Abstract: In the context of circular economy and of decarbonisation of the society, one of the uprising techniques for industrial wastewater treatment is the use of Membrane distillation (MD) system, because of its capabilities such as low carbon footprint, and being able to be coupled with waste thermal energies. However, the main drawback of these systems is the temperature polarization phenomenon which can lead to performance reduction. To overcome this problem, geometry modifications such as adding spacers in the system is considered. Thus, a simple geometry is built to study the thermal distribution through the system, and then the effects of adding spacers with different configurations is here investigated using Computational Fluid Dynamics (CFD) analysis. The different spacer configurations are characterised and their effect on MD performance are tested. The optimal configuration will be used, via 3D printing to confirm finding on an experimental setup on upcoming study.

Keywords
Computational Fluid Dynamics, Membrane Distillation, OpenFOAM

INTRODUCTION

Among all the potential techniques for industrial wastewater treatment, membrane separation technology is considered one of the promising ways for this goal due to its smaller footprint and higher energy efficiency (Kalla, 2021; Yao et al., 2020). Particularly when the wasted heat source can be accessible as it is the case in many industrial sectors. Unlink most of the membrane separation processes that are pressure driven such as Microfiltration (MF), Ultrafiltration (UF), Nanofiltration (NF) and Reverse Osmosis (RO), the driving force in the membrane distillation (MD) process is partial pressure difference of water vapor across membrane pore caused by the temperature difference (Kim et al., 2017; Martõ Ânez-Dõ Âez et al., n.d.; Shirazi et al., 2015). Hence, MD processes can be regarded as an adequate choice for challenging wastewater since they will not require high pressures (Yao et al., 2020).

However, one of the drawbacks of using MD systems is temperature polarization which is caused due to the difference of the temperature at the membrane interface in the bulk temperature and in the channel (Eykens et al., 2016). To overcome this drawback, modification of geometry using spacers in the feed and permeate channels has been suggested to promote mixing and enhance the mass and heat transfer, which finally will result in reduction of concentration and temperature polarization (Shakaib & Haque, 2019). One of the ways that we can investigate different configurations of spacers to find the optimum configuration for achieving the best performance of the MD is through computational fluid dynamics (CFD) analysis (Kuang et al., 2019; Tan et al., 2019; el Kadi et al., 2020; Hasani et al., 2019).

Thus, in this study, 3D geometries of the MD system with different spacers' configurations are prepared, and after generating the proper mesh, CFD analyses are performed to assess the MD system's performance.

METHODS

A new CFD model is developed to study the thermal and velocity distributions in the MD system. First, 3D structures of membrane distillation system with and without spacers will be designed using open-source CAD software: Salome 9.8 (SALOME Version 9.8.0 Released in December 2021., n.d.). After defining the whole geometry, a suitable mesh will be implemented to the structures. The created meshes will be exported to the OpenFOAM10 (Https://Openfoam.Org/, n.d.), an open-source CFD simulation tool, to study the characteristics of the system in the defined computational domain.

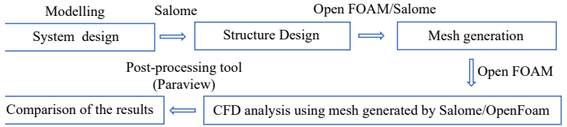

Figure 1. The schematic workflow of the study

PRELIMINARY RESULTS AND DISCUSSION

Fig.2 shows the 3D designed geometry of the MD system with spacers in both feed and permeate channels. As it is shown in the Fig.2, the spacers have a 45◦ angle with the feed and permeate flows. To understand the dimensions of the figure, Table 1. represents the dimensions of this basic case.

As part of this research, different configurations/dimensions of the spacers will be designed for CFD analysis, and after investigating mass, heat and momentum phenomena in each case, the best configuration will be selected to achieve the best MD performance.

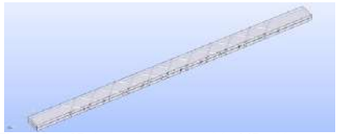

Figure 2. A 3D designed geometry of the MD with spacers.

Table 1. the dimensions of the MD geometry

Parameter	Value
Block length	200 mm
Block width	10 mm
Block height	2 mm
Initial distance	30 mm
Filament radius	0.499 mm
Filament distance	10 mm
Filament amount	11

Fig.3 shows the initial result of the thermal distribution along the MD system without spacers. As it is illustrated in the figure, the feed channel is shown on the bottom, and it has an initial feed temperature of 330◦ C, and as feed flow goes along the channel, the temperature decreases to approximately 312◦ C. The permeate channel is shown on the top, and permeate initial temperature is 290◦ C, and as it travels through the channel, the temperature increases to around 314◦ C.

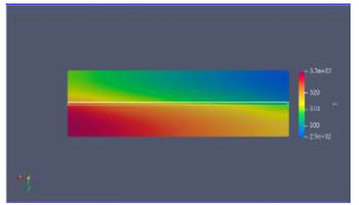

Figure 3. Thermal distribution along the MD module

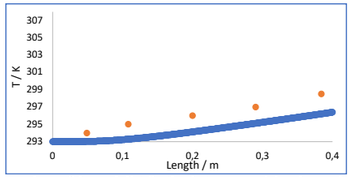

Figure 4. Comparison of thermal distribution between model and experimental results

The initial obtained CFD results showed compatibility with the previous experimental results by Harandi's group (Harandi et al., 2021), therefore for the following studies, other configurations with spacers will be designed and investigated by CFD analysis.

activated sludge model; aeration; optimal operation; cost-effective.

INTRODUCTION

Pulp and paper mills discharge large amounts of wastewater that contains various pollutants. Hence, wastewater treatment plants (WWTP) are employed with the aim to remove the maximum amount of these pollutants with minimal operational cost before discharging the wastewater into water basins. With constantly tightening environmental regulations, and the need to optimize the WWTP for economic gains, WWTPs need modern tools to improve their operation and provide cost-effectiveness.

Wastewater treatment is a complex industrial process, as shown in Figure 1. In this process, aeration treatment is used to remove organic substances from the wastewater. The concentration of the organic substances in the aeration treatment is measured as the amount of oxygen required for its oxidization, commonly called Chemical Oxygen Demand (COD). The COD in the aeration process resides in various forms that interact with each other in a complex manner (Osipchuk O. 2020). Moreover, this COD is typically dependent on the wastewater type, weather, or other environmental issues; thus, operating the WWTP without a deep understating of the aeration process may result in a higher amount of effluent COD and poor WWTP operation. The COD in aeration changes with change in the product quality and operating conditions. Additionally, the aeration process requires continuous air pumping that requires extensive energy. As the current global trend is that energy costs will continue to increase, stakeholders are keen to find new cost-effective solutions for the WWTP.

For understanding and analyzing the aeration process, one useful tool is Activated Sludge Model No. 1 (ASM1) (Orig. Henze *et al.* 1987). Such in-depth analysis of the aeration process can help the process operators to make more accurate decisions that could increase the effluent quality and reduce the energy requirement, thus reducing the economic and environmental footprint.

MATERIALS AND METHODS

For modeling the aeration process, ASM1 is considered a reference model (Mulas, M. 2006). This model is widely used in research applications and is developed primarily for municipal wastewater treatment. A typical ASM1 model consists of two parts: an anoxic part for removing nitrogen and an aeration part for oxidizing organic substances from the influent wastewater. In this study, the WWTP processes paper mills wastewater, which is nitrogen deficient. Therefore, nitrogen removal is not the primary objective here; thus, the ASM1 is modified by removing the anoxic part, and only the aeration part is considered. A schematic diagram of the ASM1 model is shown in Figure 2. A comprehensive description of the ASM1 is given in (Henze *et al.* 1987, Jeppsson, U. 1996).

ASM1 model considers that the influent COD consists of biodegradable substances, non-biodegradable substances, and two types of microorganisms. This model has 13 local processes that represent the change in the number of COD substances (Alex *et al.* 2008). In each local process, various organic substances interact with each other with varying reaction rates. The complete list of ASM1 parameters and their default values can be found in (Henze *et al.* 1987).

ASM1 requires details of the influent COD. For this purpose, a sampling campaign was performed in which the wastewater samples were taken at two points: before entering the aeration pool and after the secondary clarifier (Mustonen S. 2022). This sampling campaign was conducted during weeks 22-24, and one composite sample was taken per week. For sampling, composite samplers (HACH AS950) are used that grab a wastewater sample every 4 hours and 40 min and then combined those samples to form a composite sample. These samples were analyzed in the laboratory, and the concentration of various substrates is calculated. Details about the sampling campaign are given in Table 1 (Mustonen S. 2022). For ASM1 calibration, we used the hit-and-trial method. In model calibration, the aim is to find the appropriate model parameter values so that the model result matches the sample results that were taken during the campaign period. In the hit-and-trial method, the model is tested for various combinations of parameters, so that the model results match the benchmark results.

Data generated by the automatic measurement system in the WWTP was utilized. The dataset includes data from 2022-05-01 to 2022-09-16. Selected variables are presented in Figure 3 and the basic statistical properties of these variables are presented in Table 2. The COD and phosphorus measurements were preprocessed with the Potts functional (Weinmann *et al.* 2015) to extract the piecewise-constant functions caused by the sampling method. For outlier removal we used an approach based on running median. Removed values were replaced with linear interpolation. We analyze the delays between wastewater variables by calculating the Time-Lagged Windowed Cross-Correlation (TLWCC) matrices (Boker *et al.* 2002) and finding the lag that maximizes the average correlation coefficient.

RESULTS

The ASM1 model is simulated for the given data using the calibrated parameter, and the results are shown in Figure 4. The COD in the Pulp and Paper WWTP is composed of carbon-based substrates; therefore, only carbon-based substrates are shown here. Figure 4 shows that the model prediction matches the result of the sampling period; therefore, the calibrated model is ready to predict COD concentration in the aeration process for any given data set.

Based on the TLWCC analysis, the average correlation coefficient between influent and effluent COD is maximized with a lag of 16 hours; that is, the influent COD leads the effluent by 16 hours. However, with a larger dataset covering the whole year 2021 (not shown), the average correlation coefficient was maximized with a lag of 23 hours. When comparing effluent COD and BOD, the correlation coefficient was maximized with zero lag.

DISCUSSION

Future work includes creating comprehensive imaginary data for the ASM1, tuning and testing the ASM1 for a larger data set and integrating the secondary clarifier to the new tuned ASM1 model. Future work also includes analyzing the wastewater variables with advanced time series analysis methods.

Abstract
The presence of micropollutants in wastewater effluents is a topic of major concern, as these pollutants end up in surface and ground water. The electrochemical advanced oxidation processes (eAOP) have shown a great ability to remove these recalcitrant compounds from water. However, in eAOP the degradation of pollutants is mainly caused by oxidation at anode. Whereas, the cathodic part of the cell does not play a significant role in pollutant oxidation. Recently, there has been an increase in the research interest to generate H_2O_2 at the cathode by supplying air/oxygen. Hydrogen peroxide (H_2O_2) is often used for the treatment of (waste)water due to its highly oxidative and non-polluting nature as it breaks down to harmless compounds (i.e., water and oxygen). H_2O_2 is mainly produced in industrial settings which are relatively expensive and demands extreme care with handling, shipping and storage. Therefore, it is important to devise an in-situ, decentralized H_2O_2 generation and utilization facility for the purpose of water treatment. Electrochemical production of H_2O_2 has become an attractive option as it can be instantaneously brought into utilization for in-situ treatment of water in an eAOP system.
In an electrochemical system, H_2O_2 is produced at cathode surface via oxygen reduction. Various carbonaceous catalyst and electrode materials have been developed over the past decade to enable H_2O_2 production at the cathode. In this study, a carbonaceous cathode material has been prepared and coated with a novel carbon black catalytic coating to efficiently generate H_2O_2. Furthermore, H_2O_2 generated in the system was utilized in-situ for the treatment of pharmaceutical compounds losartan and irbesartan which are often detected in wastewater effluents. The new cathode composition prepared in this study, was found to produce H_2O_2 with >80 % faradaic efficiency. Furthermore, the degradation rate of losartan and irbesartan was increased 6 folds by activating the in-situ produced H_2O_2. In conclusion, the results from this study illustrate that a novel inexpensive carbonaceous catalytic coating for cathode can greatly enhance the efficiency of an eAOP.

INTRODUCTION

The increasing accumulation of parameters compounds in natural waters has led the researcher to devise efficient tertiary treatments for the removal of such compounds from the water before it is being discharged into the aquatic environment. Recently, electrochemical advanced oxidation processes (eAOP) have emerged as efficient and environmentally friendly technology for tertiary treatment. In a traditional eAOP, the degradation of pollutants is mainly caused by their oxidation at the anode, whereas at the cathode H_2 gas is produced which doesn't help in pollutant removal. Therefore, recently there has been an increase in research interest in inducing the oxygen reduction at the cathode to produce H_2O_2. This way, the in situ produced H_2O_2, after activation, can further enhance the pollutant oxidation. In the present study, a carbonadoes cathode is prepared by coating carbon black catalytic ink onto the reticulated vitreous carbon (RVC) surface. The cathode is tested for the production of H_2O_2. Two pharmaceutical compounds, losartan (LST) and irbesartan (IBT) have been have been selected to treat in the electrochemical system because of their frequent detection in water bodies (Khosravi et al. 2021) and resistance towards biological treatment (Tran et al. 2015). The H_2O_2 produced in the system is activated with the help of cobalt ferrite ($CoFe_2O_3$) particles as a catalyst to enhance the degradation of LST and IBT as compared conventional electrooxidation.

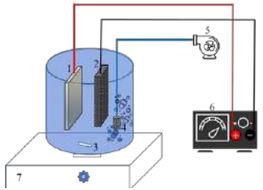

Figure 1. Schematic of the electrochemical system used in the study. 1. BDD anode 2. fabricated cathode 3. magnetic stirrer 4. air diffuser 5. air pump 6. Potentiostat 7. Stirring plate

MATERIALS AND METHODS

All the chemicals were purchased from Sigma Aldrich (Overijse, Belgium), BDD plate electrode from NeoCoat (La Chaux-de-Fonds, Switzerland), and Ag/AgCl reference electrode was purchased from redox.me (Norrköping, Sweden). The working volume was 400 mL, where anode was BDD and cathode was RVC coated with carbon black ink prepared in the lab. RVC was prepared by polymerization of poly-furfuryl alcohol on a polyurethane sponge as a template followed by carbonization at 900-1300°C. The catalytic ink was prepared by mixing carbon black with water, methanol and polytetrafluoroethylene in certain ratios. Air was continuously purged with the help of an aerator. The production of H_2O_2 was monitored by potassium titanium oxalate spectrophotometric method stated elsewhere and the degradation of LST and IBT was tracked by Agilent 1260 Infinity II Prime Online HPLC System (Agilent Technologies, Waldbronn, Germany).

RESULTS AND DISCUSSION

The removal of LST and IBT is represented by C/C_0 in figure 2, where C is the concentration of the compound at any time (t) and C_0 is the concentration at the start of the experiment. Furthermore, in figure 3 the degradation rate (k) is calculated by taking natural log of C/C_0. Since, the graphical plot between "ln C/C_0" and "t" is a straight line with $R^2 > 0.99$, it suggests that the process follows pseudo first order kinetic. The results, as shown in Figure 2 and 3, show that the degradation of LST and IBT in the electrochemical system was enhanced in the presence of $CoFe_2O_3$. The increase in degradation rate indicates the production and activation of H_2O_2 in the system which improved the degradation rate by around 6 times.

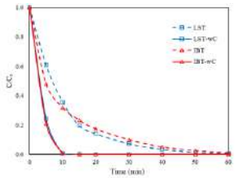

Figure 2. The removal of LST and IBT in the presence and absence of CoF_2O_3 catalyst.

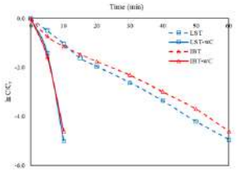

Figure 3. The degradation rate of LST and IBT in the presence (wC) and absence of CoF_2O_3 catalyst.

INTRODUCTION

In recent years, there has been a growing call for a paradigm shift toward circular nutrient management [1]. This call is a response to the biogeochemical planetary boundary being pushed beyond its threshold, mainly due to the release of anthropogenic reactive nitrogen (N) and phosphorus (P) into the environment [2]. Environmental impacts are apparent in eutrophication and algae blooms in various water bodies worldwide [3]. Synthetic fertilizers have frequently been associated with these environmental impacts. Additionally, most nutrients that enter the human food chain end up in wastewater and are either partly removed in wastewater treatment plants or discharged directly into water bodies [4]. One approach to enable the recovery of nutrients is urine source separation [5]. Recently, several urine recycling technologies (URTs) have emerged [6]. However, despite their high potential for advancing circularity and relieving ecological perils, these technologies have not yet advanced into large scale implementation/diffusion [7].

In the early stages of adoption, emerging technologies are sheltered from mainstream competition in niches i.e., protected breeding spaces for radical innovations (e.g., labs, etc) [8]. Niches gain momentum as they mature and become technological innovation systems (TISs) with a more shaped structure of actors, networks, rules and regulations [9]. In order to understand why the diffusion of emerging technologies has been delayed a TIS analysis needs to be conducted. This paper therefore aims to explore why URTs failed to catch on and diffuse in terms of large-scale implementation after more than two decades since their introduction. We will examine the state of urine recycling in Sweden and Switzerland, as well as the fundamental processes responsible for its development and diffusion. Our objective is to identify blocking mechanisms that may have hindered the expansion and to formulate recommendations targeting actors and entities, illustrate scenarios for future implementations and pinpoint where change has the most potential for creating the most effects.

METHODOLOGY

The TIS performance is evaluated in relation to a group of essential functions (entrepreneurial experimentation, knowledge development and diffusion, guidance of search, market formation, resource mobilization, and legitimacy creation) [10]. Scholars regard these functions as critical processes within the TIS necessary for the successful development and diffusion of emerging technologies. A TIS analysis identifies lagging functions and their blocking mechanisms.

An essential function in developing TISs, especially early in the formative phase, is "knowledge development and diffusion" [11]. This function is considered to be the most critical system function as it reflects the breadth and depth of the knowledge base and how knowledge is diffused within the TIS [12]. To evaluate this function, we developed a novel multi-criteria framework Table 1. The other functions have been evaluated using a list of indicators Table 2 generated by the co-authors through an iterative process. Subsequently, the Delphi method was followed to perform the evaluation, i.e., the evaluation was conducted by professionals in the field rather than the analyst to prevent any possible bias from occurring.

RESULTS AND DISCUSSION

The knowledge function was rated weak to moderate in terms of innovation in scientific research and diversification of emerging technologies into the TIS, with a tendency for strong publication rate growth and diffusion between countries. For the first criterion results in **¡Error! No se encuentra el origen de la referencia.** showed that the rate of growth in urine recycling publications was between 5 and 10 folds over the decades thus it was deemed high and scored 4. The second criterion revealed very few pilot-scale implementations per technology around the globe thus the criterion was deemed weak and scored 2. From the temporal changes in publications on urine technologies, it is evident that new technologies have been incorporated into the urine recycling TIS over the past three decades. Thus, the third criterion was deemed moderate and scored 3. Based on temporal and spatial changes in publications on urine technologies **¡Error! No se encuentra el origen de la referencia.**, 10 to 30 countries entered the urine recycling TIS in the past two decades (2000-2021) thus the fourth criterion was deemed high and scored 4. For the fifth and sixth criterion, urine recycling was placed in a broader context, i.e., in relation to existing conventional systems. A Scopus search, limited to the same timeframe 1990-2021 and study areas as the comprehensive mapping, was performed results showed that source separation made up a relatively small proportion of total wastewater publications. Urine recycling is a subset of source separation, meaning urine recycling-related publications are less than 1%. As regards the proportion of relevant conferences, mapping of IWA conferences showed that urine recycling TIS conferences made up less than 10% of total conferences in the wastewater sector from 1990-2021. The fifth criterion was therefore deemed weak and scored 1. Despite the low proportion of urine recycling in wastewater publications, looking at the progression of urine recycling TIS over time shows an increasing trend thus the sixth criterion was rated high.

The evaluation of the other functions identified various blocking mechanisms the urine recycling TIS faced, ranging from lack of knowledge, technological advancement, investment, and legal support. Recycling urine goes beyond simply diverting urine; it encompasses the entire value chain, from diversion and collection to post-treatment and application. This was one of the main challenges facing the industry in the 1990s when the value chain was lagging behind [13]. There were issues with urine collection, the technology used was poor, and end users were untrained in handling urine. A robust system was not implemented and responsibilities between the actors were vaguely distributed i.e., it's not clear who and how urine should be collected, treated and handled. To kick off urine recycling and increase its market share and reputation, actors need to work collectively. The direction of intervention needs to be a combination of a top-down and a bottom-up movement; what matters most is that all involved actors are equally motivated. Equally engaged and motivated actors are essential to developing a robust value chain. The absence of government intervention (top-down movement) and reliance only on grass-roots initiatives (bottom-up movement) is a major reason why the current value chain lags behind its potential - the Swedish experience during the 1990s is a relevant example. **¡Error! No se encuentra el origen de la referencia.** below shows our scenarios and combinations for diffusing today's urine recycling TISs.

Table 1: The multi-criteria framework utilized for evaluating the knowledge development and diffusion function in the urine recycling technological innovation system (TIS). The analysis is based on the urine-recycling technologies.

	Evaluation criterion	(1-5) scale Evaluation		
		1-2 (Weak)	3 (Moderate)	4-5 (High)
F1- Knowledge development and diffusion	**Growth in scientific publications within the TIS per decade**	TIS publications increased zero-fold* per decade. TIS publications increased < 2-fold* per decade. (Less than double)	2-fold* ≤ TIS publications growth < 4-fold* per decade. (More than double)	4-fold* ≤ TIS publications growth > 8-fold* per decade. TIS publications increased ≥ 8-fold*.
	Innovation in scientific research per technology within the TIS	Zero pilot-scale trials, and follow-up publications per technology. < 5 pilot-scale trials, and follow-up publications per technology.	5-10 pilot-scale trials, and follow-up publications per urine technology.	11-30 pilot-scale trials, and follow-up publications per technology. >30 pilot-scale trials, and follow-up publications per technology.
	Diversification of emerging technologies into the TIS	Zero new technologies entering the TIS per decade. < 5 new technologies entering the TIS per decade.	5-10 new technologies entering the TIS per decade.	11-30 new technologies entering the TIS per decade. >30 new technologies entering the TIS per decade.
	Diffusion of knowledge between countries	Zero new countries entering the TIS per decade. < 5 new countries entering the TIS per decade.	5 - 10 new countries entering the TIS per decade.	11 - 30 new countries entering the TIS per decade. >30 new countries entering the TIS per decade.
	TIS knowledge volume compared with conventional systems	TIS publications < 1% of conventional systems & TIS conferences < 5% of total conferences /year. 1% ≤ TIS publications ≤ 2% of conventional systems & 5% ≤ TIS conferences < 8% of total conferences /year.	3% ≤ TIS publications ≤ 5% of conventional systems & 8% ≤ TIS conferences < 10% of total conferences /year	6% ≤ TIS publications ≤ 9% of conventional systems & 10% ≤ TIS conferences < 12% of total conferences /year. 12% ≤ TIS publications ≤ 15% of conventional systems & 12% ≤ TIS conferences ≤ 15% of total conferences /year.
	Development of urine recycling publications over time compared to conventional systems **Actors' engagement in knowledge generation**	Negative trend i.e., the progression of urine recycling publications compared to conventional systems is decreasing over time. Not yet defined	Static trend i.e., the progression of urine recycling publications compared to conventional systems is not changing over time. Not yet defined	Positive trend i.e., the progression of urine recycling publications compared to conventional systems is increasing over time. Not yet defined

Table 2: TIS functions and the indicators used for the evaluation.

	Indicators
F1- Entrepreneurial experimentation	▲ The diversity level in the TIS ▲ The engagement and activeness level in the TIS ▲ The experimentation rate in the TIS
F3- Knowledge development	▲ The engagement in knowledge generation in the TIS
F4- Guidance of the search	▲ National strategy for nutrient recovery from wastewater ▲ National policy / incentives enabling urine recycling ▲ Vision and expectations of the sanitation system
F5- Market formation	▲ The number of urine diversion toilets ▲ The number of pilot-scale projects ▲ The price for urine diversion installation ▲ The service fees for urine recycling ▲ The agricultural sector attitudes toward urine-based fertilizer
F6- Resource mobilization	▲ The availability level of human resources in the TIS ▲ The availability level of infrastructure in the TIS
F7- legitimacy creation	▲ The level of lobbying activities against urine recycling ▲ The level of lobbying activities to legitimize urine recycling ▲ The willingness of conventional systems to adopt urine recycling ▲ Users acceptance of urine recycling

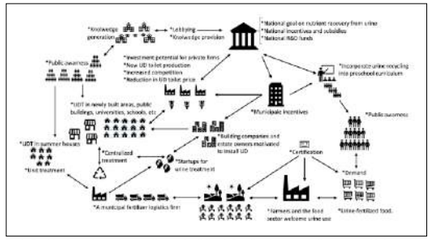

Fig 1: Combination on how urine recycling can be diffused. One direction arrow indicates a one-sided relationship, two directions arrow indicates a two-sided relationship. This illustration shows both bottom-up and up-bottom interventions .

Abstract
Wastewater containing monoethanolamine (MEA) is generated in nuclear power plants as it is used to minimize metal pipes' corrosion in steam cycles. If not treated, it can cause environmental problems due to its COD and nitrogen content. Physicochemical processes have traditionally been used to treat MEA, but a more sustainable and cost-effective alternative is possible through biological means. Research on MEA biodegradability is limited to determine if bioprocesses could be a viable option for treating MEA at large-scale. The effect of different MEA concentrations on aerobic MEA degradation is examined using discontinuous tests to evaluate if high concentrations could inhibit biomass activity. The highest removal rate was found with 3 g COD L^{-1} of MEA, 6.2 g COD g VSS^{-1} d^{-1}. The removal rates decreased by 2 and 4 times in tests with 6 and 9 g COD L^{-1}, respectively, attributed to the accumulation of intermediary MEA degradation products.

Keywords
Biodegradation; Monoethanolamine; Industrial wastewater treatment; Batch-test assays.

INTRODUCTION

Wastewater containing monoethanolamine (MEA) is generated in nuclear power plants (NPPs) with pressurized water reactors. MEA is used in the steam cycle of NPPs to minimize the metal corrosion of pipes. If not treated, MEA can lead to serious environmental problems in the receiving water bodies due to its chemical oxygen demand (COD) and nitrogen content. To date, the degradation of wastewater containing MEA has been addressed using expensive physicochemical processes. MEA might be also treated at lower costs and in a more sustainable way by biological means. There are studies assessing the biodegradability of MEA at different redox conditions: aerobic and anoxic (Kim et al. 2010) and anaerobic (Wang et al. 2013). However, the knowledge is limited and the information available is still insufficient to assess if using biological processes might be a feasible alternative to treat this wastewater at an industrial scale. This study is aimed to evaluate if MEA could inhibit biomass activity at high concentrations. For this purpose, the impact of different MEA concentrations on the activity of biomass highly enriched in aerobic MEA degraders is evaluated employing discontinuous batch-test assays.

$$C_2H_7ON + 2.5O_2 \rightarrow CO_2 + H_2O + NH_4^+ + HCO_3^- \qquad (1)$$

MATERIALS AND METHODS

The short-term impact of different MEA concentrations (0.4, 1, 3, 6, and 9 g COD L^{-1}) on the activity of aerobic MEA degraders was examined for 8 h using discontinuous batch-test assays with constant experimental conditions (pH 7; 25°C; O_2 saturation) (Figure 1a). 200 mL of suspended biomass enriched in aerobic MEA degraders was added to each bottle. The biomass used as inoculum was taken from a sequencing batch reactor (SBR) highly enriched in MEA degraders with a specific activity of 4.9 g COD g^{-1} VSS d^{-1} and a concentration of 1.2 g VSS L^{-1}.

RESULTS AND DISCUSSION

The maximum MEA removal rate, 6.2 g COD g VSS^{-1} d^{-1}, was achieved for the assay with an MEA concentration of 3 g COD L^{-1}. In contrast, concentrations above 3 g COD L^{-1} resulted in decreasing removal rates (Figure 1b). For the 6 and 9 g COD L^{-1} tests, removal rates of 3.0 and 1.6 g COD g VSS^{-1} d^{-1} were observed, values which are 2 and 4 times lower compared to the maximum accomplished at 3 g COD L^{-1}, respectively. This drop might be attributed to the accumulation of intermediary MEA degradation products. The initial MEA hydrolysis step, where NH_4^+ and acetaldehyde are produced, seems to be faster than the oxidation of acetaldehyde or other intermediary products. This is supported by the high accumulation of NH_4^+ measured, which does not correspond to the expected ammonium production considering the observed COD removal (Figure 1c) and the negligible nitrification rates accomplished. The maximum rate achieved in the present study is three times higher than the 1.9 g COD g VSS^{-1} d^{-1} reported by Kim et al. (2010) with 1 g COD L^{-1} of MEA. Despite the high rates attained in this study, it is suggested that high concentrations of MEA might negatively affect short-term biomass activity and they should be preferably avoided inside bioreactors treating this type of wastewater. Further research is needed to determine if this inhibition could be reversed through biomass adaptation (long term).

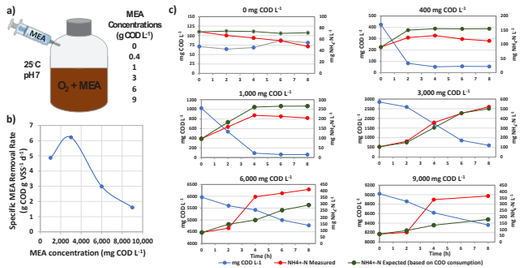

Figure 1. a) Batch-tests experimental set-up and conditions; b) maximum specific MEA removal rates at different MEA substrate concentrations; and c) evolution of the ethanolamine concentration (COD), and the measured and expected ammonium (based on COD consumption observed and stoichiometry of Equation 1) concentrations.

Abstract

Studies have shown that anaerobic digestion (AD) performs significantly better when integrated with microbial electrolysis cell (MEC). However, the role of MEC in enhancing the performance of AD is still not well understood. In this study, five sets of reactor conditions based on introducing a virgin electrically conductive electrode, pre-enriching electrically conductive electrodes with a culture of *Geobacter sulfurreducens* (anode) and hydrogentrophic methanogens (cathode) and operating the MEC-AD reactors with or without power supply (0.8 V) were examined for their role in enhancing the efficiency of methane production in AD. The findings offer new insight for pre-enriching the electrically conductive electrodes and applying external voltage (0.8V), both of which are essential for improving resource recovery (CH_4) from wastewater.

Keywords

Pre-enrichment; *Geobacter sulfurreducens;* hydrogentrophic methanogens; microbial electrolysis cell; anaerobic digestion

INTRODUCTION

Anaerobic digestion (AD) is an effective process for recovering resources as CH_4 from wastewater, but stable performance necessitates a longer hydraulic retention time. In AD, syntropy between fermenters and methanogens is required for the complete breakdown of organic compounds to CH_4. However, the buildup of H_2 and volatile fatty acids (VFAs) at high organic loading rates is harmful for AD process. Therefore, for AD to function properly, the concentration of H_2 and VFAs must be reduced. It has been reported that the overall AD performance has been enhanced by the incorporation of microbial electrolysis cells (MEC) (i.e., insertion of electrically conductive electrodes into AD) (De Vrieze et al., 2014). In the MEC-AD system, the anode enriches electroactive bacteria (EAB) to oxidize organic compounds and reduce the concentration of VFAs, while the cathode promotes the enrichment of hydrogenotrophic methanogens (1) and/or electromethanogens (2) to convert H_2 and/or electrons to CH_4. As a result, MEC-AD systems have shown to be more effective at removing organic matter and producing CH_4 than AD systems alone (Feng et al. 2015).

$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$ (1)

$8H^+ + 8\,e^- + CO_2 \rightarrow CH_4 + 2H_2O$ (2)

Despite the advantage of this integration, the role of MEC in enhancing the performance of AD is still not well understood. For instance, it is not clear which of the following factors has the greatest influence in improving the performance of AD: i) bioelectrochemical processes at the bioanode and biocathode, ii) biomass retention due to the additional surface area of electrodes, or iii) direct interspecies electron transfer (DIET) between EAB and methanogens at the electrode in the absence of current generation. Therefore, to assess the effect of electrodes in MEC in enhancing the overall performance of AD, five sets of reactor conditions were examined in this study.

MATERIALS AND METHODS

Four sets of MEC-AD reactors (EE-O.C, EE-0.8 V, VE-O.C, VE-0.8 V) and one set of AD reactors (NE-AD) were constructed to test five different start-up strategies (Fig. 1). In EE-O.C, duplicate reactors were started with pre-enriched electrodes (i.e., anode and cathode were pre-enriched with *Geobacter sulfurreducens* PCA and mixed culture of hydrogenotrophic methanogens, respectively) and operated under open circuit mode. In EE-0.8 V, duplicate reactors started similarly as EE-O.C reactors but 0.8 V was applied using a power source (3645 A, Array, Inc.). In VE-O.C, duplicate reactors were started with virgin electrodes (i.e., no pre-enrichment of anode and cathode) and operated under open circuit mode. In VE-0.8 V, duplicate reactors started similarly as VE-O.C reactors but 0.8 V was applied using a power source. The NE-AD reactors represent conventional AD reactors without electrodes. All reactors were made of glass bottles filled with 300 ml of liquid and they had 20 ml of headspace. The reactors were sealed with a bromobutyl rubber stopper held on with an open top screw cap. Gas bags (0.5 L) were connected to the top of the rubber stopper to collect more volume of gas. The anodes in MEC-AD reactors were carbon felt (8 cm L X 6 cm W). The cathodes were nickel mesh (8 cm L X 6 cm W). Sludge collected from an existing lab-scale AD reactor operated at 30°C was used as the inoculum. The sludge composition was: total chemical oxygen demand of 18000 ± 600 mg/L, soluble COD (SCOD) of 310 ± 40 mg/L, total suspended solids of 15400 ± 650 mg/L, and a volatile suspended solids of 11300 ± 400 mg/L. The anaerobic growth medium (pH 8.0) used for the experiments consisted of glucose (2.5 g/L) as the sole carbon source, bicarbonate buffer (80 mM), nutrients (6.71 g/L NaH_2CO_3, 0.31 g/L NH_4Cl, 9.2 g/L Na_2HPO_4, 4.9 g/L NaH_2PO_4, 0.3 g/L KCl, Wolfe's vitamin (10 mL/L)), and trace mineral (10 mL/L) solution. For the first cycle, a growth medium with 20% (V/V) of inoculum was used. The reactors were operated in a fed-batch mode by replacing 60% of the liquid with fresh medium at the end of each cycle. The duration of each cycle was determined based on low current or end of gas production from all reactors. All reactors were operated in a temperature-controlled room at 30 °C. The current in the circuit was determined by measuring the voltage across a resistor (10 Ω) in the circuit using a data acquisition system (Pico data logger, UK), at 15 minutes intervals. Biogas was analyzed using a gas chromatography (SRI Instruments, USA). The SCOD was analyzed using standard methods (Hach Company). The concentrations of glucose and VFAs (acetate, propionate, and butyrate) were analyzed by a high-performance liquid chromatograph (HPLC) (Agilent, USA). The total and suspended solid concentrations were measured according to a standard method (Associations et al., 1920). All chemical analyses were performed in duplicate. The performance of the MEC-AD reactors was evaluated on the basis of the current density of the reactor, I (A/m^2); methane production volume (mL) per fed-batch; coulombic efficiency, CE (%); and COD removal (%). Microbial community analysis was performed using gene amplicon sequencing targeting the Archaea/Bacteria/Eukarya 16S/18S rRNA gene variable regions 4-8 (abeV48-A).

