-based plaster wall paintings. The goal is to support decision-making processes, allowing for the adoption of more flexible environmental controls within collections, ultimately reducing the carbon footprint. Additionally, artificial intelligence (AI) is employed to detect early signs of damage, thereby enabling the formulation of preventive conservation strategies. On the remedial side, the project aims to develop new eco-friendly solutions for cleaning paintings and metals, as well as sustainable stabilisation materials for metals and glass objects. These advancements draw inspiration from historical recipes, bioprocesses, and green chemistry. We are, for instance, producing electrospun nonwoven mats, made from either recycled polymers or bio-based compounds, combined with greener solvents for the removal of aged varnishes from paintings. These mats utilize micro- and nano-porosity to facilitate capillarity, ensuring varnish removal without the need for mechanical action. Similar technologies and bio-based methods are applied for treating tarnished metals (silver, copper and iron), using green chelating agents. Moreover, a water-based synthesis process at room temperature has been developed to produce silica-gel nanostructures for the stabilization of glass. Biosorption and biomineralization processes are also studied for the stabilisation of copper and iron artefacts. To validate the effectiveness of these materials and methods, GoGreen develops specialized and cutting-edge analytical procedures for surface and volume assessment. A key goal of GoGreen is to empower the conservation community to embrace sustainable practices. This is being achieved through the development of a digital web-app and decision model designed to assist conservators in designing and implementing green preventive and remedial treatments. Moreover, educational initiatives are being organized to instill a green mindset within the conservation field, aligning future practices with the objectives of the Green Deal.

simona.galoppo@unicampania.it

Spreading wastewater generated in the agro-zootechnical field to the soil is among the sources of total nitrogen in the environmental matrices. Wastewater is rich in ammonium nitrogen, which is transformed into nitrate by aerobic bacteria spontaneously present in the soil. Nitrate is highly soluble in water and leaches into the soil, surface water and groundwater, leading to environmental, humans, economic and social risks; for example, it could compromise the DOP brand of buffalo mozzarella. Therefore, removing ammonium nitrogen is crucial. Traditionally, ammonium nitrogen is removed from wastewater by biological and chemical approaches, but nitrate generation is carried out in this case. This research proposes an innovative approach based on electroxidation (EO). The research started with the design of the reactor and continued with its operation to intensify the electrochemical process and evaluate its engineered application. Applying electric current EO allows the transformation of ammonium nitrogen into gaseous nitrogen, avoiding nitrate and nitrite generation[1], and without sludge production, which contribute to the pollution of the environmental matrices. The tests were performed by using an advanced flat reactor made of titanium oxides (20*22.5 cm^2), operated to investigate the effect of applied current, after 3 hours. Preliminary investigations were conducted with a synthetic matrix, an initial concentration of NH_4Cl of 50 mg L^{-1} and NaCl of 250 mg L^{-1} in Milli-Q water; the initial pH was 6. This study also combines the ethical and application principles of sustainable development, Agenda 2030[2], and circular economy thanks to the recovery of wastewater.

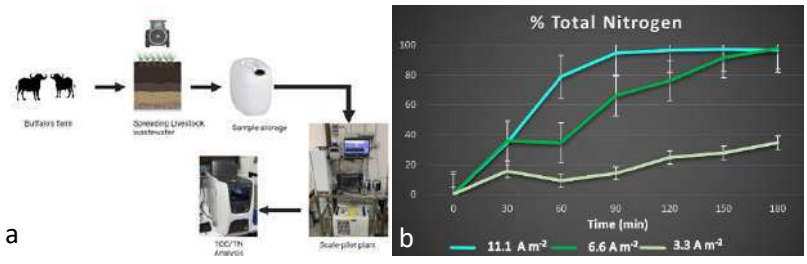

Figure 1: a) Flow chart of the research to removal of total nitrogen in livestock wastewater; b) EO results

federico.bedogni2@unibo.it

The landfill remains one of the most frequent final destinations for the end-of-life of waste today at the national level (20% of MSW and 51% of industrial waste)[1]. Wastes permanence in landfill generates a heavily polluted liquid fraction (leachate) that, if not collected and treated, could constitute a threat to local superficial and subsoil water with consequential environmental and human health concerns[2]. A comprehensive examination of a full-scale facility that treats landfill leachate was conducted. The plant is composed of a chemical-physical treatment and a biological treatment designed for the abatement of nitrogen (90.3%), COD (92.2) and SS (95.1%), heavy metals and other pollutants. The precipitated sludges are centrifuged and sent to landfill. The study of the environmental impacts has been performed by applying the principles of the Life Cycle Assessment (LCA) techniques using ReCiPe 2016 [3] as the assessment method. $1m^3$ of leachate entering the plant is used as a functional unit (FU). Twelve impact categories have been analysed including in the system boundaries of the study the production and transport of the chemical used in the process, the electricity production and distribution, maintenance of the plant, sludge disposal and the law-compliant discharge of the clarified residues into seawater (including PFAS). The results show that chemicals, in particular sodium hydroxide (NaOH) and phosphoric acid (H_3PO_4), and electricity are major contributors in most of the impact categories while regarding eutrophication categories the discharge of the final clarified is by far the most impacting one. The next advancements will concern a focus on the PFAS removal efficiency of the plant and a life cycle assessment (LCA) including this removal in the functional unit (FU).

Toxins of freshwater microorganisms, from bio- to chemodiversity

L. Cerasino,[a] N. Salmaso,[a,b]

[a] *Fondazione Edmund Mach, Research and Innovation Centre, via E. Mach, 1, San Michele all'Adige (TN)*
[b] *NBFC, National Biodiversity Future Center, 90133 Palermo, Italy*
leonardo.cerasino@fmach.it

Cyanobacteria are prokaryotic microorganisms that are present in all freshwater environments. A certain number of cyanobacterial species have the ability of producing toxic secondary metabolites. The massive growth (or bloom) of toxigenic cyanobacteria can lead to high concentrations of toxins in the water, thus posing a threat to human health. Eutrophication is the main driver of cyanobacterial blooms, but ongoing climate changes can exacerbate the problem. Cyanobacterial toxins (cyanotoxins) are secondary metabolites with a huge chemical diversity due to the high flexibility of their biosynthetic pathways.[1]

Research conducted in the last fifteen years at Fondazione Edmund Mach has revealed that the biosynthetic pathways are common to all toxigenic cyanobacteria, but that the resultant toxic molecules are very dependent on the species.[2] For instance, the cyanobacteria *Planktothrix rubescens* and *Microcystis aeruginosa* (among the most frequent responsible of toxic blooms around the world) both have the same gene cluster of the hepatotoxic microcystins (MC), but they synthetize different variants of MC. Moreover, the same set of MC are produced in different ratios by different strains of *P. rubescens*. These examples show how an integrated biological and chemical approach can be very effective in studying toxigenic cyanobacteria. This approach has demonstrated to be very useful in addressing the toxic potential of populations of cyanobacteria in different natural lakes.[3]

The presence of cyanotoxins in freshwaters is a matter that is taken into consideration by legislation in most countries and specific monitoring programs are routinely carried out by sanitary/environmental agencies. An emerging issue that is not yet considered by legislation is the presence of toxic cyanobacteria attached to different types of substrates (rocks, stones, vegetation) on the shores of lakes and rivers. Our recent studies revealed that some potent neurotoxins (anatoxins) can be produced in very high quantities by cyanobacteria growing in these environments. Such "biofilms" can constitute a relevant sanitary problem, considered that they can be easily accessed by people and animals walking on the shores.[4]

The fascinating discovery of two antiviral drugs Raltegravir and Grazoprevir: the relevance of the scientific method and serendipity in drug discovery

V. Summa[a]

[a]*Department of Pharmacy – University of Naples Federico II - Via Domenico Montesano, 49 - 80131 – Napoli, Italy*

In drug discovery, the scientific method and serendipity are always key elements of the successful story. The presentation is a journey in the antiviral drug discovery and development process of the author related to two drugs, Raltegravir[1,2] (Isentress™), the first in class HIV integrase inhibitor approved, and Grazoprevir[3], a pan-genotype HCV protease inhibitor approved in combination with Elbasvir (Zepatier™) to cure HCV patients in interferon free therapy. HIV and HCV differ significantly at the molecular level and with respect to their resultant pathogenesis. However, the development of effective therapies present similar challenges, rapid turnover and high viral load together with the propensity to select resistant variants and the need for chronic treatment months (HCV) or for even the entire life span (HIV). Failure and success will be presented in the strategies from hit identification to POC in animal model, candidate selection and clinical development including. Regarding HIV integrase, particularly relevant was the understanding of the hit mechanism of action and the required pharmacophore eventually leading to the switch from HCV polymerase to HIV integrase that combined with creative medicinal chemistry, led to the generation of a novel class of selective HIV integrase inhibitors allowing the selection and approval of Raltegravir. Instead, the profound analyses of the structural features of the different genotypes and in vitro selected mutants of the HCV protease, combining X-Ray and modelling studies, were the key elements for the discovery of Grazoprevir. Two drugs (Figure 1), two different Med Chem approaches and two-historical case of the antiviral development.

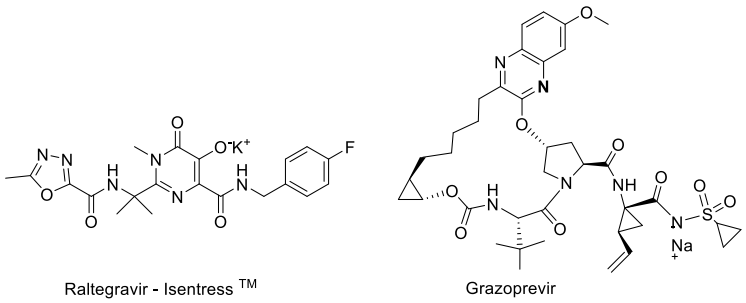

Figure 1: Raltegravir and Grazoprevir.

Tauopathies encompass over twenty neurodegenerative diseases characterized by the aggregation of the Tau protein.[1] Physiologically, Tau is involved in the regulation of microtubules (MTs) dynamic stability.[2] However, when aberrantly phosphorylated or mutated, Tau can dissociate from MTs to assemble into aggregates responsible for neurodegeneration.[1,3] On these premises, the design of compounds restoring the physiological Tau-MTs interaction represents a promising strategy for tauopathies treatment. In search of compounds endowed with such an activity profile, we first performed extensive *in silico* analyses, identifying a series of 2-phenyloxazole (PHOX) compounds as potential candidates for the treatment of the Alzheimer's disease tauopathy. To assess the candidates' activity, we then performed extensive experimental analyses, and developed a novel *in vitro* cellular assay that enables to monitor pathological changes in human Tau. These analyses (Figure 1) allowed us to identify one candidate (PHOX15) able to restore Tau-MTs interaction and to reduce Tau aggregation.[4] Finally, *in silico* structure-based simulations allowed us to identify a series of cryptic pockets in Tau cryo-EM structures, one of which being potentially involved in the PHOX15 binding.[4]

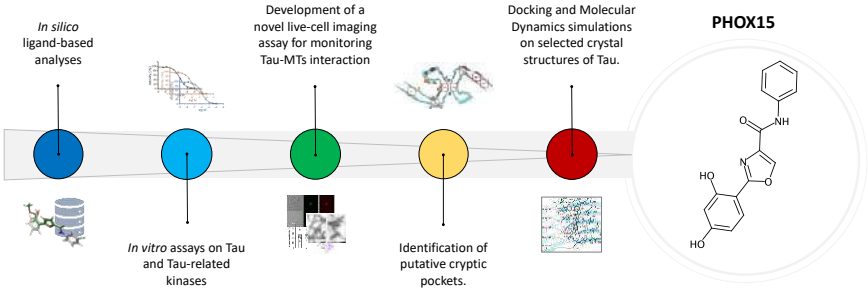

Figure 1: In silico and experimental workflow that led to the identification of the PHOX15 candidate.

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is the causative agent behind the 2019 global pandemic (COVID-19). Despite the successful vaccination programs, little has been accomplished in the development of specific antivirals. The disparity in COVID-19 vaccine resistance, the emergence of SARS-CoV-2 variants of concern, and the potential to evade both vaccination and acquired immunity emphasize that the development of antiviral drugs to treat SARS-CoV-2 infections is of utmost importance. Among potential drug targets, the SARS-CoV-2 non-structural protein 13 (nsp13) is highly attractive thanks to its critical role in viral replication. Nsp13 utilizes the energy of nucleotide triphosphate hydrolysis to catalyze the unwinding of double-stranded DNA or RNA.[1] Moreover, nsp13 is the most conserved nsp among the coronavirus family.[2] This implies that small molecule nsp13 inhibitors may serve as pan-CoV antiviral agents and that previously found compounds targeting nsp13 in other CoVs species might be effective against COVID-19. Although the roles of nsp13 in the viral lifecycle, there is a paucity of information about small molecules endowed with nsp13-inhibitory activity. Basing on literature data and thanks to our longstanding expertise in the design and synthesis of DKA derivatives, we carried out a semi-random screening on our in-house library of DKA compounds, identifying a promising hit compound as micromolar nsp13 inhibitor.[3] We synthesized new DKA derivatives structurally related with the identified hit, obtaining dual SARS-CoV-2 nsp13 ATPase and unwinding inhibitors, also capable of inhibiting viral replication. Mode-of-action studies revealed ATP-non-competitive kinetics of inhibition, not affected by substrate-displacement effect, suggesting an allosteric binding. Docking studies suggested a possible binding mode within an allosteric pocket of nsp13. Moreover, the broad-spectrum antiviral activity was evaluated, highlighting their potential as pan-CoV inhibitors.