RESULTS AND DISCUSSION

The electrodes were pre-enriched with *G. sulfurreducens* (anode) and mixed culture of hydrogenotrophic methanogens (cathode) in a dual-chamber MEC configuration. The pre-enriched electrodes were then switched to single chamber MEC-AD reactors (EE-O.C and EE-0.8 V) following successful pre-enrichment (reproducible current or CH_4 production). Regardless of the tested conditions, pre-enriched anode (EE-0.8 V) and virgin anode reactors (VE-0.8 V) produced reproducible current after several fed-batch cycles (Fig. 2). Additionally, both the pre-enriched anode reactors and the virgin anode reactors displayed peak current densities of about 5 A/m^2 (Fig. 2). However, compared to the virgin anode (VE-0.8 V) (batch time:~100 hours), the pre-enriched anode (EE-0.8 V) demonstrated more steady and reproducible current generation and a longer batch time (~120 hours) (Fig. 2). Moreover, the CE was higher in EE-0.8 V (60 %) than VE-0.8 V reactors (46 %) (Table 1). The methane accumulation volume per batch was highest in EE-0.8 V (445 ± 16ml) followed by VE-0.8 V (391 ± 15ml), EE-O.C (388 ± 14ml), VE-O.C (342 ± 19 ml) and NE-AD (325 ± 21ml). The COD removal followed a similar trend like methane accumulation where EE-0.8 V reactors exhibited the highest COD removal efficiency of 86±6% (Table 1). The VFAs profile analysis revealed that acetate, propionate and butyrate were produced from glucose and used for CH_4 production (data not shown). Overall, EE-0.8 V reactors showed the best reactor performance (i.e., CH_4 production and COD removal efficiency) compared to the other tested conditions which shows that pre-enriching the electrodes and applying a voltage (0.8 V) improved the MEC-AD performance.

Following 90 days of reactors operation, the microbial community at the anode, cathode, and suspension was characterized with 16S rRNA gene sequencing. PCA analysis showed that the pre-enriched anode and cathode were clustered separately from other samples and they were clustered according to the sample type (i.e., pre-enriched anode and pre-enriched cathode) (Fig. 3). Additionally, samples from the duplicate reactors were clustered together indicating similar microbial composition which is consistent with the identical reactor performance seen between the duplicate reactors operated under the same conditions (Fig. 3). The most abundant 20 operational taxonomic units (OTUs) in each sample were presented in a heatmap with their relative abundance and taxonomic classification at the genus and phylum level. Higher abundance of EAB belonging to *Geobacter* sp. was observed in the anode of EE-0.8 V (24±2%) compared to other reactors which showed lower abundance of *Geobacter sp.* (< 1.5%) (Fig. 4). Higher abundance of *Streptococcus sp.* (2.4- 27.4%) and *Enterococcus sp.* (1.6-20.8%) were observed in the anode and suspension of pre-enriched reactors (EE-O.C & EE-0.8V). However, they were absent from the inoculum (Fig. 4). Higher fraction of fermenters, such as *Trichococcus* sp. (13.7-40%) in the anode and suspension and Chloroflexi (4-13.4%) in the suspension, along with the detection of VFAs in the suspension, suggest their fermentative role in MEC-AD. Acetoclastic methanogens (*Methanosarcina sp.* & *Methanosaeta sp.*) and hydrogentrophic methanogens (*Methanobacterium sp.*, & *Methanospirillum* sp.) were observed in the anode, cathode, and suspension of all tested conditions. The dominant methanogen family varied depending on the biomass type (i.e., anode, cathode, or suspension). For example, *Methanobacterium sp.*, (2-34.5%) was dominant in the cathode and suspension of the reactors. This is expected given the availability of H_2 through the hydrogen evolution reaction at the cathode which provides a better niche for their growth at the cathode. Hydrogenotrophic methanogens also contribute to CH_4 generation by utilizing the H_2 generated through fermentation of complex organics. In contrast, the acetoclastic methanogens, *Methanosaeta sp.,* and *Methanosarcina sp.,* were dominant in the anode of MEC-AD reactors. The existence of *Methanosaeta* sp. at the anode support their role in converting a portion of acetate generated from fermentation to CH_4. In comparison, higher abundance of *Methanosaeta* sp. was observed in the virgin anode reactors (VE-0.8 V &VE-O.C) than pre-enriched anode reactors. This could be explained by the relatively higher abundance of acetoclastic EAB, *Geobacter sp.* on the anode of pre-enriched reactors (EE-0.8 V), outcompeting *Methanosaeta sp.* for acetate. These findings demonstrate that pre-enriching the electrodes with acetoclastic EAB and hydrogenotrophic methanogens and applying external voltage (0.8 V) are successful operating strategy for enhancing the overall performance of AD.

Abstract
Perfluorooctanoic acid is a toxic and recalcitrant perfluoroalkyl substance commonly detected in environmental samples. Recent advances in chemical-free photocatalysis emerge for the sustainable degradation of PFOA. This work (I) classifies the state-of-the-art of chemical-free photocatalysts for PFOA degradation in families of materials, (II) describes the evolution of catalysts and discusses the strategies to enhance their performance, and (III) identifies current research gaps and future research opportunities. This study will assist researchers and practitioners to develop rational photocatalyst designs for green degradation.

Keywords
Chemical-free, Near-zero PFAS discharge, Photodefluorination, PFAS perspectives

INTRODUCTION

Photocatalysis has emerged as a viable option for PFOA degradation due to its free chemical additives, low cost, and production of different reactive spices. The recent upgrowth in the number of works, the different parameters, and the variety of catalysts developed challenge their comparison to optimize the photocatalytic degradation of PFOA. It is therefore critical to structure the main families of materials, compare their performance, practical strengths, and drawbacks, and provide insights for future research trends.

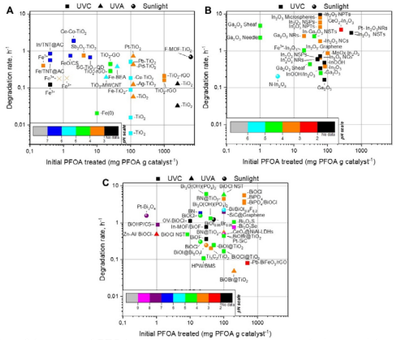

Figure 1. Map of the reported PFOA treatment efficiency of photocatalytic materials, a) Ti and Fe-based materials, b) In and Ga-based materials, c) Bi and novel materials.

CHEMICAL-FREE PHOTOCATALYSTS FOR PFOA DEGRADATION

We extended the PFOA-degrading materials classification (Xu, Ahmed, et al., 2017) to 7 families (Ti, Fe, Ga, In, Bi, Si, and BN, Figure 1). From our evaluations, the defluorination is not the only important parameter of photocatalyst performance, while the catalyst stability, solution pH, and irradiation energy are also critical. Novel photocatalysts have also been devloped to overcome the limitations of Ti-based materials, the catalyst recovery, and the scarcity and high cost of the post-transition catalysts. Technoeconomic analysis is an underdevelopment tool to compare materials and technologies.

WHAT DO WE KNOW AND WHERE DO WE GO FROM HERE?

Highly efficient photocatalysts are produced, although complete defluorination in a time-feasible frame has not been achieved yet. The improvement of the materials design (electropositive materials, oxygen vacancies, amination), effective heterojunctions (Type II p-n materials), electron trapping strategies (Pt, graphene), and reactive species production (facet engineering, crystal phase tunning) can realize the chemical-free zero PFAS discharge. Practical inconveniences such as low concentrations, light spending, and complex matrixes can be overcome by developing adsorptive photocatalysts (Arana Juve, Li, et al., 2022) and further understanding of the role of coexisting species. Additionally, the material stability, irradiation parameters (photon flux, fluence dose), energy input, and mass balances need to be further discussed to solve the global PFAS problem.

Abstract
Spent Caustic from petrochemical industries is a complex concoction of various pollutants, not only making it a threat to the environment, but also very difficult to treat using conventional treatment processes. EPC-EqTech creates a novel solution capable of processing spent caustic at low-cost and within regulatory parameters. Different laboratory scale experiments have been performed obtaining a degradation of more than 80% COD and 100% sulphide. The obtained results allow to design a prototype (1 m^3/h) based on a pre-peroxidation step followed by Electro-peroxicoagulation (EPC) unit that will be operated for 12 months to demonstrate a cost-effective spent caustic processing solution for the Oil&Gas sector that minimises environmental impact and enables refineries to meet ever tightening regulations. The prototype will be located in an oil refinery of Tupras company, Turkey.

INTRODUCTION

In the petrochemical industry, alkaline washing processes for oil product desulphurisation purposes result in spent alkaline solutions, known as spent caustic (SC) or sour water, which contains very high Chemical Oxygen Demand (COD) levels and several other hazardous contaminants such as sulphides, mercaptans, etc. Due to these contaminants, these wastewaters are difficult to treat and very harmful and toxic to the environment. Consequently, SC wastewater treatment can be both challenging and expensive.

Today, the global Oil&Gas industry spends ~3.5 bn€ p.a. to process spent caustic making it a critical challenge [1]. However, due to regulatory tightening designed to reduce environmental impacts, costs are now climbing further. These complex wastewaters are difficult to treat using conventional processes. Traditionally, various SC disposal techniques were adopted for disposal such as: deep well injection, biological treatment with careful dosage, incineration, wet air oxidation or disposal off-site. Many of these traditional spent caustic treatment processes have proven to be unattractive due to key issues: (i) difficult operation; (ii) significantly cost prohibitive; (iii) damaging to the environment (i.e. toxic volatile organic compounds, air contamination and soluble mobile organics) and/or (iv) inability to treat extremely hazardous materials meaning they do not meet regulations [2].

Since 2016 Cetaqua and Aquatec have been collaborating in the development of an innovative solution: "EPC-EqTech" – a plant that combines three electrochemical technologies to create a novel solution capable of processing SC at low-cost and within regulatory parameters.
EPC-EqTech technology demonstration is within FTI-H2020 project that focuses on the adaptation of the EPC technology for suitability with spent caustic, the novel materials selection required for reactors and other equipment and, the adaptation to the layout design; process configuration and combination of processes to achieve optimal processing capability.

This present study, based on the EPC-EqTech project, is focused on the optimization of the process, to ensure both, a cost-effective spent caustic processing solution for the Oil&Gas sector that minimises the environmental impact and enables refineries to meet ever tightening regulations, and the safety of the process, taking into account the gas generation, and the temperature stream regulation.

MATERIALS AND METHODS

The stream selected for treatment has a high COD - range of 60-85 g/L - an average pH of 11.5 ± 0.2, a conductivity of 223 ± 0.5 mS/cm, and highly odorous reduced sulphur compounds, such as sulphides (average concentration of 3 ± 0.5 g/L) and mercaptans, as well as corrosive organic species.

The variables for process optimization were the reaction time, the H_2O_2 dosage, and the electrical current during the EPC process. Calorimetry tests were carried out in conditions equivalent to those that the system will be operating in the final design of the plant. Last, respirometry tests were performed varying the pH and the amount of treated spent caustic that is introduced in the biological reactor.

RESULTS AND CONCLUSIONS

During the laboratory phase, the key goals of the project were achieved by degrading more than 80% of COD and 100% of the sulphides (Figure 1). Removal efficiencies and costs seemed to be better compared with other techniques used for eliminating spent caustic. There have also been identified other benefits such as treatment on site, eliminating the need for transport, possibility of roving units to be used by the same client at different sites, etc. In addition, the technology is modular, so reactors and pumps can be added and can be scaled up for different customer size.

Apart from the tests performed to optimize the process itself, calorimetry and respirometry tests have been carried out to optimize the cooling system and the effluent pH adjustment and flow conditions respectively. Based on theoretical calculations and laboratory tests, two parallel heat exchangers are needed to dissipate the energy generated during the reaction and to maintain the spent caustic stream at about 30-35ºC (Figure 2). The effluent conditions have been determined through respirometry trials. It has been concluded that the optimal option is to adjust the pH of the treated spent caustic to 10.5-11 and discharge it upstream to biological treatment at a flow rate of 1 m3/h (Figure 3).

On the other hand, to ensure safe operation from the point of view of health and safety, a gas treatment ventilation has been added. The forced ventilation installed in the main reaction tank will allow the dilution and dispersion of the hydrogen generated during the process. The minimum air flow has been calculated for the worst case scenario, in which the generation of hydrogen and hydrogen sulphide (generated in uncontrolled acid pH events) gases are maximized.

The results obtained from the laboratory scale tests allowed to optimize the operational and safety design of the plant. Once the pilot of the EPC process has been constructed, commissioning will be performed. At this point the system will be operating at design conditions. Finally, 12-months of commercial trials at Tüpraş technically will validate the processing capability of the plant and the materials capability to withstand spent caustic. As an output a case study of results will be produced that will be used to prove the capability and commercial benefit potential of EPC-EqTech to our stakeholders.

Abstract
Erythromycin (ERY), colistin (KOL), fluoxetine (FLUO), amoxicillin (AMO) and 17-alpha-ethinylestradiol (EST) are pharmaceuticals (PhCs) whose concentrations in water and wastewater have been reported to exceed normative levels. As the methods used so far to remove ERY, KOL, FLUO, AMO, and EST from aquatic environments have not been effective, it is necessary to develop effective methods for their removal. In the present study, fly ash (FA)-based zeolite materials that have not been previously investigated as ERY, KOL, FLUO, AMO, and EST sorbents, were used. The effects of adsorbent mass, contact time, and initial concentration of PhCs on the removal of ERY, KOL, FLUO, AMO, and EST were analysed. The analysed PhCs were removed within the first 2 min of reaction with efficiencies above 85%. The most efficient sorption was obtained at a sorbent dose of 1-2 g L-1. The removal efficiency of PhCs decreases according to the order: EST>AMO>COL>FLUO>ERY. A five-fold regeneration of the sorbents showed no significant loss of adsorption efficiency. These results indicate that zeolite materials effectively remove ERY, KOL, FLUO, AMO, and EST and can be further investigated for removing other pharmaceuticals from water and wastewater.

Keywords
adsorption; zeolite; carbon–zeolite composite; wastewater; antibiotics

INTRODUCTION

Pharmaceuticals are among the pollutants that are often found in wastewater but also surface water. This is because conventional wastewater treatment processes using mechanical, chemical and biological processes are not designed to remove PhCs (Park et al., 2020). In addition, various chemical reactions during wastewater treatment can produce metabolites and transformation products of PhCs, making the treated wastewater a source of surface water pollution (Tarpani, Azapagic, 2018). Therefore, the search is for advanced materials and technologies that can eliminate PhCs in wastewater or water treatment. PhCs and their metabolites can be removed by adsorption or photocatalytic degradation (Mansouri et al., 2021). The adsorption efficiency depends on the sorbents' surface properties, the PhCs' physico-chemical properties and the environmental conditions in the aqueous phase. The present work reports the results of adsorption efficiencies from solutions through selected PhCs: ERY, KOL, FLUO, AMO, and EST. Their occurrence dictates the selection of these compounds in wastewater and that these PhCs should be monitored, so that surface water quality does not deteriorate. ERY, KOL and AMO are different-generation antibiotics, while FLUO is an antidepressant and EST is a hormonal drug. Synthetic zeolites and zeolite-carbon composites were used as sorbents.

MATERIALS AND METHODS

Sorbents

Zeolites are tectosilicates consisting of about 50 minerals with synthetic analogues. Their structure is formed by three-dimensional networks of Al/Si tetrahedrons arranged in channels containing water and exchangeable alkali metal or alkaline earth metal cations. Due to these particular structural features, they are widely used in the separation and refining industry as catalysts, adsorbents and ion exchangers (Novembre et al., 2021). Zeolite NaP1_FA was produced by hydrothermal synthesis from fly ash (FA). Hydrothermal synthesis of the zeolite-carbon composite NaP1_C was obtained using carbon-rich FA fly ash. The main difference between the sorbents used is the use of FA with different carbon contents as substrate in the synthesis reaction. Thus, the carbon content of NaP1_FA is 5.5% and that of NaP1_C is 42.2%.

Adsorption and desorption experiments

Static sorption experiments were performed to examine the effect of the initial PhCs concentrations, adsorbent dosage, and contact time on adsorption performance. The samples from the experiment of the initial concentration influence were subjected to desorption using ethanol. Five subsequent cycles of regeneration were performed. PhCs were determined using a Modular (U) HPLC system - Nexera (LC-40) series, Shimadzu, with a triple quadrupole analyzer and a QTrap 3200 reaction chamber (AB Sciex). Electrospray ionization (ESI) and multiple reaction monitoring were applied.

RESULTS AND DISCUSSION

The effect of the initial concentrations

The sorbents NaP1_FA and NaP1_C achieve high FLUO and KOL sorption efficiencies (70 to 100%) over the entire range of initial concentrations tested, 0.1 - 200.0 mg L^{-1}. In the case of ERY, a high 90% sorption efficiency was achieved for the NaP1_C sample, only in the concentration range from 0.1 to 2.5 mg L^{-1}. In contrast, for higher ERY concentrations, the sorption efficiency is a few percent. Comparing the sorption efficiency of ERY on NaP1_FA and NaP1_C sorbents, it can be seen that about 30% less ERY is removed by NaP1-FA. The reason for this may be the higher porosity of NaP1_C, resulting in a higher sorption capacity of the sample. In the case of FLUO, which is a smaller molecule than ERY and KOL, the sorption capacity of the sorbents is the highest (already at the lowest FLUO concentrations, sorption reaches 90% efficiency).

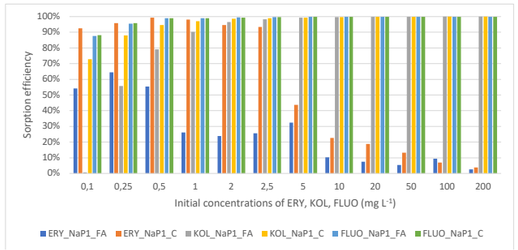

Fig. 1. Influence of the initial concentration of ERY, KOL, and FLUO on the sorption efficiency.

The effect of dosage

Adsorbent doses of 1 and 2 g L^{-1} resulted in the removal of PhCs to the greatest extent (Fig. 2). The initial concentration of ERY, KOL, FLUO, AMO, and EST was 100 µg L^{-1}. The concentrations after adsorption decreased to 35 µg ERY L^{-1} for NaP1_C and 23 µg ERY L^{-1} for NaP1_C, and 3.5 µg AMO L^{-1} for NaP1_C and 3.6 µg AMO L^{-1} for NaP1_FA. In the adsorption of KOL and EST on NaP1_C, the best removal results were obtained using a dose of 2 g L^{-1}, while the sorbent NaP1_FA was most effective using a dose of 1 g L^{-1}. After using a 2 g L^{-1}, NaP1_C reduced the concentration of KOL to 7.1 µg L^{-1} and EST to 2.2 µg L^{-1}. In contrast, the concentrations after adsorption using a dose of 1 g L^{-1} and NaP1_FA decreased to 5.7 µg KOL L^{-1} and 2.7 µg EST L^{-1}, respectively. A dose of 1 g L^{-1} of NaP1_C sorbent and 2 g L^{-1} of NaP1_FA sorbent results in the most effective removal of FLUO. The concentrations after adsorption are 7.5 µg L^{-1} for NaP1_C and 10.8 µg L^{-1} for NaP1_FA, respectively.

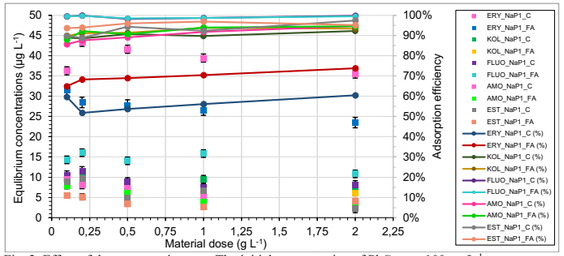

Fig. 2. Effect of dose on sorption rate. The initial concentration of PhCs was 100 µg L^{-1}.

The effect of time reaction

Pharmaceuticals are effectively removed after 2 minutes of reaction. Four kinetic models were analysed to determine the sorption mechanism of selected PhCs on NaP1_C and NaP1_FA sorbents: pseudo-zero-order, pseudo-first-order, pseudo-second-order and the Behnajada-Modirshahl-Ghanbery (BMG) kinetic model. The coefficient of determination (R^2) was used to measure the quality of model fit. It was determined that the NaP1_FA sorbent should exhibit the lowest contaminant degradation efficiency of 84% during AMO adsorption, and the NaP1_C sorbent should exhibit the highest efficiency of over 99% during ERY adsorption.

Regeneration

Differences in the strength of methanol-analyte interaction for individual pharmaceuticals depend primarily on the desorbed substance's chemical properties and the sorbent-analyte bond's strength. Exemplary differences in the desorption capacity of pharmaceuticals with methanol from the NaP1_FA and NaP1_C sorption materials are presented in Fig. 3. Methanol, as a polar-protic solvent is the most commonly used extraction solvent due to its high polarity. Due to its high volatility, it can extract lipophilic and hydrophilic substances and remove them easily at room temperature. The high efficiency of desorption of analytes (ERY, FLUO) from sorbents occurs practically in the first regeneration cycle. The results show that methanol can be successfully used as a reagent to remove residues of adsorbed pharmaceuticals in sorption materials.

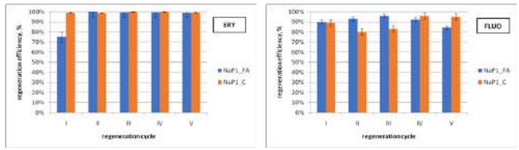

Fig. 3. The ERY and FLUO efficiency of NaP1_FA and NaP1_C after regeneration cycles.

CONCLUSIONS

The removal efficiency of pharmaceuticals depends on several factors, both physical (related to the degree of physical (associated with the degree of wastewater treatment) and chemical (related to the composition of the water matrix). However, the most critical parameter in pharmaceutical adsorption methodology is the selection of the appropriate adsorbent composition and process conditions. We have conducted numerous laboratory experiments that confirm that the zeolite NaP1 and the NaP1-C composite can effectively remove pharmaceuticals from aqueous solutions.

Activated biochar from rice husk for the removal of micropollutants: Characterization and application in real wastewater

B. Bayarri*, A. Sales*, P. Llopart* and C. Sans*

* Department of Chemical Engineering and Analytical Chemistry, Chemistry Faculty, Universitat de Barcelona C/Martí i Franquès, 1 – Barcelona (SPAIN)

Abstract
Biochar derived from husk rice was synthesized and activated with CO2 to be used as adsorbent of micropollutants present in wastewater. Physical and chemical characterization showed that it was an alkaline solid, with good porosity (380 m^2 g^{-1}) and low density of functional groups. Biochar was tested for the removal of three different pesticides obtaining that it could adsorb between 100 and 260 µmol g^{-1} of biochar. pH did not affect greatly the biochar performance but when testing with real wastewater adsorption performance decreased.

Keywords

INTRODUCTION

Water scarcity has become one of the major issues that human being has to face this century. To respond to this challenge the scientific community is increasing efforts to develop safe water treatment methods with low environmental impact. Among these methods, adsorption is a well-known, effective technology widely tested in several wastewater treatment plants. Related to it, biochar (BC) is being considered as a good precursor to create activated carbon capable of adsorbing several of pollutants present in current wastewater. BC can be generated from organic waste by pyrolysis, thus reducing its carbon footprint and making this material very appealing.

In this work, BC from a common waste, rice husk, was synthesized. Then it was activated with CO_2 to improve its adsorption capacities. The final goal was to obtain and characterize an activated carbon and assess its capacity to adsorb different micropollutants present in wastewater.

MATERIAL AND METHODS

Rice husk was milled and 250 µm fraction was washed with $NaCO_3$ and water, and then dried and pyrolyzed in a tubular oven under a N_2 atmosphere at 500ºC for 4 hours. Then, it was activated in the same oven under a CO_2 atmosphere, at 800º during 1 hour. In both steps, the temperature ramp was fixed at 5 ºC $minute^{-1}$.

Obtained BC was characterized by different techniques. Physical parameters (moisture, ashes, fixed carbon) were determined by proximate analysis [1], surface morphology was investigated by field emission scanning electron microscope (FESEM), Fourier-transform infrared spectroscopy (FTIR) was used to determine the presence of functional groups on the surface of the material, surface area was estimated by BET analysis, C-H-N-O was monitored by elemental analysis and surface charge was determined by the pH drift method.

Biochar adsorption capacity was assessed by the adsorption of three micropollutants, all pesticides, with different octanol-water distribution coefficients (K_{ow}): clothianidin (CTD, K_{ow} =0.7), thiacloprid (TCP, K_{ow} =1.26) and atrazine (ATZ, K_{ow} =2.61). Solutions of these compounds were prepared in deionized water at different pH with concentrations between 20 and 200 µM. Experiments were carried out in 100 mL glass vials by adding 5 or 20 µmol L^{-1} of micropollutant solution and 50 mg L^{-1} of BC. Then vials were agitated at 330 rpm up to 145 hours at the dark at 22 ºC. Micropollutants concentration was monitored by an Infinity 1260 HPLC provided by Agilent Technologies (USA) equipped with a C-18 Tecknokroma column. Some of the experiments were carried out spiking the micropollutants in wastewater (pH= 7.6, TOC= 25 mg L^{-1}, total suspended solids = 38 mg L^{-1}) obtained from the secondary effluent of a WWTP in the area of Barcelona.

RESULTS AND DISCUSSION

Characterization results

Table 1 shows the main values of the BC characterization. Material before and after activations are listed.

Table 1. Main properties of the synthesized biochar, activated with CO_2 and non-activated. *H* refers to humidity, *VM* to volatile matter, C_{fixed} to the fixed carbon, *EC* to electrical conductivity, *pH pzc* to the point of zero charge, *BET* to the surface area, *PV* to pore volume and *PS* to the pore size.

	Yield	H	VM	Ash	C_{fixed}	pH	EC	pH pzc
	%	[%]	[%]	[%]	[%]		[mS cm^{-1}]	
ACTIVATED BC	26.95	1.57%	45.89%	43.21%	9.32%	11.06	8.01	10.2
NON Activated BC	40.09	0.64%	59.32%	36.28%	3.76%	10.73	5.82	-

	BET [m^2/g]	PV [cm^3/g]	PS [nm]	% C	% H	% O	% N	% S
ACTIVATED BC	379.95	0.123	5.56	37.83	0.00	5.18	0.27	0.08
NON Activated BC	1.22	4.48 . 10^{-4}	65.78	56.31	1.76	7.48	0.40	0.00

Values obtained are aligned with similar materials reported in literature [2]. Remarkable is the amount of ashes in the sample, about 40%. In spite of the previous washing with $NaCO_3$, the percentage of mineral compounds was very high, far away from the optimum 6-8% recommended for obtaining the best adsorption capacities [2]. Thus, further reduction of the amount of ashes could greatly improve the BC properties. Obtained material was alkaline with a pH = 11, indicating the absence of acidic groups on the surface and linked to the high amounts of ashes. BET analysis was carried out, showing a remarkable surface area close to 400 m^2/g for the activated BC. Before activation, BC surface area was only 1.22 m^2/g proving the efficiency of the activation step in spite of the high presence of ashes. Activated BC presented an adsorption isotherm of type II: most of the adsorption took place at low relative pressure but adsorption still went on when increasing relative pressure, confirming the presence of mesoporous which are very interesting for adsorption of big pollutants molecules presents in wastewater. Elemental analysis reported the low presence of oxygen and almost null presence of hydrogen or other atoms. This indicates that pyrolysis was long enough to volatilize most of common functional groups. This point was confirmed with the FTIR analysis showed in figure 1 for the activated BC. The typical peaks for hydroxyl groups or C-H bonds were not observed, which is in agreement with the % of hydrogen measured. This fact corroborates a low polarity of the BC. Detected peaks are proposed to correspond to C-O or C=C (1430 cm-1) bonds or even Si-O bond (1047 cm-1) and Si-O-Si (618 cm-1). Si presence can be explained because it is the main compound of the ashes.

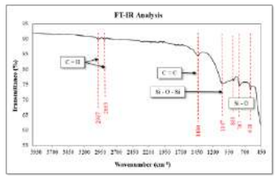

Figure 1. FTIR spectra of rice husk biochar activated with CO_2 at 800 ºC for 1 h.

Figure 2 presents FESEM images of the activated and non-activated BC. As it can be observed, after the activation with CO2, most of pore-blocking substances were driven off, appearing well-developed porous, honeycomb-like structures. These images confirm the important increasing in the surface area detected by BET analysis.

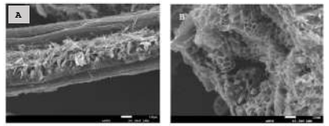

Figure 2. FESEM images of (A) non activated and (B) activated rice husk BC at x850 magnifications.

Adsorption results

Firstly, the activated BC was tested as adsorbent of three micropollutants (CTD, TCP and ATZ) dissolved in deionized water at different pHs, as described in figure 3. . Despite each micropollutant owns different K_{ow} and pK_a, no big differences were observed for the different pHs tested. For example, it was expected that there would be electrostatic repulsions to CTD in the pH between 2 and 10, since the point of zero charge for the BC was determined to be 10.23 and pKa for CTD was 11.09. Thus, both species would be positively charged hindering the adsorption process. However, experimental results showed that adsorption was relatively stable for all the tested conditions. The same can be said for ATZ and only TCP showed a higher adsorption at pH 12. Therefore, it seems that pH and electrostatic interactions do not play a key role in the adsorption mechanism of these species.

Adsorption performance of biochar was also tested spiking the same micropollutants in the effluent from a WWTP, and results are shown in figure 4. TCP and CTD presented similar adsorption rates, despite having different K_{ow} and polarity. ATZ adsorption was quite slower, and less amount was eliminated. Results show how important is the matrix for the adsorption process.

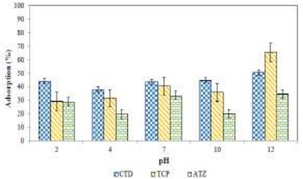

Figure 3. Adsorption in activated BC after 74 hours for solutions of micropollutants in deionized water at different pH values. $[ATZ]_0$= $[CTD]_0$= $[TCP]_0$= 20 µmol L^{-1}, $[BC]_0$= 50 mg L^{-1}, T=22 ºC

In previous experiments working with deionized water, the amount of micropollutants retained was about 3-5 times higher. Real matrix contains several compounds which are competing with the micropollutants for the adsorption site. Thus, it seems clear that new materials must be tested in real conditions to understand properly their real potential and more selective materials must be designed.

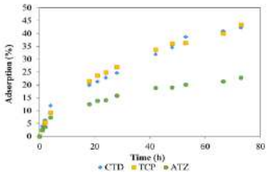

Figure 4. Adsorption profile of CTD, TCP and ATZ simultaneously on BC with wastewater matrix. $[ATZ]_0$= $[CTD]_0$= $[TCP]_0$= 2 µmol L^{-1}, $[BC]_0$= 50 mg L^{-1}, T=23 ºC, pH_0=7.6

CONCLUSIONS

BC derived from rice husk has proved to be a valid material for the adsorption of organic micropollutants in water. Even in real wastewaters it shows a good capacity to retain these compounds. Activation with CO_2 has demonstrated to be a valid procedure to significantly/enormously increase the adsorption properties of the biochar.

Abstract
Anaerobic membrane bio-reactors (AnMBR) arise as a key technology to reduce the environmental impacts of the present-day wastewater treatment plants (WWTPs) while promoting the obtention of biogas, digestate for composting or agricultural use and permeate enriched in nutrients suitable for irrigation from urban wastewater (UWW). Its co-treatment together with the food waste fraction from the municipal solid waste (MSW) is an opportunity to achieve the net production of energy during the process whilst meeting the legal targets of reduction in landfilling and incineration and preparation for re-use and recycling of the MSW. Coupling the co-treatment of both fractions in AnMBR system with the use of food waste disposers (FWDs) to grind the food waste before its transportation through the sewerage can be an efficient integrated urban sanitation system to facilitate the fulfilment of recycling targets with a low environmental impact related to transport, since it overcomes the low citizen participation in the selective collection of MSW and reduces the content of impurities in the final compost.
In the LIFE Zero Waste Water project (LZWW), an AnMBR-based Water Resource Recovery Facility (WRRF) has been built to treat 50 m^3/d UWW and 125 kg/d bio-waste in the Valdebebas WWTP. The treatment train is completed with an AQU-ELAN system, a nutrient extraction and recovery unit and a smart water monitoring and control system.

Keywords
AnMBR, bio-waste, food waste, integrated urban sanitation system, WRRF

INTRODUCTION

The upgrade of already built WWTPs, mostly based on energy demanding processes, to convert them into WRRFs plays an essential role in the reduction of the worst effects of the challenging scenarios of climate change and resources scarcity. In this context, the AnMBR process arises as an opportunity to reduce or even remove the energy requirement for the organic matter removal from UWW whilst producing valuable products such as biogas, a reduced amount of digested sludge suitable for composting or agricultural application and an effluent suitable for irrigation free of pathogens without requiring any tertiary treatment (Jiménez-Benítez et al., 2020). Moreover, including the separately collected food waste, which accounts for up to the 77% of the bio-waste fraction and more than the 30 % of the MSW production in Spain (Favoino & Giavini, 2020), in the influent stream together with UWW entails an opportunity to convert WRRFs into net energy producers. Additionally, the joint management of both fractions is an opportunity to meet the legal targets of preparation for re-use and recycling and the ban on the disposal of the separately collected bio-waste required in the Waste Framework Directive (2018/851/CE).

Within the LZWW project, besides the co-treatment of UWW and food waste in an AnMBR-based WRRF, the environmental aspects of using FWDs located under the kitchen sink to grind the food leftovers before its transportation from households together with UWW through the sewerage towards WRRFs will be also studied, as an alternative to conventional systems of bio-waste collection in specific bins located in the street, which have shown problems to reach a high enough citizen participation, or door-to-door collection, which requires high efforts from operators and municipalities and is related to higher environmental impacts related to waste transportation (Rossi et al., 2022).

MATERIALS AND METHODS

In the Valdebebas WWTP (Spain) a demo-scale WRRF (300 P.E.) has been built to treat an average of 50 m^3/d of UWW and 125 kg/d of separately collected food waste (see Figure 1). The food waste will be firstly provided from nearby HoReCa services and subsequently from brown bins and door-to-door collection systems (see Figure 2a) to study the influence of the collection system on the co-treatment process and the quantity and quality of the recycled materials obtained.
The WRRF treatment train comprises 1) a reception site and dosing system for the bio-waste, 2) a 100 m^3 AnMBR reactor, 3) an AQU-ELAN system for partial nitritation-Annamox nitrogen removal in the main stream, 4) a nutrient extraction and recovery unit, and 5) a Smart Water Monitoring and Control System for the WRRF management according to the nutrient content in the effluent, depending on the end-user demand and regulations (see Figure 2b).