Endocannabinoids (ECs) are neuromodulatory signaling molecules implicated in a plethora of biological processes including cognition, analgesia, stress, anxiety, neuroprotection, and motor coordination. Arachidonoyl ethanolamide (anandamide or AEA) and 2-arachidonoyl glycerol (2-AG) are the most important ECs and function through the G-protein coupled cannabinoid receptors (CBRs, CB1R and CB2R). Since the discovery of CBRs, many efforts have been made to develop highly selective orthosteric compounds that would be suitable as potential therapeutic agents. In many cases, direct-acting agonists proved to cause serious adverse effects, such as psychotropic effects or immune dysfunction, which limited the clinical development of classical orthosteric CBR ligands. For this reason, interest in allosteric regulation as a new way of modulating receptor activity without the drawbacks associated with direct agonist activation is steadily increasing in the CBR field. By binding to topologically and often functionally distinct sites from their orthosteric counterparts, allosteric ligands typically allow high levels of selectivity. Notably, a new approach in medicinal chemistry has been reported in the literature based on the design of bitopic (or dualsteric) agents as single chemical entities capable of simultaneously interacting with both the orthosteric and allosteric binding sites. The idea behind the development of bitopic ligands is to combine the activation properties of orthosteric ligands with the higher selectivity profile of allosteric ligands. During my doctoral studies, I applied the concept of bitopic modulation to CBRs, resulting in the identification of the first two hetero-bivalent bitopic ligands for CB2R[1,2,3]. Following extensive biochemical and computational studies to confirm their bitopic nature, the therapeutic potential of these newly developed modulators was investigated. This exploration revealed potent anti-inflammatory activity in a human microglial cell inflammatory model for both ligands,[1,3] as well as antinociceptive activity in an experimental mouse model of neuropathic pain and pro-autophagic effects *in vitro* in an Alzheimer's Disease model for one of the ligands[1].
Afterward, expanding bitopic modulation to the other CBR subtype using potential CB1R dualsteric agents brought to light even more intriguing aspects of orthosteric/allosteric hybrid modulation.

Exploring innovative approaches to revolutionize leishmaniasis drug discovery: new chemical modalities and chemotypes

A. Salerno[a]

[a] *Department of Pharmacy and Biotechnology, Alma Mater Studiorum—University of Bologna, Via Belmeloro 6, Bologna 40126, Italy*
alessandra.salerno5@unibo.it

Leishmaniasis causes considerable mortality and morbidity in many parts of the world. The most severe form of the disease, the visceral leishmaniasis, causes 20000–40000 deaths annually according to the WHO. None of the current front-line treatments are ideal for use due to cost, toxicity, resistance, and parenteral administration. As a result, there is an urgent need for new leishmaniasis treatment options. Trypanothione reductase (TR) represents one of the most robustly validated drug targets for *Leishmania* parasites. TR has been assessed for its suitability as a target in terms of level of genetic and chemical validation, assay feasibility, toxicity, resistance and druggability. However, the main area for caution for this target remains its druggability since the enzyme active site is large and featureless. For this reason, despite the efforts, TR is still considered a highly challenging target for conventional small-molecule-based inhibition approaches. A change in perspective is therefore needed. In this regard, drug discovery has experienced an incredible paradigm shift in the past two decades and includes now an innovative wave of chemical modalities to efficiently address difficult biological targets.

Based on this, the aim of my research was to develop novel approaches for the leishmaniasis drug discovery through four complementary projects that incorporate new chemical modalities (i.e., Targeted Protein Degradation, *TPD* for infectious diseases)[1] and novel chemotypes. Moreover, we harnessed a fragment-based drug discovery (FBDD) strategy to develop new TR inhibitors[2] in order to demonstrate the importance of employing diverse medicinal chemistry strategies and chemotypes as new tools in the drug discovery scenario for leishmaniasis.

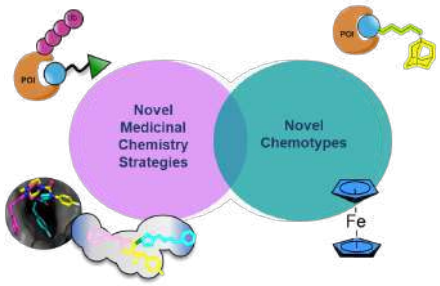

Figure 1: Schematic representation of the new chemical modalities for leishmaniasis

Targeted Positron Emission Tomography (PET) imaging, along with Liquid Biopsy for detecting circulating tumor cells (CTCs-LB), offers the potential to precisely identify tumour locations and track disease progression, respectively.[1] These techniques require the identification of pertinent cancer hallmarks, whose detection enable highly specific diagnostics and therapies. In this perspective, the C-X-C chemokine receptor type 4 (CXCR-4) is arising among the most promising targets due to its overexpression in more than 30 different cancer types.[2] We have recently described a family of small cyclic peptide acting as CXCR4 antagonists endowed with high receptor affinity, selectivity, and metabolic stability.[3] Herein, we report the use of the lead peptide R54 to develop radiolabelled probes and to decor self-assembling amphiphilic dendrimers (SAADs) for *in-vivo* PET imaging of CXCR4-overexpressing tumours. Additionally, we explore the use of its derivative, R54-L10, for functionalizing photonic biochips designed to detect CXCR4-overexpressing circulating tumour cells (CTCs). The resulting [^{68}Ga]NOTA-R54 was successfully employed for *in vivo* PET imaging studies using CHO-hCXCR4 and Daudi lymphoma cells, revealing high CXCR4-specific tumour uptake and high tumour/background ratios.[4] Currently, [^{68}Ga]NOTA-R54 is awaiting approval by the Italian Minister of Health for a microdose clinical phase 1 study involving 5 patients at the Istituto Nazionali Tumori di Napoli "G. Pascale." Promising results were also achieved with [^{68}Ga]NOTA-R54-decorated SAADs, which were characterized *in vivo* using mice carrying xenograft CHO-CXCR4. Finally, as a proof of concept, the R54-L10-functionalized biochips were preliminary assessed in the presence of CXCR4$^+$ and CXCR4$^-$ CHO cells (1 x 10^2 to 2.5 x 10^4 cells/ml), showing the capability to specifically detect the receptor at cell concentrations comparable to those of the CTCs.

Cancer is undeniably one of the most intricate diseases in the healthcare community. Epigenetic enzymes, responsible for the spatial-temporal regulation of gene expression, are key targets for oncotherapy. Among these, SET and MYND domain-containing protein 3 (SMYD3) is a lysine methyltransferase whose aberrant activity has been linked to several types of cancer, making it an exceedingly attractive target for oncotherapy. Although the development of SMYD3 inhibitors as anticancer drugs has faced attrition, recent findings have reignited interest in this target, showing that SMYD3 is involved in DNA repair mechanisms and its inhibition could impact cancer cell sensitivity to DNA-damaging drugs.[1] To support and expedite early-stage discovery campaigns on SMYD3, reliable and informative analytical platforms need to be established to prioritize the best promising inhibitors. Both chemical tools and drug-like compounds are required for progressing on SMYD3. In this scenario, and as part of a collaborative project involving multiple research groups, we developed various fit-to-purpose analytical methods, which have been used to ensure the required level of information was achieved. These include a mass spectrometry (MS)-based assay to overcome the use of radiolabelled activity assays, surface plasmon resonance (SPR) screenings, and top-down/bottom-up MS investigations to provide insights into the mechanism of action and site of interaction of new ligands. Results collected in these studies were combined with those achieved by others within an iterative medchem process to identify promising SMYD3 inhibitors. These efforts led to the groundbreaking discovery of the first allosteric ligand for SMYD3 and of a previously unknown allosteric site in the C-terminal domain.[2] Additionally, a screening campaign for targeted covalent inhibitors (TCIs) led to the identification of a potent 4-aminopyridine-based ligand bearing a 2-chloroethyl group as a reactive warhead. Further SPR and MS investigations provided a thorough definition of the kinetics and affinity parameters for the initial reversible complex, kinetic parameters for the subsequent covalent adduct formation, and the identification of the specifically targeted amino acid in SMYD3 structure[3].

Acknowledgments: This research was partially supported by EU funding within the NextGenerationEU-MUR PNRR National Center for the Development of Gene Therapy and RNA-based Drugs, Spoke Cancer.

Inverse design has revolutionized how medicinal chemists approach drug discovery.[1] Pharmacological targets are now at the forefront of the discovery process to tailor the design of new compounds with desired physicochemical and pharmacological features but minimal side effects.[2] This new paradigm is very promising for exploring unknown regions of the chemical space in the search of new synthetically feasible bioactive molecules to prioritize for biological testing. We developed a user-friendly platform[3] based on artificial intelligence and multiobjective optimization methods to guide the human-like design of compounds reflecting the distributions of relevant druglike properties and the structural similarity of known compounds towards specific biological targets available from ChEMBL.[4] Several quality metrics were employed to evaluate the goodness of the new generated compounds. Results can be retrospectively evaluated by employing molecular docking simulations or, especially for large volume of data, by ligand-based screening carried out with PLATO,[5,6] a free web-platform designed for target fishing and bioactivity predictions.[7,8]

Integrated Phenotypic Strategies for Unlocking Challenging Biological Pathways

M. Radi

University of Parma, Department of Food and Drug
marco.radi@unipr.it

The accurate prediction of the precise molecular interactions needed to modify a disease phenotype is still a challenging task in medicinal chemistry, and hinders the translation into safe and effective drug candidates. Although different target-based approaches have been successfully employed for rational development of different drugs, mounting evidences suggest that the reductionist lock-and-key target-based approach often results in molecules unable to exert their intended effects on complex biological systems (such as cells or animal models), despite evidences regarding target engagement and modulation. [1] Over the past decade, the re-evaluation of the role played by target-centric approaches in drug discovery has sparked a renewed interest in phenotypic approaches for the discovery of first-in-class candidates.

In this presentation, the phenotypic strategies recently undertaken by my research group to discover novel pharmacological tools capable of effectively modulating the CCL20/CCR6 and PCSK9 pathways will be discussed. [2, 3] These biological networks play a pivotal role in the pathogenesis of numerous chronic and infectious diseases. Although the druggability of these pathways was already proven by monoclonal antibodies, no small-molecule drugs have yet received approval for their modulation, presenting ample opportunities for the discovery of first-in-class drugs.

sfederico@units.it

Ecto-5'-nucleotidase (CD73) is a potential target in cancer (immuno)therapy since its blockade prevents the formation of immunosuppressive and cancer-promoting adenosine from AMP.[1,2]

Here, we report on the development of a series of small molecules that mimic adenine nucleotides acting as non-cleavable competitive CD73 inhibitors. The ribose moiety of adenosine was replaced by an alkyl chain whose length was found to be crucial for potency.

The most potent CD73 inhibitor of the present series was the N^6-substituted acyclic ADP analog (N^6-benzyl,N^6-methyladenine-9-yl)hexyloxydiphosphonate which exhibited submicromolar potency at human CD73 displaying a Ki value of 563 nM towards the soluble enzyme, and of 481 nM towards the membrane-bound CD73 of triple-negative breast cancer cells. Investigation on the mechanism of inhibition confirmed a competitive inhibition mode of this compound. An X-ray co-crystal structure of the compound bound to the catalytic site of human CD73 has been obtained, providing information on the key interactions established between the inhibitor and the enzyme.

Acyclic nucleotide analogs may be advantageous compared to nucleotidic CD73 inhibitors due to their high chemical stability, and because less off-target effects are to be expected.

The structure-activity relationships discovered in this study, along with the obtained crystal structure provide valuable insights which will be useful for the future development of improved CD73 inhibitors as immunotherapeutic drugs.

sarahjane.rezzi@uniupo.it

Background. Indoleamine 2,3-dioxygenase 1 (IDO1), an appealing target for cancer immunotherapy, is a moonlighting protein that, aside from its role as a tryptophan-metabolizing enzyme, functions as a complex signal-transducing molecule.[1] Following the disappointment with epacadostat, a holo-inhibitor, in a Phase III trial,[2] enthusiasm within academia and industry has declined, prompting scientists to reconsider the future direction for targeting IDO1. **Aims and results.** To address the constraints encountered with traditional catalytic inhibitors, we employed three distinct approaches for targeting IDO1. **i) Development of small molecules that modulate both enzymatic and signalling activities: VS-15** (A375, IC_{50} = 480 nM) and its analogue compound **1** represent the first apo-inhibitors that negatively modulates the SHP-mediated signalling activity of IDO1, with a great potential for decreasing IDO1 *de novo* synthesis and expression. Moreover, compound **1**, acts as a dual inhibitor of IDO1 and TDO and it has been encapsulated within silk fibroin nanoparticles[3] for preclinical studies due to its short *in vivo* half-life. **ii) Development of drug-like apo-IDO1 inhibitors: VS-13**[4] is a potent apo-IDO1 inhibitor (A375, IC_{50} = 16 nM) and it suffers from poor metabolic stability in mouse liver microsomes. Hence, a SAR/SPR exploration around **VS-13** relying on the use of different isosteres (deuterium, halogens, and ring equivalence) was carried out to increase its ADME profile. **iii) Synthesis of PROTACs**: a sustainable and environmentally friendly platform based on multi-component reactions[5] was exploited to synthetize a library of PROTACs characterized by linkers and linkage points of different nature and length. Cellular assays and Western Blot analysis are currently ongoing.

New Pyrrole Derivatives as Ferroptosis Inducers

G. La Regina[a]

[a]*Laboratory Affiliated with the Institute Pasteur Italy - Cenci Bolognetti Foundation, Dipartimento di Chimica e Tecnologie del Farmaco, Sapienza University of Rome, 00185 Rome, Italy*
giuseppe.laregina@uniroma1.it

Ferroptosis is an iron-dependent cell death which is different from apoptosis, necrosis, autophagy, and other forms of cell death [1]. We synthesized new aroyl diheterocyclic pyrroles (ARDHEPs) as tubulin polymerization inhibitors [2]. Among these compounds, the derivative (4-(furan-2-yl)-1-(pyrimidin-2-yl)-1*H*-pyrrol-3-yl)(3,4,5-trimethoxyphenyl)methanone (**1**) exhibited the hallmarks of ferroptosis (Figure 1). The new compound strongly inhibited U-87 MG, OVCAR-3, and MCF-7 cancer cells and induced an increase in cleaved PARP but was not toxic to normal human primary T lymphocytes at 0.1 μM concentration. Analysis of the levels of lactoperoxidase, malondialdehyde, lactic acid, total glutathione, and ATP suggested that the *in vivo* inhibition of cancer cell proliferation by the new compound occurred through the stimulation of oxidative stress injury and Fe^{2+} accumulation. Quantitative polymerase chain reaction analysis of mRNA expression in U-87 MG and SKOV-3 tumor tissues from new ARDHEP-treated mice showed the presence of *Ptgs2/Nfe2l2/Sat1/Akr1c1/Gpx4* genes correlated with ferroptosis in both groups. Immunofluorescence staining revealed significantly lower expressions of proteins Ki67, CD31, and ferroptosis-negative regulation proteins glutathione peroxidase 4 (GPX4) and FTH1. Finally, the new ARDHEP was found to be metabolically stable when incubated with human liver microsomes.

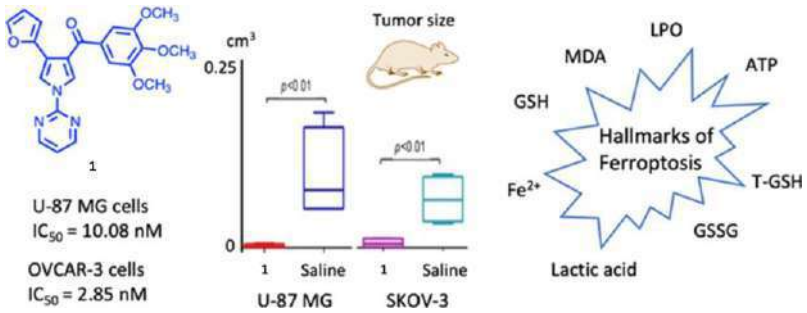

Figure 1: ARDHEP **1** as ferroptosis inducer.

Human dihydroorotate dehydrogenase (*h*DHODH), a crucial enzyme in the *de novo* pyrimidine biosynthesis, is a validated target for treating autoimmune diseases, solid tumors, and, more recently, acute myieloid leukemia (AML).[1] Through a *non*-classical bioisosteric approach supported by structure-based drug design, our research group recently discovered **MEDS613**, a molecule exhibiting 15-fold greater potency in cell-based assays compared to brequinar, a known *h*DHODH inhibitor. Unfortunately, **MEDS613** suffered from poor *in vitro* metabolic stability, thus limiting further preclinical studies.[1] This work unveils the identification process of **MEDS613**'s alkoxy chain metabolic soft spot, which finally led to the design of **MEDS700** (**Figure 1**), a metabolically stable analogue. **MEDS700**, whose *h*DHODH binding mode has been elucidated through x-ray crystallography, demonstrates comparable or even improved performance to **MEDS613**, in terms of enzymatic inhibition and pro-apoptotic and pro-differentiating induction on AML cell lines. **MEDS700** represents a promising candidate for further steps in the drug development process, thus, prior to future *in vivo* toxicity/efficacy studies, the pharmacokinetic profile of the new lead compound has been outlined and here fully discussed.

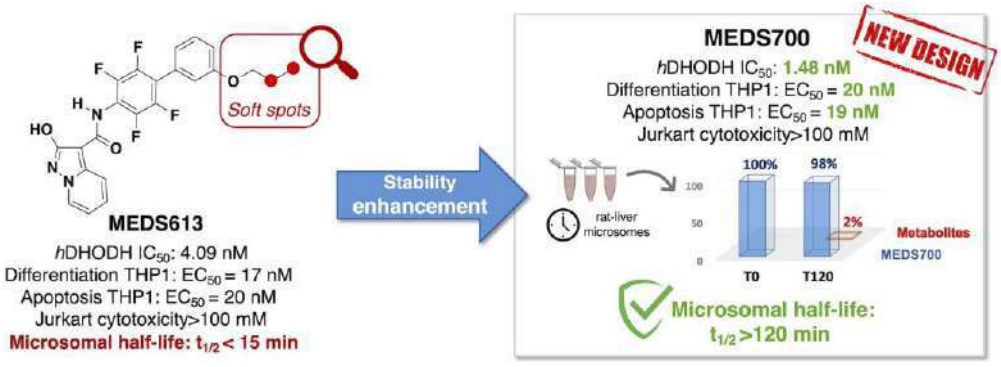

Figure 1: Optimization of **MEDS613** metabolic soft spots with the design of **MEDS700**.

Design and Synthesis of Selective PPI Inhibitors Against the EphA2 Receptor Targeting Glioblastoma Multiforme (GBM)

L. Guidetti,[a] R. Castelli,[a] L. Scalvini,[a] M. Tognolini[a], A. Lodola[a]

[a] *Dipartimento di Scienze degli Alimenti e del Farmaco, Università degli Studi di Parma, Viale delle Scienze 27/A, 43124 Parma,*
lorenzo.guidetti@unipr.it

Compealing evidence show the cardinal role of the Eph-ephrin system in tumour initiation and sustenance. EphA2 has been found often overexpressed and deregulated in Glioblastoma Multiforme (GBM).[1] Agents able to prevent EphA2-ephrin-A1 association are available and include bile acid conjugates, such as **UniPR1447** (N-(3β-hydroxy-5-cholen-24-oyl)-L-β-homotryptophan, IC_{50}= 5.4μM). However, the compound lacks selectivity towards Eph receptors (Fig.1)[2]. A combined experimental and computational approach was exploited to selectively identify inhibitors of EphA2, targeting a peripheral pocket of the ligand binding domain (Fig.1), over the EphB2 receptor. **UniPR1449** (N-(3β-hydroxy-5-cholen-24-oyl)-1-benzensulfonyl-L-β-homotryptophan, Fig.1) was firstly identified as selective inhibitor of the EphA receptors (Fig.1), while inactive on EphBs.[2] A further rational exploration guided by the combined application of an experimental design on physicochemical descriptors and docking simulations led to the discovery of **UniPR1454** (N-(3β-hydroxy-5-cholen-24-oyl)-(4-(trifluoromethyl)phenylsulfonyl)-L-β-homotryptophan, Fig.1), acting as potent and competitive EphA2 ligand (IC_{50}= 2.6μM) able to inhibit ephrin-A1 dependent signals in intact cancer cells and to block the growth of GBM cell lines at low micromolar concentrations.

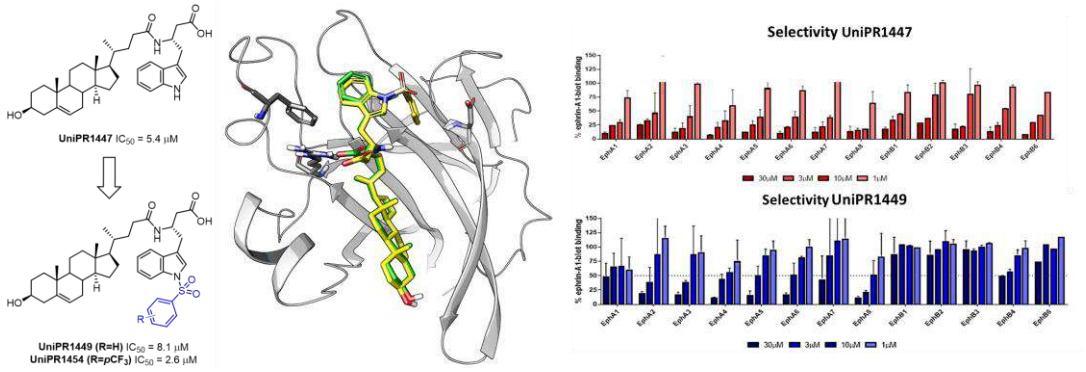

Figure 1. (left) Chemical structure of **UniPR1447** and selective inhibitors. (center) Docking poses of **UniPR1447** (green) and **UniPR1449** (yellow) within the LBD of EphA2. (Right) Selectivity profile of **UniPR1447** and **UniPR1449** against Eph receptors.

In the last years, several pyrazole derivatives have been reported as antiangiogenetic agents.[1,2] In particular, 5-phenylamino pyrazole **I** (Scheme 1) proved to inhibit Akt phosphorylation in human foreskin fibroblasts (HFF) and human umbilical vein endothelial cells (HUVEC) and to interfere with HFF migration in wound healing assays, being more active than our reference compound **GeGe-3** (Scheme 1).[2] In functional proteomics investigations on HUVEC, **GeGe-3** proved to affect intracellular Ca^{2+} levels in a dose dependent fashion through the interaction with calreticulin (CALR).[3] Docking simulations helped to elucidate the molecular basis of pyrazole **I**/CALR interaction.[2] To further extend the SARs of derivatives **I**, novel 5-arylamino pyrazoles **II** and **III** were designed and synthesized. The new molecules share with **I** and **GeGe-3** the *N*1- hydroxyalkyl or hydroxy phenyl chains and the free amino group at position five of the ring. Differently from their parents' compounds, the novel derivatives presented variously substituted aryl-amino moieties at position three.

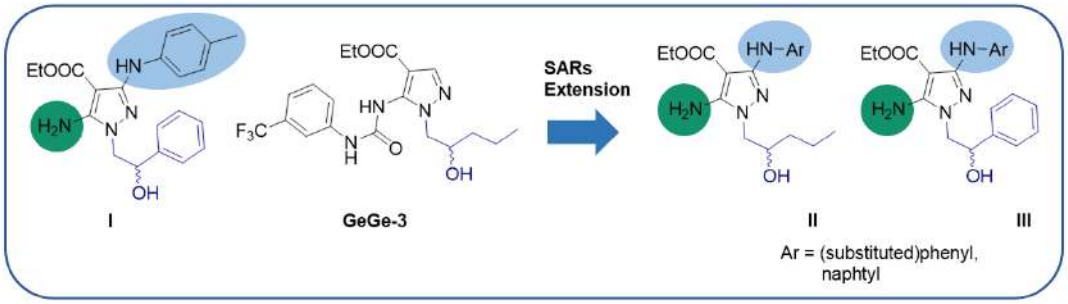

Figure 1: Structures of previously reported pyrazoles **I** and **GeGe-3** and new derivatives **II** and **III**.

All the isolated compounds were preliminary screened by MTT assays to prove the absence of cytotoxicity against normal human cells. Additionally, the effects on angiogenesis and calcium mobilization were evaluate *in vitro* on HUVEC. Selected derivatives showed improved antiangiogenic activities compared to **GeGe-3** and **I**.

Unveiling the potential anticancer activity of newly developed Cu(I) phosphino complexes

M. De Franco,[a] V. Gandin,[b] E. Pratt,[a] J. S. Lewis[a]

Platinum(II) complexes are nowadays the unique metal-based drugs clinically approved for the treatment of a large number of solid tumors. However, platinum drugs cause severe toxic effects on normal tissues and induce the appearance of resistance phenomena.[1] These drawbacks have stimulated an extensive search for the development of alternative metal-based drugs with improved pharmacological properties and able to target different tumor-specific molecular determinants. Among a variety of tumor predictive and prognostic biomarkers, protein disulphide isomerase (PDI) recently emerged as a potential family of enzymes to inhibit to disrupt cell proteostasis, thus triggering a non-apoptotic cell death pathway, called paraptosis, that could represent a getaway to overcome cancer-related apoptosis resistance phenomena.[2] Among different classes of PDI inhibitors, copper complexes showed encouraging perspectives. Copper-based complexes have been originally investigated as potential anticancer agents on the assumption that endogenous metals may be less toxic than non-essential metals for normal cells. Actually, copper (Cu) is an essential cofactor in the redox chemistry of proteins performing key biological functions involved in cellular growth and development.[1,2] However, current knowledge shows that Cu homeostasis is dysregulated in cancer cells, which are prone to enrich their intracellular Cu content to fuel tumor progression. On the contrary, normal cells strictly regulate intracellular Cu concentration by homeostatic mechanisms. Due to this altered Cu metabolism and trafficking, cancer cells react differently than normal ones to Cu overload and this unique homeostatic feature can be therefore exploited for selectively targeting cancer cells.[3] In this work, we present a series of newly developed homoleptic copper(I) phosphino complexes tested on a wide panel of human cancer cell lines for their anticancer potential both in bidimensional and spheroid models. Mechanistic studies were also performed to assess the ability of these complexes to hamper PDI activity end to better elucidate the cell signaling and cell death induction pathways. As a step forward towards preclinical evaluation, their anticancer activity was validate in *in vivo* murine models. In light the promising result obtained, the newly developed copper(I) phosphino complexes were radiolabeled using ^{64}Cu in order to investigate their theragnostic potential. To this aim, preliminary PET/CT imaging and biodistribution studies in human xenografts mice models have been performed.