RESULTS AND DISCUSSION

The real advantages of the joint management of both fractions in the Valdebebas WRRF will be quantified during the plant operation under stable conditions. However, some of them have already been quantified separately in previous studies. Among these advantages are: 1) the reduction in the environmental impact of food waste management due to its transportation through the sewer system, 2) a positive energy balance with an average production of 1.0 kWh per m^3 of treated UWW, 3) the possibility of 95 % of UWW reclamation, 4) around 50 % reduction in sludge production and 5) 150 % in the CO_2 emissions related to the operation in comparison to conventional activated sludge-based WWTPs (see Table 1).

Abstract
Microbial Electrochemical Cells coupled with Anaerobic Digestors (MEC-AD) improve upon the performance of conventional AD systems, allowing shorter hydraulic retention times and higher organic loading rates due to enriched biofilm bound microbial consortia and bioelectrochemical catalysis of key process reactions. MECs have been used as biosensors to sense VFA concentrations but have not yet been utilised as a control sensor for MEC-AD.

A small scale (2L) continuous flow MEC-AD reactor was designed and constructed to operate autonomously treating high strength simulated brewery wastewater (10-30 g/L tCOD). The feed rate of the MEC-AD reactor was modulated by using the electrodes as a biosensor, utilising the current response of the system as a performance indicator and control parameter. Autonomous feed rate control was implemented using a threshold-based algorithm to interpret trends in current output and control feed pump speed - allowing the reactor to feed itself as it requires.

We investigate whether stable operation at loading rates between 2-8 kgCOD/m^3/d can be effectively maintained by adjusting feed rate in response to the current draw of the MEC reactor. The system performance and stability will be evaluated to determine the effectiveness of such autonomous control and the effect on reactor health over time. The ability of the system to respond to changing influent characteristics will be tested to simulate real world operation.

Development of biosensor led, autonomous feed rate control will allow reduced laboratory testing and operator burden on commercial scale MEC-AD systems. This may reduce downtime while increasing waste treatment rates and methane yields, improving the commercial viability of the technology. This will enable the implementation of MEC-AD systems in remote areas or in response to humanitarian crises to provide sanitation and renewable energy without the need for skilled operators.

Natural Clay-Based Materials for the Removal of Antibiotics from Contaminated Water

1. Introduction

Environmental pollution by emerging contaminants is one of the hot spot problems. Many pollutants released into the environment are very easily found in aquatic compartments, both in drinking water (Benotti et al., 2009) and in wastewater (Pascale et al., 2020). Major pollutants include heavy metals, organic micropollutants, personal care products, and pharmaceuticals (Nielsen and Bandosz, 2016). Among the latter, two of the most detected compounds are trimethoprim and sulfamethoxazole (Figure 1). The first one is a synthetic antimicrobic molecule belonging to diaminopyrimidine class (Wróbel et al., 2020). The second one is an antimicrobic belonging to the sulphonamides family and acts as a competitive inhibitor of the enzyme dihydropteroate synthase (Gupta et al., 2013). The persistence of these hazardous compounds in the environment is very concerning because trace levels, such as µg/L (Nielsen and Bandosz, 2016), can promote the formation of antibacterial resistance genes (Yang et al., 2017). Considering their potential impacts on environment and health, additional treatments have to be applied to drastically reduce the load of such molecules in dis-charged effluents and best achieve non-detectable concentrations. Several technologies have already proven to be effective for this purpose such as activated carbon adsorption as well as advanced oxidation processes. In the last decade, hybrid configurations (adsorption/oxidation) have been extensively studied for the degradation of organic compounds. Recently, a hybrid process of classical adsorption of pollutants on a fixed bed of activated carbon followed by batch wet catalytic oxidation at higher temperature and pressure on the same bed of activated carbon, which is then regenerated in situ, has been also evaluated for the remediation of phenols. The drawback of the mentioned technologies is the high cost and the low applicability at large scale. However, natural-based solutions can be a promising alternative. In this context, the present paper has two objectives related to the remediation of selected antibiotics: first, to characterize the natural soil from Mt Vulture volcano (Basilicata, Italy); second, to test its capacity to adsorbed/oxidate contaminants.

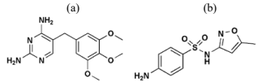

Figure 1: Chemical structure of a) trimethoprim and b) sulfamethoxazole

Experimental work on the oxidative process is still in progress and is focused on degradation mediated by sulphate radicals to remove sulfamethoxazole. Laboratory batch experiments were (and are) performed in order to study the adsorption kinetics.

2. Materials and methods

Analytical grade standards of trimethoprim, sulfamethoxazole (purity <=100 %) and potassium peroxymonosulfate, with the commercial name of Oxone ® (PMS, KHSO5, 0.5 KHSO4, 0.5 K2SO4), were purchased from Sigma Aldrich (St. Louis, USA). For chemical analysis acetonitrile and formic acid were HPLC grade from Honeywell (Wabash, Indiana, US). Water was ultrapure Milli-Q grade (18.2 MΩ cm-1 resistivity at 25 °C). Stock solutions 1,000 mg/L were prepared in methanol (LC-MS grade) provided by Carlo Erba reagents (Milano, Italy). The natural soil adsorbent used within this work is from Mt. Vulture volcano (Basilicata, Italy) was characterized by XRPD and XPS analysis.

2.1 XPS analysis

XPS analysis was carried out by spectrometer (Phoibos 100- MCD5, SPECS) operating at 10 kV and 10 mA, in medium area (Θ=2 mm) mode, using achromatic MgKα (1,253.6 eV) radiation and a pressure in the analysis chamber higher than 10^{-9} mbar. Wide spectra were collected in fixed analyser transmission (FAT) with a constant pass energy of 20 eV and channel widths of 1.0.

2.2 HPLC-DAD analysis

The concentrations of trimethoprim and sulfamethoxazole were monitored by a high-performance liquid chromatography (HPLC) system (Agilent Technologies 1200 series, USA) equipped with a Kinetex C18 100Å column (250 x 4.6 mm i.d., 5 µm particle size) and a diode array detector (DAD), set at λ = 270 nm. The mobile phase consisted of biphasic gradient using water acidified with 0.1% formic acid (A) and acetonitrile (B), structured as follows: 0-2 min 100 % A, 2-3 min. from 100 % A to 60 % A, 3-8 min 60 % A, 8-9 min. from 60 % A to 0% A, 9-12 min 0 % A, 12-15 min from 0 % A to 100 % A and finally, 15-18 min 100 % A.

2.3 Batch adsorption and catalytic degradation experiments

Batch adsorption experiments were carried out whit different solid-to-liquid ratio in flasks containing 100 mL of liquid solutions at different concentration of trimethoprim (TRM); they were continuously mixed with magnetic stirrer. The initial and final concentrations of TRM were measured regularly for each experiment. The equilibrium experiments were performed by stirring 100 mL of TRM solution with initial concentration of 4 mg/L as optimum condition. The aqueous samples were taken at fixed times. After adsorption, the adsorbent samples were separated by filtration at 0.2 µm, and the supernatants were analysed for residual TRM by HPLC-UV.
Preliminary, batch oxidative processes were performed in 100 mL of solution containing SMX 5 mg/L and 800 µM of PMS as oxidant agent. The amount of adsorbent material was 28.2 g.

3. Results and discussion

3.1 Characteristics of volcanic soil

Mt. Vulture volcano is a large volcano of post-Calabrian age, located near the western edge of the Bradanica trench in Southern Apennine chain, Basilicata, Italy (Fiore et al., 1992). Inside the crater of a minor cone, there are the two natural lakes of Monticchio (Basilicata). Soil present in this area have different characteristics, many of them exhibiting andic properties and is the largest hydrocarbon reservoir in continental Europe (Gizzi et al., 2029). XPS analysis of samples showed different signals, including the Si 2s (153.6 eV), which is attributable to a pyroxene and olivine structure according to Seyama and Soma (1985) (Table 1). The signal Si 2p (103.6 eV), according to Wagner et al. (1982), is attributable to pyroxene. Noteworthy are also the signals of Al 2p (74.0 eV) that, according to Seyama and Soma (1985) are attributable to pyroxene and the signal of Fe 2p (710.6 eV) attributable to the presence of olivine (Seyama and Soma, 1987).

Table 1: Results of XPS analysis

Element	eV	Reference
Si 2s	153.6	Seyama H, 1985 olivine, piroxeno
Si 2p	103.6	Wagner C.D., 1982 piroxeno
Mg 2s	93.6	
Al 2s	128.6	
Al 2p	74.0	Seyama H., Soma M., 1987 piroxeno
Fe2p	710.6	Seyama H., Soma M., 1987 olivina
Ca 2p	350	
K 2p	293.6	
O1s	553.6	
O2s	33.6	

3.3 Effect of contact time

The effect of contact time on the rate of removal of trimethoprim was investigated. In batch adsorption experiment, all of the parameters including solid/liquid ratio (0.02 ÷ 0.04 g/mL), agitation speed (450 ÷ 750 rpm), initial contaminant concentration (4 ÷ 8 mg/mL), were considered. From the data shown in the table 2, it can be seen that the variation in contact time is closely related to molecule concentrations. Indeed, while at a concentration of TRM 4 mg/L, all other parameters being constant, the variation of contact time determines a variation of absorption ranging from 7 to 13.21 %, while at a concentration of 8 mg/L it is registered a variation ranging from 4.3 to 15.28 %. In a more evident way, it can be observed that at a concentration of 6 mg/L a variation of 30 min of adsorption time determines a variation of 36 % of adsorbed molecule.

Table 2: Effect of contact time on the rate of removal of trimethoprim

C_0 (mg/L)	v (rpm)	t (min)	Solid/Liquid (g/mL)	% of adsorption
4	450	20	0.02	51.66
4	450	50	0.02	62.17
4	750	20	0.02	56.52

8	450	20	0.04	56.58
8	450	50	0.04	69.94
8	750	20	0.04	57.86
8	750	50	0.04	73.14

3.4 Catalytic oxidation in the adsorption processes

The natural presence of metals into the natural adsorbent allows the material to exhibit excellent capacity to be used for catalytic applications. During the adsorption processes, a known amount of PMS (800 µM) was added into the reaction systems with 4 mg/L of sulfamethoxazole. Benefiting from the effective transfer of electrons on volcanic soil/PMS, the degradation rate of SMX was significantly faster than its adsorption rate and its oxidation by Fenton processes. The blank test showed that 43 % of the SMX was removed from water using only PMS or Fenton like process (PMS/Fe). It can be seen from Figure 2 that SMX degradation rate in the volcanic soil/PMS was efficient and could be completely removal within 2 h.

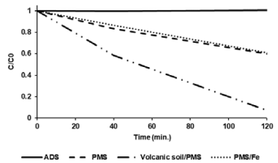

Figure 2: Sulfamethoxazole degradation profiles in the adsorption process using Fenton like oxidation based on PMS activation

4. Conclusion

The application of natural based material for the removal antibiotics from contaminated water was successfully investigated using abundantly available low-cost adsorbents. Preliminary results showed that the tested volcanic soil is an effective adsorbent for the removal of trimethoprim from aqueous solutions. Batch adsorption experiments showed that volcanic soil was efficient to remove trimethoprim, but did not show any appreciable ability in taking out sulfamethoxazole. In contrast, its ability to activate oxidant agent such as peroxymonosulfate demonstrated to be very effective in oxidation of sulfamethoxazole.
The results of the tests carried out on this innovative material are very encouraging. Obviously, as these are preliminary studies, it is necessary to investigate variables such as treatable pollutants, interferences, conditions (pH, temperature, pollutant concentration, etc.), optimal dosages as well as the engineering solutions to be adopted in order to ensure its safe use in real-scale plants. Additionally, experiments should be scheduled to test the natural activation of different oxidant agents; it would be interesting to extend the ability of this natural material as a potential disinfection treatment.

Towards next generation LUCAS® technology for cost-efficient municipal wastewater treatment plants

S. Wyffels*, H. Stes*, N. Calabuig* and M. Caluwé*

* Waterleau Group NV, Nieuwstraat 26, 3150 Wespelaar, Belgium
(E-mail: *stijn.wyffels@waterleau.com; michel.caluwe@waterleau.com)**

Abstract
By adopting novel insights in the activated sludge process and embracing hydrodynamic engineering aspects, Waterleau's continuous flow SBR technology branded as LUCAS®, has been future proofed. Featuring a construction footprint reduction of 44% and an energy consumption saving of 41% compared to conventional variable volume SBRs, the next generation LUCAS® becomes an interesting alternative to serve the secondary biological treatment of large municipal wastewater treatment plants. A sludge densification strategy is added primarily selecting for better settling sludge, and inclined tube settlers further support the solid-liquid separation during the clarification and settling process. Plant developers and plant operators choosing for reliable and affordable technology may count on a dual improved functionality and a combined cost reduction of 13% compared to conventional continuous flow activated sludge systems.

Keywords
continuous flow SBR; hydrodynamics; sludge densification; treatment cost; tube settlers

INTRODUCTION

Over the last two decades various types of SBRs have been reported and applied successfully in municipal wastewater treatment plants worldwide (Wilderer et al., 2001; Dutta et al., 2015). UNITANK and LUCAS® systems are truly continuous flow, fixed volume SBR configurations consisting of hydraulically connected compartments undergoing periodic and cyclic steps of feed to biomass accumulation, biomass regeneration, effluent withdrawal, sludge settling and sludge wasting without any additional pumping nor external sludge recirculation, which are therefore considered amongst the more advanced activated sludge SBR technologies (Bui et al., 2022). LUCAS® technology developed by Waterleau generally features a lower construction footprint compared to conventional continuous flow activated sludge systems and a lower energy consumption compared to conventional variable volume SBRs (Gerards et al., 2005). Recently developed control strategies for sludge densification aiming to select for aerobic granular sludge (AGS) in industrial wastewater treatment plants (Caluwé et al., 2022), together with the integration of inclined tube settlers improving solid-liquid separation and promoting selective sludge retention (Kent et al., 2018), has allowed to gear up the LUCAS® technology for further application into today's eco(nomic)-efficient municipal wastewater treatment plants.

MATERIALS AND METHODS

A pilot-scale LUCAS® reactor is operated during a 200-days period to study the metabolic strategy for sludge densification under continuous flow conditions. The reactor consists of three compartments with constant volume of 40 L that are interconnected with three control valves. Each compartment is equipped with influent control valves, effluent control valves, mechanical stirring, diffused aeration, and measurement devices for dissolved oxygen, pH, ORP, turbidity and conductivity. Control loops based on OUR and pH/ORP slope are implemented to dynamically adjust the time-controlled LUCAS® process steps. In addition, a full-scale LUCAS® reactor is modelled with the aid of Computational Fluid Dynamics (CFD) to investigate the hydrodynamic effect of inclined tube settlers on the sludge settling process. After adoption of the sludge densification strategy and incorporation of the inclined tube settlers, the novel LUCAS® technology is benchmarked high-level with other state-of-the-art secondary biological treatment technologies.

RESULTS AND DISCUSSION

Sludge densification

The continuous flow LUCAS® reactor configuration has been studied to impose subsequent and pronounced feast and famine conditions enabling the selection of slow-growing organisms (SRT > 30 days) that are understood to produce extracellular polymeric substances (EPS) and induce sludge densification and to a further extent, sludge granulation, and thus contribute to a better sludge settling behaviour (SVI_{30}< 100 mL/g). With a three compartment set-up it was possible to build up a substrate gradient in the feeding compartment under non-mixed anaerobic conditions, followed by a sudden mixing step promoting the substrate accumulation by the facultative anaerobic organisms and thereby preventing the degradation of readily biodegradable carbon by fast-growing heterotrophic organisms, and to regenerate the accumulated biomass in the adjacent second compartment under aerated aerobic conditions, whilst the third compartment was taking part in the sludge settling process and enabling further hydraulic selection for fast settling sludge. The time-controlled feeding, mixing, aeration and settling steps and rotation of biological treatment and settling functions between the compartments, allowed to progressively grow, select, and maintain dense sludge flocs and small granules in the range of 200–400 µm in the LUCAS® system consistently. Operational data further show the feasibility of the LUCAS® system as a continuous flow densified sludge reactor: MLSS are in the range of 7.0–7.7 g/L with SVI_{30}/SVI_{10} ratio > 0.71.

Sludge settling

The LUCAS® sludge settling process consists of a batch settling step with supernatant clarification followed by a dynamic settling step with clean effluent flowing over from the surface and without the need for an external recirculation of the settled sludge, thereby allowing to increase the sludge bed over time (Figure 1). When dealing with diluted or primary treated sewage and when facing a peak flow regime, the hydraulic load factor on the secondary settling function becomes more important than the organic and nutrient load factor on the biological treatment function. Means to improve solid-liquid separation may contribute to the performance of the settling process.

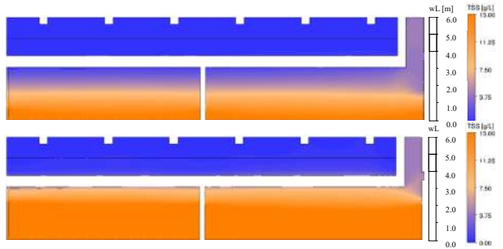

Figure 1. LUCAS® compartment (24.4 m W x 24.4 m L x 6.0 m wL) with settling function showing the settled sludge bed height after 60 minutes of batch settling (top) and after 180 minutes of subsequent dynamic settling with production of 1,080 m^3/h solids-free treated effluent (bottom). The inclined tube settlers have a height of 1 m and are positioned between the 5 – 6 m water level.

Inclined tube settlers. During batch settling, the tube settlers show to act as 'flocculator', promoting collision, cohesion and drag of the sludge particles into the settling sludge bed. During dynamic settling, the tube settlers work as 'polisher', inducing re-flocculation of fragmented sludge particles and a downward solids flow whilst the treated supernatant flows up (Figure 2). The clean effluent is collected from a series of overflow weirs evenly distributed at the tank surface with a surface overflow rate (SOR) of 1.81 $m^3/m^2/h$ at average flow conditions. During peak flow at SOR = 2.86 $m^3/m^2/h$ – when some solids may be allowed to wash out temporarily with effluent TSS < 30 mg/L – the tube settlers may act as 'selector' for larger and dense sludge aggregates versus smaller flocculent particles, and thus retain selectively the best settling sludge fraction.

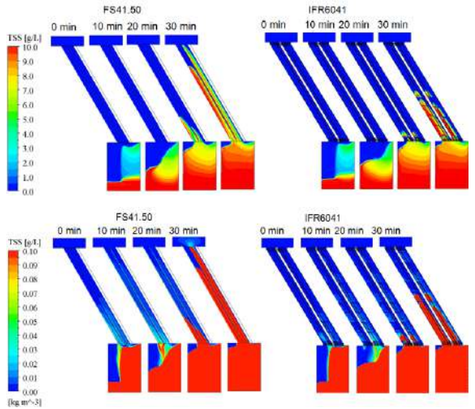

Figure 2. Two different types of inclined tube settlers type FS41.50 (equidistant, chevron shape, 11 m^2/m^3 sedimentation area) and type IFR6041 (non-equidistant, trapezoid corrugated shape, 9.5 m^2/m^3 sedimentation area) compared at the same hydraulic rate of 6.64 10^{-4} m/s during the final 30 minutes of a dynamic settling step at peak flow regime, thereby reaching critical bi-directional flow inside the tube settlers with solids building up and sloughing-off to the sludge bed underneath (top) and with clean effluent moving up to the collecting overflow weirs above (down). Although the flow pattern is laminar in the tube settlers of type FS41.50 and irregular in the tube settlers of type IFR6041 because of wave-like internal structures, there was no significant difference in solid-liquid separation efficiency between the two different types.

Cost performance indicators

A theoretical comparative design using BioWin and a cost benchmark performed on a municipal wastewater treatment plant with a 100 MLD capacity of the water line, consisting of pre-treatment, primary settling, secondary treatment, and tertiary treatment, allowed to assess the economic efficiency of next generation LUCAS® technology in relation to other frequently applied secondary treatment technologies, being Continuous Flow Activated Sludge technology (CF-AS), Integrated Fixed Film Activated Sludge (IFAS) technology, and Variable Volume Sequencing Batch Reactor (VV-SBR) technology (Table 1). Enabling the lowest combined cost of secondary treatment within this exercise, LUCAS® technology may become an interesting biological treatment alternative for future municipal wastewater treatment plants. Current examples include the incorporation of LUCAS® technology within the Independent Sewage Treatment Plants (ISTPs) of Taif (100 MLD), Tabuk (90 MLD), Buraidah (150 MLD) and Madinah (200 MLD) in the Kingdom of Saudi Arabia.

Table 1. Comparison of secondary treatment technologies treating influent loads of 38,584 kg COD/day, 18,200 kg BOD/day, 13,416 kg TSS/day, 4,685 kg TN/day, 634 kg TP/day, and wet weather peak flow up to 8,000 m^3/h. Process volume and footprint accounts for the sum of volumes and construction footprint for pre- and post-buffer tanks, reactor tanks and settling tanks. Energy consumers include equalization pumps, excess sludge pumps, sludge recycle pumps, submersible mixers and blowers for diffuser aeration. Capital expenditures and combined cost of secondary treatment are relative numbers within the cost context of a municipal WWTP in the Middle East North Africa (MENA) region. Combined cost of secondary treatment (CC) is calculated using Net Present Value (NPV) method including CAPEX and OPEX during 20 years of design flow.

	Volume	Footprint	Power consumption	CAPEX		CC
	(m^3)	(m^2)	(kWh/m^3)	(% E&M)	(% Civil)	(%)
CF-AS	73,845	16,664	0.26	100	100	100
IFAS	77,848	18,865	0.28	135	102	115
VV-SBR	94,000	15,667	0.25	92	128	103
LUCAS®	53,000	8,833	0.15	113	72	87

Abstract

Food and drink small and medium enterprises (SMEs) are highly water-intensive sector, that urgently needs an eco-efficient solution to treat their wastewater and decrease the associated energy costs. Being aware of the gap in the market, LIFE Multi-AD consortium scaled-up and automatized a high-performance multiphase anaerobic reactor. Multi-AD devise was industrial-scale installed in the winery WWTP and has been validated in continuous operation. The results show that Multi-AD reactor is capable of achieving COD removal higher than 93%, as well as biogas production of 3.6 m^3/m^3·d for organic load rate up to 10 kg COD/m^3·d. The ground-breaking reactor design, based on 4 chambers, achieves that organic matter is degraded in a stepwise conversion, fact that may make it more effective than conventional reactors. Multi-AD innovative solution allows SMEs to count with decentralized, automatized and eco-innovative technology for treatment of their wastewaters, allowing them to save 60% of energy and 34% of operational expenditures.

INTRODUCTION

The food and drink (F&D) industry, the largest manufacturing sector in the EU, is comprised of 290,000 small and medium enterprises (SMEs) – making up 99% of the entire industry [1]. F&D SMEs are highly water-intensive sector worldwide, producing significant volume of wastewater. These industrial effluents are characterized by high concentration of biodegradable organic matter, which results a significant environment pressure [2]. Thus, they are most commonly treated by aerobic biological system at the industrial facility where the wastewater is generated. Due to the typical process selection, aerobic biological treatment, relative energy consumption is high [3]. Moreover, due to typical on- or near- site disposal of biosolids without biogas recovery, there is little or no opportunity for carbon emission offset [4].

On the other hand, anaerobic system appears as a more environmentally friendly and economical process for treatment high-load wastewater [2,4]. However, high-rate anaerobic reactors already on the market (*e.g.*, UASB, EGSB or IC) are optimised for large enterprises (>1,000 m^3/d, being 2,500 m^3 a standard capacity) where economies of scale make vast technology investment affordable. In contract, the F&D sector, dominated by SMEs, does not discharge an enough organic load for existing anaerobic reactors to prove economically viable.

Being aware of the gap in the market, AEMA developed and patented a 100 L prototype of a high-performance multiphase anaerobic reactor (ES-2541078-B1). The continuous operation of the ground-breaking anaerobic reactor with winery wastewater showed COD removal efficiency higher than 90%, as well as an average biogas conversion of 0.45 m^3 biogas/kg COD removed [5]. With this experience, AEMA decided to lead LIFE Multi-AD project (LIFE17 ENV/ES/000331) in cooperation with four more partners in order to demonstrate the technical, economic and environmental viability of a high-performance multiphase anaerobic reactor at industrial scale.

The aim of this study was the industrial scale-up, automatization and validation of a ground-breaking high-performance multiphase anaerobic reactor for treatment of industrial wastewater from food and drink sector.

MATERIAL AND METHODS

Industrial wastewater

Industrial wastewater to be treated by Multi-AD reactor was produced by a winery located in Fuenmayor (Spain), which discharges around 40,000 m^3 per year through different seasons. Physico-chemical characteristics of wastewater sampled from July until November are shown in Table 1. Analytical determinations were carried out using standard methods [6]. Produced wastewaters are characterized by variable flow rates (as they are seasonal in nature), high organic loading, the low pH and nutrient levels as the bibliography shows [7].

Demonstration plant

Multi-AD technological solution is industrial-scale installed in the current WWTP of the cited winery, which is based on aerobic process by membrane bioreactor. Figure 1 shows the lay-out of Multi-AD technology, which is mainly composed of a water and gas line. The water line consists of conditioning physico-chemical (*i.e.*, sieving, equalization, settling, pH, nutrient and temperature adjustment), as well as anaerobic biological processes, which takes place in the Multi-AD reactor.

Multi-AD reactor is a multi-stage anaerobic reactor with a volume of 110 m^3 (9.1 m of height and 8.5 m of diameter at the bottom) that has a maximum OLR of 20 kg COD/m^3 d and is capable of treating up to 200 m^3/d of wastewater. Multi-AD device is made up of an influent system distribution, an anaerobic reactor core (4 chambers bordered by 3 baffles) and a three-phase separator. It is important to note that Multi-AD reactor was scaled-up from the 100 L prototype. The upscale process was supported by simulation results in order to predict the performance of the new design, as well as reducing the risk and costs associated with uncertainty. The CFD model developed was used for optimizing the design of the 110 m^3 demo unit, with special emphasis being placed on influent, chamber baffles and three-phase separator.

Thus, in the Multi-AD reactor, the wastewater is pumped from the bottom, uniformly into the reactor, where it moves upwards through the granular sludge bed (20 kg TS/m^3) located along the different chambers. At the top of the reactor, sludge, biogas and treated effluent are separated in a three-phase separator. On the one hand, treated water is sent to an aerobic process for a polishing treatment before it is discharged into the Ebro River, and, on the other hand, biogas is used as fuel in a boiler after desulfurization process by means of bio-scrubber system.

Multi-AD technological solution has an intelligent optimized control thanks to the development of a heuristic automation solution integrating current innovative technologies like Industry 4.0 [8] and Internet of Things. This was achieved through a two-level decision approach ready to be adopted by F&D SMEs: one local and one for remote monitoring and control [9].

RESULTS

Scaling-up

An analysis of numerical simulations showed that different modifications should be done in designing the industrial-scale Multi-AD reactor in order to achieve a cost-effective technological solution. The most significant modifications of the 1:1 industrial-scale Multi-AD reactor over the 100 L prototype were *i)* elimination of external biogas recirculation, *ii)* increment of diameter/height ratio (*i.e.*, reactor geometry) *iii)* reduction of number of chambers, as well as *iv)* new design of feed distribution pipping and three-phase separator.

Automation

An advanced control system was designed and developed in order to optimise Multi-AD reactor performance by adjusting the controllable output variables such as temperature, pH (DRD1R5.99, Hach), total solids (LXV424.99.00100-Solitax, Hach), ORP (DRD1R5.99, Hach), COD (SP-1-001-p0-s-NO-075 spectro::lyserTM, s::can) and biogas (EHS 9G3B25-1LJ1/0, Endress-Hauser).

The control logic was developed using a "cause-effect" approach by means TIA Portal V16 software. The logic was implemented on a Siemens S7-1500 PLC with analog and digital IO modules. This approach allows to operate the innovative solution at constant organic load by means of a mass balance over the Multi-AD reactor. Two continuous COD-analyzer were situated inline at the inlet of the conditioning tank and the outlet of the effluent tank, respectively. The analysers produce a continuous measurement value every 2 minutes, that allows the PLC tunes raw wastewater flow to be treated by means a group of flowmeters (MAG 5100, Siemens) and flow control valves (SIPART PS2 electropneumatic positioner, Siemens).

The architecture to carry out the monitoring and control of Multi-AD technology was developed in order to achieve an unattended and fully automated operation. Equipment and instrumentation of demo unit were connected to the power and automation-control panel. The control panel, which integrates the PLC and HMI, was connected to the power panel and the remote-control centre using a SCADA application developed in PcVue.

Validation

Multi-AD innovative solution was operated in continuous mode for four months. During this period, the anaerobic reactor treated more than 5,000 m^3 of winery wastewater at increasing organic load rate (OLR) (Figure 2). Despite influent variability, OLR was gradually increased from 0.5 to 10 kg COD/m^3·d thanks to COD based control strategy.

The planned increase in OLR took place once anaerobic reactor reaches the steady state. Thus, the values of the following process parameters were evaluated: pH, alkalinity, VFA and COD. pH, alkalinity and VFA had optimal values for the anaerobic digestion process, which shows that Multi-AD devise did not have any episodes of destabilisation or overloading. It is worth to note that the effluent COD concentration was usually lower than 600 mg/L during the validation period. This fact, taking into account the influent COD concentration, results in degradation efficiencies above 93%. These results are in line with previous study with this kind of wastewater [3,5].

Figure 3 shows that there is a decrease in soluble organic matter through Multi-AD reactor chambers. It can be seen, therefore, that there is a stepwise conversion, chamber by chamber, in line with the design propose of a multi-stage reactor, where each chamber behaves as a CSTR. This fact may indicate that Multi-AD reactor is capable to achieve better degradation rates for the same volume than a conventional anaerobic reactor such as UASB.

Anaerobic degradation of winery wastewater generated biogas conversion of 0.4 m^3/kg COD removed, with a biogas production of 3.6 m^3/m^3·d at the highest studied OLR (*i.e.*, 10 kg/m^3 d). The combustible gas generated after Multi-AD technological solution was characterized by a methane mean value of 71%. Moreover, it is important to highlight that hydrogen sulfide concentration was lower than 10 ppm after bio-scrubber system.

Economic assessment

Finally, a comprehensive process design was performed in this study to investigate the economic viability of Multi-AD innovative solution. Two different scenarios were selected for treatment of 100 m^3/d of winery wastewater: baseline, based on aerobic process, and Multi-AD scenario, based on anaerobic system coupled with post aerobic treatment.

As indicated in the Table 2, the Multi-AD scenario would achieve savings in OPEX around 50,000 €/y comparted to base line baseline scenario. This one-third potential reduction in operational costs is mainly due to energy saving. The integration of anaerobic process in the WWTP allows to save 175,000 kWh/y, *i.e.*, 60%. On the other side, a notable reduction in biosolid management cost line was also achieved by Multi-AD scenario due to the significant reduction in sludge produced by the anaerobic reactor operation.

CONCLUSION

Multi-AD reactor allows SMEs to count with decentralized, automatized and eco-innovative technological solution for treatment of their wastewaters, allowing them to save energy and operational costs.

Abstract In this work, new configurations of anaerobic fixed-film reactors were operated under conventional methanogenic conditions (single phase - SP-R, M1), and in a sequential two-phase system, acidogenic reactor followed by methanogenic reactor (TP-R, Ac+M2), in order to verify the impact of the phase separation on the biomethane production and some target pharmaceutical compounds removal - sulfamethoxazole, diclofenac, carbamazepine, and metoprolol. The results found evidenced that the TP-R enhances significantly the volumetric methane production rate (182 ± 45 and 312 ± 47 $mLCH_4 \cdot L^{-1} \cdot d^{-1}$, respectively for M1 and M2), and the biotransformation of pharmaceutical compounds. The reduction of the drugs load driven by the acidogenic reactor contributed to the optimization of the methanogenic activity on the bioconversion of the pharmaceutical compounds in the reactor.

Keywords
Acidogenesis; Anaerobic reactor; Bioenergy; Biofilm; Methanogenesis; Micropollutants

INTRODUCTION

There is a growing trend to face municipal wastewater as a potential source of value-added products that can be recovered, such as biomethane in the form of bioenergy (Kong et al., 2021). The pharmaceutical compounds are micropollutants frequently detected in municipal wastewater around the world, and in many cases they are not effectively removed in conventional biological treatment processes (Mejías et al., 2021). Recent studies have shown that the different stages of anaerobic digestion, e.g., acidogenesis and methanogenesis, may act differently on the biotransformation of organic micropollutants (Carneiro et al., 2020). Thus, this work intends to promote the phase separation of anaerobic digestion in order to enhance the biomethane production and the pharmaceutical compounds removal in wastewater treatment plants.

MATERIAL AND METHODS

The experimental apparatus comprises two anaerobic digestion (AD) systems: a single-phase methanogenic reactor (SP-R - M1), and a two-phase reactor - acidogenic followed by a methanogenic reactor (TP-R - Ac + M2). The bench scale anaerobic reactors (useful volume of 2 L) are fixed bed with polyurethane foam as support material for biofilm formation. The operation is carried out continuously at 30 °C and the applied organic loading rate is 2 $kgCOD\ m^{-3}\ d^{-1}$. For M1 and M2, the inoculum biomass was a granular methanogenic sludge from a full-scale UASB bioreactor (Tietê, São Paulo, Brazil). For Ac reactor, the same sludge was pretreated at pH 3 with HCl 5M. The reactors were fed with a lab-made municipal wastewater (1 $gCOD\ L^{-1}$) spiked with 10 $\mu g\ L^{-1}$ of some target pharmaceutical compounds belonging to different classes - the antibiotic sulfamethoxazole (SMX), the anti-inflammatory drug diclofenac (DCF), the neurodrug carbamazepine (CBZ), and the beta-blocker metoprolol (MTP). The analytes were quantified by using column-switching online solid phase extraction coupled with liquid chromatography / hybrid triple quadrupole-linear ion trap mass spectrometer. The performance assessment of the reactors was monitored in terms of COD (chemical oxygen demand) removal efficiency, and volumetric methane production rate (VMPR, in $mLCH_4 \cdot L^{-1} \cdot d^{-1}$, Equation 1). Q_{biogas} is the biogas flow rate in $mL \cdot d^{-1}$ and X_{CH4} is the percentage of methane in biogas; and $V_{reactor}$ is the reactor volume in L.

$$VMPR = \frac{Q_{biogas} \cdot X_{CH_4}}{V_{reactor}} \quad (1)$$

RESULTS AND DISCUSSION

Both treatment systems showed excellent performance in terms of COD removal - SP-R - 86 ± 16%, TP-R - 92 ± 7%. Fig. 1 shows the average results obtained during the operation bioreactors. It can be noticed a better performance of TP-R compared to SP-R evidenced by the higher VMPR in M2 (Fig. 1a - 182 ± 45 and 312 ± 47 $mLCH_4 \cdot L^{-1} \cdot d^{-1}$, respectively for M1 and M2). The percentage of methane in biogas (X_{CH4}) was significantly higher in M2 (89 ± 6%) compared to M1 (76 ± 7%). The biomethane production was potentiated by feeding the methanogenic reactor from the acidogenic effluent. Fermentation products from acidogenesis facilitated the bioconversion and organic matter removal kinetics in TP-R. Regarding the pharmaceutical compounds removal, the results (Fig. 1b) suggest that the two phase system considerably improves the bioconversion of the compounds carbamazepine, metoprolol and diclofenac: SP-R removal - CBZ = 74%, MTP = 58%, DCF = 56%; and TP-R removal – CBZ = 55%, MTP = 44%, DCF = 29%. The sulfamethoxazole removal was complete in both systems, being fully biotransformed both in methanogenic and acidogenic conditions. It can be concluded that acidogenesis acts as a key factor in the biotransformation of microcontaminants during anaerobic digestion. The reduction of the applied load of the xenobiotics on the populations of methanogenic archaea in M2 reactor and the presence of short-chain volatile fatty acids readily bioavailable for acetogenesis/methanogenesis may have contributed to the enhancement of the methanogenic enzymatic activity, facilitating the biotransformation of the pharmaceutical compounds. The results indicate that the anaerobic fixed-film reactors system with phase separation (acidogenesis / methanogenesis) is a promising biotechnology for optimizing the biomethane production and the removal of pharmaceutical compounds in municipal wastewater from biological treatment plants.