Novel Dual HDAC1,2/LSD1 Inhibitors as Epi-pharmacological Approach to Combat Cancer

C. Lambona,[a] B. Noce,[a] E. Di Bello,[a] C. Castiello,[a] A. Mattevi,[b] A. Nebbioso,[c] L. Altucci,[c] S. Valente,[a] A. Mai[a]

chiara.lambona@uniroma1.it

Nowadays a simultaneous inhibition of two or more targets involved in cancer can improve therapeutic efficacy over a single-target inhibitor [1]. In collaboration with the Cole's and Mattevi's team, we previously developed Corin, an hybrid molecule that targets the CoREST complex resulting in the inhibition of LSD1 and HDAC1 at sub-micromolar doses [2]. The aim of our present research is to develop, synthesize and validate anticancer activity of new GSK2879552-based hybrids, which could specifically inhibit the specific isoforms HDAC1 and/or HDAC2, in addition to LSD1. Particularly, the carboxylic acid of GSK-2879552, an LSD1 inhibitor undergoing clinical trials (NCT02929498, NCT02034123, NCT02177812), was modified by incorporating the *ortho*-aminoanilide portion of Entinostat, an inhibitor of HDAC 1-3. The resulting compound **1a** was primarily obtained. Later, the amino group in the *para* position of the *o*-aminoanilide portion was replaced with different substituents including a fluorine atom (**1b**) to study hydrogen bonding effects, a thiophene (**1c**) known to confer selectivity to HDAC1/2 [3], and various aromatic monocyclic groups (**1d-m**) isomers/bioisosters of the 2-thienyl group. Our preliminary results proved that the novel hybrid compounds **1c**, **1h** and **1m** displayed nanomolar inhibition against HDAC1 and HDAC2 and sub-micromolar inhibition against LSD1. These three most promising hybrid compounds were tested in typologically different cancer cell lines (SKMEL28, U937, HL60, A549, HCT-116 and MCF7) and the dual inhibitor **1c** displayed a higher cell vitality reduction than the reference inhibitor Corin, with the A549, HCT-116 and MCF7 cell lines being the most responsive ones. During the next months we will perform further in-depth biochemical and biological assays by evaluating the HDAC- and LSD1-target-engagements, cell death mechanism, targets-related genes modulation, migration-invasiveness impairment in one of the most sensitive cell lines aforementioned.

Nowadays, synthetic lethality (SL) is a known effective paradigm in anticancer therapy.[1] However, SL has been mostly limited to the combination of pre-existing mutations with drugs against their synthetic lethal partners.[1] In this context, we envisioned SL as paradigm to design synergistic combinations of drugs, targeting pairs of synthetic lethal targets. We selected the synthetic lethal pair PARP/BRCA2, taking advantage of the approved PARPis. We picked BRCA2-RAD51 protein-protein interaction (PPI) as target for our medicinal chemistry campaign, reasoning that its inhibition would mimic BRCAness and trigger SL with PARPi.[2] To design small molecule PPI inhibitors, we explored three distinct approaches. First, we used BRC4-RAD51 crystal structure to perform virtual screening against two distinct PPI hot spots, zone I and II. Pyrazoline hit **1** from zone II led to **2** (Fig. 1), which induced SL with PARPi and gave us the first proof-of-concept of a "fully-small-molecule induced SL".[2] In parallel, we used protein-templated dynamic combinatorial chemistry (ptDCC) on RAD51 and identified ten *N*-acylhydrazones, as micromolar PPI inhibitors. In particular, **3** was found to bind at BRC4 binding site by ^{19}F-NMR (Fig. 1).[3] Finally, we used a ^{19}F-NMR fragment screening and identified **4** and subsequently developed the pyrazole pyrimidinone **5**, which induced SL in several pancreatic cancer models (Fig. 1).[4] Despite issues related to PPI inhibition by small molecules, this work shows the variety of effective approaches that can be used to reach that goal, opening to future development of PPI inhibitors. Moreover, it consolidates SL as paradigm for anticancer drug combinations, promoting future medicinal chemistry efforts against synthetic lethal targets, especially if involved in the DNA damage response.

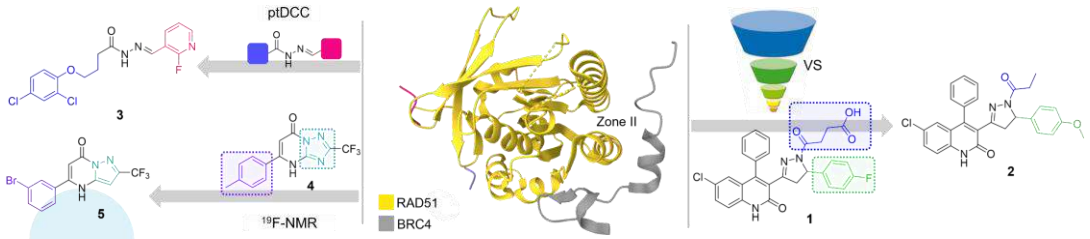

Figure 1: Approaches employed for the development of BRCA2-RAD51 PPI inhibitors (PDB: 1N0W).

Reshaping therapeutic options for triple negative breast cancer: selective histone deacetylase 6 inhibitors on the stage with merit

S. Barone,[a] I. Bello,[a] V. Summa,[a] E. Panza,[a] M. Brindisi[a]

[a]*Department of Pharmacy, University Federico II of Naples, Via Domenico Montesano 49, 80131, Naples, Italy*
simona.barone2@unina.it

Triple negative breast cancer (TNBC) accounts for about 20% of all breast cancer (BC) subtypes, lacking the expression of progesterone, estrogen and HER2 receptors, thus rendering ineffective hormone therapy. For this reason, TNBC represents the most aggressive BC subtype, due to its invasiveness and challenging therapy, with about one year life expectancy. TNBC cells show uncontrolled matrix remodeling and the consequent epithelial-mesenchymal transition (EMT), related to uncontrolled cell invasiveness, proliferation, and differentiation. Recent studies pointed out the role of epigenetic players in TNBC insurgence and progression, whit particular emphasis on the effectiveness of targeting histone deacetylases (HDACs) against TNBC tumorogenesis[1,2]. We recently discovered a novel class of spirocyclic compounds acting as potent and selective HDAC6 inhibitors[3-5]. The behavior of all synthetized compounds was assessed in MDA-MB-231 TNBC cell line, showing efficacy against TNBC. In particular, compound 1 ($IC_{50\ HDAC6}$ = 7.7 nM, $IC_{50\ HDAC1}$ = 2188 nM; Selectivity index $_{HDAC6/HDAC1}$= 275) stood out as the most promising compound for its highly efficient anti-proliferative effect in MTT assay, related to the activation of apoptotic process. Cytofluorometric assay also confirmed no effects on necrosis pathways, further validated by western blot analysis, with the detection of cleaved caspase-3, a reliable marker for apoptotic process. Also, increased levels of both Beclin-1 (BECN1) and Bcl-2 interacting protein 3 (BNIP1) were observed after 24 hours of treatment with compound 1, thus also suggesting the involvement of autophagy process in cell death induction. The in vivo validation of the best performing compound 1 is currently ongoing in order to confirm the promising results obtained in the in vitro assays. Taken together, our results underscore the key role of epigenetic modifications driven by HDAC6 enzyme in TNBC tumorogenesis and cancer progression, providing a solid groundwork to reshape canonical chemotherapeutic approaches.

Human hemoglobin (Hb) is the preferred iron source of Staphylococcus aureus. This pathogenic bacterium exploits a sophisticated protein machinery called Iron-regulated surface determinant (Isd) system to bind Hb, extract and internalize heme, and finally degrade it to complete iron acquisition. IsdB, the surface exposed Hb receptor, is a proven virulence factor of S. aureus and the inhibition of its interaction with Hb can be pursued as a strategy to develop new classes of antimicrobials.

To identify small molecules able to disrupt IsdB:Hb protein-protein interactions (PPIs), we carried out a structure-based virtual screening campaign and developed an ad-hoc immunoassay to screen the retrieved set of commercially available compounds. Saturation-transfer difference (STD) NMR was applied to verify specific interactions of a sub-set of molecules, chosen based on their efficacy in reducing the amount of Hb bound to IsdB. Among molecules for which direct binding was verified, the best hit was submitted to ITC analysis to measure the binding affinity to Hb, which was found to be in the low micromolar range.

The results demonstrate the viability of the proposed in silico/in vitro experimental pipeline to discover and test IsdB:Hb PPI inhibitors. The identified lead compound will be the starting point for future SAR and molecule optimization campaigns.

.

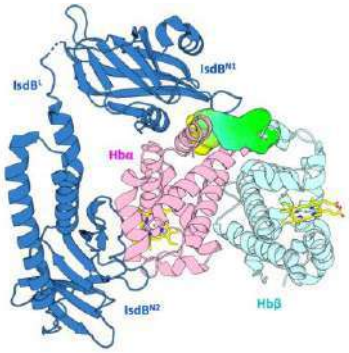

Figure 1: Model of IsdB:Hb complex.

Exploiting new medicinal chemistry trends to fight the antimicrobial resistance big challenge

E. Diamanti,[a] A. K. H. Hirsch,[b] M.L. Bolognesi,[a]

[a]*Department of Pharmacy and Biotechnology Alma Mater Studiorum-University of Bologna, Bologna, Italy*
[b]*Helmholtz Institute for Pharmaceutical Research (HIPS) − Helmholtz Centre for Infection Research (HZI), Saarbrücken, Germany*
Eleonora.diamanti2@unibo.it

Antimicrobial resistance (AMR) is a serious global problem listed by the World Health Organization (WHO) among the top 10 health threats. The fact that anti-infective R&D pipeline is risky, time-consuming, and expensive undertaking, is hampering the discovery of new chemical entities that ultimately reach patients.[1] With the aim to overcome the current innovation gap, we are developing two different projects that address this problem by exploiting two innovative concepts.

First, the Energy-Coupling Factor (ECF) transporters are a hitherto underexplored target involved in the simultaneous uptake of several micronutrients in bacteria. Their central role in the metabolism of bacteria and absence in humans make the ECF transporters a novel invaluable antibacterial target. A Structure-Based-Virtual Screening performed on *Lactobacillus delbrueckii* ECF-FolT2 led to the identification of the first ECF small-molecule inhibitor.[2] Then, (1) we performed extensive structure-activity relationship to improve potency; (2) we run unbiased coarse-grained molecular dynamics simulations to profile the binding mode and, (3) we demonstrated that the expression of the genes encoding ECF are essential for bacterial growth in *Streptococcus pneumoniae*.[3]

Second, we leveraged the proteolysis targeting chimeras (PROTAC) strategy to develop a new class of small molecule antivirals that induce proteasomal degradation of viral proteins. We applied the innovative PROTAC approach to target the NS2B-NS3 protease which is essential for the replication of West-Nile, Dengue and Zika virus that belong to the Flavivirus family. PROTACs are heterobifunctional degraders with the ability to activate the ubiquitination and, subsequent proteasomal degradation, *via* a molecule that simultaneous bind to the protein of interest and an E3 ligase.[4] We successfully manage to set out the multi-step synthetic pathway to get access to final PROTAC molecules, to establish the conditions for co-crystallization and, to assess the cellular degradation.

Antimicrobial resistance is seriously threatening the Public Health system and affecting the efficacy of the current antibacterial drugs armamentarium, highlighting the need for new treatment options. We recently reported AlkylGuanidino Ureas (AGUs) as promising membrane-active broad-spectrum antibacterial agents (minimal inhibitory concentrations (MICs) ranging from 0.12 to 16 µg/mL), with a bactericidal behavior.[1-3] Herein, a new series of AGUs were designed and synthesized through a straightforward orthogonal protecting groups strategy and tested on a panel of representative bacterial strains, allowing the establishment of robust structure-activity relationships (SARs). The membrane-based mechanism of action was then investigated through molecular dynamics (MD) on simulated membranes via a previously validated *in silico* protocol.[3] In the end, the whole library of compounds (more than 70) was tested in combination with subinhibitory concentrations of the last-resort antibiotic colistin, assessing synergistic or additive effects also on colistin-resistant isolates. Moreover, all the AGUs were analyzed via cheminformatics and machine learning to gain a deeper understanding of the key features required for bioactivity.

Noncanonical α9α10 nicotinic receptors expressed in the cells of immune system can be targeted to reduce pain related to inflammation.[1] The 2-triethylammonium ethyl ether of 4-stilbenol (MG624) is an unselective antagonist of the α7-nAChR and α9α10-nAChR expressed in *X. laevis* oocytes.[2] Aiming to increase the functional selectivity toward α9α10- over the α7-nAChR subtype, the synthesis of more than sixty MG624 analogues and their pharmacological characterization was previously performed. The SAR study allowed to define that selective inhibition of ACh-evoked currents at α9α10-nAChR could be achieved by modifying different moieties of the lead compound MG624 (*i.e.*, ammonium head, linker, and stilbene, **Figure 1**).[2] Compound **1** was identified as the most interesting of the series, being a potent and selective antagonist of α9α10-nAChR (5.74 μM IC_{50}), and completely devoid of activity at the α7-nAChR subtype at 100 μM.[2]

To deeply investigate the activity of **1**, new electrophysiological experiments using *X. laevis* oocytes expressing *human* α9α10-nAChRs showed both agonist (385 nM EC_{50}) and antagonist activity (60.2 nM IC_{50}). Due to the interesting activity at the α9α10-nAChRs and selectivity *versus* α7-nAChR possessed by compound **1**, a new series of analogues modified at the ammonium head, and at the linker were designed, synthesized, and pharmacologically characterized to investigate the impact on α9α10- *versus* α7-nAChR activities. Furthermore, compound **1** and some analogues are currently being investigated as potential immunoregulatory agents *in vitro*. Preliminary results showed **1** as an effective modulator of the ATP-mediated release of the pro-inflammatory cytokine interleukin-1β by LPS-primed *human* monocytic THP-1 cells.

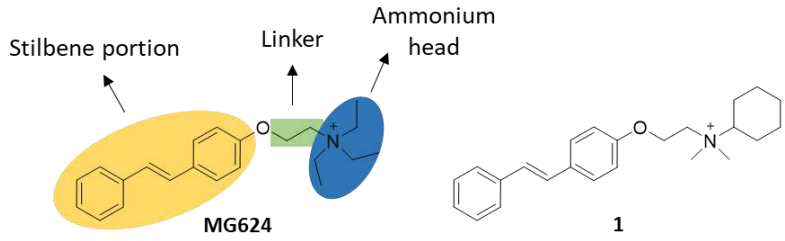

Figure 1: Representation of SAR study on MG624 and structure of compound **1**

Retinitis Pigmentosa (RP) is a genetic disorder characterized by gradual rod-cone degeneration and vision loss, without effective pharmacological treatments. Experimental approaches aim at delaying disease progression plus supporting the survival of cones, which are crucial for human vision[1].

Histone deacetylases (HDACs) mediate the activation of epigenetic and non-epigenetic pathways[2] that modulate cone degeneration in *cpfl1* and *rd1* mice, in which HDAC inhibitors promote cone survival and vision rescue. A new family of tetrahydro-γ-carboline-based HDAC inhibitors (**5a-p**), was developed and characterized by high inhibition potency, selectivity, and balanced physicochemical properties for *in vivo* studies. The compound **5d** (IC_{50} HDAC6 = 6.32 nM, Fig. 1) showed specific inhibitory activity on HDAC6 on ARPE-19 cells and was able to limit cell death of 661W retinal cells stressed with hydrogen peroxide (H_2O_2), by inhibiting HDAC6. **5d** also promoted a significant rescue of vision in the *atp6v0e1*$^{-/-}$ zebrafish model of photoreceptor dysfunction. When used in the *rd10* mouse model of RP, **5d** supported morphological and functional preservation of cone cells and maintenance of the retinal pigment epithelium array. **5d** is a new pharmacological tool useful to treat Retinitis Pigmentosa.

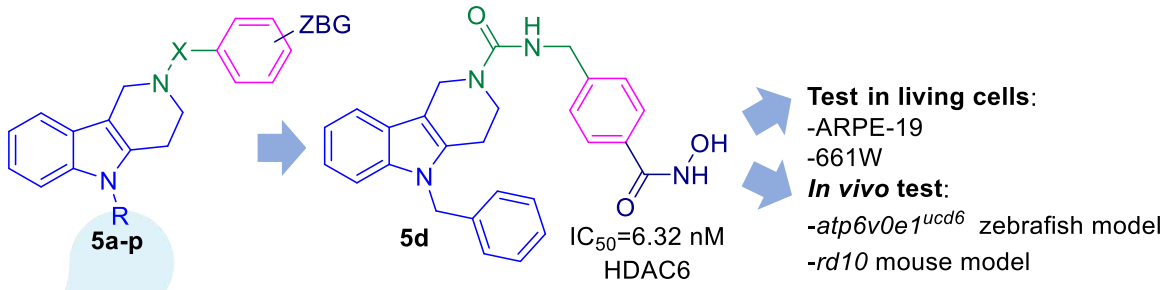

Figure 1: New HDAC6 inhibitors **5a-p** and the most potent compound **5d.**

Cannabinoid receptors, CB1 and CB2, are highly expressed in the central nervous system (CNS), where they mediate the biochemical activities of endogenous cannabinoids.[1] Their role ranges from physiological processes such as appetite regulation[2] and neuroprotection,[3] to pathological processes such as cancer,[4] pain, and neuroinflammation.[5] Furthermore, CB2 receptor is upregulated under neuroinflammatory, oxidative and ischemic conditions and several agonists are reported to exert neuroprotective activity in models of neurodegenerative conditions.[6] In the present work, we tested a series of molecules from an in-house library, upon filtration by virtual screening protocol, as CB2 agonists. The compounds were initially tested by chemical-physical assays for their ability to bind both CB1 and CB2 receptors. In this way a hit compound was identified, with outmost selectivity over CB2 isoform. This compound was then subjected to a hit-to-lead rational development, designing a new library of analogues. The new compounds were screened for their ability to activate CB2 receptors using functional assays. Compound **70** was selected as the most potent derivative, also showing suitable pharmacokinetic properties, and was then further characterized for its in vivo impact on short-term memory, using a scopolamine-induced amnesia protocol. Moreover, compound **70** was challenged for its capability in modulating neuromodulators levels, using MALDI-imaging technique. Collectively, compound **70** displayed high in vivo effectiveness, suggesting pyrrole scaffold as starting point for further development of new small molecules for the treatment of neuroinflammatory diseases.

Neurodegeneration is a multifaceted condition underpinning several diseases that constitute major therapeutic challenges nowadays. In this context, multi-target directed ligands (MTDLs) are considered a promising approach to achieve enhanced therapeutic effects. They can also validate new, unexplored protein-protein crosstalk and interactions.[1] Herein we report on the development of bivalent ligands that target Sigma-1 Receptor (S1R) and the 18kDa Translocator Protein (TSPO). S1R is a ligand-operated molecular chaperone highly expressed in the central nervous system (CNS) and involved in neuroprotection.[2] TSPO is a transmembrane protein that takes part to different pathways affecting cells survival. It is clinically used for neuroinflammation imaging, but its therapeutic potential is still poorly explored.[3] Considering these premises and the convergence of S1R and TSPO pathways on the modulation of mitochondrial function, targeting both receptors could enhance therapeutic effects. Accordingly, to verify that this could be an effective strategy to manage neurological disorders, we designed and synthetized dual S1R-TSPO ligands, based on our in-house developed S1R agonist, RC-33, and the clinically validated TSPO ligand PK-11195. Their interaction with the targets and pharmacodynamic profile were assessed through binding and functional assays. Their stability is currently under evaluation as well. The results obtained demonstrated the usefulness of such compounds as pharmacological tools, and provide a starting point for the development of drug-like compounds.

Literature studies and clinical trials report that sigma-1 receptor (S1R) ligands exhibit significant antiallodynic effects in neuropathic pain animal's models and demonstrate fewer side effects compared to conventional therapy.[1] Therefore, the aim of the present study was the development of new potent and selective S1R antagonist for the treatment of neuropathic pain. For this purpose, several piperazine and *N*-methylpiperidin-4-amine derivatives have been designed and synthesized. Radioligand binding assays allowed to assess affinity towards S1R and sigma-2 receptor (S2R).[2] Among the tested compounds, AC1 emerged as particularly noteworthy. It displayed high binding affinity to S1R and selectivity over S2R (K_iS1R = 0.54 nM; K_iS2R > 10,000 nM) and a moderate inhibition of K^+hERG channel (IC_{50} = 1.6 μM).

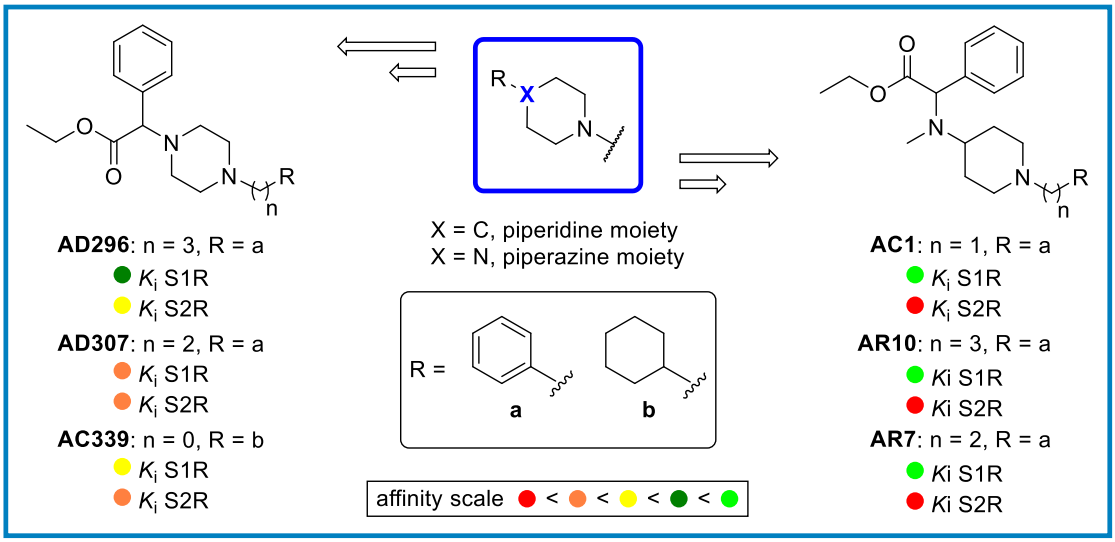

Figure 1. Structure and affinities of novel piperazine and piperidine derivatives.

Molecular modeling studies, functional profile, toxicity tests and the *in vivo* analgesic effects of the best developed molecules will be further evaluated.

Multitarget Neuroprotective Potential of Novel BChE-Selective Inhibitors 6-Alkyl-Bridged 4-Arylalkylpiperazin-1-yl Azepino[4,3-*b*]indol-1(2*H*)-ones

Given the proposed function of butyrylcholinesterase (BChE) in controlling acetylcholine levels and its role in the advanced stages of Alzheimer's disease (AD)[1], the use of selective inhibitors (BChEIs) is being considered as alternative to acetylcholinesterase inhibitors (AChEIs).

In this study, we identified a series of N*6*-substituted 3,4,5,6-tetrahydroazepino[4,3-*b*]indol-1(2*H*)-one (THAI). These compounds demonstrated their efficacy as nanomolar potent inhibitors of BChE, with additional neuroprotective effects against NMDA-induced excitotoxicity. The potency of enzyme inhibition and the selectivity between BChE and acetylcholinesterase (AChE) were modulated by the incorporation of alkyl chains bearing differently decorated piperazine fragments.[2]

Molecular docking simulations provided a critical evaluation of the observed differences in the BChE inhibition potency (Fig. 1). The binding kinetics of these compounds, studied through surface plasmon resonance (SPR), revealed differences in their residence times on BChE. The most promising compounds exhibited in vitro efficacy against other mechanisms known to instigate neurodegeneration underlying AD and other central nervous system disorders. These mechanisms include the inhibition of self-induced aggregation of the neurotoxic amyloid-β (Aβ) peptide and the counteraction of glutamate excitotoxicity due to over-excitation of NMDA receptors.

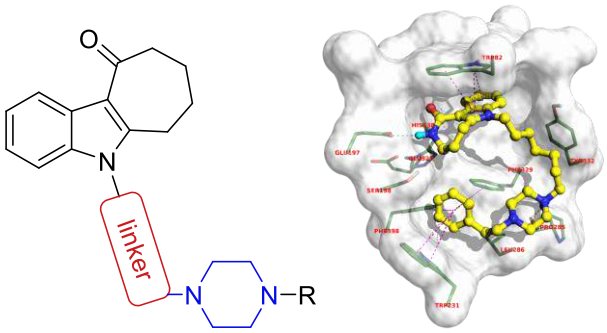

Figure 1. Schematic representation of N*6*-alkylpiperazine-substituted THAI (left) and docking pose of one compound of the series into the BChE binding site (right).

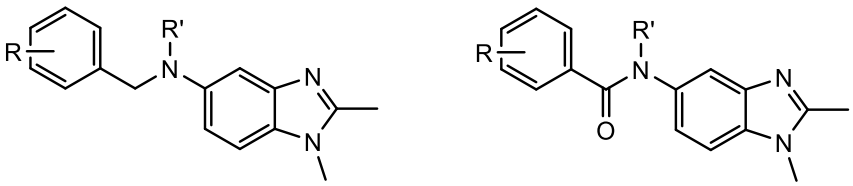
The co-enzyme nicotinamide adenine dinucleotide (NAD) plays a pivotal role in the metabolism of human cells. Since it is continuously used up by cellular processes and replenished by its biosynthetic pathways, its concentration is vital to maintain the cellular homeostasis[1]. Indeed, it has been shown that a lack of NAD can lead to neurodegenerative disorders, while an excessive production of the co-enzyme can support tumor growth. The enzymes nicotinamide phosphoribosyltransferase (NAMPT) and nicotinate phosphoribosyltransferase (NAPRT), which regulate NAD biosynthesis from nicotinamide and nicotinic acid, respectively, are considered promising targets to modulate intracellular NAD levels[2]. While several NAMPT inhibitors and activators have been identified over the years, the search for NAPRT modulators is still in its infancy[3]. By screening more than 200 lead-like molecules available in our labs and characterized by different chemical scaffolds, we have identified the properly substituted 1,2-dimethylbenzimidazole nucleus as a novel chemotype for the preparation of ligands able to modulate NAPRT activity (Figure 1).



R = $CH_2NHCOCH_3$, CH_2NH_2, $NHCOCH_3$, NH_2
R' = H, CH_3

Figure 1: 1,2-benzimidazole scaffold with a substituted amine (left) or amide (right) on 5 position.

This study identified new NAPRT inhibitors and activators, which might represent useful pharmacological tools to explore the therapeutic potential of NAPRT modulation.