Abstract: Graphene oxide (GO) has been studied as conductive material during anaerobic digestion. The methane production and pharmaceutical removal kinetics were assessed by adding 0.075 g GO/g VS to the anaerobic digestion process using the biochemical methane potential test as a methodologic approach. The results obtained demonstrated that the formation of biologically reduced GO enhanced the methane production rates by 40%, although an adaptation period was necessary that compromised the specific methane production in the first ten days. In general, the removal of persistent pharmaceuticals was improved in those tests with GO (e.g. Carbamazepine removal was enhanced by 60% with GO). A microbial population change was detected in those cultures in the presence of GO, with enrichment of the hydrogenotrophic archaea. According to this study, the addition of GO improves methane production kinetics and pharmaceutical removal during the anaerobic digestion process.

Keywords biotransformation; bio-reduced GO; carbamazepine; kinetics; micropollutants

INTRODUCTION

Anaerobic digestion is a more economical alternative method to conventional aerobic treatment in the wastewater treatment process, with lower energy requirements and greater energy and resource recovery (Li et al., 2022). Increasing research efforts have been directed over the last decade to study the fate and removal of pharmaceuticals (PhAC) in aerobic treatment reactors, as many of these compounds are adsorbed in the sludge and can be released during the anaerobic digestion process of waste-activated sludge (Zhang and Li, 2018). This biological process consists of four steps and involves a heterogenous consortium of microorganisms, which can be understood as an electron flux between bacteria and archaea genera. The addition of carbon-based materials into anaerobic digestion reactors has been studied as a methodology to enhance microbial activity in anaerobic environments. Syntrophic bacteria can use these conductive materials for electron exchange, thus facilitating direct interspecies electron transfer (DIET). This resulted in increased methane production kinetics and enhanced biotransformation of organic micropollutants (Johnravindar, et al., 2020).

MATERIALS AND METHODS

To assess the impact of graphene oxide (GO) on anaerobic digestion the biochemical methane potential test methodology was used with an inoculum/substrate ratio of 2. The impact of 0.075 g of GO and hydrothermally reduced GO (rGO) (Baptista-Pires, et al., 2021) per g of inoculum volatile solid (VS) on specific methane production (SMP) and PhAC removal was assessed using cellulose as substrate and the fed-batch strategy: GO or rGO was only added at the beginning, while 3 pulses of cellulose were added (day 0, day 15 and day 30 resulting in 3 sets of consecutive batch tests: FB1, FB2, and FB3). The SMP was monitored online using a Gas Endeavour instrument (BPC Instruments, Sweden). Twelve PhACs were spiked to a final concentration of 1 µM at the beginning of the BMP tests.

RESULTS AND DISCUSSION

Impact of graphene oxide on methane production

Although there are some studies published in the literature there is no agreement concerning the effect of the addition of graphene oxide on methane production (Dong, et al., 2019; Muratçobanoğlu, et al., 2021). The fed-batch strategy allowed us to assess the impact of GO on methane production and compare the methane production kinetics of three sequential batches in the presence and absence of GO and hydrothermally reduced GO. The methane production rate (μ_{max}) was not affected by the presence of GO/rGO in the first batch (FB1), with values ~140 mL CH_4/ g VS · d in all conditions (**Figure 1**), but a reduction in the total amount of methane produced (~22% mL CH_4/ g VS), as well as a longer lag phase, was detected in the presence of GO (**Figure 2**). Once the GO was biologically reduced and incorporated into the sludge matrix, a significant enhancement ($p < 0.05$) in the μ_{max} was detected in the GO batch tests as well as in the rGO tests (~37% and ~50%, respectively) after adding the 2nd pulse of cellulose (FB2), whereas in the Control condition was not detected a significant enhancement ($p > 0.05$) (**Figure 1**). In the third addition of cellulose (FB3), the GO-batch tests and the rGO-batch tests increased the methane production rate up to 234.79 ± 16.59 and 243.75 ± 24.41 mL CH_4/ g VS · d respectively, which means the production rate was ~40% faster than the Control (**Figure 1**). We hypothesize that the addition of GO produces electron scavenging during the first days of the anaerobic digestion process (1st addition of cellulose). Once GO is bioreduced, the sludge recovers the same specific methane potential as the control as it is shown in **Figure 2**.

Impact of graphene oxide on pharmaceuticals removal

The removal kinetics of twelve PhACs were monitored (**Figure 3**) during the first (FB1) and third (FB3) sets of batch tests. Carbamazepine (CBZ) presented the highest removal enhancement in the tests conducted with GO as compared to the other conditions tested. No variation along the time was detected in the Control condition and was poorly removed in presence of rGO (13 ± 8%). Regarding the removal in presence of GO, 22 ± 1% removal was detected after 24 hours by the addition of GO and was enhanced up to 63 ± 1% by the end of the first batch. The detected removal could be associated with biological transformation since no adsorption was detected in the blank conditions measured after 48 hours (**Figure 3**). Trimethoprim (TMP) transformation was highly influenced by the addition of GO and rGO, with removals of 90 ± 2% and 79 ± 2% respectively, in just 24 hours. At the same time, only 13 ± 3% was removed in the Control condition. Iohexol presented high removal rates at the beginning of the experiment (FB1) but stopped after 36 h of reaction.. Tetracyclines showed a high tendency to adsorb on both materials (GO and rGO) and were associated with chemical interaction as π-π interactions and hydrogen bonds.

Additional experiments are being conducted to determine the different mechanisms that involve the GO on the removal of the different pharmaceuticals.

Conclusions: The addition of GO enhances the methane production rate by ~40%, and pharmaceutical removal. The results obtained determine the specific methane production is reduced during the biological reduction of GO but once reduced, the same methane production as the control or the rGO tests is obtained.

Abstract
The removal of contaminants of emerging concern (CECs) and antibiotic resistance genes (ARGs) were investigated at pilot-scale with partially saturated vertical flow constructed wetland bioaugmented or not with the *Trichoderma asperellum* (strain T34) by means of the non-target liquid chromatography high-resolution mass spectrometry and SmartChip™ Real-Time PCR methodological approaches. Bioaugmentation testing was successful as *Trichoderma* was able to grow in competitive conditions resulting from the use of secondary treated domestic wastewater. The most significant beneficial effect was observed with benzotriazole and diclofenac. High variability in removal efficiency (RE) along a four-week experiment remained the chief constraint for the proper assessment of treatment performances. There was a clear relationship between the RE and the biodegradability as well as the sorption capacity of the identified compounds. Sorption prevailed over biodegradation for hydrophobic (log Dow > 3) and slowly biodegradable compounds. For moderate hydrophobic compounds (0 < log D_{ow} > 3), the RE appeared to be dependent on functional groups and transformation reactions. But RE higher than 65% was obtained for selected slowly biodegradable compounds. The most difficult compounds to be eliminated were the most polar ones (log Dow < 0). Transformation products (TPs) were also investigated. N-oxide TPs and 14-hydroxyclarithromycin were formed in wetland treatment while TPs which were prone to undergo further N-dealkylation or hydroxylation reactions were partly eliminated. Bioaugmented wetland treatments have cause a shift in the ARGs composition but there was no statistical difference in average ARGs removal rates.

Keywords: Antibiotic resistant genes; bioaugmentation; constructed wetlands; contaminants of emerging concern; transformation products; *Trichoderma*

INTRODUCTION

The so-called partial saturated vertical subsurface flow CW (VSSF-CW) has shown enhanced removal of total nitrogen and selected CECs without the requirement of external energy input. This result was mainly assigned to a more diverse and metabolically versatile bacterial communities. However, saturated conditions and anaerobic conditions, despite favoring the elimination of certain antibiotics, may result in the spread of ARGs in bacterial communities. VSSF-CW could remove ARGs from wastewater by directly eliminating microorganisms. Bioaugmentation has appeared to be a promising approach to improve the functioning of wetland treatments, considering that natural mycorrhization has been detected in wetlands. However, little evidence exists to show that bioaugmentation of CW through bacterial or fungal inoculation substantially improves their efficiency in CECs and ARGs removal. In this context, we decided to inoculate at a pilot scale VSSF-CW with *Trichoderma* fungi because (i) they are known to be plant symbionts which might promote plant performances and contaminants plant uptake and (ii) they possess a machinery of unspecific enzymes (e.g., laccase and peroxidase enzymes), similarly to *Trametes Versicolor,* which makes their application in CECs removal attractive.

MATERIALS AND METHODS

Experimental set-up: The CW consisted of three lines of three CW units each and operated in parallel. Each unit has been designed to treat 96 L/d distributed in 8 batches along the day and was partially saturated with water (0.2 out of 0.6 m height), allowing for a combination of oxic and anoxic conditions. The first line consisted of substrate and plant, while in the second line *Trichoderma asperellum* (strain T34) was inoculated. A third line without plant was also implemented as a reference system. The CW was fed with secondary treated wastewater.
CECs analysis in wastewater: SPE and non-target liquid chromatography-high resolution mass spectrometry (LC-HRMS) screening.
ARGs: analysis: A SmartChip™ Real-Time PCR methodological approach.

RESULTS AND DISCUSSION

This study provided additional data on the capacity of VSSF- CW units to eliminate a large array of CECs. The most easily eliminated compounds were those which are known to be readily biodegradable (e.g., nicotine). Interestingly, from 22 compounds with RE > 65%, 17 compounds have a log Dow between 0 and 3 (optimal plant uptake). The most difficult compounds to be eliminated were the most polar ones (log Dow < 0) such as melamine. Our treatment wetland also generated TPs. Interestingly, N-oxide TPs of tertiary amines and 14-hydroxyclarithromycin were frequently detected in effluent. Attempts in bioaugmentation with *Trichoderma* were successful since the fungus was able to grow in competitive conditions. However, the high range of standard deviation values associated with RE values resulted to be the main issue for a proper assessment of treatment efficiency. This calls for more fundamental research into the mechanisms of compound attenuation to find strategies to limit fluctuating RE. None of the wetland treatments (with and without bioaugmentation) was able to significantly reduce the overall bacterial and ARGs loads. Hybrid treatment systems combining CW and advanced oxidation processes are currently implemented in our research group to avoid antibiotic resistance spreading.

Abstract
Ionizing radiation by γ-ray was applied to treat the real polymer-containing oilfield produced wastewater with high viscosity and emulsification. The viscosity decreased rapidly from initial 3.7 mPa s to 1.5 mPa s with the absorbed dose of 1.0 kGy, and then gradually to reach the level of pure water at 5.0 kGy. The produced wastewater was negatively charged and the absolute value of zeta potential diminished stepwise during γ-irradiation, indicating the stability of oil/water emulsion was destroyed. γ-ray radiation pretreatment contributes to the oil removal by coagulation. The efficiency of oil removal raised remarkedly from 47% by coagulation alone to 85% with 1.0 kGy of γ-ray pretreatment at the same flocculant dosage of 100 mg/L. γ-irradiation is also effective to disinfect the three typical bacteria in oilfield wastewater, saprophytic bacteria (TGB), sulfate-reducing bacteria (SRB) and iron bacteria (IB). With the absorbed dose of 1.0 kGy, more than 99.8% of TGB, SRB and IB were killed and a complete deactivation was observed at 2.5 kGy. Oxidation by ·OH formed in water radiolysis is the major pathway to reduce viscosity and kill bacteria, while the direct γ-ray irradiation also plays a role. The members belonging to genera *Thauera*, *Defluviimonas* and *Comamonadaceae* were predominant in the produced wastewater. Based on PICRUSt analysis, the function genes related to metabolism exhibit the highest abundance (25%) and their abundance increased at the low dose of 1.0 kGy and declined at 10 kGy. This suggests that ionizing radiation at low dose might stimulate the bacterial activity for metabolism. In practical application, ionizing radiation by electron accelerator can be added before coagulation in the conventional produced wastewater treatment processes for reinjection.

INTRODUCTION

Petroleum is an important and nonrenewable energy source. Among the enhanced oil recovery (EOR) methods, polymer flooding is the most often used and efficient method (Pogaku et al., 2018). The wastewater produced during polymer flooding with huge amount has become a challenging issue in the oilfield. Partially hydrolyzed polyacrylamide (HPAM) is one of the most popular polymer. HPAM has extreme high molecular weight (MW) of several to dozens million Daltons. HPAM can increase the viscosity of produced wastewater significantly and leads to high emulsification and stability (Gao, 2013). As a result, the oil droplet and particles exist stable in the produced wastewater and are hard to be removed by the gravity or coagulation.

The advanced oxidation processes (AOPs) are developed to decompose the polymer and reduce viscosity. Ionizing radiation involving γ-ray and electron beam (EB) is a novel AOPs. Under both the direct adsorption of high-energy ray/EB and the oxidation and reduction of active species involving ·OH, e_{aq}^- and ·H formed in water molecule's radiolysis, a variety of recalcitrant pollutants are able to be degraded effectively. (Wang and Chu, 2016). Ionizing radiation might be a promising option to treat the polymer-containing produced wastewater to decompose polymers, reduce viscosity, break emulsion and kill bacteria simultaneously.

The objective of the study was to treat the real oilfield produced wastewater from polymer flooding by ionizing radiation. The effect of ionizing radiation on viscosity reduction, the changes in wastewater characteristics and inactivation of three typical bacteria were evaluated. The enhancement of ionizing radiation as pretreatment to flocculation for oil removal was investigated. This research provides a new strategy for treating the polymer-containing produced wastewater with high viscosity and emulsification by ionizing radiation.

MATERIALS AND METHODS

The produced wastewater was taken from an oilfield wastewater treatment plant in north China. Table 1 shows the characteristics of the produced wastewater. The experiments of ionizing radiation were conducted using gamma-ray derived from the radioisotope ^{60}Co with radioactivity of 7.4×10^{14} Bq. Around 50 mL of wastewater were put into tubes and delivered for γ-ray irradiation at ambient temperature of around 25 °C. The dose rate maintained at 11.5 kGy/h. After γ-ray irradiation, the wastewater samples were analyzed directly for the parameters involving COD, oil, HPAMzeta potential, number of saprophytic bacteria (TGB), sulfate-reducing bacteria (SRB) and iron bacteria (IB), and the bacterial community and function, etc.

RESULTS AND DISCUSSION

Viscosity reduction and demulsification

Figure 1 depicts the changes in solution viscosity, HPAM content and zeta potential during γ-radiation. The viscosity declined sharply from initial 3.7 mPa s to 1.5 mPa s with the absorbed dose of 1.0 kGy and then gradually with rising the absorbed doses, reaching to the level of pure water under the same temperature at 5.0 kGy. The HPAM decomposition rate is lower than viscosity reduction rate. The efficiency of HPAM removal was around 22% at 2.0 kGy and increased to 35% at 10 kGy. the produced wastewater was negatively charged and the absolute value of zeta potential declined stepwise during γ-irradiation. This implies that γ-irradiation is efficient to decrease the stability of emulsion of the produced wastewater.

Organics and oil removal

Figure 2 presents the changes in COD, TOC and oil content in the produced wastewater during gamma irradiation. The concentration of COD and TOC decreased slowly with increasing the adsorbed doses. The removal percentage of COD and TOC was 5.5%-10.7% at 1.0 kGy and reached 11.0%-22.7% at 10 kGy. The reduction of oil content is higher than COD/TOC removal. Oil removal reached 24.6% with the absorbed dose of 1.0 kGy and rose to 40.3% at 10 kGy.

Deactivation of TGB, SRB and IB

With the absorbed dose of 1.0 kGy, more than 99.8% of TGB, SRB and IB were killed and a complete deactivation was observed as increasing the dose to 2.5 kGy (Fig. 3). This is beneficial for treating the produced wastewater for reinjection because the consumption for germicidal agent is going to be saved.

Changes in bacterial community and predictive function

The bacterial diversity of the oilfield produced wastewater was relatively low. At the phylum level, *Proteobacteria* was predominant remarkable with the relative abundance of 94.5%, followed by *Campilobacterota* (2.0%), *Firmicutes* (0.8%) and *Desulfobacterota* (0.4%). At the genus level, the members *Thauera*, *Defluviimonas* and *Comamonadaceae* were predominant.

Based on PICRUSt analysis (Fig. 4), the function gene related metabolism exhibits the highest abundance (25%), followed by environmental and genetic information processing (8.4% and 6.8%). The abundance of almost all the genes coding for metabolism increased with the low absorbed dose of 1.0 kGy and then declined with increasing the dose to 10 kGy. This suggests that ionizing radiation at low dose might stimulate the bacterial activity for metabolism.

Enhancement of γ-radiation pretreatment to coagulation for oil removal

γ-ray pre-treatment with the low absorbed dose of 1.0 kGy improved oil removal by coagulation remarkably. The efficiency of oil removal was 39-47% by coagulation alone and reached 73-85% with γ-ray pre-treatment at PFAC dosages of 50 mg/L and 100 mg/L (Fig. 5).

Table 1. Characteristics of oilfield produced wastewater

Parameters	Values	Parameters	Values
pH	7.92~7.99	SS (mg/L)	85.0 ± 5.0
COD (mg/L)	629 ± 12	CH_3COOH (mg/L)	37.3 ± 0.6
TOC (mg/L)	311 ± 1.5	C_3H_7COOH (mg/L)	60.0 ± 0.3
Oil (mg/L)	295 ± 36	$C_5H_{11}COOH$ (mg/L)	18.3 ± 1.0
HPAM (mg/L)	334 ± 17	Cl^- (mg/L)	887 ±15

Abstract
Cyanobacteria are photoautotrophic microorganisms able to adsorb and/or accumulate heavy metals. Thus, they can be exploited as eco-friendly tools to remove and recover metal ions from wastewater. In this work, we evaluated the biosorption ability of three marine cyanobacteria in laboratory-prepared three-metal solutions and real electroplating wastewaters containing mainly Cu, Ni, Zn, Au, Pd, and Cr. We found that the pre-treatment influences the performances of the biosorbents, with a strain-specific effect. Furthermore, the feasibility of the process is strongly influenced by the concentration of the metals and the composition of wastewater.

Keywords
Biosorption; electroplating wastewaters; heavy metals; marine cyanobacteria; precious metals

INTRODUCTION

Cyanobacteria are cosmopolitan photoautotrophic microorganisms able to survive in extreme conditions, comprising environments containing pesticides, petroleum by-products, xenobiotics, and heavy metals. This ability has risen the attention for their possible exploitation as a clean green technology for the degradation or detoxification of contaminants (Gehlot et al., 2022; Zanganeh et al., 2022). Cyanobacteria have been proposed as biosorbents for heavy metal remediation from contaminated waters thanks to their ability to passively bind positively charged ions on the cell's surface (Singh, 2020). Many cyanobacteria are able to produce a high amount of exopolysaccharides (EPS), which are heteropolymers characterized by six or more different types of monosaccharides and strong anionic nature that may help chelating positively charged heavy metals (Cui et al., 2021; De Philippis and Micheletti, 2017).
Biosorption by cyanobacteria may represent an eco-friendly approach for heavy metal remediation. Additionally, metal ions can be recovered from cyanobacteria biomass to enter again into the productive cycle of the industries. Otherwise, metal-organic materials can be valorized as hybrid catalysts or antimicrobials (Gandolfi et al., 2022; Netanel Liberman et al., 2021). The possibility to recover and reuse these compounds may represent an economic opportunity for the industry sustaining the "end of waste". Previous studies mainly focused on the use of cyanobacteria with single-metal solutions. Nevertheless, the biosorption process is strongly influenced by the composition of the water and the presence of other ions that can cooperate in a competitive or synergistic way (Aranda-García et al., 2020; Zinicovscaia et al., 2018).
This study aims to evaluate the biosorption ability of three selected cyanobacteria strains in *i)* laboratory-prepared three-metal solutions comparing a different pre-treatment and *ii)* real electroplating wastewater adopting confined whole cultures.

MATERIALS AND METHODS

Cyanobacteria and growth conditions

Two unicellular marine cyanobacteria, namely *Cyanothece* sp. CE 4 and *Dactyloccocopsis salina* sp. 16Som2, and a co-culture of *Halothece/Euhalothece* spp named VI 22M, previously selected for their ability to produce EPS and remove Cu, Ni, Zn from single-metal solutions, were grown in 1-L glass bottles with enriched seawater medium (De Philippis et al., 1993), under continuous illumination (200 µmol m^{-2} s^{-1}) and insufflation of CO_2-enriched air.

Biosorption assays

One week-grown cultures were harvested, confined in dialysis tubing (MW cut-off 12-14 kDa) and pre-treated to remove the excessive salts contained in the cultivation medium, with deionized water and HCl or NaOH 0.1M. The same pre-treatments were carried out with dialysis tubing only containing the culture medium (blank). Next, the confined pre-treated cultures or the blank were dipped in the metal containing solutions with a ratio 1:10 (v:v, biosorbent and metal solution, respectively) and maintained under continuous agitation at 25°C. Three replicates were set for each condition. After 24 h the dyalisis tubings were removed and residual metals concentration in the solutions was determined by ICP-OES. The specific metal uptake was expressed as mmol of metal g^{-1} DW. Biomass dry weight (DW, g L^{-1}) was determined by filtering cell suspension after the pre-treatment on pre-weighted 0.45 µm filters and drying the filters at 105°C per 4 hours.

Three-metal solution

A starting solution containing 10 mg L^{-1} of Cu ($CuCl_2$), 10 mg L^{-1} of Ni ($NiCl_2$), and 10 mg L^{-1} of Zn ($ZnCl_2$) was prepared. The cyanobacteria were tested evaluating the effect of both acid and basic pre-treatment (HCl and NaOH 0.1M, respectively). The trial was set as described above maintaining the pH at 5.0 ± 0.3.

Electroplating water

Five wastewaters from electroplating baths were provided by Galvanica Aricci Srl (Ghisalba, BG, Italy) and characterized (table 1). A mixed solution (E1) and the other three solutions (E2, E3, E4) were adopted to verify the biosorption capability of cyanobacteria in real electroplating wastewater. Acid or basic pre-treatment was chosen based on the pH of the solutions to not affect the solubility of the metals. The trial was set as described above.

Table 1. pH and metal composition of five wastewaters provided by Galvanica Aricci Srl

Main metal of electroplating bath	pH	Au	Cr	Cu	Ni	Pd	Zn	Reference name for the assay
		mg L^{-1}						
Cu	1.66	<0.01	0.01	29.52	0.29	nd[a]	21.19	E1[b]
Ni	6.67	nd	nd	0.19	747.22	nd	0.75	E1[b]
Ni	4.11	nd	nd	0.67	386.94	nd	1.01	E2
Pd	7.19	<0.01	0.16	7.31	0.64	24.55	0.14	E3
Au	5.30	7.22	4.49	0.25	6.30	nd	1.66	E4

[a] nd not detected; [b] The first two wastewaters were mixed 1:4 (v:v) to increase the pH of the first solution while decreasing the concentration of Ni in the second solution and named E1.

RESULTS AND DISCUSSION

Three marine cyanobacteria able to produce high amounts of EPS were adopted as biosorbents for heavy metal removal from multi-metal solutions.

Three-metal solution

At the end of the pre-treatment, the cultures had a pH of 3.1 ± 0.3, or 10.1 ± 0.2 when treated with HCl or NaOH 0.1M, respectively. All the cyanobacteria highlighted a stronger affinity towards Cu with acid pre-treatment. VI 22M showed a slightly higher total specific uptake compared to the other strains both with acid and basic pre-treatment (1.30 and 2.19 mmol metal g^{-1} DW, respectively), mainly due to greater Ni removal (figure 1a, 1b). Basic pre-treatment appeared more efficient in Ni and Zn uptake, this statement is particularly evident for VI 22M and 16Som2 (average increment percentage of Ni and Zn uptake within the range of 134% for VI 22M and 243% for 16Som2 with basic pre-treatment), whereas acid pre-treatment improved Cu uptake for CE 4 (+187%). The different behaviour based on the pre-treatment may be explained by different EPS composition (Philippis & Micheletti, 2017).

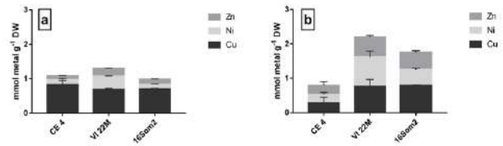

Figure 1. Specific uptake (mmol metal g^{-1} DW) by CE 4, VI 22M, and 16Som2 after 24h contact with three-metal solution (mean ± sd): a) acid pre-treatment, b) basic pre-treatment.

Electroplating water

According to the pH of the wastewater provided by Galvanica Aricci Srl, we adopted basic pre-treatment for E1 and E2, acid pre-treatment for E3 and E4. We compared Ni uptake in E1 and E2 since these solutions were characterized by an extremely high Ni concentration (table 1). VI 22M and 16Som2 showed higher Ni uptake in E2 compared to E1 (figure 2), despite the lower initial concentration of the metal in E2, whereas CE 4 showed a slightly higher uptake in E1. The comparison of Ni uptake per gram of biomass between electroplating water and three-metal solution assays (figure 1b) revealed higher uptake in real electroplating water by all the cyanobacteria, that may be explained by a higher Ni content in the solutions.

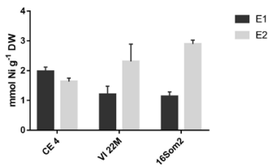

Figure 2. Ni uptake (mmol Ni g^{-1} DW) by CE 4, VI 22M, and 16Som2 after 24h contact with E1 and E2 effluents (mean ± sd).

The possibility to recover precious metals like Au and Pd is extremely important for the industry sector. We evaluated the biosorption ability from palladium and gold-plating bath's wastewater (E3 and E4). The specific uptake considering a single metal was always lower than 80 µmol metal g^{-1} DW (data not shown). The highest Pd and Au uptake was shown by CE 4. Additionally, CE 4 showed a total metal uptake in E4 roughly 4 times greater than VI 22M and 16Som2.
Plating baths containing precious metals are usually rich in conductive salts to reduce the resistance of the solutions, the presence of coexisting ions can negatively affect the biosorption of the metal of interest (Aranda-García et al., 2020), probably reducing the uptake in E3 and E4 solutions.
Exopolysaccharide-producing cyanobacteria may represent an eco-friendly strategy to remove and recover metal ions from wastewater. Nevertheless, we found that the feasibility of the process is strongly influenced by the concentration of the metals and the composition of wastewater.

Abstract
Effective management of heavy metal pollution requires a multi-faceted approach that includes regulations, monitoring, and remediation efforts. Cyanobacteria are photosynthetic prokaryotes that can be exploited for water remediation of heavy metals through the biosorption process. The aim of this study was to evaluate the ability of two halotolerant cyanobacteria to adsorb Cu^{2+}, Ni^{2+}, and Zn^{2+} from aqueous solutions adopting confined systems. Additionally, in order to improve the feasibility of the system, the use of cyanobacteria-based biosorbents in consecutive adsorption cycles was also assessed.

Keywords
Adsorption; desorption; halotolerant cyanobacteria; heavy metals

INTRODUCTION

The negative effects of population growth, industrialization, and resource overuse on ecosystems have prompted the search for effective and eco-friendly strategies for their restoration. Heavy metals can be released into the environment through industrial activities, agricultural practices, and natural processes and can have several negative effects on the environment and human health (Briffa et al., 2020). Biosorption, which utilizes biological materials to remove pollutants, can be used for heavy metal remediation and supports the principles of the circular economy by allowing the recovery and reuse of the absorbed materials. During biosorption, ions from aqueous solutions passively bind onto the functional groups on the surface of the biomass, thus, the cells are not affected by heavy metal concentration and can undergo several adsorption/desorption cycles (Bashir et al., 2019; Paperi et al., 2006). Halotolerant cyanobacteria are particularly promising in this regard as most of them are able to produce a large amount of exopolysaccharides around their cells which possess strong anionic properties, making them effective chelating agents for positively charged heavy metals (Al-Amin et al., 2021; Gehlot et al., 2022).
The aim of this study was to evaluate i) the ability of two halotolerant cyanobacteria to adsorb Cu^{2+}, Ni^{2+}, and Zn^{2+} from aqueous solutions, ii) the stability of the binding in water, and iii) the possibility to use the cultures for a second consecutive adsorption cycle.

MATERIALS AND METHODS

Two halotolerant cyanobacteria strains belonging to *Cyanothece* cluster 3 of *Halothece* and named CE 4 and 16Som2, were grown in 1-liter glass bottles adopting enriched seawater medium. The cultures were managed in semi-continuous mode, replenishing half-culture weekly with fresh medium. Harvested cultures were confined in dialysis tubings (12-14 KDa, MW cut-off), pre-treated with HCl 0.1M solution, and adopted for the assays. Each week, a different metal was tested, namely Cu^{2+}, Ni^{2+}, Zn^{2+}. Firstly, metal uptake was determined after 24 hours of contact with lab-made solutions containing 10 mg L^{-1} of metal, then the stability of the binding between biosorbents and adsorbed metals in the water was evaluated while maintaining the confined cultures in agitation with distilled water for 3 hours. Finally, in order to check the possibility to use the cyanobacteria-based biosorbents for a second adsorption cycle, a test based on consecutive adsorption (I cycle) – desorption – adsorption (II cycle) was performed. HCl 0.1M was adopted as desorbing agent. Metal quantification from water solutions was carried out by adopting an adaptation of the bicinchoninate, 1-(2-pyridylazo)-2naphthol and Zincon method (HI 93702, HI93740 and HI93731 reagents kit, respectively, Hanna Instruments Srl, Italy) following manufacturer's instructions.
Metal uptake was expressed as mg metal g^{-1} DW (dry weight) of biomass.

RESULTS AND DISCUSSION

We observed stronger stability of Cu-biomass complexes. Indeed, the percentage of Cu released in water by the biosorbents was 4-6% of the previously adsorbed amount (data not shown). This percentage increased up to 73% for the other metals, suggesting a stronger affinity of the biosorbents toward Cu. To evaluate the possibility to reuse the cyanobacteria-based biosorbents, two consecutive adsorption cycles were carried out. Generally, metal (mainly Cu and Ni) uptake in the second adsorption cycle was reduced compared to the first adsorption cycle (Figure 1). On the contrary, we found Cu uptake by CE 4 in the second adsorption cycle even higher (+53%) than in the first cycle, probably suggesting that two acid treatments, carried out for pre-treatment and desorption, may improve Cu adsorption by CE 4.

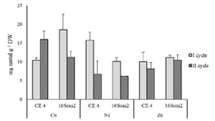

Figure 1. Cu, Ni, Zn uptake (mg metal g^{-1} DW) by confined cultures of CE 4 and 16Som2 in a first adsorption cycle (I cycle) and second adsorption cycle (II cycle).

Cu, Ni, and Zn are common metals in the industry. Thus, they can easily be found in industrial effluents. The biosorption of these metals with halotolerant cyanobacteria may represent a valid bioremediation approach. The use of confined systems promotes easy management of the biosorbents that can be used in consecutive adsorption cycles increasing their shelf-life and economic value, while adsorbed metals can be recovered to enter again in the productive cycle.

Abstract

The use of pesticides for agricultural purposes is responsible for generating an important volume of wastewater. In 2009, 13 treatment processes were authorized but they are expensive and the toxicological impact of the secondary metabolites that are formed is not clearly established. In this field, Pulsed Light (PL) seems to be an interesting alternative to modify pesticide structure. Optimization of operating parameters was carried out in terms of intensity and flash number for 20 pesticide molecules. The untargeted analysis identified 118 secondary metabolites and 53 structure hypotheses were proposed. Then, a quantitative method was developed to quantify the secondary metabolites and the parent compounds.

Keywords (maximum 6 in alphabetical order)

Degradation, pulsed light, pesticides, secondary metabolites

INTRODUCTION

According to the FAO (Food and Agriculture Organization), the total pesticides use increased in the most recent decade by nearly 50 percent compared to the 1990's. Statistically, more than 300 liters per hectare of pesticide preparations are sprayed each year. This use is directly linked to an important production of wastewater. Indeed, each year, the cleaning of the sprayers generates a volume of effluent ranging from 400,000 to 900,000 m^3. Recently photodecomposition processes have been studied and proved an effectiveness to degrade pesticides (Martínez-López *et al.,* 2018 ; Gómez-Morte *et al.,* 2020 ; Fortunato *et al.,* 2021). Organic molecules absorb UV light and therefore are impacted and modified (Coly and Aaron, 1994; Patria et al., 1995). Among these techniques, pulsed light has shown its efficiency (Baranda et al., 2012, 2014, 2017). Pulsed light (PL) is a non-thermal technology based on the accumulation of high discharge voltage in a capacitor where the stored electrical energy is delivered as intermittent short pulses through a light source filled with xenon gas. PL relies on a wide wavelength range from 200 to 1000 nm. However, research focusing on the degradation of phytosanitary products by PL (Baranda et al., 2012, 2014, 2017) or UV-C (Maheswari *et al.,* 2010, Lassale *et al.,* 2014) was carried out on a few number of pesticides. Moreover, these experiments did not study toxicity through in-vivo biotoxicity assay. Therefore, the aim of this work was to investigate the PL technology as a new process for the degradation of pesticides. The degradation parameters for 20 pesticides and the formation of their metabolites were studied. The optimization of operating parameters was achieved for each pesticide.

MATERIALS AND METHODS

Pesticide Selection : 20 pesticides (Tab. 1) widely used in viticulture were selected according to their high toxicity, with a low LC50 (Lethal concentration 50) for *Daphnia Magna*.

LP Box : The LP Box is a compact and ergonomic machine, in "office" format (fig 1). As mentioned above, the principle of pulsed light is based on the emission of polychromatic light covering a wide spectrum (200 to 1000 nm, UVC 20%, UVB 10%) by light flashes (between 1 µs and 100 ms per flash).