Development of Synthetic Chemical Methods for Advanced Molecular Functionalization in Medicinal Chemistry

M. Giustiniano

University of Naples Federico II- Department of Pharmacy, via D. Montesano 49, 80131, Napoli
mariateresa.giustiniano@unina.it

The present lecture will be focused on the development of synthetic strategies to achieve *late-stage functionalization* of complex structures, such as drugs and natural compounds, by exploiting convergent multicomponent reactions and light-triggered mechanistic pathways.[1-3] Due to mild reaction conditions, both multicomponent and photocatalytic methods are considered as a valuable tool to achieve exquisite chemo-selectivities. Such synthetic methods, by enabling the introduction of either specific functional groups or structural moieties directly on *hit*/*lead* compounds, have been receiving increasing attention both from academia and pharmaceutical companies. Representative applications will span from the synthesis of deuterium-labelled compounds to the identification of promising lead compounds targeting brain cancers.[4-6]

laura.fumagalli@unimi.it

In the quest for novel drug candidates, marine ecosystems have emerged as a valuable source of biologically active compounds. Among the diverse array of marine products and metabolites, (+)-Harzialactone A has garnered substantial attention due to its remarkable antitumor and antileishmanial properties[1,2]. In this work, a chemoenzymatic strategy was applied for the synthesis of (+)-Harzialactone A. The core of this synthetic pathway revolves around the precise, stereoselective reduction of the prochiral ketone of 4-oxo-5-phenylpentanoic acid and its corresponding esters. Our investigation encompassed an extensive exploration of various promiscuous oxidoreductases, including wild-type and engineered variants, together with a diverse set of microorganism strains. In addition, to optimize the bioreduction process, different co-solvent and co-substrate were investigated as well. Tailoring synthesis parameters allowed the identification of ADH442 and the conjunction of *T. molischiana* together with a choline hydrochloride and glucose NADES (non-aqueous deep eutectic solvent) as the most promising entries. These biocatalysts enable the synthesis of the (*S*)-enantiomer of (+)-Harzialactone A achieving enantiomeric excess (*ee*) of the biotransformation product ranging from 97% to over 99%, coupled with robust conversion rates ranging from 88% to 80%.
In essence, this successful endeavour introduces an innovative chemoenzymatic approach that holds great promise for the efficient production of the valuable marine natural product (+)-Harzialactone A[3].

francesca.annunziata@unimi.it

Food-derived phenolic compounds are well known for their antioxidant and antimicrobial effects[1]. Because of their hydrophilic nature and their intrinsic stability and bioavailability issues, their use as active ingredients is limited. Lipophilization of phenolic derivatives is a valid strategy to obtain amphiphilic compounds that can be used as multifunctional additives in the pharmaceutical, nutraceutical, and cosmetic fields[2]. In particular, the synthesis of carbonates and carbamates is an attractive strategy to increase the lipophilicity of phenolic derivatives. However, their classic synthesis requires the employment of toxic acylating agents, unsafe solvents and experimental conditions.

In this context, we developed a reproducible, green, and scalable chemo-enzymatic flow process for the obtainment of a series of lipophilic carbonate and carbamate derivatives (Scheme 1) of natural tyrosol (Ty) and hydroxytyrosol (HTy)[3,4]. Immobilized CaLB was used in a packed bed reactor for the selective carbonation of the primary alcohol of Ty and HTy in a non-conventional green solvent as *tert*-amyl alcohol. Then, two selected carbonates were reacted in flow with the appropriate amine to obtain the desired carbamates. A telescoped two-step process was set up allowing to reduce the manual handling, time, and costs of the process.

All compounds were tested as antimicrobials and radical scavengers and they showed similar or even better activity compared to the parent compound, with a significant increase in their lipophilicity.

Scheme 1: Schematic representation of the chemo-enzymatic continuous synthesis.

The lifespan of a cell is intricately linked to the shortening of its telomeric DNA through the telomere maintenance mechanism.[1] Many cancer cells take advantage of this mechanism by employing the telomerase enzyme, assisted by RNA and the Shelterin protein TPP1, to elongate telomeric DNA strands.[2] This enables evasion of cellular senescence, granting the attainment of immortality.[3,4] Inhibiting the formation of the telomerase-TPP1 complex emerges as an attractive, yet unexplored, strategy to induce senescence in cancer cells. A targeted virtual screening in the "Oligonucleotide/Oligosaccharide-Binding" (OB) domain of TPP1, which is the binding interface in the TPP1-hTEN (the TPP1 binding domain of telomerase) complex, led to the identification of the first two ligands of TPP1, namely LRG4 and LRG17. To experimentally validate these results, we performed ligand-based NMR experiments, specifically Saturation Transfer Difference (STD)[5] and WaterLOGSY (WL)[6] techniques, that confirmed the binding of the ligands to the TPP1 OB domain. This binding was further confirmed using a macromolecule-based approach, particularly through NH-HSQC[7] spectra acquisition. These experiments offer insights into the ligands' specific binding region, contingent upon protein assignment. To this end, we acquired and are currently analyzing 3D NMR spectra using artificial intelligence.[8] The pharmacological activity of the ligands was also tested through anti-proliferative, pro-senescence, and telomeric DNA shortening experiments. Therefore, by intertwining computational predictions with experimental methodologies, we can affirm the inhibitory potential of LRG4 and LRG17 in disrupting telomere maintenance mechanisms. This integrated approach underscores the significance of TPP1 as a therapeutic target for various cancers, providing a promising foundation for future drug design campaigns focused on developing effective anticancer agents.

The Sigma 1 Receptor (S1R) has emerged as a therapeutic target in drug discovery for CNS diseases. While a variety of ligands with diverse chemical structures are able to interact with S1R, literature underscores crucial pharmacophore features, embracing two hydrophobic regions and a central basic core.[1] The exploitation of crystallographic structures of human S1R co-crystalized with various ligands have provided valuable insights for developing pharmacophore models.[2,3] However, relying solely on rigid crystal structures shows limitations, as they represent only one conformation and lack thorough insight into ligand-residue interactions. To achieve a comprehensive study on S1R-ligand complexes, molecular dynamics simulations were employed here to generate an extensive ensemble of conformations for each complex. Subsequently, each ensemble was explored to characterize the most energetically favorable interactions between ligands and residues using the Grid-Based Pharmacophore Model method.[4] The resulting data were exploited to build a shared pharmacophore model, thus identifying new potential ligands. Corroborated the predictiveness of our S1R pharmacophore, a set of candidate ligands was designed based on query features and the synthesized compounds were evaluated through *in vitro* sigma receptor binding assays. These candidates revealed good K_i affinity values (ranging from 4.8 to 25.4 nM), thus supporting the robustness of our computational approach. The proposed pharmacophore model holds promise as a valuable tool for designing and discovering new effective S1R ligands.

Proanthocyanidins (PACs) are plants secondary metabolites whose health benefits on inflammatory-based diseases are supported by several studies. A large portion of orally ingested PACs reach the colon where they are catabolized by colonic microflora into phenyl-γ-valerolactones, which showed anti-inflammatory activity. The aim of this study was to evaluate (i) the catabolic conversion of a standardized oligo-polymeric PACs grape seed extract (GSE, Ecovitis®), both in vitro and in a human intervention study, and (ii) the biological activity and molecular mechanism of the main metabolite, namely 5-(3′,4′-dihydroxyphenyl)-γ-valerolactone (VL), by an integrated metabolic, in silico and proteomic approach. An in vitro human fermentation model allowed to identify VL as the main PACs colonic microbiota catabolite. VL was identified as sulfate and glucuronide phase II metabolites by LC-ESI-MS/MS in the urine of volunteers treated with PACs. VL was synthesized and its effect evaluated by two phenotypic cell models: HEK293 with the cell reporter for Nrf2 activation and R3/1 with cell reporter for NF-κB activation. A dose-dependent activity was observed in both experiments. The molecular mechanism of Nrf2 activation by VL was then elucidated in silico studies which clarified the molecular engagement of VL with the thiol group of KEAP-1. The ability of VL to modulate the NF-κB levels was confirmed on human colon Caco-2 cells. Quantitative proteomics studies were then carried out on Caco-2 cells, in physiological and inflammatory conditions. When a pro-inflammatory stimulus was used (TNFα), VL reverted the expression levels of certain integrin signalling pathway genes. Moreover, the activation of the Nrf2 cascade was indirectly observed through the modulation of the downstream gene products, including COX2, upregulated in the inflammatory state and downregulated in the presence of VL. In conclusion, we demonstrated how VL can enhance body's resilience through Nrf2 activation, which works as an hormetic mediator protecting biological systems and conserving resources through its controlled reaction, as reported for phytochemicals that act by such a mechanism that can be called "parahormesis".[1]

Recent technological developments in high resolution mass spectrometry now allow the deep characterization of complex *in vitro* and *in vivo* biological systems. By processing thousands of proteins and quantifying their fluctuations in expression, the combination of MS proteomics with bioinformatics allows the investigation of the subcellular mechanisms triggered by a drug administration or a combination of medicines[1]. Also, the brand-new invention of peptide labelling kits, like the TMT-tagging system (Thermo Fisher), makes it possible to analyse multiple samples in a single MS run, detecting even smaller differences in protein concentrations. By exploiting this powerful tool, the Drug Discovery Network has recently examined the mechanism of action of their novel thymidylate synthase inhibitors (namely dimer destabilizers, or Ddis), that induce cancer cell death by targeting the enzyme at the interface of the two monomers. Unlike 5-FU and antifolates, this innovative medicinal chemistry strategy delays/halts drug resistance onset[2]. Herein, by MS proteomics, we demonstrate that the co-administration of a low-dose of Ddis with 5-FU, with respect to 5-FU only, significantly reduces the drug sentitization in HCT-116 cells. Overall, we have identified a total of 5900 proteins, 19 of which differentially expressed proteins (DEPs), *i.e.* whose expression is significantly different from control cells. These proteins were investigated with dedicated bioinformatic tools, which suggested a strong overexpression of the RNA catabolic process (Nonsense Mediated Decay pathway), mitochondrial ATP-related metabolism, and pro-apoptotic p53 path for the drug combination (PI3K and mTORR), whereas 5-FU-only effect is less significant (no DEP was identified). Interestingly, despite both treatments have evidenced TS downregulation, only in drug combination the SHMT enzyme significantly decreases, which may suggest a folate imbalance. Overall, this study contributes to the demonstration MS proteomics is a powerful tool to speed up the drug discovery pipeline, providing insightful information about molecular mechanisms of drugs.

andrea.carotti@unipg.it

The main aim of the study was to determine the molecular weight (MW) of the fragments generated from poly(L-lactide) (PLLA) after treatment with UV radiation in the presence/absence of different nano bio-materials. MWs were determined through gel permeation chromatography (GPC) analysis, using a PLgel 5 µm Mixed-C column (from Agilent Technologies), and a number of polystyrene standards with molecular weight distribution in the 2,500-100,000 Da range. A calibration curve was built up plotting the logarithm of the molecular weight (log MM) vs the retention volume [V (mL)].

Chloroform was used as eluent at 1.0 mL/min flow rate, while the column temperature set at 40 °C. For most of the investigated composites, a progressive reduction of the MW turned out with the exposition time to UV-radiation. Instead, a counter-intuitive behavior was observed for the systems including softwood Kraft lignin (SKL) and titanium dioxide (TiO2): in these cases, an increase of the MW turned out.

In order to deeper investigate the synergic stabilizing effect on the photodegradation of the PLLA observed by adding SKL and titanium dioxide to the nanocomposites, four in silico molecular dynamic simulations (MDs) have been performed. The four simulated systems were composed by: (1) 404 tetramers of PLLA; two binary systems composed by (2) 402 tetramers of PLLA and 1 SKL molecule, (3) 402 tetramers of PLLA and 7 titanium dioxide molecules; one ternary system composed by (4) 402 tetramers of PLLA, 1 SKL and 7 titanium dioxide molecules. After a simulation lasting 500ns, we measured the total number of atomic contacts explored by each heavy atom of the system. Interestingly, the box plot generated for the obtained data well correlates with the degradation effect experimentally measured at 60 and 180 minutes. In particular, when SKL and the titanium dioxide are added together to the system they display a synergic effect, leading to a massive increment of the MW measured, as analogously reported in a recent publication.[1] To the best of our knowledge, this is the first approach able to rationalize at a molecular level the synergic effect of SKL and titanium dioxide on the PLLA degradation. This work has been supported by the European Union – Next Generation EU under the Italian Ministry of University and Research (MUR) National Innovation Ecosystem grant ECS00000041 – VITALITY - CUP J97G22000170005, and Università degli Studi di Perugia and MUR for support within the project Vitality.

After a long limbo, RNA has gained its credibility as a druggable target, fully earning its deserved role in the next generation of pharmaceutical R&D.

The emergence of new viruses highlighted the dearth of first-line antivirals for the urgent care of patients as well as the urgent need for the development of new RNA-targeting therapeutics to fight old and new diseases associated with RNA viruses. Conserved structured RNA regions of viruses genome such as HIV-1 and SARS-CoV-2 play critical functional roles in the viral replication cycle representing potential drug targets. We will illustrate mass spectrometry (MS)-based strategies for the identification and functional investigation of drug-like molecules capable of binding to essential regulatory structures of the viral RNA. Examples will be provided in which our biophysical-analytical approach enabled the determination of stoichiometries and binding modes, as well as the evaluation of the binding affinities for selected RNA targets and the inhibitory properties of specific complexes involving such targets and cognate viral proteins[1-3].

Additionally, human non-coding RNAs (ncRNAs), such as human microRNA-21 (miR-21), are involved in the regulation of a variety of cellular functions and their dysregulation is often observed in human diseases, including solid tumors[4]. In this context, we show how native MS plays a leading role in early drug discovery by enabling the screening of new potential ligands for the RNA target and by providing valuable information on their interactions, thus guiding the synthesis of more effective and selective RNA binders.

Advanced analytical approaches for the evaluation of small molecules as G-quadruplex stabilizers

M. Giannangeli,[a] M. Anyanwu,[a] G. Ribaudo,[a] A. Gianoncelli[a]

[a]*Department of Molecular and Translational Medicine, University of Brescia, viale Europa 11, 25123 Brescia*
matteo.giannangeli@unibs.it

In guanine-rich sequences, DNA and RNA can fold into non-canonical arrangements that are called G-quadruplexes (GQs).[1] The structure of GQ is based on guanine quartets organized through non-canonical Hoogsten base pairing and stabilized by monovalent cations at the center, which are stacked on the top of each other.[2] They are mainly present in telomeres and in promoter regions of oncogenes, and their stabilization with small molecules represents an attractive therapeutical approach.[3] Our group developed a protocol based on a combination of advanced analytical techniques for evaluating the ability of small molecules to interact with GQs in vitro, from a structural and quantitative point of view. In this context, Nuclear Overhauser Effect (NOE)-based NMR experiments, such as Saturation-Transfer Difference (STD), are an ideal option to characterize the ligand-target interaction from a structural perspective. NOE causes the transfer of nuclear spin polarization from one population of spin-active nuclei to another. Thus, it is possible to gain insights on the ligand-target interaction in conditions that closely resemble the physiological environment. STD relies on the nuclear spin polarization transfer between the target and the ligand, as bound and unbound fractions of ligands behave differently. This technique can be applied to nucleic acids including GQs.[4] Moreover, in addition to a previously established approach for ligands screening, based on electrospray mass spectrometry (ESI-MS), the nano-ESI setup recently implemented in our laboratory can provide more accurate quantitative insights regarding the binding of small molecules to GQs in native conditions. Through this work, we present a combined approach, highlighting that the use of different advanced techniques is pivotal to fully characterize the interaction of small molecules with GQs.

Q-raKtion: A Novel Data Curation Tool to Aid Drug/Agrochemical Discovery

D. Palazzotti,[a] S. Sabatini,[a] S. Massari,[a] M.L. Barreca,[a] A. Astolfi [a]

[a]*Department of Pharmaceutical Sciences, University of Perugia, Via del Liceo, 1, Perugia 06123, Italy*
andrea.astolfi@unipg.it

Predictive models can be developed using a wealth of ready-to-use data that has recently become more readily available to the scientific community and stored as activity datapoints in chemogenomic repositories. However, the lack of uniformity and consistency of data from various sources, which necessitates a process of integration and harmonization, strongly offsets the advantages provided by the availability of such a vast amount of accessible information.[1,2] In this context we developed Q-raKtion,[3] a systematic, semi-automated, flexible, and customizable KNIME workflow that effectively aggregates information on biological activities of compounds retrieved by two of the most comprehensive and widely used repositories, namely PubChem and ChEMBL. The main advantages of the developed tool consist of i) the availability of a general pipeline that integrates different data curation and integration tasks, ii) the use of a graphical interface that allows the visual representation of each curation step, and iii) the high propensity of the protocol to be easily interpretable and reproducible.

As a practically case studies, we reported the application of the Q-raKtion pipeline to build well-annotated, high-quality compound datasets and their use in drug/agrochemical discovery projects.

annalisa.fanizzi@uniba.it

CB2R is a Gi-protein-coupled receptor (GPCR) which, together with CB1R, the endocannabinoids and the enzymes responsible for their synthesis and degradation, forms the endocannabinoid system (ECS). The expression of CB2R at the level of immune tissues, its over-expression, and up-regulation at the level of microglia cells in the CNS in pathological states, have led to questions about its role in inflammatory and neurodegenerative diseases. In 2023, we synthesized, evaluated, and published *N*-adamantyl-anthranil amide derivatives as CB2R selective ligands (Fig. 1B)[1]. We based our design on the proposed binding mode of the most potent CB2R antagonist AM10257, called "three-arm pose" (Fig. 1A). The best results in terms of affinity were observed in compounds presenting the phenyl ring or hydrogen on arm 1 and an alkyl chain with 5-carbon atoms as arm 2. The carboxy-adamantyl amide group as arm 3 was found to be critical for interaction with CB2R. We rationally explored a series of substitutions on the *N*-adamantyl-anthranil amide structural core as to assess any variations in affinity for CB2R. We also tested these synthetized compounds to evaluate their CB2R affinity and selectivity towards CB1R, obtaining interesting results. Compounds exhibiting the best pharmacodynamic profile in terms of CB2R affinity were also evaluated for the functional behavior and molecular docking simulations provided sound rationale.

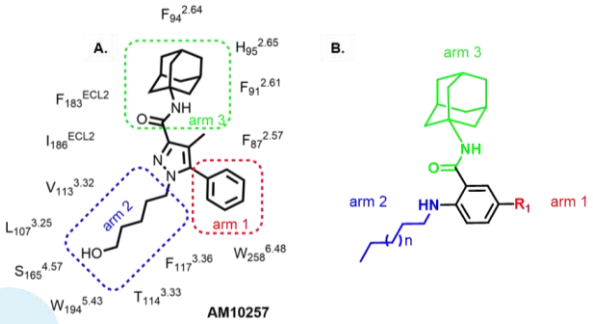

Figure 1: AM10257, CB2R antagonist (A), General structure of our N-adamantyl-anthranil amide derivatives (B).

Cannabinoid 2 receptor (CB2R) is a G-protein coupled receptor and, together with Cannabinoid 1 receptor (CB1R), is part of the Endocannabinoid system (ECS). CB2R resulted overexpressed in cells of the immune system and play a key role in disorders based on an inflammatory state, such as neurodegenerative diseases, neuropathic pain and cancer. We designed, synthesized, and biologically evaluated a series of new N-adamantyl-anthranil amide derivatives as CB2R selective ligands (Figure 1A).[1] Molecular docking simulations provided a sound rationale by highlighting the relevance of the arm 1 substitution to prompt CB2R action (Figure 1B). Moreover, the modulation of the pro- and anti-inflammatory cytokines production was also investigated to study the ability of the best compounds to modulate the inflammatory cascade (Figure 1C).

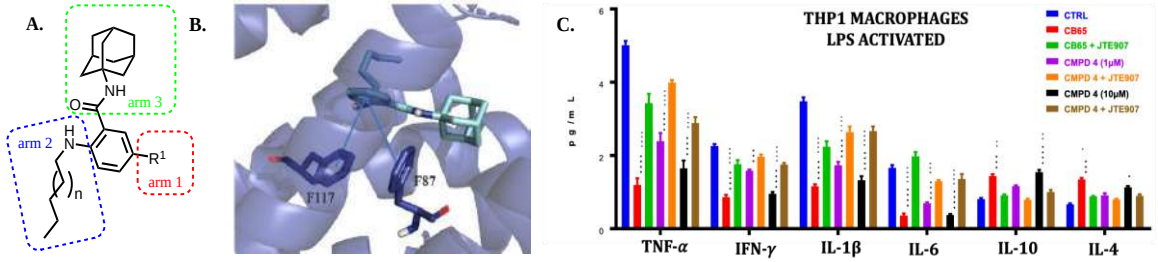

Figure 1. General structure of our *N*-adamantyl-anthranil amide derivatives (A), top-scored docking poses returned by docking simulations (B) and modulation of the best compound on cytokine production (C)

Their promising anti-inflammatory effect prompted their investigation in different models: on gastric cancer onset and in vivo on a murine model of Alzheimer disease. Our latest studies were principally directed to the improvement of their pharmacokinetic properties.

Sirtuins (SIRTs) are a family of NAD^+-dependent deacetylases including seven members, named from SIRT-1 to SIRT-7 and characterized by diverse subcellular localizations and distinct enzymatic activities.[1] The SIRT family is involved in translation, metabolism, and genome stability.[2,3] Hence, their dysregulation is closely associated with several diseases such as cancer, diabetes, and neurological illnesses. The availability of different X-ray crystallographic structures of SIRT-2−ligand complexes made it possible to build up a structure-based investigation in the hunt for SIRT-2 inhibitors (SIRTIs).[4] A series of *in-house* pyrazolo[3,4-*d*]pyrimidine derivatives as a class of SIRT-2 inhibitors were evaluated *in silico* and *in vitro*, leading to the identification of two effective compounds, **1** and **2** (**Figure 1**). Then, further modeling studies drove the synthesis of a library of analogue compounds. The identified derivatives have been tested *in vitro*, and an accurate structure-activity relationship study was carried out. Interestingly, few compounds showed a low micromolar/nanomolar activity towards SIRT-2. The synthesis and the biological results will be discussed.

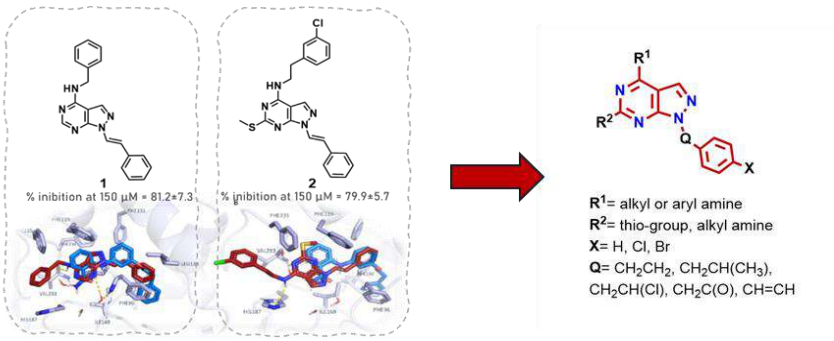

Figure 1: Structure, inhibitory activity towards SIRT-2, and docking pose of the first series of pyrazolo-pyrimidines **1**,**2** and general structure of newly synthesized inhibitors.

The widespread use of herbicides, including glyphosate, has raised concerns about potential health risks. Glyphosate, a primary herbicidal agent used globally, has been linked to various human health issues, prompting scrutiny from regulatory bodies. Despite its approval for use until 2033 in the European Union, questions persist regarding its safety [1]. This study utilizes the MAATrica assessment metric [2] to analyse the scientific validity and coherence of publicly available literature and studies utilized by the Glyphosate Renewal Group [3] and European Commission [4] to support glyphosate renewal efforts.
By analyzing accessible studies, we aim to provide insights into the reliability of scientific evidence surrounding glyphosate, contributing to informed decision-making in public health policy.

Current clinical trials investigate the role of interleukin (IL) blockade as innovative cancer treatment approaches, thus targeting IL20 receptor (IL20R) which is elevated in breast cancer, might modulate TME (Tumor Microenvironment) and could be an efficient direct anticancer treatment as well. The aim of the project is to identify ligands that can simultaneously interact on both subunits (α and β) of the receptor and on IL-20. The considered ternary complex is IL20/IL201/IL20R2, deposited with the accession code 4DOH[1]. The structure was energetically optimised using the Protein Preparation Wizard[2] tool. Subsequently, the complex was subjected to 300 ns Molecular Dynamics through Desmond[2], with the aim of studying the adaptation process of the complex over time. The resulting trajectory was clustered according to the RMSD and of the resulting clusters, the most representative was chosen according to the probability estimated by the Boltzmann Population for subsequent studies. Subsequently, the selected cluster was used as an input structure for protein mapping and identification of binding pockets via SiteMap[2]. Of the eight sites identified, three were taken into account: two constituted the binding site at the interface between the α subunit and IL-20 and one constituted the binding site at the interface between the β subunit and IL-20, in accordance with what has been described in the literature. Three grids were constructed considering the same coordinates for the left side of the protein (complexA, IL-20Rα, IL-20A), and three others on the right side (complexB, IL-20Rβ, IL-20B) again using the same coordinates for all three. Virtual screening was conducted using the database downloaded from Zinc[3] and containing 307814 ligands of natural origin, which were prepared with the LigPrep[2] tool. For each of the 6 grids generated, molecular docking calculations were performed using the Glide[2] Standard Protocol (SP) algorithm to obtain the theoretical binding affinities for each ligand expressed in terms of energy values (Kcal/mol); 10 poses per ligand were generated. At the moment, analysis of the results are still in progress. This work is supported by a PRIN project[4].

Targeting hypoxia in cancer therapy

M. Serafini,[a,b] F. Spyrakis,[a] S. J. Conway[b,c]

[a] *Department of Drug Science and Technology, University of Turin, Italy*

marta.serafini@unito.it

Hypoxia, defined as a condition of lower-than-normal oxygen levels, is a key feature of most solid tumours, associated with therapy resistance and poor patient prognosis.[1] Alongside, the chemically reducing environment found in hypoxia allows it to be targeted with pro-drugs. Hypoxia-activated prodrugs based on indolequinone and nitroaryl groups have been exploited by our group to specifically target the oxygen-deficient fraction of tumour cells,[2] reducing the systemic exposure. By using this approach, we have developed two series of hypoxia-activated PROTACs (HAP-TACs) targeting BRD4 which degrading activity is triggered when oxygen levels are reduced below 2%. Our HAP-TACs are stable in normoxic conditions (21% O_2) and undergo enzyme-mediated bioreduction in cells to release the active PROTACs in hypoxia (2-0.1% O_2). The conditional degradation of BRD4 is reflected by a selective antiproliferative activity in colorectal cancer cells exposed to hypoxia, whereas proliferation of normoxic cells is not affected. As the bioreductive groups used to develop our HAP-TACs are attached to the cereblon and VHL E3 ligase ligands (Figure 1), this strategy is applicable to any PROTAC that recruits these E3 ligases, with the potential of increasing the therapeutic index of already reported PROTACs against a wide range of target proteins. Complementary work to develop hypoxia-triggered biorthogonal reactions to form anticancer agents inside tumour cells will also be presented.

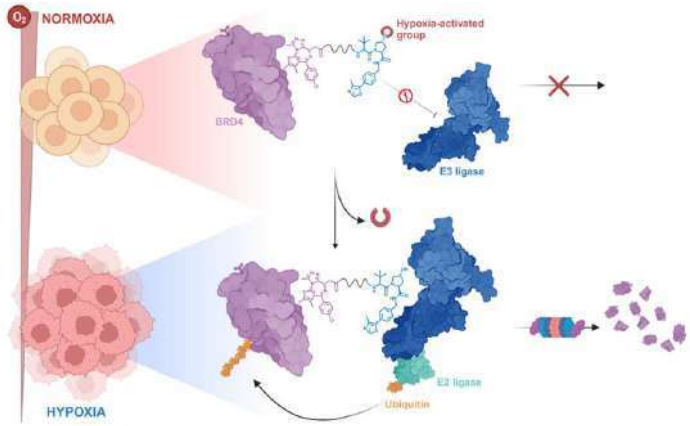

Figure 1: The concept of hypoxia-activated PROTACs.