Untargeted Analysis : Each pesticide was prepared in aqueous solution at a concentration of 10 mg/L, 10 ml of the mix were placed into glass petri dishes, PL fluence values ranged from 19 J/cm^2 to 153 J/cm^2. After treatment, the samples were analyzed in scan mode with a HPLC/MS-MS (HPLC 1260 infinity coupled to a triple quadrupole 6430 from Agilent) in reverse phase with a Poroshell 120 CS-C18 column (2.1×150 mm, 2,7µm). The electrospray ionization was performed in positive mode (ESI$^+$).

Quantitative analysis: The quantification method was developed using the same conditions than for the untargeted analysis but in MRM mode (Multiple Reaction Monitoring). For the specific purpose of developing a method for absolute quantification of the 20 pesticides chosen (Tab.1), a quantitation range from 1 to 200 µg/L was validated (linearity $r^2 > 0.98$, accuracy 70-120%) and limits of quantification were determined by the regression line method.

Fragmentation experiments were performed between 5 and 50 eV on each metabolite previously identified in order to determine 2 transitions per compound and create a relative quantification method for these molecules.

Degradation study :

In order to study the degradation ability of LP Box on pesticides, 7 pesticides were selected because of their rapid degradation with PL. An optimization was made to identify the number of pulses needed to degrade each one of the 7 pesticides. This study used increasing flashes on solutions at LC50 (*Daphnia Magna*) until obtaining concentrations below the LOQs. The samples were analyzed after each 100 flashes of treatment to identify the fluence needed to totally degrade pesticides.

RESULTS AND DISCUSSION :

Untargeted analysis : The aim of this part was to identify secondary metabolites of pesticides and to elucidate their structures. High concentrations were used with the aim of having strong signals in order to detect all metabolites produced during PL degradation. The untargeted analysis showed that PL was able to degrade all pesticides tested. It also demonstrated that HPLC coupled to a triple quadrupole was an effective tool to detect secondary metabolites in treated samples and to make structural hypotheses about them. This study allowed to detect 118 metabolites and 53 hypotheses of structures were proposed using m/z, isotopic patterns of the molecules containing halogens as well as results previously obtained in the literature (fig. 2 and 3). The reactions mainly observed are halogen losses if they are presents in the parent compounds or an addition/substitution of an hydroxyle group.

Quantitative analysis : A MRM method was built for the 20 studied pesticides and for the compounds previously identified as secondary metabolites. Two transitions per compound were used following fragmentation experiments. The developed MRM method allows absolute quantification of the parent molecules and relative quantification of 87 secondary metabolites.

Degradation study :

These experiments show that LP Box is able to degrade pesticides from their LC50 (*Daphnia Magna)* to a concentration lower than their LOQ (fig. 4). These experiments also demonstrated that it was possible to relatively quantify secondary metabolites of pesticides after PL degradation (fig.5). This study also permitted to determine the fluences needed to degrade pesticides from their LC50 to a concentration lower than the LOQ (Tab.2).

CONCLUSION

In conclusion, our results proved that pulsed light has an effective impact on all pesticides treated although the fluence needed is molecule-dependent. Metabolites were detected and a method was built to absolutely quantify 20 pesticides and relatively quantify 87 secondary metabolites. An optimization in terms of fluence showed that it was possible to degrade 7 pesticides from a toxic concentration to a concentration below the LOQ.

Abstract
Limited design information hampers applications of the return sludge side-stream (RSS) process to promote enhanced biological phosphorus removal. Extended anaerobic batch tests were carried out to examine phosphorus release profiles commonly associated with polyphosphate accumulating organism (PAO) activity for the selection of a side-stream tank (SST) hydraulic retention time (HRT). 16 hours was selected and employed in a lab scale RSS system which demonstrated stable long-term N&P removal. A combination of *Tetrasphaera* and *Accumulibacter* PAOs were observed, where both groups played a key role in P removal as assessed by Raman-FISH. A high abundance of GAOs were also observed, although phosphorus removal was not impacted. The multiple PAOs with synergistic removal mechanisms are likely advantageous towards ensuring phosphorus removal stability in RSS systems. Follow up extended anaerobic batch tests with RSS biomass support 16-24 hours as an appropriate SST HRT for the enrichment of *Tetrasphaera*. This simplified approach highlights the potential for SST HRT to be designed and selected by assessment of phosphorus release exhaustion.

Keywords (maximum 6 in alphabetical order)
Polyphosphate accumulating organisms (PAOs), phosphorus, return sludge sidestream (RSS); sidestream enhanced biological phosphorus removal (S2EBPR); *Tetrasphaera*

INTRODUCTION

Anaerobic side stream tank (SST) hydraulic retention times (HRT) in return activated sludge side-stream (RSS) systems have been observed to range from 1-60 hours (Jonsson and Jansen, 2006; Onnis-Hayden et al., 2020; Vale et al., 2008; Vollertsen et al., 2006). This range can be considered extremely broad, with the fundamental rationale for SST HRT selection unclear. For the RSS processes to be applied more widely, particularly outside of Denmark and in variable climates, a clearer understanding of design parameters such as SST HRT needs to be developed for designers. It is hypothesised that if there is an advantage for both VFA consuming and fermenting PAOs under extended anaerobic conditions, pinpointing where phosphorus (P) release is exhausted should elucidate the optimal time range for SST HRT, as no additional substrate storage by PAOs would be possible after this point. In this work, extended anaerobic batch tests were carried out with waste activated sludge (WAS) from the Luggage Point sewage treatment plant (STP) to examine initial P release dynamics. Based on these results, a SST HRT was selected and implemented in a lab scale RSS sequencing batch reactor (SBR) to assess if the design methodology was valid. A range of advanced microbial techniques were applied to assess the contribution and mechanism of different PAOs. This work furthers our understanding for RSS process design, particularly on how to actively select and enrich for *Tetrasphaera*.

MATERIALS AND METHODS

Waste activated sludge (WAS) collected from Luggage Point Sewage Treatment Plant, in Brisbane, Australia was used for the extended anaerobic batch tests. Each reactor had a working volume of 1 litre and was continuously mixed and sparged with nitrogen gas to ensure anaerobic conditions. Samples were collected at the start of each batch test and subsequently at 8-hour intervals up to 48 hours and analysed accordingly for NH_4-N, PO_4-P, COD, sCOD, TSS/VSS and VFAs. The RSS sequencing batch reactor was operated with a working volume of 4L and inoculated with WAS from Luggage Point STP. The system was operated on a 12-day solids retention time (SRT), a SBR HRT of 16 hours and an SST HRT of 16 hours. 2L of feed per cycle, comprising average influent COD, NH_4-N and PO_4-P concentration of 494.5±16.4mg COD/L, 55.6±5.1 mgN/L and 10.9±0.8 mgP/L was fed to the reactor. The COD was a mixture of glucose, casein amino acids, glycerol, acetate and propionate proportioned to mimic real wastewater. Each cycle lasted 8 hours (3 cycles per day) and comprised four main phases where alternating anoxic/aerobic conditions were employed, followed by a waste, settle, and decant phase. 200mL of RAS (10%) was transferred to the sidestream tank after the decanting phase mixed and then 200mL returned to the SBR for the next cycle.

RESULTS AND DISCUSSION

Extended anaerobic batch tests highlighted P release occurring within 16-24 hours of extended anaerobic conditions (**Figure 1a**). The initial rate of orthophosphate release (PO_4-P) was determined to be inconsistent with both PAO maintenance and general biomass decay. P release associated with substrate uptake was assessed to be occurring during the first 16-24 hours, after which a transition occurs to a constant rate likely associated with cell decay. Synergistically, the VFA concentration also appears to increase at this transition point (**Figure 1b**). These observations suggested an SST HRT of 16-24 hours could be optimal for enabling efficient RSS performance. An RSS SBR system was then implemented and operated with an SST HRT of 16 hours to test the substrate related P exhaustion hypothesis.

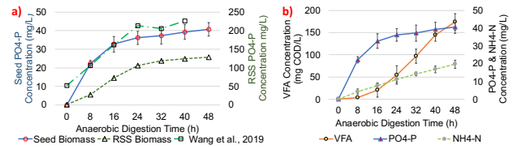

Figure 1. a) Phosphorus release profiles from extended anaerobic batch tests with seed biomass taken from a 5 stage Bardenpho bioreactor (Luggage Point STP), biomass acclimated in an RSS SBR system and P release from Wang et al., 2019. b) VFA, PO4-P and NH4-N concentration profiles from the extended anaerobic batch tests with seed biomass.

The RSS SBR system reached steady state within 3 SRT's and was operated for a total of 180 days. The effluent NH_4-N, NO_x-N and & PO_4-P effluent concentrations measured 0.10±0.14 mgNH_4-N/L, 6.45±0.14 mgNO_x-N/L and 0.35±0.43 mg PO_4-P/L, respectively. Microbial community analysis through FISH, 16s rRNA sequencing and Illumina metagenomics analysis indicated that operational conditions implemented in the RSS SBR were able to enrich for *Tetrasphaera* and maintain a stable presence in the system for the duration of the reactor operation, as highlighted in **Table 1.** Contrary to full-scale studies showing GAOs in lower abundance in full scale RSS systems, *Competibacter*, *Defluviicoccus* and *Micropruina* (not shown in **Table 1** but validated through metagenomics) were observed to be in high abundance in the lab scale RSS system. It is not currently clear if this observation is due to the SST HRT or due to other unknown factors. Nevertheless, it does highlight that both VFA driven and fermenting GAOs did not impact P removal stability in the RSS system. RSS can likely rely on two or more P removal mechanisms occurring in tandem, the fermentative PAO metabolism (e.g. *Tetrasphaera*) and VFA-driven PAO metabolism (e.g. *Accumulibacter*) supporting P removal. *Ca*. Microthrix were not observed in this study, unlike Petriglieri et al. (2022), who identified this group as a contributor to P removal in some RSS plants. A follow up extended anaerobic batch test was conducted using acclimated biomass from the RSS reactor. In agreement with the original batch tests (**Figure 1a**), P release associated with substrate uptake appears to occur within 16-24 hours before transitioning to a slower constant rate.

Table 1. FISH quantification for RSS system day 63 and day 137 (biovolume ± standard error of the mean).

Target Organism Probe Mix	Day 63 %vol fraction	Day 137 %vol fraction
Tetrasphaera TetMix	24.7±10.3	18.2±5.1
Accumulibacter PAOMIX	4.7±2.7	2.3±1.6
Competibacter GAOMix	6.4±1.9	7.1±1.6
Defluviicoccus DEFMix	7.4±2.4	8.1±1.9

Single cell Raman spectroscopy (SCRS) was also performed on samples from the main RSS reactor and the SST before RAS fermentation to ascertain intracellular polyP content within *Tetrasphaera* and *Accumulibacter*. **Figure 2** highlight changes in intracellular polyP content (expressed as Raman peak intensity, CCD counts) across key SBR phases. Results indicate *Tetrasphaera* released most of their polyP reserves during the anaerobic phase in the SST rather than in the mainstream system, which is in agreement with Fernando et al. (2019). Moreover, despite the substantially higher abundance of *Tetrasphaera*, both *Tetrasphaera* and *Accumulibacter* activity were instrumental towards achieving P removal, with 57% of the P stored by *Tetrasphaera* and 43% stored by *Accumulibacter*.

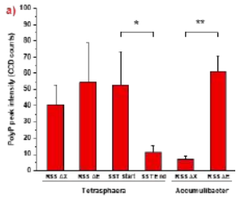

Figure 2. Intracellular polyP content (expressed as Raman peak intensity) in FISH-identified *Tetrasphaera* and *Accumulibacter* cells in different samples (error bars represent standard error, *p<0.05, **p<0.01).

CONCLUSIONS

Outcomes from this work highlights how the enrichment of both PAO groups can be beneficial for stable P removal performance and supports the hypothesis that intracellular polyP exhaustion associated with substrate uptake can be used a selection tool for SST HRT in applications of RSS. It also validates that an SST HRT between 16-24 hours could be used as a design basis for RSS applications to enrich for *Tetrasphaera* PAOs. It is suggested further work should be carried out to examine the influence of temperature on the SST HRT range.

Abstract
Pharmaceutical and personal care products (PPCPs) consumption was increased mainly during COVID-19 pandemic. Nature-based solutions, such as biofilters could be a technological alternative for rural areas and developing countries. The objective of this study was to evaluate the fate of PPCPs within biofilters based on hazelnut shell/sawdust and fed domestic wastewater. Wastewater (influent/effluent), plant, and soil samples were collected for PPCPs analysis from 4 biofilters. Chromatographic analysis (LC-DAD-MS) used C18 column and with/without clean-up method's extraction. Caffeine (CAF), losartan (LOS), ibuprofen (IBU) and triclosan (TRI) were monitored. The results showed that PPCP concentrations at influents and effluents were between 0.35 and 4.57 µg/L and from 0.01 to 0.48 µg/L, respectively. In plants, PPCPs (LOS, IBU and TRI) accumulated at concentrations between 0.02 and 1.68 µg/L; while that, soil concentrated between 0.02 and 9.08 µg/L. Therefore, soil was the main fate of lipophilic PPCPs and plants when PPCPs are more mobile.

Keywords
Biofiltration; PPCPs, Plant; Soil; Treatment; Wastewater

INTRODUCTION

Pharmaceuticals and personal care products (PPCPs) are among the relatively new and concerning contaminants detected around the world (Almeida et al., 2021). Caffeine (CAF, $C_8H_{10}N_4O_2$), Ibuprofen (IBU, $C_{13}H_{18}O_2$), Losartan (LOS, $C_{22}H_{23}ClN_6O$) and Triclosan (TRI, $C_{12}H_7Cl3O_2$) were studied, due to the high rate of usual consumption and during the COVID-19 pandemic (Buchan and Quiñones et al., 2016; Chicaiza et al., 2020). The fate and time half-lives of PPCPs are variable when assessing environmental risk by the influence of dispersion, degradation, or sorption (O´Malley et al., 2021). For the antibiotics, NSADs, and physical stimulants class, maximum concentrations of 0.0199 µg/mL were detected in influent and effluent samples, respectively (Papageorgiou et al., 2016; Dhangar and Kumar, 2020). Furthermore, during the confinement due to the SARS-CoV-2 pandemic, the consumption of PPCPs was high (<0.1–1.19 µg/mL), and it becomes necessary the treatment, as using biofilters that are nature based on solutions. Biofilters based on plant–earthworms–microorganisms are particularly interesting for developing countries, due to their easy operation and low-cost (Tejedor et al., 2019). Support materials are extremely important when using this technology since they impact in the treatment-cost. Technologies that utilize plants (as constructed wetlands) remove contaminants associated rhizosphere, have a pronounced ability for uptake and phyto-depuration that function as a media nature and biological. Ibuprofen has reported being removed using plants at concentrations to up 0.06 µg/mL within WWTPs (He et al., 2017). In this work, we study the evaluation of 4 biofilters typologies (BM, BEM, BH and BPM) in lab-scale, as a natural environment of removal of PPCPs, and identify the mechanisms involved in biotic components/support, to establish the fate and mobility of the PPCPs studied, from rural domestic wastewater Chilean.

MATERIALS AND METHODS

Materials

Hight Performance Liquid Chromatography (HPLC) grade methanol (99%, CH_3OH), water (100%, H_2O) and acetonitrile (99%, CH_3CN) were obtained from Sigma-Aldrich (Santiago, Chile), Hydrochloric acid (32%, HCl) and Ammonium hydroxide (92%, NH_4OH) were obtained from Spectrum (Santiago, Chile). Analytical-grade formic acid (88%, CH_2O_2) was obtained from Merck (Brazil). Caffeine (99%, $C_8H_{10}N_4O_2$, CAF), Ibuprofen (98%, $C_{13}H_{18}O_2$, IBU), Losartan (99%, $C_{22}H_{23}ClN_6O$, LOS) and Triclosan (99%, $C_{12}H_7Cl_3O_2$, TRI) standards were purchased from Sigma–Aldrich (Santiago, Chile). Oasis HLB cartridge-SPE (6 cc, 200 mg) were purchased from Waters Corp., Milford, USA. Fiberglass filters (ø = 0.45 µm) and nylon syringe filters (ø = 0.22 µm) were obtained from Millipore, Billerica, MA.

Experimental models

The domestic wastewater samples to feed the biofilter systems were taken in situ at a domestic wastewater treatment plant (WWTP), located in the Santiago Metropolitan Region, Chilean. The location of this plant corresponds to the coordinates (33°0'29.41"S.; 70°53'21.50"W), WGS-84 datum. The material used in the active layer of the biofilters was a mixture of hazelnut shells and sawdust. The shell was crushed and sieved in 2 mm. The proportion used was 75% sawdust and 25% hazelnut shells (v/v). *Eisenia feotida* Saving earthworms were used with 57 individuals per biofiltration column, following the density recommended by the literature of 10,000 individuals/m^3 (Kumar et al., 2016). The plants *Zantedeschia aethiopica* L., 1 individual per column was used, according to Vera-Puerto et al., (2021). The physical model consisted of 4 biofiltration typologies. Each column was divided into 3 different horizontal layers: active (sawdust/hazelnut shell, 0.6 m high), medium (gravel sand, 0.2 m high) and support (gravel, 0.1 m high). The columns used were polyvinyl chloride (PVC), with a diameter of 0.11 m and a height of 0.9 m. The hydraulic load rates used corresponded to a nominal value of 2 (m^3/m^2 d) and applied to 4 biofilters of different types operating. The typologies used were: biofilter based on microorganisms (BM), on earthworms (BEM), on plants (BPM), and hybrid microorganism+earthworms+plants (BH). The feed with the wastewater was applied to each biofilter a regimen of 2 hours of flow and 2 hours of rest, during 5 day/week from March to December of 2022. In this way, the corresponding nominal flow for rate 2 biofilters was 9.5 (L/d).

Analytical methods

Wastewater samples (influent) from rural WWTP (33°00'29.7"S 70°53'22.7"W) located close to Santiago city, which uses vermifiltration technology as secondary phase. Biofilters wastewater samples (effluent) at lab-scale was collected using an aliquot of 0.5 L each typology biofilters (BM, BEM, BPM, y BH) by 24 hours of end a cycle operational (2 m^3/ m^2 d). In lab, centrifugation (5000 rpm, 25 min) and vacuum filtration (fiberglass filters: 0.45 µm (GF/B, Whatman, UK), nylon syringe filters: 0.22 µm (Millipore, Billerica, MA) were applied prior to SPE/HLB (Solid Phase Extraction–Hydrophilic Lipophilic Balance) extraction method. Finally, wastewater samples were stored/kept refrigerated under dark conditions at 4 °C. Root and Sheets/Stem tissue were extracted from 0.5 g of frozen plant tissue. Samples were ground to a fine powder in liquid nitrogen and mixed with 1 mL of 0.1 M HCl/acetonitrile (50/50, v/v) by vortexing, and after centrifugation at 12 000 rpm for 15 min under 4 °C. Solid phase extraction (SPE) was performed with Oasis HLB cartridges (6 cc/200 mg), preconditioned with 6 mL methanol, and equilibrated with 6 mL deionized water. After loading 1200 µL sample, the cartridge was washed with 12 mL deionized water and eluted with 12 mL of 25% NH_4OH: MeOH (8/92, v/v). To determine the PPCPs concentration in soil samples, solid-liquid extraction method. 2 g of soil (organic support of biofilters in different points) were weight in plastics tubes with lids. Subsequently, 10 mL of methanol were used for the extraction method. The mixture was stirred for 1 h and centrifuged at 15,000 rpm for 20 min at 4◦C.

Chromatographic analysis

Wastewater, plant, and soil samples concentrations were determined by LC-DAD-MS (Schimadzu, Kyoto, Japan). The column was a Cl Kinetex C18 (2,6 um, 100 mm x 2,1 mm). The wavelength for the quantification were 205 nm (CAF) and 223 nm (LOS, IBU and TRI), in PDA. MS were evaluated in Full Scan mode (m/z) of the PPCPs, in ESI (+) and (-). In (+): CAF (195), LOS (423); (-) IBU (205), TRI (289). The PPCPs compounds were determined in gradient condition using formic acid 0.2% (A) and acetonitrile (B). Flow was set at 0.2 mL/min. The column was thermostated at 35 °C The retention times under these conditions were 4.322, 15.910, 17.557, and 18.616 min for CAF, LOS, IBU and TRI, respectively.

Data analysis

Data were acquired by means of Postrum and processed/recollected applying Microsoft Excel Software. The contaminant removal behavior was obtained as a linear function, where the independent variable is the concentrations of each system and adjusted for the statistical measurement of R^2.

RESULTS AND DISCUSSION

Table 1 shows the occurrence data of the 4 selected PPCPs inside wastewater (influent/effluent), plant and soil samples from biofilters based on hazelnut shell/sawdust (4 typologies). Within each biofilter (BM, BEM, BH and BPM) they present very high concentrations, with respect to the PPCPs/Matrices, in values of up to 0.722, 0.424, 0.424, 0.612 µg/mL, respectively. In wastewater, results were obtained from biofilters versus PPCPs (CAF, LOS, IBU and TRI) presenting a concentration variation in ug/mL from (0.023–0.722, BM), (0.299–0.424, BEM), (0.198–0.424, BH) and (0.392–0.612, BPM). Meanwhile, plant reported values in BH and BPM of 0.010 to 0.754 µg/L, and 0.017 to 0.318 µg/L for the PPCPs, respectively. LOS, IBU and TRI were very prevalent concentrations ranging between 0.01 and 1.68 µg/L in the biofilters of plants and hybrid. Soil sample concentration were between (0.027-0.362, BM), (0.015-0.353, BEM), (0.021-0.720, BH), (0.024-9.082, BPM) for biofilters. Caffeine was analysed low with quantification (<LQ) and detection limit (<LD). Losartan presented concentrations from up to 0.054 µg/mL in within biofilters analysed. In the case Ibuprofen presented high concentration in the soil with 9.082 µg/mL due influence the sorption. Triclosan were the range of 0.021 to 0.031 in within biofilters analysed.

Table 1. Wastewater, plant, and soil with total range of concentrations (min–max in µg/mL) with mean values in brackets and limit of detection/quantification. LQ: is the limit of the calibration curve; LD: the limit is 3.3x lower than that of the calibration curve.

Matrices	PPCPs	BM	BEM	BH	BPM
Wastewater	CAF	<LD	<LD	<LD	<LD
	LOS	(0.023-0.475)	(0.299-0.401)	(0.198-0.424)	(0.392-0.423)
	IBU	0.722	0.424	0.234	0.612
	TRI	<LD	<LD	<LD	<LD
Plant	CAF			<LD	<LD
	LOS			(0.010-0.016)	<LQ
	IBU			(0.156-0.754)	(0.156-0.318)
	TRI			0.017 – 0.018	0.017
Soil	CAF	<LD	<LD	<LD	<LD
	LOS	(0.030-0.054)	(0.015-0.038)	(0.029-0.044)	(0.024-0.039)
	IBU	(0.161-0.362)	0.353	0.720	(0.615-9.082)
	TRI	(0.025-0.027)	(0.023-0.026)	(0.021-0.027)	(0.024-0.031)

For caffeine and triclosan, their concentration (µg/L) ratio in domestic wastewater/soil was consistently higher, with from 0.02–0.452 (TRI) and 0.006–0.070 (CAF) in agriculture sectors and from irrigation of treated effluents with concentration of 0.116–3.529 (TRI) and 0.0179–0.178 (CAF), suggesting that these compounds might be unsuitable as chemical markers of wastewater leakage (Tran et al., 2019; Mojiri et al., 2021). Moreover, triclosan is a broad-spectrum antibacterial agent present as an active ingredient in some personal care product such as soaps, toothpastes and sterilizers, with and low average in effluents (<40 µg/L) (Olaniyan et al., 2016). Losartan is among the most prescribed drugs in Chile in people with high blood pressure (ISP, 2022). According to He et al., (2017), concentrations of ibuprofen was analysed in the liquid medium with plants, that an immediate exponential-wise decline of IBU contaminant was observed with 0.45 ± 0.10 µg/mL.

Abstract
Benzene, Toluene, Ethylbenzene, and Xylene (BTEX) are among the major contaminants in refinery wastewater, and they pose serious detrimental effects on both human and environmental health. Although there are existing treatment methods targeting the removal of BTEX such as coagulation and filtration, there is still a need to improve the treatment scheme to ensure a safer and more effective process for their removal. In this study, green-synthesized iron oxide nanoparticles were used to improve the physical properties and performance of PVDF ultrafiltration membranes, and further functionalization using polyvinyl alcohol (PVA) was performed. The BTEX rejection of the optimum modified membrane (PVDF-1%wt.Fe_3O_4) was 80% which increased to 94% upon further functionalization using PVA. The Flux Recovery Ratio (FRR) of the pristine membrane was 62% while that of the optimum modified membrane was 81% and increased further to 92% when blended with PVA, thus indicating a significant improvement in its antifouling capacity. The modified membranes also showed improvement in other properties such as mechanical, chemical, and thermal stability which is ideal for withstanding the operational conditions during the wastewater treatment process. Therefore, the modified membranes have good potential in providing an alternative means of removing BTEX from refinery wastewater before discharge to any receiving water body.

Keywords
BTEX; Green-synthesized Fe_3O_4; Nanoparticles; PVA; Ultrafiltration membrane; Wastewater

INTRODUCTION

The global water challenge that mainly originates from perilous human activities requires continuous approaches to tackle it. Emerging membrane technology offers possible solutions to ensure wastewater is properly treated before being discharged into the water bodies (Zhang et al., 2016). Functionalized PVDF membranes provide a safe and effective means to treat refinery wastewater to ensure their safe discharge into water bodies.

MATERIALS AND METHODS

All the chemicals used for synthesizing the nanoparticles, preparing the membranes, and analyzing the prepared membranes were purchased from Sigma Aldrich. Iron (III) chloride was used as the precursor for the green synthesis of the iron oxide nanoparticles. PVDF was adopted as the base membrane material. N-methyl-2-pyrrolidone (NMP) was used as the solvent for the preparation of the dope solutions. PVA was also used for the second step functionalization of the membranes and maleic acid was utilized as the cross-linking agent in this step. The rejection and antifouling capacity of the membranes were tested using Humic Acid (HA) and BTEX solutions. The chemical stability of the membranes was tested using BTEX, sodium hypochlorite, and chlorine solutions.
The iron oxide nanoparticles were synthesized using the green route by reducing the metal precursor with the aqueous extract of pomegranate leaves. The membranes were prepared with varying amounts of the green-synthesized Fe_3O_4 and cast through the phase inversion method and the second step functionalization of the membranes was also performed by phase inversion after blending the PVA into the dope solution, followed by subsequent cross-linking using maleic acid.

RESULTS AND DISCUSSION

A few of the results of the properties and performance of the green-synthesized nanoparticles and membranes are shown in Fig. 1. The XRD shows characteristic peaks indicating that the synthesized nanoparticles are Fe_3O_4 and the noisy patterns seen in the spectra reveal the presence of organic components in the synthesized nanoparticles. The FTIR confirms that the organic component has hydroxyl functional group which further contributed to improving the hydrophilicity of the membranes and enhanced the membranes' performance. The antifouling ability of the membranes significantly improved but reached an optimum at 1wt.%- Fe_3O_4.

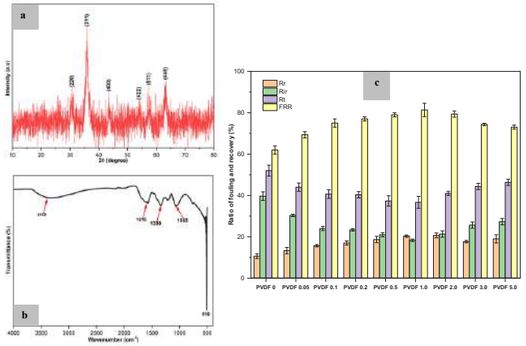

Figure 1. The properties of the green-synthesized nanoparticles and the membranes: (a) XRD of the green-synthesized nanoparticles; (b) FTIR of the green-synthesized nanoparticles; (c) antifouling behavior of the membranes

Abstract
Carbamazepine (CBZ) is one of the most frequently detected pharmaceuticals in various waters due to its extensive utilization and persistence in the environment. This study aimed to evaluate the CBZ removal through the Fenton process followed by a sequencing batch reactor (SBR). The results showed that CBZ mineralization was facilitated by subsequent biological treatment following the Fenton pre-treatment, supporting the hypothesis that the degradation intermediates from the Fenton process were more biodegradable. The CBZ removal by the Fenton process at neutral pH remained at 76.05%, implying that the combined system for CBZ removal may work at a neutral pH range. The blue-shifted signal in EEM spectra indicated the decomposition of the aromatic structure and the formation of molecular fractions. Due to the low biodegradability of CBZ, using the Fenton process as a pre-treatment for SBR-AS is a possible way to improve the aqueous CBZ removal efficiency.

INTRODUCTION

Carbamazepine (CBZ), a widely used anticonvulsant and mood-stabilizing drug for the treatment of epilepsy and bipolar disorder, has been one of the most frequently detected pharmaceutical compounds in the environment (Ferrer & Thurman 2012). Due to its molecular structure and chemical characteristics, CBZ showed persistence in conventional treatment processes (Hai *et al.* 2018). Although the CBZ removal tests by several well-known advanced technologies were reported previously, none of them was regarded as an effective treatment in WWTPs (Zhang *et al.* 2008). Thus, the discharge of CBZ residual through wastewater effluents leads to its widespread occurrence in natural water bodies, making CBZ one of the emerging and concerning contaminants. CBZ has been proposed as an anthropogenic marker of sewage contamination to assess water treatment quality (Kumar *et al.* 2016; Marcelo *et al.* 2017).

The Fenton process generates the hydroxyl radical which has a strong oxidizing ability without selectivity. It can decompose organic compounds easily to form oxidation intermediates or CO_2 as the end product. Although the contaminants may be fully degraded by the Fenton process, the mineralization rate remains relatively low (Mirzaei *et al.* 2017). The metabolites formed following the AOPs, such as ozonation and sonolysis, have been reported to be readily mineralized by the bioreactor (Prado *et al.* 2017). Along with the context, AOPs may not mineralize CBZ completely, but they shall reduce the toxicity and increase biodegradability, implying that the AOP may act as a pre-treatment process before biological treatment. It is noted that some resulting (by-)products of CBZ, such as acridine, may have higher toxicity than the parent compound when CBZ is only partially mineralized (Vogna *et al.* 2004). Therefore, effective pre-treatment should be capable of reducing the toxicity and enhancing the biodegradability of the effluents that can be effectively treated by conventional activated sludge. This study aimed to explore the feasibility of the Fenton process as a pre-treatment, followed by a biological sequencing batch reactor (SBR) for CBZ removal.

MATERIAL AND METHODS

The Fenton pre-treatment was conducted in a 1 L beaker under ambient temperature (22±1°C). The initial concentration of CBZ was 50 μM. The H_2SO_4 and NaOH were used for pH control. The Fenton pre-treatment started with the addition of H_2O_2 into the $FeSO_4$ solution, and the process was quenched after 30 minutes and the pH value was adjusted to around 7 for subsequent biological reaction. The pre-treated solution was introduced to the influent tank of the biodegradation treatment in SBR. Samples were collected at the beginning, 1, 2, 3, 4 hours after the biological process started. They were analyzed for CBZ residuals, TOC, EEM spectra, mass spectra and COD after 0.22 μm filtration.

RESULTS AND DISCUSSION

CBZ removal by combined Fenton process and activated sludge treatment

The CBZ removal results by the combined Fenton process and activated sludge treatment system of different pre-treatment conditions are shown in Figure 1. The biodegradability was evaluated using CBZ removal experiment by activated sludge without Fenton pre-treatment. The low degradation rate indicated that the biological treatment was not efficient in removing CBZ from wastewater. Since CBZ is moderately hydrophobic, its removal via sorption onto activated sludge has been reported in the range between 5 to 20% only (Zhang *et al.* 2008; Wijekoon *et al.* 2013). In addition, CBZ contains an amide group in structure, which is an electron-withdrawing functional group that makes CBZ resistant to biodegradation (Tadkaew *et al.* 2011). In short, the removal of CBZ by activated sludge was mostly via sludge sorption rather than biodegradation, and the removal was poor and unstable.

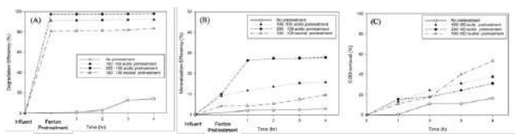

Figure 1. The (A) degradation, (B) mineralization, and (C) COD removal efficiencies of CBZ by combined Fenton pretreatment and activated sludge treatment.

Alternatively, the Fenton process was utilized as a pre-treatment to decompose CBZ before biodegradation. In Figure 1, the degradation, mineralization, and COD removal showed the activated sludge treatment was able to further degrade the CBZ oxidation by-products after Fenton pre-treatment. The pre-treatment with 200 μM H_2O_2 and 100 μM Fe^{2+} in acidic condition showed the highest relative degradation and mineralization of 97.90% and 28.87%, indicating the oxidation by-products of CBZ was more readily biodegradable than the parent compound CBZ.

The Zahn-Wellens test of CBZ and its oxidation (by-)products for evaluating their inherent biodegradability was performed by Monsalvo et al. (2015), showing that CBZ inhibited microbial activity, and the biodegradability of CBZ oxidation products by the Fenton process was enhanced and their toxicity was reduced. The Fenton oxidation was used to decompose the non-biodegradable organic compounds into fragments which were much more easily degraded by microorganisms. In this study, the Fenton process was found effective as a pre-treatment before activated sludge treatment to improve aqueous CBZ removal efficiency.

EEMs for CBZ degradation by the combined system

The excitation-emission matrix (EEM) fluorescence spectrometry was employed to characterize dissolved organic matters in water. The EEM spectra of different pre-treatment conditions were shown in Figure 2, and the original CBZ EEM features and the positions of fluorophores were sketched in Figure 2 (A). In Figure 2 (D), (G), and (J), signal C (HA-like, $\lambda_{ex}/\lambda_{em}$ = 300-370 nm/ 400-500 nm) was an apparent peak after the Fenton oxidation compared to Figure 2 (A), indicating the oxidation by-products contained HA-like structures which were likely to form in CBZ degradation.

The pre-treated solution was introduced into the activated sludge aeration tank for biological treatment, and the intensity of signal C in Figure 2 (E), (H), and (K) decreased because of the dilution effect. Signals A (FA-like, $\lambda_{ex}/\lambda_{em}$ = 220-270 nm/ 380-550 nm), B (Tyrosine-like, $\lambda_{ex}/\lambda_{em}$ = 225-237 nm/ 309-321 nm), and T (Tryptophan-like, $\lambda_{ex}/\lambda_{em}$ = 225-237 nm/ 340-381 nm) shown in Figure 2 (B) were the background resulting from the existence of activated sludge. Slight biodegradation was found without the Fenton pre-treatment in Figure 1 and the EEM in Figure 2 (B) and (C) also showed a similar result. With the Fenton pre-treatment, the biological removal of CBZ shifted the fluorescence signals towards a shorter wavelength (Figure 2 (F), (I), and (L)). To be more specific, signals A and C were blue-shifted along the excitation and emission axes. The phenomenon of EEM signal blue-shifting may be associated with the following reasons: (i) the decomposition of aromatic moieties, (ii) the breakage of large molecules into smaller fragments, (iii) the decrease in the number of aromatic rings, (iv) the decrement of conjugated bonds in a chain structure, (v) the conversion of a linear system to a non-linear system, and (vi) the elimination of particular functional groups including carbonyl, hydroxyl, and amine groups (Valencia *et al.* 2013). The blue-shifted results of EEM indicated the decomposition of the aromatic structure of CBZ and the resulting molecular fractions after activated sludge treatment. Tyrosine- and tryptophan-like (peaks B and T) compounds are small organic matters suitable for microbial activity and are predominant in wastewater (Henderson *et al.* 2009). The occurrence of signal T represented the organics under microbial oxidation emerging after SBR treatment, confirming the enhancement of the overall biodegradability of CBZ and its fractions.