Innovation in Virtual Screening: PyRMD2Dock's AI-Infused Approach

M. Roggia[a], B. Natale[a], S. Di Maro and S. Cosconati[a]

[a] *DiSTABiF, University of Campania Luigi Vanvitelli, Via Vivaldi 43, 81100 Caserta, Italy*
michele.roggia@unicampania.it

This abstract introduces a new computational approach, PyRMD2Dock, designed to enhance the efficiency of virtual screening campaigns for drug discovery by combining our Ligand-Based AI- enforced Virtual Screening tool PyRMD with the widely used docking software AutoDock-GPU (AD4- GPU).

Recent research has highlighted the importance of using ultralarge molecular databases (i.e., containing millions or even billions of compounds) for SBVS campaigns.[1] The screening of vast compound libraries, exemplified by the Enamine REAL database with approximately 7 billion compounds,[2] increases the chances of identifying novel and potent drug candidates not simply achievable with smaller databases.[3] However, screening millions or billions of compounds presents challenges, necessitating substantial computational resources and specialized software.[4]

Through the implementation of PyRMD2Dock, we demonstrated the rapid screening of massive chemical databases to identify compounds with the highest predicted binding affinity to a target protein. Benchmarking and screening experiments highlighted the predictive accuracy and speed of PyRMD2Dock, emphasizing its potential to expedite the discovery of novel drug candidates.

Overall, this research underscores the value of integrating AI-powered LBVS tools with docking software for effective and high-throughput virtual screening of ultralarge molecular databases in drug discovery. The open-source tools, PyRMD[5] and the PyRMD2Dock[6] protocol, are freely accessible on our GitHub page (https://github.com/cosconatilab/PyRMD).

AI-driven Discovery of TERRA G4 Ligands for ALT Anticancer Therapy

B. Natale,[a] M. Roggia,[a] S. Castellano,[b] J. Amato,[c] S. Cosconati[a]

[a] DiSTABiF, University of Campania Luigi Vanvitelli, Via Vivaldi 43, 81100 Caserta, Italy

benito.natale@unicampania.it

While most cancer types rely on telomerase reactivation for telomere maintenance and sustained proliferation, a subset (~15%) of cancers employs telomerase-independent mechanisms, referred to as Alternative-Lengthening of Telomeres (ALT). Several evidence demonstrates that ALT-elongated telomeres exhibit a permissive chromatin state that leads telomeres to be hyper-transcribed into long non-coding RNA transcripts, called telomeric repeat-containing RNA (TERRA)[1]. TERRA is implicated in numerous functions, including the interaction with telomeric proteins, modulation of telomeric chromatin, and transcription[2].

TERRA contains long tracts of telomeric r(UUAGGG) repeats, and as such it can form G-quadruplex (G4) structures. G4-interacting small molecules have shown potent inhibition of TERRA interaction with proteins, resulting in loss of TERRA at telomeres. This event is related to induction of telomeric DNA damage, decreased telomere length, and increased telomere aberrations[3]. These results suggest that targeting TERRA G4 could spearhead novel therapeutic strategies for the selective killing of ALT cancer cells.

The present contribution showcases the application of the newly developed AI-powered Virtual Screening method, PyRMD2Dock[4], to screen an ultra-large chemical database for the lead discovery of new chemotypes able to bind the TERRA G4 fold. Biophysical and biological evaluation is here reported to demonstrate the predictiveness of the employed method in the identification of potential ALT-selective antiproliferative TERRA G4 binders.

bruno.cerra@unipg.it

HYDAMTIQ is a potent dual PARP-1/2 inhibitor that has been advanced in pre-clinical settings for the treatment of brain ischemia, asthma and cancer.[1–3] The original medicinal chemistry route to HYDAMTIQ suffers from some limitations such as the moderate overall yield, the low scalability and the use of hazardous chemicals.[4] To bridge the gap between the initial compound discovery and development, as well as to support further medicinal chemistry investigations, in this communication we report the development of a flow chemistry approach to streamline the preparation of HYDAMTIQ and novel analogues (Figure 1).[5,6] The optimized flow process resulted in a greater sustainability and simplification for both scale-up operations and lead optimization programs, enabling the development of novel PARP-1/2 inhibitors with improved properties and therapeutic potential.

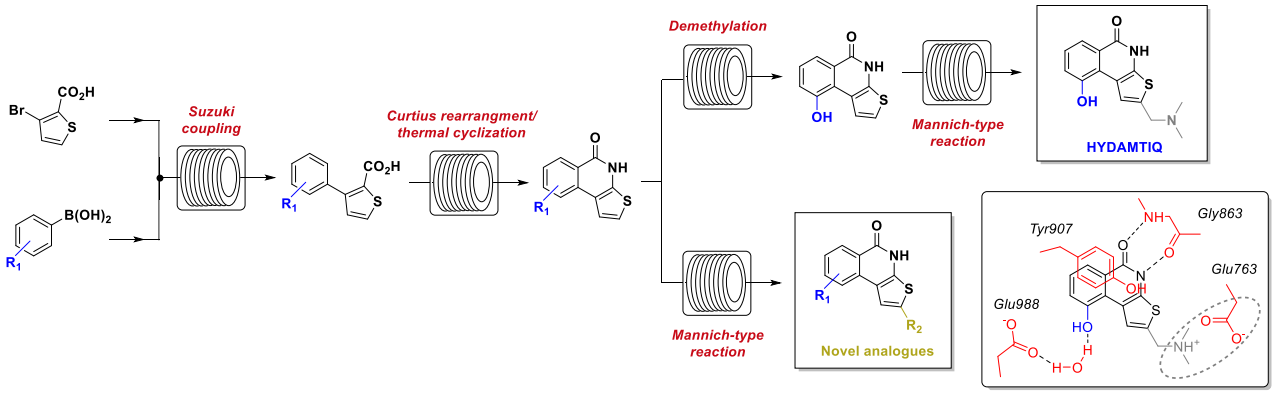

Figure 1: Multistep flow synthesis of HYDAMTIQ and its analogues.

Dafachronic acids (DAs) are steroidal hormones derived from the catabolism of cholesterol. They exhibit a unique structure featuring a C3-keto group, a double bond at the C4- or C7-position, a C25-methyl group, and a C26-carboxylic tail (Figure 1). Several evidences have shown that these signalling molecules play a pivotal role in regulating the life cycle of both free living and parasitic nematodes through the modulation of the nuclear receptor DAF-12.[1,2] Remarkably, in preclinical models of hyperinfection the activation of DAF-12 by DAs was able to suppress infection and to reduce lethality.[3] The readily availability of DAs is therefore crucial not only to better define their therapeutic potential but also to enable medicinal chemistry investigations towards more effective modulators. In this communication, we report a novel, straightforward synthesis of DAs starting from the readily available and low-cost Ergosterol (Figure 1). The new synthetic route is superior to previously reported methods as it furnishes DAs in good yield and high purity, also at large scale. The synthesized ligands have been tested in terms of human receptor selectivity, physicochemical and metabolic profile unveiling some hidden properties shared by the molecular shape of DAs that can be exploited in the design of novel and highly potent DAF-12 modulators for the treatment of parasitic disorders, such as Strongyloidiasis.[4]

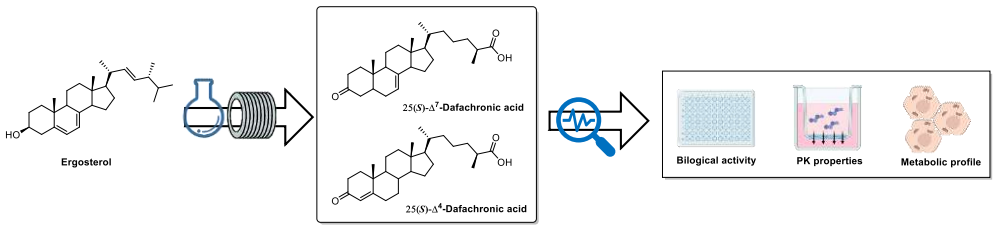

Figure 1: Overview of the synthesis, structure and profiling of endogenous DA-12 ligands dafachronic acids.

Identification of novel potential elastase inhibitors with anti-aging activity using computational alanine scanning and pharmacophore modelling

G. Pitasi,[a] A. Brancale,[b] L. De Luca[a]

[a]*Department of Chemical, Biological, Pharmaceutical and Environmental Sciences, University of Messina, Viale F. Stagno D'Alcontres 31, I-98125 Messina, Italy*
[b]*Department of Organic Chemistry, University of Chemistry and Technology, Prague, 16628. Prague, Czech Republic*
giovanna.pitasi@studenti.unime.it

Skin aging is characterized by wrinkles, fine lines, loss of elasticity, and non-uniform pigmentation due to a combination of exogenous factors, including U.V., chemicals, pollutants, and endogenous factors, such as cellular metabolism, genetic mutations, and hormonal factors.[1] A main hallmark of skin aging is the loss of structure in the extracellular matrix, which contains numerous proteins, including collagen and elastin, that play an important role in maintaining skin elasticity. Extracellular matrix degradation is mainly due to the increased activity of certain proteolytic enzymes, such as elastase, which is responsible for the breakdown of elastin.[2] Inhibition of this enzyme can lead to increased skin elasticity, preventing the formation of wrinkles and sagging.[3]

In this regard, we present a study aimed at identifying potential small molecules capable of inhibiting elastase enzyme by computational approaches. Several hotspot residues on elastase were identified using a combination of pharmacophore modelling, computational alanine scanning and molecular dynamics.

Then, an accurate pharmacophore was created, consisting of a hydrogen bond donor, two acceptors, and two hydrophobic features. This pharmacophore was used screen in silico different libraries, including naturals and synthetics compounds. Molecular docking studies were carried out to investigate the binding mode of the selected hits. Finally, binding free energy was calculated and a series of molecular dynamic simulations were performed to gain information about the stability of protein-ligand complexes.

Point-of-Care (PoC) tests based on biomarkers represent useful tools for diagnosing and monitoring tumor diseases. In this context, we aimed at implementing PoC Test devices for the development of diagnostic strategies for the early detection of circulating tumor cells (CTC). Specifically, the CXCR4 chemokine receptor, overexpressed in more than 30 different types of solid and hematological tumors1, was considered as "hallmark" to be detected by applying photonic biochips previously functionalized with CXCR4-ligands. Specifically, peptide L10 (Ac-Arg-Ala-[Dap-Arg-2Nal-His-Glu]-COOH), recently characterized as potent and selective CXCR4 antagonist, was modified to identify a suitable position within the sequence for introducing a residue of L-Cys, which could be employed to anchor the peptide on an Au-functionalized solid surface. The described peptides were endowed with the following general structure: Ac-Cys-X-Arg-Ala-[Dap-Arg-2Nal-His-Glu]-COOH, where X represents an amphiphilic linker that was modulated in composition and length. This strategy led to the identification of two promising selective and potent CXCR4 antagonists, which were employed to functionalize photonic biochips (CXCR4-PB)2. As a proof of concept, the CXCR4-functionalized biochips obtained were initially evaluated in the presence different concentration (1 x 102 to 2.5 x 104 cells/ml) of both CXCR4-positive (CXCR4+) and CXCR4-negative (CXCR4-) CHO cells, showing the capability to specifically detect the receptor at concentrations comparable to those of the CTC in cancer patients. Encouraged by these promising results, ongoing investigations involve various solid tumor-derived cancer cells expressing different levels of CXCR4 (e.g., CEM, HCT116, HT29 and ASPC-1). The primary objective is to establish the lowest limit of detection for our Point-of-Care tests before advancing to their application in more complex biological matrices such as blood.

Antimicrobial resistance (AMR) is one of the most complex threats to human health. In the field of nontuberculous mycobacteria (NTM), especially *Mycobacterium avium* complex (MAC), high intrinsic multidrug resistance (MDR) is observed due to decreased permeability of the mycobacterial cell wall and drug efflux mediated by efflux pumps (EPs). Treatment of such infections is a clinical challenge due to the long duration, cost, and high likelihood of failure. *M. avium* EPs can extrude macrolides, leading to the emergence of macrolide-resistant phenotypes. Therefore, the development of efflux pump inhibitors (EPIs) represents a strategy to restore the efficacy of already approved antibiotics that are substrates of EPs, such as clarithromycin (CLA).[1]

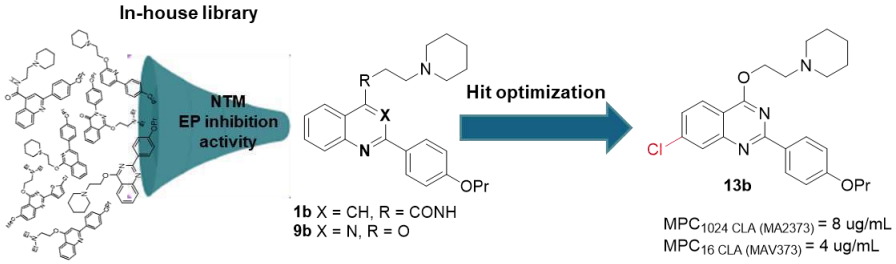

Figure 1: Schematic representation of the present work

Due to the lack of in-depth knowledge of the structure of NTM EPs, only a few molecules characterized by a narrow chemical diversity have been reported as NTM EPIs.[2] In this study, with the aim of expanding the chemical space of NTM EPIs, a selection of compounds from an in-house library was screened to evaluate their NTM EPI activity against *M. smegmatis* mc^{2}155 and the clinical isolates *M. avium* 2373. Compounds **1b** and **9b** emerged as promising hits capable of synergizing with CLA at low concentrations and exhibiting a good safety profile. Analogues were designed with the aim of obtaining more information on the structure-activity relationship and improving potency as NTM EPIs, as was the case for compound **13b** (Figure 1). The synthetic procedures together with the biological data will be presented in this study.