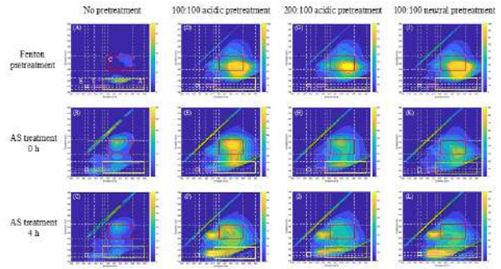

Figure 2. The EEM fluorescence spectrometry of the CBZ degradation by Fenton process in different stages of the combined Fenton process and activated sludge treatment.

CONCLUSION

CBZ possessed resistance to direct biodegradation due to its physicochemical properties, and the result showed that only 14.21% of CBZ and 2.86% of TOC were removed when CBZ was directly treated by SBR for four hours. The combined system in this study, in which CBZ was pre-treated with the Fenton process and the resulting by-products were introduced into the sequencing batch reactor, was able to remove CBZ. The almost complete removal of CBZ and up to 27.87% TOC removal were found when CBZ was pre-treated by the Fenton process. Moreover, the CBZ degradation efficiency by Fenton in neutral conditions remained at 76.05%, implying that it is feasible to combine the Fenton pre-treatment and biological treatment for CBZ removal in a neutral environment, which may solve the practical problem of pH adjustment when applying classic Fenton process to treat real wastewater. The blue-shifted EEM signal inferred the decomposition of aromatic rings and the smaller fragments' formation. Tyrosine- and tryptophan-like signals that represented the organics under microbial oxidation appeared after SBR treatment, enhancing the overall CBZ biodegradability. This study showed the possibility of using the Fenton process as a pre-treatment before conventional biological treatment when treating recalcitrant emerging contaminants. The removal efficiency of CBZ in the real wastewater by the combined system needs further study to evaluate the impact of co-dissolved molecules on the wastewater treatment performance.

Abstract
Removing contaminants from biogas is an important step in making biogas a usable product. On current work a genome scale metabolic model was developed for a designed consortium of bacteria containing both methanogenic and sulfur oxidizing bacteria (SOBs) to analyse the consortium capability of removing H_2S and reducing CO_2 concentration in produced biogas. Results show that by using such a consortium, H_2S could be consumed nearly completely by SOBs and CO_2 concentration decreases by 0.67 in comparison to the culture without SOBs as chemolithoautotrophic bacteria utilize CO_2 as carbon source and H_2S as energy source. Due to anaerobic digestion, for using such a consortium, it is necessary to integrate the process with nitrate stream as final electron acceptor. The model predicts that H_2S post-treatment process from produced biomass is capable of being removed by using the consortium.

Keywords (maximum 6 in alphabetical order)
Biogas treatment; microbial consortium; genome scale metabolic model; sulfur oxidizing bacteria

INTRODUCTION

Biogas is a valuable renewable energy source that is produced due to anaerobic digestion of wastes and wastewater (De Arespacochaga, Valderrama et al. 2014). The obtained biogas from anaerobic digestion is a mixture of different components whose composition depends on the source and varies over time due to the variation in substrate (Pirolli, da Silva et al. 2016). The main components of the biogas are methane (CH_4: 50-60 % vol.), carbon dioxide (CO_2: 34-38 % vol.) and traces of other compounds such as hydrogen sulfide (H_2S: 500-20000 ppm). To further use biogas as a fuel, biogas upgrading is needed. Among the contaminants, H_2S has received the most attention for biogas use for electricity production due to its high corrosivity. Numerous methods have been developed for H_2S removal from biogas that could be categorised in physical, chemical and biological methods. In all cases, an extra step is added to the biogas production process, which introduces extra costs and operational complications to the system(Torres, Marín et al. 2020). Although H_2S is sometimes completely removed, there is still a significant amount of CO_2 (about 30%), which strongly reduces the specific heat value of the biogas and must be removed for obtaining biomethane. Thus, finding new methods to reduce costs and operational issues by removing H_2S and CO_2 from biogas streams is desirable.

In the current study, modelling tools were used to investigate the following hypothesis: as sulfur oxidizing bacteria (SOB) are chemolitoautotrophs that consume CO_2 as carbon source and H_2S as energy source, a consortium of SOB and methanogenic bacteria would lead to a simultaneous reduction in the content of both contaminants in biogas. In this way, a genome scale metabolic model for a methanogenic bacterium was reconstructed and modified as a consortium genome scale model containing the core metabolism of chemolitoautotrophs to analyse the behaviour of the consortium in producing methane and removing H_2S and CO_2.

MATERIALS AND METHODS

For developing a genome scale metabolic model in order to analyse the behaviour of bacterial consortium in anaerobic digestion, the genome scale metabolic model reported for methanogenic bacteria *Methanosarcina barkeri* (Feist, Scholten et al. 2006) was modified to be used as a multi-cell model. The consortium is assumed to contain methanogen and sulfur oxidizing bacteria. To reconstruct the multi-cell model, the core metabolism of SOB represented in databases e.g., KEGG, UNIPROT, BIGG and biochemical reactions that are reported in literature, were added to the *Methanosarcina barkeri* model. All the data were gathered in a spreadsheet.

The metabolic network was processed using linear programming and constraint-based modelling concepts as mathematical tool. Calculations were done using MATLAB software, COBRA toolbox and the glpk (GNU Linear Programming Kit) package. The methane production was defined as objective function and Flux Balance Analysis (FBA) was used to find the fluxes of all reactions. All the calculations of FBA are simplified if Eq. (1):

$$\text{Max } Z = c \cdot v \qquad S \cdot v = b \qquad v_{min} < v < v_{max} \qquad \text{Eq. 1}$$

where Z is the objective function which is methane production in here, c is the coefficients of objective function, S is the stochiometric matrix of the metabolism (number of metabolites × number of reaction fluxes (unknown)), b is the right-hand side vector which is known reaction fluxes and v_{min} and v_{max} are the upper and lower bounds of fluxes. For proceeding FBA calculations for H_2S and CO_2 removal, the fluxes are multiplied by ratio of reported mean maximum specific growth rate of SOBs to methanogens. Considering the anaerobic, nitrate was introduced as final electron acceptor for SOB. The results of FBA were analysed in order to investigate the capability of consortium for in-situ H_2S and CO_2 removal. Also, for further investigation, Dynamic FBA was run for the model to see how the concentrations change with time.

RESULTS AND DISCUSSION

The initial network for *Methanosarcina barkeri* had 690 reactions and 215 reactions containing C, S, and N metabolic pathways, were added for building the multi-cell model. The reactions were categorised in 8 metabolic pathways among which 21% of reactions were in cofactor metabolism category. There were 52 non-gene associated reaction and the metabolite counts involved in model was 932. The results of model characteristics are illustrated in Table 1 and Figure 1.

Table 1. Detailed information about the metabolic network reconstructed for multi-cell model.

	Features	Model
Reactions	Total Reactions	905
	Metabolic Reactions	820
	Gene Associated Reactions	853
	Non-gene Associated reactions	52
	Exchange Reactions	14
	Transport Reactions	71
Metabolites	Number of Metabolites	932

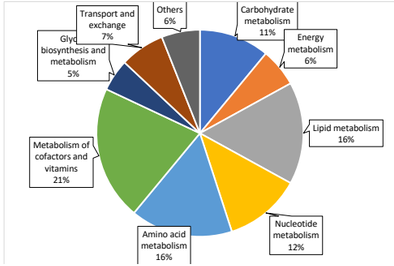

Figure 1. Contribution of pathways in metabolic model.

Model evaluation for methane production and H_2S and CO_2 Removal

The μ_{max} for methanogens is reported to be between 0.015 to 0.022 h^{-1} (Sowers, Nelson et al. 1984) and the FBA prediction for biomass growth is 0.025 h^{-1} that shows model has an acceptable prediction rate, of course with an over prediction which is reported to be accepted in FBA. Results of CH_4 production and concentrations of H_2S and CO_2 at the end of a batch culture is represented in Table 2. Produced H_2S in anaerobic digestion could be nearly completely consumed by SOBs because of the higher growth rate of SOBs (μ_{max} = 0.055) in comparison to slowly growing methanogens (μ_{max} = 0.025). Also, Table 2 shows that the CO_2 production by the consortium culture is reduced by 67% in comparison to that of a SOB-free methanogenic culture.

Table 2. Results of CH_4 production and concentrations of H_2S and CO_2 at the end of a batch culture.

Condition	Methane Production (mmol/L)	H_2S Production (mmol/L)	CO_2 Production (mmol/L)
Experiment	120	0.001	65
Methanogenic model	128	0.0012	69
Consortium model	116	$7 \cdot 10^{-7}$	22

Results of dynamic FBA are also illustrated in Figure 2a for methane and CO_2 and in Figure 2b for H_2S. In the methanogenic culture, the H_2S and CO_2 concentration increased over time. However, concentrations are predicted to be much lower in the consortium culture. The reduction of CO_2 is caused by the chemolithoautotrophic behaviour of SOBs as CO_2 is consumed as carbon source.

CONCLUSIONS

From the results of the reconstructed metabolic model for a consortium of methanogenic and SOB bacteria, the consortium is capable of in-situ removing H_2S while reducing the CO_2 concentration. Then, an external biogas treatment step can be removed to reduce costs while increasing safety. Model-based testing on the hypothesis of chemolithoautotrophic behaviour of SOBs proved successful.

Anticancer Drugs Affect the Performance and Microbiome in an Aerobic Granular Sludge System Operated in Sequential Batch Reactor

Abstract
The consumption of anticancer drugs (also known as chemotherapy drugs or antineoplastic drugs) has augmented over the last decades due to increased cancer incidence. Although there is an increasing concern about the presence of pharmaceutical compounds in natural environments and urban/domestic wastewater, anticancer drugs used in chemotherapy and anticancer medication have received less attention. We found three anticancer drugs commonly detected in influents of WWTPs can significantly reduce the efficiency of nitrogen removal and decrease the abundance of bacterial, archaeal, and fungal communities in an aerobic granular sludge (AGS) operated in sequential batch reactor. These results were observed at concentrations commonly detected in wastewater influents suggesting increased attention should be paid in the future for removing these substances from wastewater as they may impact overall´s system wastewater treatment performance and microbial communities.

INTRODUCTION

Cancer is a significant global health concern responsible for approximately 10 million deaths and almost one out of every six deaths in 2022 according to the World Health Organization (WHO). This increase in cancer incidence has led to a significant increase in the use of drugs that combat cancer (referred to as anticancer drugs, chemotherapy drugs or antineoplastic drugs) over the past two decades. A recent review study showed that anticancer drugs can pass through the entire water system in urban areas, from hospitals and wastewater treatment plants (WWTPs) to rivers and groundwater (Castellano-Hinojosa et al. 2023). Membrane bioreactors (MBR) is the main biological technology that has been examined for removing anticancer drugs from wastewater with removal efficiencies ranging from 20-90% depending on the type of anticancer drug and treatment concentration. New biological techniques such as aerobic granular sludge (AGS) systems are being explored and improved for the removal of common contaminants [e.g., organic matter and nitrogen (N)] and emerging hazardous pollutants (e.g., pharmaceutical compounds such as antibiotics). However, it is unknown how the presence of these substances at different concentrations may impact overall system´s performance in terms of removal of carbon (C) and N and the microbiome (abundance and diversity of bacterial, archaeal and fungal communities). Therefore, we examined the effect of three anticancer drugs commonly detected in influents of WWTPs applied at three different representative concentration levels (low, mid, and high) on the physicochemical performance and abundance of total bacterial, archaeal, and fungal communities in a AGS operated in sequential batch reactor (SBR).

MATERIALS AND METHODS

The bioreactor had a height of 45 cm and a diameter of 9 cm and an operational volume of 2.5 L, of which 50% was exchanged per cycle. The hydraulic retention time was 8 h and the cycles, and each cycle consisted of four stages: 3 minutes for adding synthetic water, 240 minutes of constant aeration, 3 minutes for decantation of the granules, and 4 minutes for discarding the effluent. Air was supplied to the bottom of the bioreactor through fine bubbles. The bioreactor was firstly inoculated with 1 L of activated sludge from Los Vados (Granada, Spain) WWTP. The bioreactor was fed from the top of the bioreactor using a peristaltic pump (Watson Marlow, UK) with synthetic wastewater simulating urban sewage: CH_3COONa 1.5 g L^{-1}, NH_4Cl 0.25 g L^{-1}, $MgSO_4{\cdot}7H_2O$ 0.1 g L^{-1}, K_2HPO_4 0.085 g L^{-1}, KCl 0.04 g L^{-1}, and KH_2PO_4 0.03 g L^{-1}. The bioreactor operated for a month as a steady-state phase until it reached stable conditions. Then, four consecutive phases with different levels of anticancer drug concentration were run as follows: control without anticancer drugs, low (x1), mid (x10), and high (x100) concentration levels. Each phase had a duration of 30 operational days. Finally, the bioreactor was operated for an additional 30 days during which it was feed with synthetic wastewater without anticancer drugs to investigate whether the performance and microbial community of the system would return to initial levels; this phase was named as "residual". Cyclophosphamide (CP), tamoxifen (TMX), and methotrexate (MTX) were selected for this study as they are the most studied and frequently reported anticancer drugs in hospital effluents and wastewater influents and effluents (Castellano-Hinojosa et al. 2023). Low levels were 60, 1.5, add 40 ng L^{-1} for CP, TMX, and MTX, respectively. Physicochemical analysis was carried out two times per week during the experimental period. The concentration of acetate (CH_3–COO^-), ammonium (NH_4^+), nitrite (NO_2^-), and nitrate (NO_3^-) were analyzed using an ion chromatograph (Metrohm Ion Chromatograph, AG, Switzerland). Total nitrogen (TN) removal efficiency (%) was calculated as the difference in the concentration of $NH_4^+ + NO_2^- + NO_3^-$ between the influent and effluent. Granular biomass (50 mL) was collected in duplicate after 5, 15, and 30 days of operation for each the control, low, mid, high, and residual phases and the abundance of total bacterial, archaeal, and fungal communities quantified via quantitative PCR (qPCR).

RESULTS AND DISCUSSION

Application of anticancer drugs at different levels had no impact on the efficiency of acetate removal (Fig. 1A). However, anticancer drugs at mid and high concentrations levels significantly reduced efficiency of TN removal (Fig. 1B) to return to normal levels afterward at the residual phase. The application of anticancer drugs at mid and high levels significantly decreased the abundance of total bacterial, archaeal, and fungal communities compared to control and low phases but they recovered afterward at the residual phase. Overall, we found the effect of anticancer drugs on N removal and microbiome may depend on the concentration of anticancer drugs in wastewater.

* Dept. Civil Eng., Nagoya Institute of Technology (Nitech), yoshida.naoko@nitech.ac.jp

Abstract

This study optimized electricity recovery and the secondary use strategy for twelve tubular air-cathode microbial fuel cells (MFCs) in a 245L-scale reactor. The twelve pairs of MFC and ADP5090 in 245L wastewater can lighten two LEDs; each can provide 56-70 lx of illuminance at 15 cm of distance from the light and 0.39L/h (1.6L/h/m3) of aeration flow in wastewater. The time required to meet the planned effluent quality of BOD was 41 hours without aeration and decreased to 23 hours by the intermittent aeration driven by MFC power. The intermittent aeration also grew anammox and slightly enhanced ammonia removal. However, the improvement of individual MFCs is still required for the effective energy utilization of wastewater biomass.

Keywords

Microbial fuel cell, intermittent aeration, 1ow-voltage boosting, Anammox

INTRODUCTION

Microbial fuel cells (MFCs) have been applied in municipal wastewater treatment, however, the secondary use of recovered electricity has been rarely investigated. A simple strategy to boost the output voltage from MFCs involves connecting multiple MFCs in series or parallel. However, the MFCs connected in series often failed to boost the voltage due to voltage inversion (Oh and Logan, 2007) and a parallel connection has helped successfully boost the voltage; although, the voltage has never exceeded the theoretical voltage (Aelterman et al., 2006). Another way of boosting voltage using MFCs is by voltage multiplier circuits. So far, various DC/DC converters have been used to boost the voltage of MFCs and the input and output voltages range from 0.2 to 0.4 V and 3.3 to 2.0 V. The boosted electricity has been used as a power source for light-emitting diodes (LEDs) (Kim et al., 2019), pumps (Ge and He, 2016), and for charging a mobile phone battery (Prasad and Tripathi, 2021).

Here, we examined the applicability of a DC/DC converter, ADP5090, to boost tubular air-cathode MFCs using an anion exchange membrane (AEM) as the separator, which is superior to an MFC with a cation exchange membrane (CEM) in terms of power recovery (Itoshiro et al., 2022), and which was successfully scaled up to 226 L (Sugioka et al., 2022). First, the connection of 1–12 MFCs was evaluated based on the electricity produced and the electricity density; thereafter, the MFCs were boosted using two DC/DC converters, and the secondary use of the electricity was evaluated.

Panels C and D show the top and side views of the reactor, respectively. Panels E and F indicate the sponges hang in aeration part and a mini-air pump driven by MFC.The numbers in panel B indicate the MFC numbers.

MATRIALS AND METHODS

MFC and the operation of a continuous flow of sewage wastewater

A cylindrical MFC core (diameter: 5 cm; length: 1 m) with an air cathode made of a stainless-steel mesh surrounded by a carbon-based cathode was used, along with an AEM and nonwoven graphite fabric. As an anode, five carbon brushes (CBs) (ϕ 4 cm × 1 m) were placed around the MFC core in addition to the nonwoven graphite fabric. Twelve sets of an MFC core with five CBs were installed in a cuboid reactor (32×90×93cm) made of polyvinyl chloride and reinforced with wood (Fig.1) and were filled with 246 L of the effluent from a primary sedimentation tank (PST). The reactor was operated in a sewage wastewater treatment plant and continuously supplied with the PST effluent using a tubing pump for a hydraulic retention time (HRT) of 48 h. The MFC was connected to a 1:1 boost circuit ADP5090 (Linear Technology, MA, USA).

Boosting voltage by DC/DC converters for the secondary use

Six different connections by changing the number of a DC/DC converter, ADP5090 (Analog Devices, Norwood, MA, USA) per MFC were evaluated while a capacitor (1F) was charged;12P-4ADP was the connection of 12 MFCs in parallel, and it was connected to four ADP5090; (2P-ADP) × 6, was that connecting each of two MFCs in parallel to six ADP5090; (1MFC-ADP) × 12 and (1MFC-ADP) × 6 were those connecting twelve and six MFCs to DC/DC converters, respectively; and (1MFC-2ADP) × 6 was that connecting six sets of a connection of single MFCs to two ADP5090. A mini air pump (KPM130B-3A), fan (YDM2507C05F), or white LED (osw5dk5b62a-5v) were connected to the output. To evaluate the effect of the MFC's driven aeration on the removal of organic matter and nitrogenous compounds, the reactor was partitioned to have an aeration part (8% of total reactor) with hanging of 380 polyurethane (PU) sponges (1 cm^3) exposure with intermittent aeration by a mini air-pump driven by MFC. The cell voltage between the anode and cathode with the boost circuit connected was recorded every hour.

RESULTS AND DISCUSSION

Performance of individual and multiple-connected MFCs

The single MFC showed 16 mW of maximum electric power and the parallel connection of eight MFCs showed 3.5-fold higher increase to 58 mW, although the power density was the best from single MFC or two MFCs showed 0.104 and 0.11W/m^2 (Fig.2). The comparison of electricity recovery from MFCs with changing the combination ratio of MFC and a DC/DC converter, ADP5090, showed the highest efficiency of electricity recovery (60%) in the connection of the single MFC and ADP5090 one by one.

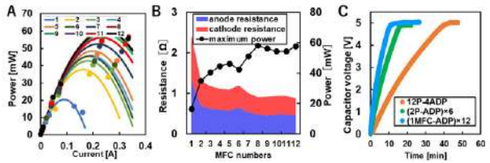

Figure 2. The effect on electric power by connecting MFCs and the ratio of the number of MFCs and ADP5090s. Panels A and B indicate the effect on power density and electrode resistance, respectively. The panel C indicates the effect of the ratio of the number of MFCs and ADP5090s on the charging time of a 1F capacitor.

Secondary use of boosted power

The MFCs were applied as the power source for the three devices. The twelve MFCs continuously lit up two white LEDs, but not three LEDs. A DC fan worked for 45 s every eight minutes and provided 12.8 L/h/reactor of airflow. Approximately 2 L of air was exchanged through the air flow every 2 h. A mini air pump could run intermittently for 30 s every 4.5 min (**Fig. 3A**); furthermore, this corresponded to give 0.45 L/h of aeration rate at a depth of 50 cm. The aeration provided 0.54 mg/L of average dissolved oxygen (DO) above the air pump (**Fig. 5B**); although, the average DO values decreased to 0.39 and 0.14 from 10 cm and 20 cm horizontal distances, respectively.

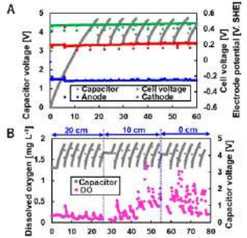

Fig. 3 The driving of a mini air-pump by twelve MFC units. Panels A shows the resulting change in voltage in response to the charge and driving of mini air pump. Panel B indicates the resulted change in dissolved oxygen. The length values on the top of graph in panel B indicates the horizontal distance from a mini-air pump.

Effect of the impact of intermittent aeration on organic matter and NH_4^+ removal

The degradation of organic matter (COD and BOD) was determined using mono-exponential regression with the concentration in influent and effluent at different HRTs, and resulted in $C_{COD}=183e^{-0.048t}$ and $C_{BOD}=75e^{-0.069t}$, respectively, under the intermittent aeration. The higher degradation rate constants for COD (0.048) and BOD (0.069) than the values without aeration (0.039 and 0.044, for COD and BOD, respectively) indicate the facilitation of organic matter degradation by MFC-driven aeration (**Fig. 4AB**). The time required to meet the planned effluent quality of BOD was 41 hours without aeration and decreased to 23 hours by the intermittent aeration driven by MFC power.

The removal of NH_4^+ was slightly facilitated by the MFC-driven aeration to have $C_N=35e^{-0.005t}$ in comparison of $C_N=35e^{-0.002t}$ without aeration (**Fig. 4C**). However, the combination of MFC and MFC-driven aeration required 112 hours to meet the planed discharge standard of total nitrogen. The DO that resulted by intermittent aeration was far lower than the minimum DO for ammonia oxidization

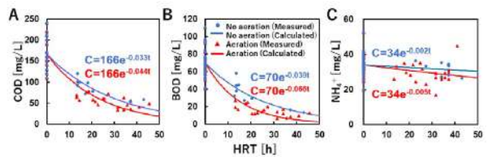

Figure 4 The effect of MFC-driven aeration on organic matter and ammonia removal. Panels A, B, and C shows the changes of COD, BOD, and NH4+ at different HRT, respectively.

(0.5 mg L^{-1}) (Hanaki et al., 1990) but similar values that observed in the partial anammox and nitrification process with intermittent aeration (0.01-0.05 mg/L) (Qiu et al., 2019).

3.4 Microbial community analysis

The 16SrRNA gene amplicon analysis showed the carbon brush was mostly dominated by the genus *Longilinea* at 12-14% and secondary with genera *Syntrophus* (3.5-5.3%) and *Methanobacterium* (2.4-4.3%), suggested the mutualistic relationship between these bacteria to provide/consume fatty acids and provide H_2/formate for methanogen. *Geobacter* species were relatively lower (1.5-1.3 %) suggesting the main energy conversion on CB was the symbiotic digestion to methane and a relatively minor contribution to recovering electric current. In contrast, *Geobacter* was more in GNWF-anode surrounding air-cathode (5.3%) and anolyte (9.2%). Interestingly, the sponge includes 2.7% of "*Candidatus Brocadia*" known as anaerobic ammonium oxidation (anammox) - bacteria together with aerobic ammonia-oxidizing bacteria of *Nitrospira* (0.7 %) (data not shown), suggested that the intermittent aeration facilitated the aerobic oxidization of ammonia to nitrite and the anammox reaction using the nitrite.

Table 1 Representative genera detected in MFC. SP1,2: sponge at the top (1) and bottom (2), CB-T, M, B: carbon brush at top (T), middle (M) and bottom (B), GNWF: GNWF-anode nearby air-cathode

	Relative proportion in total reads(%)						
Genus	SP1	SP2	CB-T	CB-M	CB-B	GNWF	Anolyte
Methanobacterium	1.1	0.1	2.4	4.7	4.3	1.9	0.0
Longilinea	12	3.3	12	12	14	0.3	0.1
"Candidatus Brocadia"	0.5	2.7	0.0	0.0	0.0	0.0	0.0
Geobacter	0.9	0.3	1.5	1.7	1.3	5.3	9.2
Syntrophus	2.9	3.7	3.5	4.5	5.3	0.2	0.3
Syntrophobacter	0.5	0.3	1.0	0.9	0.9	0.1	0.0
Arcobacter	0.5	0.1	0.1	0.1	0.1	0.6	12

Conclusion

The combined system of MFC and MFC-driven aeration reduced BOD to the planned discharge standard after 23 hours of operation without introducing external energy for aeration, but the MFC's energy was secondarily used for aeration rather than electricity recovery. However, the energy consumption for total nitrogen (TN) removal consumes 6.08 W h/g-TN, which indicates that MFC needs improvements to meet the discharge standards for both organic and nitrogenous compounds and more advantage in the removal of TN rather than energy recovery.

Abstract
Increasing environmental requirements for wastewater treatment plants (WWTPs) make it necessary to search for new wastewater treatment technologies. One such solution may be the implementation of shortcut nitrification in the mainstream of WWTPs. However, the use of shortened nitrification in the mainstream results in nitrite instead of nitrate present in the outflow of the treatment plant. Due to strict regulation of nitrite concentration in the effluent, additional removal of nitrite, for example in a variety of filters, is necessary. For this reason, denitrification filters can be used, in which wastewater is treated by flowing through a column reactor filled with a bed inoculated with activated sludge. In this study, three ways of inoculation such filters were investigated (inoculation from the top of the filters, from the bottom, and mixing the activated sludge with the bed). The best results in nitrite and COD removal were obtained for the reactor with mixed bed with the sludge reaching nitrites and COD removal efficiency even 100% and 82%, respectively.

Keywords
Denitrification filter; halloysite; nitrite; wastewater

INTRODUCTION

Reducing the operating cost of wastewater treatment plants (WWTPs) exploitation, while maintaining the high efficiency of the WWTPs operating combined with a reduction in greenhouse gas emissions, is one of the major challenges facing WWTPs. The presented research is a part of an international project to develop a technology for the utilization of free nitrous acid (FNA) for mainstream shortcut nitrification and sludge disintegration for higher energy production. This technology will provide significant savings of energy (25% reduction of aeration needs) at WWTP as well as other environmental positive impacts such as lower nitrogen discharge and carbon footprint. Since the regulations for nitrite concentration are very strict and in the outflow from the treatment plant its concentration must not exceed 1 g/m^3 this will require additional treatment of the outflow from the treatment plant of nitrite nitrogen. For this purpose, denitrification filters will be used. This technology was widely applied for nitrate removal (Gou et al., 2021; Wang et al., 2021), however, its usage for nitrite reduction from wastewater is hardly described. Thus, three ways of filter inoculation by activated sludge are presented in this study.

MATERIALS AND METHODS

The experiment was conducted in three denitrification filters (R1 – reactor inoculated from the top of filters; R2 - reactor inoculated from the bottom of filters; R3 – inoculation by mixing activated sludge with bed) with an active volume of 500 mL filled with expanded clay and halloysite. The reactors were inoculated with activated sludge (7.8 mg TSS/L) and the ratio of activated sludge to halloysite was 30% (v/v). The hydraulic retention time (HRT) was 2 h, while the concentration of nitrite was 10 mg/L and the concentration of COD was 90 mg/L. The experiment was conducted at room temperature (~ 20˚C) and pH 7.0.

RESULTS AND DISCUSSION

The obtained results (Figure 1) show that R3 presented the highest level of COD, as well as nitrite removal, and reached 100% efficiency for nitrite removal between 8 and 10 days, while in the same period, COD removal was approximately 80%. Similar results were obtained for R2. In R1, the removal efficiency of nitrite was increased from 10% on day 4 to 70% on day 8 and then maintained until day 14 when reached 97%. It can be suspected that the transfer of seeding sludge from the top needs more time for adaptation for microorganisms. Similarly, Zhang et al. (2018) obtained stability work of denitrification filters filled from the top after 20 days. In each reactor increase in the removal efficiency of both nitrite and nitrate was observed after day 10 and slightly decreased till the end of the experiment. This situation may be caused by the desorption of both nitrite and nitrate from the halloysite, however, this thesis required further analysis.

CONCLUSION

Denitrification filters seem to be a good technology for nitrite removal in tertiary treatment. As the most effective method of inoculating the bed seems to be its complete mixing of the halloysite with the sludge. Moreover, studies have shown that it only takes 8 days to achieve stable system operation. It is worth to noted that further research focusing on nitrogen load, temperature and HRT is ongoing.

Abstract

Pilot tests of the ELSAR® (ElectroStimulated Anaerobic Reactor) technology applied to the treatment of brewery wastewater showed significant improvements compared to conventional anaerobic fluidized bed reactor (AFBR), like better organic matter removal performance, higher biogas production productivity, higher calorific potential of biogas as a consequence of a higher biohydrogen content and better microbial response to sudden changes (reactor's temperature, organic loading rate or addition of inhibitors). The energy consumption of the treatment in lab-scale tests has been below 0.4 kWh·removed kg COD^{-1}, regardless of the organic loading rate of the reactor. Given these promising results, Aqualia has decided to scale up the technology, which can already be considered, according to the literature, a technical milestone. An ELSAR®-based wastewater treatment plant is being built with a treatment capacity up to 2000 kg COD·day^{-1}.

INTRODUCTION

Coupling anaerobic digestion with electrochemistry have shown promising results and opens a wide spectrum of possibilities in the wastewater sector (particularly in the food and beverage sector, where wastewaters tend to present high dissolved and biodegradable organic matter contents) due, among others, to the extra methane production that takes place thanks to bioelectrochemical electron transfer pathways on electrodes (Park et al., 2020).

The use of a microbial electrochemical fluidized bed reactor (registered as Electro-Stimulated Anaerobic Reactor (ELSAR®)) has been reported as a suitable solution where electron transfer by Geobacter stains (along with other anaerobic bacteria) allows to stimulate the degradation of organic matter (Tejedor-Sanz et al., 2018). ELSAR® (EP 2927196 A1) combines a classic fluidized reactor and a bioelectrochemical system: electroactive bacteria grow in a fluidized bed of activated carbon. These bacteria transfer the electrons from the oxidation of the organic matter present in wastewater to the activated carbon, which acts as an electroconductive material that stores electrons. After charging, the capacitive granules can be discharged at a current collector, which is poised at a higher potential than the granules. Consequently, power is produced (Figure 1).

To validate ELSAR® as a competitive solution for the wastewater market, the system has been compared to high-rate conventional existing anaerobic technologies (anaerobic fluidized bed reactors, AFBR), in terms of performance, resilience and energetic balance. This paper compiles the main results with regard to this comparison.

MATERIALS AND METHODS

In the frame of the LIFE Answer project (http://life-answer.eu/), a tubular-shaped lab-scale (1.2L capacity) ELSAR® has been operated under the following conditions:

- organic loading rates between 0.23 kg COD·m^{-3}·day^{-1} and 23.60 kg COD·m^{-3}·day^{-1}
- anode potential from +200 mV to + 800 mV vs Ag/Ag/Cl

Pilot-scale (5.4L capacity) ELSAR® and AFBR were run, monitored and compared under steady and stress conditions (described in the next chapter). All tests were done in the mesophilic range.

RESULTS AND DISCUSSION

Under steady conditions long-term bench-scale tests showed that ELSAR® outperformed anaerobic fluidized bed reactor (AFBR) in terms of COD removal and CH_4 production. Furthermore, hydrogen content (average 154 mg H_2·L^{-1}) was observed in the biogas produced by ELSAR®, while no H_2 was detected in the AFBR biogas. The consequence of this generated hydrogen is a significant increase in the calorific power of the produced biogas, meaning an improvement on the energetic balance of the system (Table 1).

Under stress conditions, a more resilient behaviour has been observed in ELSAR® compared to AFBR under the following stress operational tests: COD overload, biocide dosing, long starvation periods and operation at low temperatures (Table 1). The bioelectrochemical system achieves a higher maintenance of the process stability, which is in concordance with was widely reported in several references (Park et al., 2020).

Energy consumption on ELSAR® lab-scale tests treating real brewery wastewater has been always below 0.4 kWh·kg^{-1} removed COD, not depending on the applied organic loading rate. The mentioned value is ca. 10 times lower in comparison to typical energetic requirements of aerobic conventional activated sludge systems.

All these promising results motivated the upscaling of ELSAR® up to an industrial scale. In the frame of the EU project ULTIMATE (https://ultimatewater.eu/), Aqualia is designing and building the industrial-scale ELSAR® (treatment capacity 20 m^3·h^{-1} wastewater or 2.000 kg COD·day^{-1}) in the Mahou San Miguel brewery in Lleida (Spain) (expected commissioning mid-2023) (Figure 2).

Abstract
Antibiotic resistant bacteria and active pharmaceutical compounds such as antibiotics constitute a menace to environmental sustainability. The biodegradability of various pharmaceutical micropollutants is of concern due to the complexity of solutions used in medicine. Furthermore, conventional biological wastewater treatment plants have been revealed to be hot spots for antibiotic resistant bacteria development and accumulation. Internal recycling of sludge thickening, and dewatering reject water creates a path for non-degraded antibiotics to impact the wastewater treatment plant's overall load. This study focuses on side-stream treatment (e.g., reject wastewater) to investigate advanced oxidation processes' combination impact on antibiotics removal, antibiotic resistant bacteria reduction, and biodegradability of wastewater. Trimethoprim (TMP) and Sulfamethoxazole (SMX) mix represented the target group of antibiotics for removal efficiency and resistant bacteria reduction tests. The combination of Ozonation (O_3) and ultrasound (US) techniques was used, and different types of reject wastewater were tested. Different reject wastewater samples of full-scale Finnish plants with and without implemented side-stream deammonification were analyzed and used to collect data on the typical composition of antibiotic resistant genes. Advanced oxidation process regimes were adjusted for reject wastewater treatment considering wastewater quality: thus, ozone concentration, ultrasound frequency, and contact time were adapted. In the end, substantial antibiotic resistant bacteria reduction was achieved. In contrast, more research on biodegradability improvement should be conducted to customize the location of the advanced oxidation process in the side-stream treatment.

INTRODUCTION

Advanced oxidation processes (AOP) are often implemented at wastewater treatment plants (WWTP) in the effluent of the process, particularly for disinfection purposes if WWTP effluent is considered a water source for reuse (Sgroi et al., 2021). Environmental permits regulate effluent quality regarding microbiological contamination after the biological treatment at the plant. Nevertheless, full-scale investigation and implementation of AOP should be considered to provide the most efficient removal of antibiotics and ensure antibiotic resistant bacteria (ARB) accumulation prevention (Rodriguez-Chueca et al., 2019). Previous studies show potential biosorption for some of the micropollutants performed by activated sludge (Yang et al., 2011). TMP/SMX mix appears to be among the most common antibiotics in Finnish municipal wastewaters compared with a wide selection of antibiotic groups (Kortesmäki et al., 2020). Therefore, the trimethoprim (TMP) and sulfamethoxazole (SMX) combination creates potential hazards for the environment since antibiotic compounds could be released in the environment if further sludge treatment is not implemented. Moreover, the contribution of side-stream recycling is still unclear, and more data on antibiotic concentration and the presence of ARB are required to fulfill the picture of the wastewater treatment process with additional factors. The more information needed such as the impact of anaerobic digestion on the degradation of antibiotics and possible positive outcome of sides-stream pre-treatment with advanced oxidation processes. Thus, more studies should be conducted to investigate the best approach for antibiotic resistance prevention with possible positive side effects for biological treatment after AOP implementation.

Antibiotic removal and Antibiotic resistant bacteria

TMP and SMX presence is primarily studied in the effluent from wastewater treatment plants. In contrast, potential hot spots for resistance development and antibiotic impact on the treatment process are located within biological treatment reactors and anaerobic digestors (Wu et al., 2022). TMP and SMX are mentioned to have a high excretion rate, solubility, and persistence (Chen, 2020). Therefore, a significant fraction of the total load consumed enters the bioreactors. Antibiotic removal can be achieved to a certain extent. However, most of the biological municipal WWTPs could not provide prevention of ARB accumulation (Rodriguez-Chueca et al., 2019). Accumulation leads to the development of antibiotic resistance of microorganism groups that potentially could enter the environment after releasing effluent from WWTP.

Reject wastewater and ANITA™ Mox

Reject wastewater from sludge thickening and dewatering after anaerobic digestion significantly contributes to the total nitrogen and COD load when recycling back to the WWTP influent (Koskue et al., 2021). Therefore, this side-stream wastewater was a subject for implementing specific nitrogen load reduction processes. Few plants in Finland have incorporated ANITA™ Mox Anammox-based moving bed biofilm reactor (MBBR) deammonification process from Veolia Environnement SA for reject wastewater treatment. However, the presence of antibiotic-resistant bacteria in reject wastewater and the effect of the ANITA™ Mox process on ARB reduction have not been extensively studied. Anammox bacteria involved in the ANITA™ Mox process are microorganisms with low growth rates, sensitive to low substrate concentrations and temperature decrease (Yuan et al., 2023). All factors included are essential to prevent possible intrusion of high concentrations of micropollutants to achieve the highest treatment efficiency. Moreover, pre-treatment of reject water could improve COD fractions favorable for biological treatment.

MATERIALS AND METHODS

A combination (figure 1) of ozonation and ultrasound (O_3/US) was used with reactor volume 1.5 L, ozonizer 300.5 (Erwin Sander), ultrasonic system (Meinhardt® Ultrasonics, ultrasound transducer E 805/T/M, glass reactor UST 02/500-03/1500). Three sets of experiments were held with two repetitions of each, and the main operation parameters are described in table 2.
Reject water quality testing was performed according to the methods described in table 1. In addition, reject water quality before and after the use of AOPs was compared to define the impact on reject water suitability to recycle to the influent of WWTP.
Antibiotic resistant bacteria growth preliminary check-up was performed with the plating method by (Chen, X. S., 2020) using Mueller Hinton agar (Oxoid) and TMP/SMX concentrations 10/50 mg/l of agar (TMP/SMX, respectively).
Antibiotic concentration measurements were done at Jyväskylä University using Hewlett-Packard Agilent 1100 HPLC (Agilent Technologies).
Antibiotic resistant gene testing was performed using SmartChip qPCR (Resistomap Oy).

RESULTS AND DISCUSSION

Reject water types (impact on AOP efficiency)

Water quality parameter values of reject water used for the testing are presented in table 3. ANITA™ Mox from WWTP (2) was still in the start-up process, and the sample was collected only for the actual AOP process testing. Thus, the sample number was limited to define standard deviation. Reject water samples before and after AOP are presented in figure 2.

AOP impact on reject water biodegradability

AOP treatment could be considered a feasible pre-treatment of reject water to increase soluble biodegradable fraction of COD and improve biological side-stream treatment efficiency to remove nitrogen while reducing the impact of antibiotic resistant bacteria.

Antibiotic resistant bacteria reduction

ARB reduction was detected already during the preliminary plating tests, where a lower concentration of ARB was observed in the plated after AOP treatment, especially in the case of higher ozone dosage (test 3 in table 2).

TMP/SMX removal

A combination of higher frequency ultrasound and ozone dosage is preferred in the TMP/SMX mix degradation due to the high suspended, and total solids concentration in dewatering reject waters. In the case of antibiotic removal as a primary goal, the main challenges will be the energy efficiency of the treatment process, the risk of ultrasound equipment overheating, and extensive foaming of dewatering reject water due to the reaction with ozone.

Abstract
Microalgae cultivation offers a low-cost wastewater treatment for domestic effluents. This work evaluated the performance of an integral microalgae-based domestic wastewater treatment system was conducted in lab-scale photobioreactors under the conditions prevailing in outdoor HRAP reactors. For this purpose, seasonal and daily variations of light intensity were essayed in an open reactor with similar mass transfer characteristic that a conventional HRAP. Wastewater treatment was evaluated in terms of nutrient, organic matter, bacteria pathogen, and emerging contaminants. The photobioreactors demonstrate a very high efficiency in removal and, therefore, in the permitted water reuse.

1- INTRODUCTION

The photosynthesis reaction of these microorganisms releases the oxygen needed for organic matter oxidation while nutrients are assimilated into algae biomass, allowing for nitrogen and phosphorous recovery into biomass. Experimental set-ups must be carefully designed to simulate the conditions as close as possible to those found in outdoor photobioreactors. In this context, research studies can be differenced in two main strategies: outdoors demonstration essays conducted in long-term operation and lab-scale systems addressed to study specific issues of the bioprocess: such as rates of pollutant removal or biomass characteristics.

2- MATERIALS AND METHODS

Experimental set up

The experimental set up was located indoors, at the laboratory in Campus of Soria - Valladolid University. The system was integrated by two 2.15 L cylindrical PVC photobioreactors connected to each photobioreactor (Fig. 1).

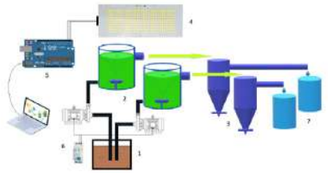

Figure 1. Schematic diagram of the experimental setup. (1) Wastewater, INLET (2) Photobioreactor for wastewater treatment, (3) Conical settler, (4) LED module, (5) Illumination program System of Arduino (6) Pumps programmed system, (7) OUTLET.

The system treated real wastewater from the municipal WWTP of Garray (Soria, Spain). The photobioreactors were illuminated with a day simulator program consisting in two LED module PHILIPS 94V covering a total surface of 0.16 m^2. The illumination was programmed with Arduino device (IDE) that modulated the light intensity by means of a Pulse Width Modulation (PWM). Reactor's temperature was controlled by thermostatic bath fixed at (20° C) in summer and (10° C) in winter (Frigiterm-SELECTA). However, light irradiation created temperature fluctuations in the bulk liquid. The photobioreactors were fed with two pumps (WATSON MARLOW 313S) at an inlet flowrate of 0.7 L d^{-1} from a 5 L homogenization tank resulting in a hydraulic retention time of 3 days. Evaporation rates were determined by the measurement of the decrease in depth in batch mode experiments. The rates of evaporation were used in every calculation for mass balances and biomass productivity (de Godos et al., 2016). The rates of oxygen exchange between the bulk liquid and the atmosphere were determined following a standard procedure of volumetric mass transfer coefficient.

Analytical methods

In order to evaluate the wastewater treatment efficiency, the following parameters were analysed: COD, NH_4^+, PO_4^{3-} total suspended solids (TSS), according to Standard Methods (APHAAWWA-WEF, 2012). All the analyses were done in duplicate and results are given as average values. Biomass productivity was determined by the measurement of total suspended solids (TSS) considering the outlet flow. In calculations of biomass production, the TSS parameter and the total surface of the photobioreactor were used. Organic matter removal was measured with Chemical Oxygen Demand (COD) concentration, total and soluble. Soluble COD was measured after the filtration through a 0.45 µ of nylon filter. The concentrations of the following parameters were determined: total suspended solids (TSS) and volatile suspended solids (VSS). Samples were collected every two days to perform the chemical analyses that were carried out on filtered samples using spectrophotometric quantitative measurements.

E. coli and coliform concentration in influent and effluent of the photobioreactors were determined using the protocol described in the ISO 9308-1:2014 (ISO, 2014) with Chromocult® Coliform Agar (CCA). The method is based on membrane filtration for 100 ml and Petri dishes cultivation, subsequent culture on a chromogenic coliform agar medium, and calculation of the number of target organisms in the sample. The method was used for detection and enumeration of *Escherichia coli* and coliform bacteria.

Fifty-nine pharmaceutical residues were measured following the analytical methodology. The CEC samples were performed according to (López-Serna et al., 2011, López-Serna et al., 2019a, López-Serna et al., 2019b). In brief, 100 mL of each sample (filtered through a 0.45 µm filter) were spiked with a 0.1% Na2EDTA solution and 1000 ng L−1 of internal standard, before solid phase extraction (SPE) using Oasis HLB cartridges (Water Chromatography, Spain). Then, the cartridges were eluted with 6 mL of acetonitrile, and the resulting solution was evaporated and reconstituted in 1 mL of 0.1% formic acid (FA) in H2O/MeOH (95:5). Finally, the extracts were analysed by ultra-high performance liquid chromatography (UHPLC) – tandem mass spectrometry (MS/MS) in selected reaction monitoring (SRM) mode. More specifically, chromatographic separation was carried out by a Sciex Exion UHPLC and a Phenomenex reversed-phase column Kinetex EVO C18 (2.1 mm × 50 mm, particle size 1.7 µm), making use of H2O- and MeOH-based mobile phases containing 0.1% FA as modifier. Mass detection was performed by the triple quadrupole Sciex 6500+ QqQ.

3- RESULTS AND DISCUSSION

The values found for the aeration coefficient (0.393 h^{-1}) were considerably lower than the reported values for similar systems. The seasonal variations, without any modification in the HRT, were particularly relevant the productivity of biomass per surface area. The production during summer conditions in two photobioreactor: photobioreactor 1 operated at 2.99 ± 0.26 days of HRT, 21.98 ± 2.58 $g \cdot m^{-2} \cdot d^{-1}$ (measured as VSS) and photobioreactor 2 operated at 2.96 ± 0.23 days of HRT, 25.09 ± 0.73 $g \cdot m^{-2} \cdot d^{-1}$ (measured as VSS). During the winter conditions the pond presented a decrease in productivity: photobioreactor 1 operated at 3.16 ± 0.40 days of HRT, 5.68 ± 2.58 $g \cdot m^{-2} \cdot d^{-1}$ (as VSS) and photobioreactor 2 operated at 3.23 ± 0.26 days of HRT, 6.75 ± 2.13 $g \cdot m^{-2} \cdot d^{-1}$ (as VSS).
The photobioreactors demonstrate a very high efficiency in removal of COD, SST, N-NH^+_4 and P-PO_4^{-3} despite the different conditions applied. Table 1 shows the results obtained from the analysis of the influents and effluents of different seasonality of two photobioreactors.

Comparison analysis of the influents and the effluents of the different seasonality in the photobioreactor experiment.

Parameter (units)	Sample point				Removal efficiency %	
	Winter		Summer			
	IN	OUT	IN	OUT	Winter	Summer

Enterococcus F.(CFU/100mL)	8.31E+3 ± 3.80E+3	290.00 ± 14.14	2.32E+5 ± 5.66E+4	9.42 ± 0.31	94.84 ± 2.51E-1	99.95 ± 2.36E-2

Table 1. Comparison analysis of the influents and effluents of different seasonality in the photobioreactors.

The photobioreactors obtained removal efficiencies above 80% in all measured parameters both winter and summers, except for CODt and P-PO_4^{-3} in summer conditions. Then, in both winter and summer conditions, the microalgae experimental systems comply with the regulation, except the TSS in summer conditions. The TN (removal efficiency 63% or 32 ± 16 $mg \cdot L^{-1}$) and the TP (removal efficiency 84% or 2 ± 2 $mg \cdot L^{-1}$) is lower than this experiment due to temperature and solar radiation. The TSS (removal efficiency 95% or 24 ± 26 $mg \cdot L^{-1}$) is constantly but in this experiment, there are different variations from summer to winter conditions.

Algae based systems provides pathogen bacteria removal as consequence of the environment created by microalgae and the light exposition. In this way, secondary and tertiary treatment take place simultaneously and final effluents can be used as reused water. High levels of disinfection were achieved in both conditions. Summer conditions resulted in a effluent with a *E. coli* concentration of 24.93 ± 1.62 CFU·100 ml^{-1}, while winter conditions decreased the level of disinfection with average value of 212.50 ± 17.68 CFU·100 ml^{-1}. Some authors suggest that UV light exposition is the main mechanism of pathogen removal, since most of bacteria are sensible to DNA damage mediated by UV light. However, light source used in this experiment only provides light in the visible spectrum.
In this experiment, in summer conditions, the class are B of the reclaimed water quality classes and the permitted uses and irrigation methods, *E. coli* (number/100 ml) was, nevertheless in winter conditions, the class are C due to *E. coli* (number/100 ml) was 212.50 ± 17.68 CFU·100 ml^{-1}. The reclaimed water quality classes and the permitted uses and irrigation methods for each class and the minimum requirements for water quality are in the Regulation (EU) 2020/741 of the European Parliament and of the Council of 25 May 2020 on minimum requirements for water reuse and the current Spanish regulation RD 1620/2007.

The removals efficiency of progesterone, caffeine, fenbendazole, clarithromycin, atorvastatin and dexamethasone in the photobioreactors (Fig. 4) were similar in both stages of operation (> 97,00 %). The CECs mass balance calculations revealed that biodegradation/biotransformation was the main removal mechanism in two conditions.

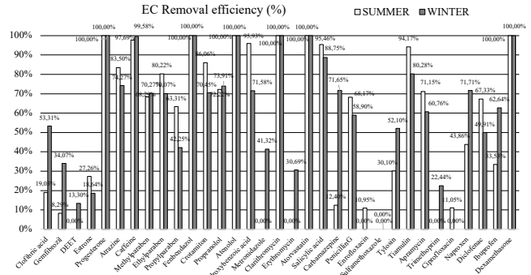

Figure 4. Removal efficiency (%) of thirty-three compounds.

In conclusion, the photobioreactors demonstrate a very high efficiency the permitted reuses with irrigation methods reducing pathogens and emerging contaminants.

Abstract
Acidogenic fermentation for volatile fatty acids production, anaerobic digestion for biomethane production, and thermochemical conversion are among the main strategies to promote the sustainable management of waste sludge produced in wastewater treatment plants. In this study, hydrothermal carbonization (HTC) was studied as pre-treatment to enhance anaerobic degradability of mixed waste sludge. The HTC process was effective in the particulate COD solubilization. BOD_{20}/COD ratio resulted in the range 67%-93%, thus showing a good degradability of the HTC process water. Batch fermentability tests showed similar results as the untreated sludge, while the biomethane potential of HTC process water was 30% higher than the untreated sludge.

INTRODUCTION

Waste sludge produced in wastewater treatment plants – WWTP – is traditionally one of the main issues in plant operation, as its treatment and disposal requires a proper management. Resource and energy recovery are key strategic elements to ensure environmental and economic sustainability of sludge management, being carried out mainly through biological treatments, direct land application, and thermochemical conversion (Bora et al., 2020). Traditionally, anaerobic digestion was one of the first processes developed, allowing to reduce the amount of sludge to be disposed and to recover energy in the form of biogas. Similarly, acidogenic fermentation designed for volatile fatty acids – VFAs – production was developed more recently in the view of applying VFAs as external carbon source for biological nutrient removal processes in the WWTPs or for the production of polyhydroxyalkanoates – PHA (Atasoy et al., 2018). Regarding thermochemical conversion, hydrothermal carbonization – HTC – is gaining attention lately as a process able to convert a high moisture stream into a carbonaceous product, the hydrochar, and a process liquid rich in organic compounds. The temperature of the process is relatively low, usually in the range 160 - 250°C, while the retention time strongly influences the process output (Chen et al., 2021). Coupling pre-treatment of sludge via HTC with the subsequential valorisation through anaerobic processes has been investigated as an opportunity for enhancing biogas production, while limited data is available on the possibility of using HTC for promoting VFAs production via fermentation (Chen et al., 2021).

The aim of the study is to assess the biological treatability and fermentability of mixed wasted sludge collected in a WWTP after pre-treatment with HTC process; the pre-treatment goal is to improve and speed-up the hydrolysis of the particulate matter, eventually to achieve a faster VFAs synthesis.

MATERIALS AND METHODS

The waste sludge was sampled in a WWTP located in northern Italy. The sludge was a mixture of primary and secondary sludge (80% and 20% w/w, respectively), and it was collected after the co-sedimentation of both streams in the primary settler.
HTC was carried out in a high-pressure laboratory reactor (BR-700, BERGHOF). After the HTC process, the liquid fraction (or process water) used for all the subsequent tests, was obtained by centrifuging at 3000 rpm the treated sludge. Preliminary screening was done testing two operative temperatures, namely 170°C and 190°C, and three residence times, namely 30, 60, and 150 minutes. Batch tests for fermentability were set up using 0.5 L bottles, magnetically stirred at 250 rpm, and maintained at the temperature of 30 ± 1 °C by means of a thermostatic chamber. Tests were run for 5 days and sludge from a full-scale fermenter (HRT = 4 d T = 27 ± 1 °C) was used as inoculum. Mesophilic BMP tests were carried out using a volumetric device (AMPTS II, Bioprocess Control®). BOD tests were performed by means of the manometric system (OxiTop Control from WTW).

RESULTS AND DISCUSSION

Experimental results from the preliminary tests indicated that the lower temperature tested, namely 170 °C, showed a better solubilization of the COD (8.0 g/L - 11.7 g/L and 7.3 g/L - 8.5 g/L respectively). Among the different residence times in the reactor, higher values resulted in a limited increase in sCOD while consuming a higher amount of energy for the reaction. Thus, 170 °C and 30 minutes were the operative conditions chosen for biological tests.
For BOD tests, two HTC runs (HTC-A and HTC-B) were performed on waste sludge sampled approximately 1 month apart. 50% v/v dilution conditions were also applied for HTC-A. Experimental results are shown in Table 1. The BOD_{20}/COD ratio showed a good degradability for both HTC-A and HTC-B, with HTC-B characterized by higher ratio. This is likely due to a lower synthesis of toxic or inhibiting compounds during HTC. The same explanation is also suggested by higher BOD_{20}/COD for diluted HTC-A in comparison with non-diluted HTC-A, that might imply a dilution of inhibiting compounds.
Results from fermentability batch tests are shown in Table 2. The inoculum used was sampled in a full-scale fermenter located in the same WWTP and thus acclimatized with the same waste sludge. HTC-B did not result in a better fermentability in comparison with the untreated sludge, while the diluted HTC-B was slightly higher than the latter. Nevertheless, acclimatization for the HTC process water might be needed to adapt the biomass to a very different substrate than the one usually fed to the full-scale reactor. Furthermore, potential inhibitory effects might occur, as suggested by the result of the diluted HTC-A, that might as well be mitigated by the biomass adaptation. Regarding the VFAs composition, HTC pre-treatment favoured more complex VFAs synthesis, as butyric and valeric (and their isomers) content increased, as shown in Figure 1. This is relevant for possible downstream applications such as PHA production (Albuquerque et al., 2011). On the other hand, BMP tests showed a greater degradability for HTC-B than untreated sludge, being BMP values respectively 106 ± 4.6 $NmlCH_4/gCOD_{in}$ and 81.2 ± 3.2 $NmlCH_4/gCOD_{in}$. The higher BMP productivity for HTC-B suggests that methodological improvements (such as biomass adaption and higher inoculum content) for the fermentability tests might lead to a higher VFAs production as well.
Currently ongoing activities include semi-continuous tests for HTC process water fermentation.

Abstract
Iron (Fe) electrocoagulation-floatation (EC-F) technology was investigated in view of zero chemical municipal wastewater (MWW) (pre-)treatment. Eleven operational settings were evaluated employing various current densities (CDs) in continuous mode using a flow through and a recirculation mode, various current supply systems, and various cathode materials (Cu, SS). The optimum operation was when recirculation was used (with two EC-F runs (2R)) at a CD of 12 A/m^2. Maximum Faraday efficiency, good total chemical oxygen demand (tCOD) (i.e.,78%) and total phosphate (TP) (i.e.,85%) removal and low OPEX were taken into consideration for this. Furthermore, using SS as cathode material was found beneficial to remove heavy metals (93±9 % Zn, 70±15% Pb and Cu 49±10%). As such the EC-F technology was demonstrated to be a green and feasible technology for facilitating zero chemical use and energy efficient MWW pre-treatment around the world.

Keywords: Electrocoagulation-Floatation; energy efficiency; heavy metal; low-cost; phosphate removal; total COD removal.

INTRODUCTION

Municipal wastewater (MWW) treatment technology application depends on efficient operation at low energy and chemical costs. Electrocoagulation (EC) can effectively remove total chemical oxygen demand (tCOD), total phosphate (TP), suspended solid (SS), turbidity, and heavy metal from a myriad of wastewater types with a variety of anode and cathode materials(Chen *et al.* 2004; Mollah *et al.* 2004; Elazzouzi *et al.* 2020). During EC-F electro-chemical reactions are triggered by electricity without adding any chemicals as dissolution of a sacrificial anode (e.g. iron (Fe) or aluminum (Al)) occurs as well as hydrogen gas production at the cathode.

In the last two decades, electrocoagulation-flotation (EC-F) was investigated with either synthetic MWW or with adjusted pH and conductivity, utilizing different current densities (CDs) and current supply mode, electrode gap and flow rate in batch mode (Merzouk *et al.* 2009; Que *et al.* 2021; Vasudevan and Lakshmi, 2011; Devlin *et al.* 2019; Ebba *et al.* 2021). Research on continuous EC-F systems in view of operational optimization is rarely found with MWW treatment (López-Guzmán *et al.* 2021). As such, this study aimed to optimize EC-F for a low-cost treatment of real MWW in a continuous operating mode. Different operational settings are investigated, focusing on increasing floatation, lower coagulant dose, electrode life, and energy efficiency to enhance reactor design efficiency (Parmentier *et al.* 2020; Moussa *et al.* 2016; Yang *et al.* 2020). Single pass operation or multiple recirculation at low operational CD, alternating pulsed current (APC) mode, and choice of cathode material are looked at in view of optimal pollutant removal and operational expenses.

MATERIALS AND METHODS

An EC-F set-up with an iron (Fe) sacrificial tubular metal anode was used to treat freshly collected MWW at a flow rate of 10L/h. Single pass EC-F treatment (1R) compared to two or three sequential EC-F passes (2R and 3R) and alternating pulsed current (APC) supply versus direct current (DC) supply mode and different cathode materials (copper (Cu) and stainless steel (SS))were considered as different operational experimental settings (Exp) for optimization at various CDs (i.e., 12, 40, 80, 120, and 160 A/m^2). Duplicate experiments were performed using various grab MWW samples from a MWW treatment plant (Kortrijk, Belgium).

Common physical-chemical parameters, i.e. pH, dissolved oxygen (DO), electrical conductivity (EC) and oxidation reduction potential (ORP) before and after each experiment was determined. Optimized performances were evaluated based on removal of tCOD, TP, total nitrogen (TN), Faraday efficiency (FE)(i.e., applied CD efficiency to dissolved metal from anode) and total operational expenses (OPEX) (i.e., sum of energy and electrode consumption) according to Parmentier *et al.* (2020).Sludge production were calculated from volume of sludge produced and measured total solid (TS) contains. TS and dry solid (DS) contains of EC-F sludge were measured following standard methods. Heavy metals analysis were also performed according to Lakho *et al.* (2020).

RESULTS AND DISCUSSION

Operation of Fe EC-F unit with 2R at 12 A/m^2 (experiment #2) resulted in optimized treatment performance, i.e., 78±11 % tCOD, 85±0.5 % TP and 32±22%TN removal at the second lowest total OPEX (i.e., 0.215±0.014 €/m^3) at a FE 1.08±0.32 (Figure 1 and Table 1). Maximum pollution removal and FE were obtained with 1R at 80A/m^2 (experiment #5) while the total OPEX was 3 times higher than with 2R at 12A/m^2 (experiment #2) (Figure 1 and Table 1).

Recirculation increases the contact time for electrochemical reactions and floc formation to increase floating, which is good for more pollutant removal at optimal OPEX with the studied EC-F unit at lower CD. The lowest sludge volume production were also obtained with 0.097±0.01 mg/L TS and 0.023% DS at experiment#2. The effluent quality were suitable with higher DO, and similar ORP in comparison to 1R 40 A/m^2 (experiment #4) and 1R 80 A/m^2 (experiment #5) (Table 1). Effluent obtained when operating with 2R Fe EC-F at CD 12 A/m^2 contained biodegradable matter and TN, suitable for subsequent simple biological treatment.

Interestingly with 3R at 12 A/m^2 (experiment #3), and 2R 120 A/m^2 (experiment #10) resulted in anodic passivation demonstrated lower FE at the final recirculation step (Table 1). Green flocs (GR) were visible in all experimental condition at different operational step up (experiment #2 to experiment #11) and CDs, except at (experiment #1) with 1R with at 12 A/m^2. Among single pass (1R) operation, using 40 A/m^2 (experiment #4) resulted in comparable removal performances and resulted in half the OPEX compared to using 80 A/m^2 (experiment #5). DC mode operation (experiment #5) was found suitable for higher pollutant removal efficiency and minimal operational cost differences in comparison to APC mode operation (experiment #7). Fe EC-F with SS cathode were found beneficial to remove heavy metals (93±9 % Zn, 70±15% Pb and Cu 49±10%).

Table 1. Quality of effluent of Fe EC-F and Faraday efficiency at different operational experimental settings(Exp).

Sample ID & Exp No.	EC-F Setup	CD A/m^2	pH	DO mg/L	EC µS/cm	ORP mv	FE

On-site Regeneration of A modified Activated Carbon by Ozone

Chihpin Huang and Shanshan Chou

Environmental Technology and Smart System Research Center
National Yang Ming Chiao Tung University
Hsinchu, Taiwan
huang@nctu.edu.tw

In recent years, due to stricter environmental regulations, the global demand for granular activated carbon (GAC) has increased. Therefore, the reuse of GAC has become an important effective method to save cost. At present, thermal regeneration of saturated activated carbon is the only large-scale and commercialized way of reusing activated carbon. However, it has several drawbacks such as high energy consumption and large space, besides, the adsorption capacity of GAC drops rapidly after thermal regeneration because of the serious carbon loss and destroyed GAC structure. Therefore, this study evaluates the regeneration efficiency of a polymetallic metal oxide modified activated carbon (mGAC) by ozone. The surface of mGAC is loaded with noble metal ruthenium (Ru), Ru in mGAC is turned into higher oxidation states after oxidized by ozone. The high valance Ru compound can act as a strong oxidant to oxidize organic matter, and it can also be used as a catalyst for catalyzing ozone to generate hydroxyl radicals.

In this study, firstly, 1 gram of mGAC is in equilibrium at benzoic acid solution. Then comparing the regeneration efficiency (RE) under different parameters. The results show that the optimal RE condition is at pH 9 or above, 80°C, and regeneration time of 4 hr. After getting the optimal RE parameter, we compare RE with GAC after multi-cycle batch adsorption/regeneration experiments. Secondly, mGAC stability is evaluated. Conducting mGAC adsorption in continuous flow mode and observing the changes in adsorbed amount and surface characteristics after several adsorption/regeneration cycles. The results show that after 4 cycles, BET specific surface area drops from 1060 to 698 m^2/g. Accumulated adsorbed amount decreases a little at cycle 2 to 4. it is speculated that some of the noble metal Ru active sites, which are not shielded by carbon deposition, still remain their high valence state to mineralize part of the adsorbate as well as promote ozone to generate hydroxyl radicals.

The results show that mGAC by ozone regeneration can maintain the adsorption capacity after a prolonged period, and has a strong ability to remove adsorbate, indicating that the application of mGAC in the industrial wastewater treatment can effectively reduce the cost of replacing activated carbon and achieve the goal of circular economy.

$RE = \frac{q_{reg}}{q_{fresh}} \times 100\ \%$, in which q_{reg} and q_{fresh} means the adsorption capacity of regenerated mGAC and fresh mGAC, respectively.

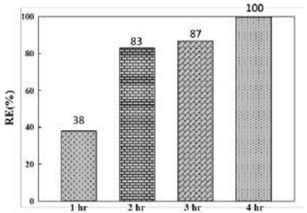

Fig. 1. Effect of regeneration time with ozone on RE of mGAC at pH 9 and 80°C.

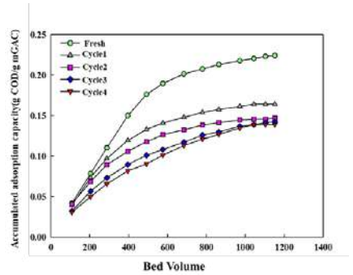

Fig. 2. Changes in accumulated adsorption capacity of mGAC in continuous flow mode with 12 BV/h after several adsorption/regeneration cycles. Regeneration condition is pH 9, 80°C and 4 hrs with 0.024 mg/L of ozone.

Flotation and Fenton Process Pilot Technology for the treatment of Real Olive Mill Waste Water

I. Oliveira-Inocêncio*, M. Silva*, A. G. Nogueira*, S. Castro-Silva*

Abstract
Waste water from an olive pomace extractor factory, equivalent to 3- stage centrifugal OMW, was treated using flotation and Fenton Process. Influence of flocculant, coagulant and flocculant dosage and pH was assessed for the flotation unit. Influence of Fe:H2O2 ratio, reaction time, pH control and iron reagent was evaluated for Fenton process. The best flotation results were obtained with 1.2 L/m3 of PAX18 and 33 L/m3 of AS01. In the Fenton, pH control and reaction time do not affect COD removal significantly. Best results were obtained for 8:16 ratio, with FeSO4.7H2O during one hour, with 58 % COD removal and 89 % TPh removal. Further tests with the Fenton pilot will be performed aiming the hydrogen production through steam reforming after membrane distillation.

Keywords (maximum 6 in alphabetical order)
Fenton Process, Flotation, Olive-mill waste water, Pilot Technology

INTRODUCTION

Olive oil industry is a significant sector at a worldwide level. About 2.7 million tons of olive oil were produced in the 2022/2023 campaign, of which 55 % in the EU (Council, 2022). About 0.5 to 1.68 cubic meters of waste water are produced for each ton of olives processed (Amor, 2019, Paraskeva, 2006). These effluents contain heavy loads of COD, BOD, TSS and different phenolic compounds, along with high EC, acidic pH and dark brown colour (Amor, 2019, Papaphilippou, 2013).

The commonly investigated pre-treatment processes for these WW are advanced oxidation processes (AOP) and physical-chemical treatments.

The aim of this work is to study the combined process, in pilot units, of flotation and Fenton Process, using real OMW from an olive oil pomace extractor factory in the Center of Portugal. The influence of coagulant and flocculant concentration was assessed in flotation, and the influence of the Fe:H_2O_2 ratio in the Fenton Process. The effluent produced after Fenton will be used in a membrane distillation and reforming unit at pilot scale in future work.

MATERIALS AND METHODS

Tests were performed in 600 mL beacons using a jar-test. For the pilot scale, two pilot units were used: the flotation unit for the treatment of 1 m^3/h and the Fenton process unit to treat 400 L/h in semi-discontinuous mode, used sequentially.

Flotation was performed with coagulant Kemira PAX18 and AS01 flocculant, prepared at 2 g/L, from SNF. Fenton process was performed with ferrous sulfate ($FeSO_4.7H_2O$), richness higher than 87.6 %, from Sociedade Portuense de Drogas, or $FeCl_3$, and hydrogen peroxide 49.5 %. pH adjustment was made with sulfuric acid 30 % and sodium hydroxide 48-50 %, all 4 from Brenntag.

Trials were executed between April 2022 and January 2023. For the Fenton trials, the inlet was the outlet of the flotation unit.

RESULTS AND DISCUSSION

Coagulation/Flocculation – Flotation

The best results were obtained, at laboratory scale, with anionic flocculant, showing a more consistent COD removal for lesser amounts of flocculant. It stayed between 44 and 51 %.

In the pilot unit, flotation efficiency varied significantly along the trials, showing lower removals than the ones obtained at laboratory scale. The best results showed COD removals of about 30 %, at the waste water's initial pH, with AS01. pH adjustment showed no significant correlation with treatment efficiency, as did the variability of the waste water's initial COD.

The increase of PAX18 dosage seemed to have a positive impact in COD removal, with the highest removals of above 28 % for 1 and 1.2 L/m^3. AS01 concentration seems to be optimum around 30 L/m^3, decreasing efficiency for lower and higher concentrations.

Fenton Process

The efficiency of Fenton was assessed essentially at laboratory scale. The variable with highest influence in COD removal was the Fe:H_2O_2 ratio. The increase in reaction time for 2 hours did not have a significant impact in COD or TPh removals, with some efficiency decrease. pH control in the acid stage did not show relevant changes. The exchange of reagent to $FeCl_3$ showed lesser COD removal, but slightly higher TPh removals.

The best results were obtained for 8:16 g_{Fe}/g_{H2O2}, with COD removal of 58 % and TPh removal of 89 %. Further pilot tests will be performed in the future.

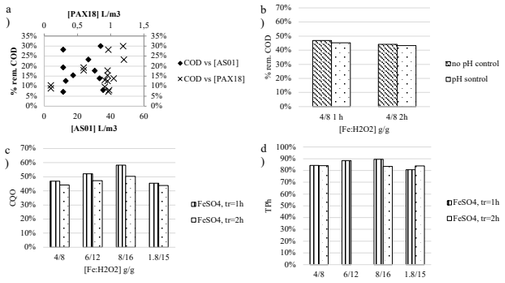

Figure 1. Flotation: a) COD removal related with coagulant and flocculant concentration; Fenton: b) COD removal with pH control, c) COD removal with different Fe:H2O2 ratios and reaction times and d) TPh removal with different Fe:H2O2 ratios and reaction times.

Abstract
Acid mine drainage (AMD) is serious problem in mining industry because of generating waste harmful water. Once AMD is generated, it will discharge even mining site is closed. Neutralization using slaked lime is generally applied to deal with AMD. It generates heavy metal sludge which should be disposed as industrial waste. Metal removal before neutralization is efficient to decrease the industrial waste. Thus, we proposed a novel process using bacteria which can tolerate and adsorb metals under AMD conditions. In this study, acid and metal tolerant bacteria were isolated from closed mining site and neutral environmental soil. Isolated strain *Paenarthrobacter* sp. removed 42% arsenic and 8.7% iron from the AMD in Horobetsu sulphur mine (pH 1.95, initial concentrations were 5.75 and 301 [mg/L], respectively). Although further research is required to improve removal efficiency, this study potentially contribute to achieve sustainable AMD treatment.

Keywords
Acid mine drainage; acid tolerant bacteria; biosorption

INTRODUCTION

Acid mine drainage (AMD) is generated in not only operating mining sites but also mines closed decades ago. Due to the abundant heavy metals, AMD discarded into rivers is harmful for ecosystems and people who use the river water. Currently, neutralization and precipitation treatment with addition of neutralizer like slaked lime is applied to remove heavy metals from AMD before discarding. With this process, mixture of iron, arsenic, and calcium is generated as waste sludge. It should be treated as industrial waste. Considering the limitation of industrial waste deposit, it is desired to reduce amount of generated waste from both an environmental and economical point of views. Recently, passive treatment and biosorption are studied as an alternative technology to remove metals. However, passive treatment also generates metal-rich residues ([1]Marouen *et al.* 2019) and most of current biosorption research are mainly conducted under neutral pH conditions. Considering this situation, we devised the concept of novel AMD treatment process using acid tolerant bacteria (**Fig. 1**). In this process, bacterial biosorption is performed under acidic conditions before neutralization to reduce sludge generation. In this study, we attempted to obtain bacteria that can selectively adsorb metals under acidic conditions as an environmentally friendly metal adsorbent.

MATERIALS AND METHODS

Material

Environmental water and soil for bacterial isolation were sampled from some mining sites and Hokkaido University Sapporo campus. AMD was collected from several Japanese mining sites. Metal concentrations was quantified using inductively coupled plasma atomic emission spectroscopy (ICPE-9820, Shimazu, Kyoto, Japan, ICP-AES) and standard curve prepared using ICP standard solution IV (Merck, Germany) and Arsenic standard solution (Fujifilm Wako pure chemical Co. Ltd., Japan). Specialized cellulose film (SCF, [2]Aoyagi *et al*, 2022) and non-woven fabric were purchased from Futamura Chemical Co. Ltd. (Japan). Nutrient Broth (Becton, Dickinson and Company, U.S.A.) and R2A medium (Fujifilm Wako pure chemical) were applied to bacterial isolating cultivation.

Isolation of acid and metal tolerant bacteria

SCF was placed on non-woven fabric which was soaked with mixture (1:1) of AMD and NB medium (**Fig. 2**). Environmental samples (70 µL) were inoculated on the surface of SCF and incubated (30°C, 19 days). To obtain pure bacterial strain, formed colonies were isolated and streaked on agar plate (AP) of R2A medium. After overnight incubation, formed colonies were steaked on fresh AP again. This purification process was repeated 5 times. Isolated strains were identified using 16S rRNA gene sequences and evaluated growth ability under neutral pH conditions.

Evaluation of metal biosorption ability

Isolated bacterial strain was cultured (30°C, 160 rpm) in 50 mL R2A medium until reached to stationary phase. Then, bacterial cell was harvested by centrifugation and suspended into filtered 50 mL AMD of Horobetsu mining site (pH 1.95). Biosorption treatment was conducted for 3 h (30°C,160 rpm) and bacterial cell was removed. One mL of initial and treated solutions were collected and 25 times diluted with 1% nitric acid. Metal adsorption abilities of each strain were evaluated based on metal concentrations quantified using ICP-AES.

RESULTS AND DISCUSSION

Isolation of acid and metal tolerant bacteria

Three acid and metal tolerant bacterial strains were isolated and identified as *Paenarthrobacter* sp. and *Bacillus* sp. (**Table 1**). All strains were classified as biosafety level 1. These bacteria can be cultivated under neutral pH conditions and survived under acidic metal existing conditions. This means that acidic wastewater is not generated by biomass production. According to these results, isolated bacteria are potentially available for metal biosorption process under acidic conditions.

Evaluation of metal biosorption ability

All isolated strains adsorbed arsenic and iron from AMD of Horobetsu mining site (**Fig. 3**) The strain H1 showed the highest adsorption ratio of arsenic 40% and iron 8.77%, respectively (Initial concentrations were 5.83 [mg/L] and 295 [mg/L], respectively, pH 1.95). Comparing the metal adsorption ability [mg/g-dry cell], the strain H2 showed the highest ability that arsenic 1.95 [mg/g-dry cell] and iron 14.0 [mg/g-dry cell] (**Table 2**). These results indicate that arsenic and iron in AMD can be adsorbed by acid tolerant bacteria under strongly acidic conditions. In Japan, arsenic concentration standard of discharged AMD is generally 1 [mg/L]. Although adsorption efficiency was not satisfied the standard in this study, it was succeeded to remove arsenic from AMD without generating waste sludge.

Conclusion

In this study, acid tolerant bacteria were isolated which can adsorb arsenic and iron from AMD under strongly acidic conditions. With those bacteria, it was achieved to remove metals from AMD without generating waste sludge. This is the first step to establish environmentally friendly AMD treatment process.

Table 1. Bacterial strains and their growth abilities under neutral pH condition.

Strain number	Strain	Biomass [g/L]
H1	*Paenarthrobacter* sp.	1.04
H2	*Paenarthrobacter* sp.	0.596
H3	*Bacillus* sp.	0.706

Abstract
Iron-rich carrier particles can be ionized into Fe^{2+} and Fe^{3+} which improves the activity and aggregation of anammox bacteria. Three samples from a carrier assisted granulation reactor with size groups including Flocs, FL (0 – 300μm), Small Granules, SG (300 – 500μm) and Large Granules, LG(500 – 1000μm) were used in this study. It was observed that as the granule size increased, the iron rich carrier content increased, and their active crystals improved the microbial cell density. Specific anammox activity (SAA) was 34.63 ± 5.02, 55.29 ± 5.14, and 63.81 ± 7.50 mg-N/g-VSS/d for FL, SG and LG, respectively. In addition, in heme c content of LG was 31.5% higher than SG and 62.9% higher than FL. An in-depth study into the extracellular polymeric substances (EPS) showed that the secretion intensity of essential proteins followed the order of FL<SG<LG in LB-EPS and FL>SG>LG in TBEPS. Functional group analysis confirmed that the hydrophobic C-N and N-H stretching vibration band had almost 3.5 times higher transmittance intensity in LG than the other sizes and the corresponding ratio of α-helix/(β sheet + random coil) in secondary derivative proteins analysis showed tightness in the protein structures of FL. The relative abundance of Brocadia Sinica increased from 0% in FL to a high of 20.46% in LG. This study aims to communicate the essence of in-depth EPS analysis beyond the usual EPS yield and major contents of proteins (PN) and polysaccharides (PS) analysis..

INTRODUCTION

In this study, a detailed characterization of three distinct sizes (0~300μm, 300~500μm, 500~1000μm) of iron-rich carrier assisted granules was carried out focusing on nitrogen removal activity, Heme c production, sectional and total EPS secretion and its importance in maintaining the granules stability and performance. Specific microbial species and enzyme response for each granule size is also looked at to help identify the overall optimal granule size and performance in the anammox process when iron rich particles are employed as carrier.

MATERIALS AND METHODS

The three distinct anammox sludge sizes used in this study were taken from a 2.3 L lab-scale sequencing batch reactor (SBR) that has been operated with the addition of 0.5 g/L iron-rich carrier particles (45-75μm) to enhance granulation. The nitrogen loading rate (NLR) of the SBR reactor was 0.96 gN/L/d. The three kinds of EPS (S-EPS, LB-EPS and TB-EPS) were extracted using the modified heat extraction method (Wang et al. 2020c). To measure the heme c contents of each granule size, the uniformly homogenized samples were centrifuged at 12,000 rpm for 10 min. The supernatants were collected and used in the measurement of heme c concentration according to the methods stipulated in Ma et al. (2019) and using a millimolar extinction coefficient of 23.97. Extraction of DNA was carried out using a PowerSoil DNA kit (Mobio Laboratories Inc., USA) following keenly the manufacturers protocol. For each granule size, 2 mL of settled sludge sample was collected for the extraction of DNA.

RESULTS AND DISCUSSION

(Size effect of Anammox activity) In the anammox study, microbial activity is measured through the specific substrate consumption of a unit cell per day as well as through the production of the heme variant (heme c) that remains bounded to the holoprotein and cytochrome c to promote multiple electron transfer reactions (Jetten et al. 2009). In order to accurately characterize the different granule sizes, the variation in their activity was measured and presented together with the microscopic representative granules of each size in Figure 1. It can be seen that as the granule size increases, the core encompassed iron-rich carrier contents increase and hence provides the attraction force to enable additional subunits adhesion and thereby increase the granule's size.

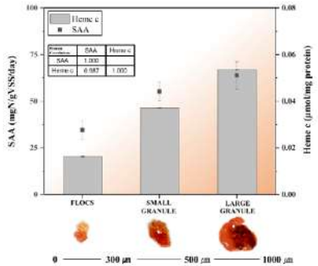

Figure 1. Anammox Activity and heme c production for the three distinct size granules

(Anammox Extracellular Polymeric Substances (EPS)) In Figure 2, the extracted EPS for all three anammox sizes is presented in the sectional and total form. For all sizes, the PN contents didn't not show any significant differences when observed as individual EPS types. Therefore, the total PN showed an infinitesimal difference between SG and LG and just slightly higher in FL.

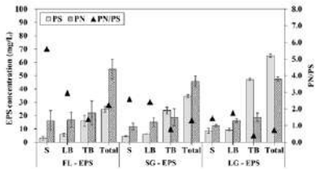

Figure 2. EPS and PN/PS ratio for FL, SG and LG

(Anammox size and microbial consortia) The relative abundance of the three distinct microbial sizes at the phylum and class level is shown in Figure 3. From the Figure 3, the general decrease in microbial diversity as iron-rich particles and granule size increase is emphasized through the class level obervation.

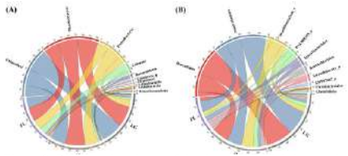

Figure 3. Relative abundance of the three microbial sizes at the Phylum (A) and Class (B) level

Abstract
The growing interest in the anaerobic ammonium oxidizing (AMX) process in treating high nitrogen containing wastewaters and a comprehensive study into the granulation mechanism of these bacteria under diverse environmental conditions over the years have been unequal. To this effect, the distinctive differences in saline adapted AMX (S_AMX) and non-saline adapted AMX (NS_AMX) granules are presented in this study. It was observed that substrate utilisation profiles, granule formation mechanism, and pace towards granulation differed marginally for the two adaptation conditions. The different microbial dominant aggregation types aided in splitting the 471 days operated lab-scale SBRs into three distinct phases. In both reactors, phase III (granules dominant phase) showed the highest average nitrogen removal efficiency of 87.9% ± 4.8% and 85.6% ± 3.6% for the S_AMX and NS_AMX processes, respectively. It was observed that granules of the S_AMX reactor were mostly loosely and less condensed aggregates of smaller sub-units and flocs while those of the NS_AMX reactor were compact agglomerates. The ionic gradient in saline enrichment led to an increased activity of the Na + /K + – ATPase, hence enriched granules produced higher cellular adenosine triphosphate molecules which finally improved the granules ac-tive biomass ratio by 32.96%. Microbial community showed that about three to four major known AMX species made up the granules consortia in both reactors.
Keywords

INTRODUCTION

In this study, we tried to provide an in-depth differentiation between the granulation profiles of the S_AMX and NS_AMX granules through adapting physiological and morphological analysis techniques. It focuses and highlights the differences in the general granule health in terms of microbial energy production and maximum specific activity. Also, the disparities in settleability and granules floatation mechanisms as well as the expression of major proteins and functional genes are summarized and discussed in detail. Practically, understanding and realizing these differences can help wastewater treatment plants operators identify the occurrence of unexpected nutrient conditions that may gradually lead to domi- nance shift if not curtailed in time.

MATERIALS AND METHODS

Two water jacketed sequencing batch reactors (SBR) with 2.3 L and 1.8 L operational and effective volume, respectively were used for the granulation profile determination. The reactors were installed side by side and labelled S_AMX and NS_AMX for saline adapted and non-saline adapted AMX process, respectively. The bioreactor operation was similar for both reactors except for the gradual NaCl injection into the S_AMX reactor. The reactors were operated with 4 cycles per day and the treatment capacity was fixed at 2 L/day. The hydraulic retention time (HRT) was there- fore 21.6 hr and the average operational temperature (35 ±1.1°C) and pH (7.75 ±0.8) were maintained with a thermostatic water bath and intermittent CO_2 supplied when the reactors' pH surpasses 8.1.

RESULTS AND DISCUSSION

(**Substrate utilization & removal**) Table 1 summarizes in details the characteristics of the different phases in both reactors. Salinity in the form of NaCl was introduced from a minimum of 0 to 10 g/L into the S_AMX re- actor in phase I. After the initial stepwise increase of saline levels, a longer duration of 86 days was maintained for the 5 g/L NaCl injection in phase I on account of reports that saline inhibition of freshwater AMX species is mostly experienced at this salt concentration.

Table 1. Average performance characteristics of the AMX reactors at the different enrichment phases

Phase	S_AMX					NS_AMX

(**Granule morphology and characteristics**) In order to comprehend the apparent differences in the granules formed in the saline and non-saline enriched environments, it is important to consider comprehensively the mi- nor but essential physiological and morphological factors and characteristics of the two distinct granules and their granulation techniques. Fig. 1 shows the physical appearance of the S_AMX and NS_AMX granules and the annotated granulation mechanism for the two different AMX adaptation conditions.

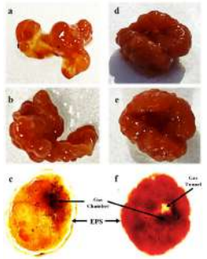

Figure 1. observation of the S_AMX (a-c) and NS_AMX (d-f) granules

(**Community and functional genes expressions**) In a typical AMX process, an analyses of the major microbial proteins and functional genes expressions enhances the understanding of the metabolic activities and correlates this to the performance of the granules in a specific enrichment environment. Several important proteins and enzymatic functional genes based on the distinct expressions between the two differently enriched environments are summarised as a heat map in Fig. 2. The dominant AMX species in all three samples (Inoculum, S_AMX and NS_AMX) expressed these proteins and functional genes in accordance to their abundance in the extracted DNA samples. A close observation of Fig. 2 also shows that the ATPase genes responsible for the intracellular transportation of Na+ and K+ were expressed distinctively different for all samples.

Algal-Bacterial Biofilms to Purify Wastewater, Reduce Power Consumption, and Minimize Carbon footprint.

D.B. Johnson*

* Algaewheel Inc, 180 Tower Rd Cary NC, 27512
(E-mail: *dan.johnson@algaewheel.com)**

Abstract

Hybrid algal-bacterial wastewater systems are effective natural solutions to decentralized wastewater purification, reducing electrical usage by 75% and greenhouse gas emissions by 87%. Algaewheel functions similarly to a river in a box. The rotating algal contactors combine the synergistic performance benefits of algae, and bacterial biofilm to oxidize COD and ammonia while directly assimilating carbon dioxide, nitrogen, and phosphorus. Algaewheel can meet permit limits as stringent as 5 $CBOD_5$ and <1 NH_3-N. The low energy requirement makes the system favorable for rural decentralized, or developing areas where it is impractical to have complicated systems or pump waste. Algaewheel has few mechanical moving parts, reducing maintenance, and making it easier to operate than activated sludge processes. Algaewheel treatment results in a large reduction of CO_2 emissions, less complexity, and high-quality effluent. This presentation will review existing facility data and processes in the US, Mexico, and MENA region.

Abstract
N-damo bacteria are microorganisms that could be used in innovative processes for the removal of dissolved methane and total nitrogen present in the effluents of anaerobic bioreactors treating municipal wastewater. Sewage treatment plants in coastal areas suffer seawater intrusion. There are few studies on the possible inhibitory impact of N-damo bacteria under saline conditions, which should be evaluated for practical application at industrial scale. In this study, batch tests have been carried out to evaluate the impact of salt concentration on the activity of N-damo bacteria. The preliminary results of this study indicate that salinity may have a profound impact on the activity of these microorganisms.

Keywords (maximum 6 in alphabetical order)
Anaerobic methane oxidation; batch assays; N-damo bacteria; nitrite removal; salinity.

INTRODUCTION

The presence of dissolved methane and nitrogen compounds in liquid effluents from anaerobic bioreactors in water treatment plants is an issue, currently being studied to reduce greenhouse gas emissions [1]. In order to diminish the negative impact of anaerobic treatment, the use of N-damo microorganisms could be an alternative [1]. These microorganisms, discovered in 2010, are capable of simultaneously removing nitrite and dissolved methane under anaerobic conditions [2]. They are characterised by their low activity and slow doubling times, which makes their practical application difficult [2]. Previous studies, in which the role of NaCl on N-damo biomass was determined by He et al. [3], found that increased salinity had a negative impact on N-damo activity. However, biomass with a very low N-damo specific activity was used, less than 2-3 mg $N{\cdot}g\text{-}VSS^{-1}{\cdot}d^{-1}$, which is significantly lower than that found in our laboratories, of around 95 mg $N{\cdot}g\text{-}VSS^{-1}{\cdot}d^{-1}$[1]. Therefore, it is important to corroborate the impact of salinity with biomass of greater specific activity, using not only NaCl but other ions. The aim of this study is to analyse the effect of salt concentration on N-damo biomass with high specific activity.

MATERIALS AND METHODS

The assays were carried out in 500 mL Pyrex bottles with screw cap and teflon septum, with biomass from an enriched N-damo MBR bioreactor [1]. For the preparation of the necessary solutions, 120 mL glass bottles with metal septum and washer were used. The bottles were filled with the base medium described by Allegue et al. [1] and the following elements: $NaHCO_3$ (100 mg L^{-1}) acting as a buffer element, $Na_2S_2O_3$ 0,4 mM to maintain reducing conditions, 10 mg L^{-1} NO_2^--N as a nitrogen source and different concentrations of salt solution prepared from a stock of 33 g L^{-1} NaCl in base medium (5%, 20% y 50% v/v). In the gas phase, 20 mL of CH_4 and CO_2 are added under overpressure from a gas mix 90% CH_4 10% CO_2. This volume of CH_4 establishes a concentration that is in excess which allows the limiting reagent to be nitrite.
A stream of argon was passed through the solutions for 10 min to desorb oxygen and maintain anoxic conditions. The different solutions were added to the assays through the septum via syringes. The assays were inoculated with a concentration of 0.077 g L^{-1} N-damo biomass and placed on a thermostatic shaker (125 rpm) at 28° C in the dark. Liquid and gas phase sampling were performed at time zero and periodically every 24 h until the end of the assays. At the time of sampling, the same extracted volume of inert gas Argon is injected to maintain the pressure inside the bottle. Measurements of pH, conductivity, nitrite concentration and biogas composition are carried out.

RESULTS AND DISCUSSION

The inoculum comes from a enriched N-damo culture grown in a membrane bioreactor (MBR) as described by Allegue et al. [1]. The concentration of volatile suspended solids in the mixing liquor was 4.85 g MLVSS L^{-1}. The system operated at 29º C with a permeate flow rate of 5.54 ± 0.50 L d^{-1}, maintaining a hydraulic retention time of 1.21 ± 0.09 d. The nitrite load in the feed ranges between 112 and 123 mg NO_2^--N L^{-1} reaching average nitrite concentrations at the permeate of 0.05 with minimum values of 0 and maximum values of 0.21 mg NO_2^--N L^{-1}.
During the experimental period the nitrite removal rate of the MBR was 95.8 ± 8 mg NO_2^--N L^{-1} d^{-1}, achieving a maximum nitrite removal rate of 117 mg NO_2^--N L^{-1} d^{-1}, similar to the maximum values reported previously by Allegue et al. [1]. The apparent specific activity resulting from the N-damo was 20 ± 1.8 mg NO_2^--N g^{-1} MLVSS d^{-1}, lower than those of 95.5 mg NO_2^--N g^{-1} MLVSS d^{-1} reported by Allegue et al. [1]. This lower specific activity rates of the N-damo bacteria could be explained by the increase of the biomass concentration accumulated in the MBR.
Figure 1 shows the preliminary results obtained in the first activity experiments, and showed a remarkable stimulation in N-damo activity using the lowest salt concentration (5% or 1.65 $g{\cdot}L^{-1}$ NaCl) with respect to the test in in which salt was not added. The 5% salt test consumed almost all the nitrite in 96 h, with specific activity values at this adaptation stage of 23.4 mg NO_2^--N g^{-1} MLVSS d^{-1}. At 168 h a second pulse of 20 mg NO_2^--N L^{-1} was added, increasing the activity to 51.7 mg NO_2^--N g^{-1} MLVSS d^{-1}. On the other hand, the activity measured with intermediate salt concentration (20% or 6.6 $g{\cdot}L^{-1}$ NaCl) was similar to that without any salt addition (Biotic 0%). Nevertheless, in the 50% test (16.5 $g{\cdot}L^{-1}$ NaCl) N-damo denitrifying activity was almost negligible. These preliminary results, using N-damo biomass with high activity, indicate that the impact of NaCl is similar to that previously reported by He et al. [3]. However, unlike this study, it has been found that a lower concentration of 1.65 $g{\cdot}L^{-1}$ NaCl could be stimulatory for the N-damo activity. Thus, low saline concentrations could have a positive effect on the N-damo process.

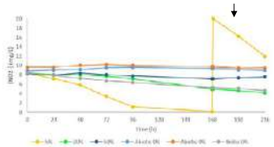

Figure 1. Evolution of the NO_2^- concentration obtained in the activity assays (with the different % salt and the abiotic controls with and without salt). The arrow indicates the addition of a new pulse of 20 mg NO_2^--N L^{-1} for the 5% salinity test.

Photo-Membrane Reactor (PMR) for Removal of Per- and Polyfluoroalkyl Substances (PFAS)

A. L. Junker & Z. Wei*

*Department of Biological and Chemical Engineering, Aarhus University, 36 Universitetsbyen, 8000 Aarhus, Denmark (Email: *ajunker@bce.au.dk*; *zwei@bce.au.dk*)

Abstract
A novel technology combines membrane separation and advanced oxidation processes in a single photomembrane reactor to safely and effectively "concentrate and destroy" aqueous micropollutants. The reactor operates with an adsorptive photocatalyst immobilized on the membrane surface. The membrane and adsorptive photocatalyst both promote the concentration of PFAS at the membrane surface, where it is mineralized under UV irradiation mediated by the photocatalyst.

Keywords
Membrane separation; PFAS degradation; photocatalysis; zero pollution

INTRODUCTION

Persistent micropollutants, such as per-and polyfluoroalkyl substances (PFAS), endanger society due to their mobility in the environment and resistance to degradation, posing long-term exposure risk if not effectively eliminated during wastewater treatment. While conventional treatment methods are ineffective, reverse osmosis and activated carbon can remove PFAS from water but generate contaminated waste streams. Advanced oxidation processes (AOPs) and thermolysis treatments show potential to mineralize PFAS into benign compounds; however, these methods are expensive, energy intensive, and difficult to scale up. By combining membrane separation and AOPs, a single-step reactor can efficiently concentrate and destroy PFAS, without harmful waste products and under the same mild conditions normally found at WWTPs.

MATERIALS AND METHODS

Four adsorptive photocatalysts were synthesized via hydrothermal process from inexpensive base materials: carbon, titanium dioxide, and post-transition metals. The catalysts were evaluated for PFAS removal, degradation and defluorination rates, after exposing them to UVC irradiation. Catalyst trials were conducted in both a slurry suspension and immobilized on a membrane. PFOA was selected as a model PFAS.
Catalyst loadings and membrane coating methods were tested and compared. The samples were analysed for fluorine ion and PFAS content via ion chromatography (IC) and ultra-performance liquid chromatography with a quadruple mass spectrometer (UPLC-MS/MS), respectively. The results of the heterogeneous catalyst were compared with PFAS degradation via UV/sulfite treatment, with sulfite added as a photosensitizer in lieu of the photocatalyst.
The most effective catalyst was immobilized on ultrafiltration and nanofiltration membranes, which were then placed into the photo-membrane reactor (PMR) system. Reactor conditions were optimized for flow mode, pressure and permeate flux. The system was run continuously for 8 hours, with samples taken every 2 hours. At the end of the run time, the catalytic membrane was sonicated in a 100 mM ammonium acetate in methanol solution, and the supernatant was analysed for PFAS extracted from the solid phase. In addition, the degradation of five pharmaceuticals (e.g. carbamazepine, trimethoprim, diclofenac, sulfamethoxazole, and propranolol) were tested in the same setup.

RESULTS AND DISCUSSION

A simple method was developed for immobilizing the catalyst on membranes. Short-chain PFAS species and fluorine ion observed during sample analysis are indicative of PFAS degradation and high rates of defluorination. In slurry, the photocatalysts removed > 99.9% of PFOA in 4 hours, with an overall defluorination rate of up to 57% at an initial concentration of 100 ppb, and even higher at lower concentrations. The iron-doped titanium nanotubes on activated carbon (Fe/TNT@AC) showed the highest defluorination rates, although all synthesized catalysts had a similar adsorption capacity. Comparatively, the UV/sulfite system exhibited very low defluorination rates, less then 3%.
During the static membrane tests, the catalyst removed up to 46% of PFOA, even though only a tenth of the catalyst (by weight) was used to treat the same sample volume of water. However, the membrane's removal abilities diminished when reused cyclically.
In the PMR system, up to 87% of PFOA was removed by the coated ultrafiltration membrane operating at low pressure. Meanwhile, the nanofiltration membrane was able to exclude up to 100% of PFOA from the permeate, when operated at a low pressure and permeate flux. The analysis of the extracted solid phase revealed that only 33 – 46% of the initial PFOA loading was still adsorbed to the catalytic membranes at the end of the run, indicating a significant portion of PFOA had been captured and destroyed in the PMR. The PMR system was less effective at removing the pharmaceuticals from the water, with only sulfamethoxazole and diclofenac showing any significant removal.

Take-home message

The adsorptive photocatalyst, Fe/TN@AC, is effective at removing PFAS, even when immobilized on a membrane. The PMR technology easily combines membrane and AOP treatment processes in a single-step, making its scale up viable. Initial testing indicates excellent removal rates and high degradation rates in the PMR system. However, improving the photocatalytic effect of the membrane could improve its lifetime, resulting in a system that could completely breakdown PFAS.

Abstract

The detection of emerging contaminants (ECs) in our water environment is a serious concern for the whole ecosystem as these can cause known or presumed adverse ecological and/or health impacts. ECs consist of pharmaceutical compounds, personal care products, pesticides, microplastics, industrial chemicals, synthetic dyes, surfactants, etc. Amoxicillin (AMX) is an antibiotic used to treat a variety of bacterial infections and is one of the widely prescribed antibiotics around the world for both human and animal medicine. AMX is an EC, and its impact on the environment and health is still uncertain. Due to its common use, traces of AMX have been detected in rivers, lakes, groundwater, drinking water, coastline water, urban effluents, water, and wastewater treatment plants, etc. The conventional wastewater treatment plants are comparatively ineffective in achieving complete removal of AMX, so there is an urgent need for advanced technology. Electrochemical oxidation (EO) is a very promising technology for wastewater treatment in which electro-generated radicals result in the complete mineralization of organic pollutants. This study is aimed to evaluate the EO of AMX and analyse its removal efficiency. The AMX Concentration has been detected by reverse phase HPLC with an ultraviolet-visible (UV-Vis) detector spectroscopy and the degradation by-products through QE Orbitrap LC-MS. Under the optimal conditions, the removal rates of AMX reached 99.1% after 3 hours of treatment at 7.5 voltages in 0.05M Na_2SO_4 solution. The results indicated that the electrochemical degradation of AMX fitted first-order reaction kinetics.

Keywords: Emerging contaminants, amoxicillin, antibiotic, wastewater, electrochemical oxidation

MATERIALS AND METHODS

Amoxicillin Trihydrate ($C_{16}H_{19}N_3O_5S.3H_2O$) has been purchased from Zeta Scientific for amoxicillin (AMX) source. Sodium sulphate (Na_2SO_4) have been purchased from EMPARTA® ACS. HPLC-grade methanol, used for HPLC analysis, have been obtained from Merck. Ultra-purified water obtained from Millipore-Q system for all the solutions. All the chemicals are analytical grade and used without further purification in this study. Fresh electrolyte solution with 0.05M Na_2SO_4 and DI water and 0.05M NaCl and DI water has been prepared at room temperature for each electro-oxidation experiment. The electrodes were characterized using a scanning electron microscope (SEM) and Raman spectroscopy of the graphite electrode for physical and chemical characteristics and performance. The electro-oxidation experiments were performed in a 100 ml cylindrical rector. Voltage-controlled conditions for electrolysis were maintained using a regulated D.C. power supply (HTC Instruments; DC POWER SUPPLY DC3005; 0-30 V, 0-5 A). Electrooxidation reactions began when the power supply was switched on.

RESULTS

In all electrochemical processes, the applied voltage is one of the important parameters to control reaction rate in electrochemical reactors. It manages the flow of the electron transfer, the capability of ‘OH generation, and determines the energy efficiency concerning the size of a reactor, resistance of the materials, etc. (Pan et al., 2020; Sopaj et al., 2015; Xu et al., 2019). Electrochemical experiments have performed using 1 mg/L of Amoxicillin (AMX) with variable voltage conditions and the analysis performed in HPLC. The results showed that the removal efficiency increased from 60.3 to 98.7% (Figure 1) as the voltage increases and the pseudo-first-order rate constant (k_{obs}) increased from 0.3977 to 0.9025 min^{-1} and the k_{obs} had excellent corelations with the voltage (R^2=0.991).

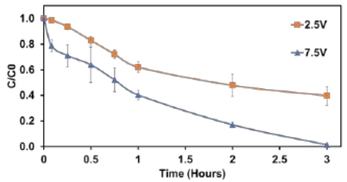

Figure 1: Removal efficiency for 1mg/L AMX initial concentration at different time intervals for different voltage.

Abstract
Marine ecosystems are facing eutrophication problem due to intensive accumulation of nutrients mainly from wastewater discharge and agricultural runoff. Nature-based solutions (NbS) are promising in terms of in-situ treatment eutrophic marine waters in a sustainable way. The aim of this study is to assess nutrient removal from eutrophic brackish sea water (the Baltic Sea) via lab-scale NbS systems mimicking conditions in the envisioned floating vertECO© raft constructed wetland technology. Six lab scale systems containing substrate mixture (zeolite, pumice and biochar) and two different plants (*Bolboschoenus maritimus* and *Schoenoplectus tabernaemontani*) as triplicates and one control system with substrate mixture (without plants) were operated with eutrophic brackish sea water. The results showed that lab-scale vertECO© wetland systems could remove nutrients and the systems with *Bolboschoenus maritimus* had a better performance.

Keywords (maximum 6 in alphabetical order)
Eutrophication; floating wetland; nature-based solutions; nutrients

INTRODUCTION

Marine eutrophication is a global concern that has adverse effects on both ecosystem and human services. It is stated that 762 coastal areas are impacted by eutrophication and/or hypoxia (World Resources Institute, 2013). For managing marine eutrophication, the strategies should include in-situ/ex-situ engineering approaches to remove nutrients in addition to nutrient input reduction strategies on wastewater discharge and agricultural runoff (Kendir Cakmak *et al*, 2022). Nature-based solutions (NbS) can provide a sustainable way to tackle eutrophication and floating wetlands are one of the successful examples commonly applied on freshwater sources. However, the main application of coastal/marine areas is erosion control, food web support, sediment trapping and aesthetic enhancement (Takavakoglu *et al*, 2021) and knowledge gap is huge for treatment of eutrophic waters.

MATERIALS AND METHODS

Seven lab-scale constructed wetland systems (open-air) were constructed in the premises of alchemia-nova (Vienna, Austria). The eutrophic sea water was collected from the Stockohlm Archipelago, the Baltic Sea. The systems included triplicates with two different local plant species (*Schoenoplectus tabernaemontani* and *Bolboschoenus maritimus*) and one control system without plants. Horizontally placed plastic columns (inner Ø:15 cm, height:1 m, total volume:18 L) were modified by cutting the top open and inserting an outlet pipe to control the water level. The plastic columns were filled with a substrate mixture (zeolite:30%, pumice:60%, biochar:10%). 5 bunches of the plants (roots were pre-washed) were planted except the control system. The systems were fed from a 250L storage tank by a submerged pump. Graduated buckets were placed at the outlet to collect the outlet water and measure the actual flow. During an initial acclimation phase, the systems were firstly fed with i) 20 days with artificial sea water (6 psu salinity, 0.55 mg/L NO_3-N, 0.06 mg/L PO_4^{3-} and 0.03 mg/L NH_4^+-N mimicking the collected Baltic Sea water). Later, the systems were fed with ii) higher concentrated eutrophic artificial sea water (0.831 mg/L PO_4^{3-} and 1.968 mg/L NH_4^+-N mimicking an eutrophic bay in the Baltic Sea as stated in Rydin *et* al, 2017) to assess nutrient removal under higher eutrophic inflows. The average initial nutrient concentrations of this artificially prepared water were 0.875 mg/L PO_4^{3-}, 2.675 mg/L NH_4^+, 0.55 mg/L NO_3-N and 0.006 mg/L NO_2-N. After the acclimation phase, the systems were fed with iii) the real Baltic Sea water set to higher eutrophic conditions as stated above for 9 days. Both outlet and inlet samples were analysed for pH, conductivity (EC), NH_4^+ NO_3-N, NO_2-N and PO_4^{3-}. The plant growth was visually monitored. One-way ANOVA was performed to compare the effect on treatment (with/without plants) on nutrient removal.

RESULTS AND DISCUSSION

The average NH_4^+ and PO_4^{3-} removal efficiencies were highest with *Bolboschoenus maritimus* (99.9% for NH_4^+ and 54.6% for PO_4^{3-}). PO_4^{3-} removal was lowered after 4 days due to the saturation of the adsorption sites of substrates (Dotro *et al* 2012). For PO_4^{3-} and NH_4^+ removal, the differences between plant treatments as well as control and treatment with *Bolboschoenus maritimus* were significant ($p<0.05$). The differences between control and treatment with *Schoenoplectus tabernaemontani* were insignificant ($p>0.05$). NO_3-N and NO_2-N were not removed in the systems. pH values increased from 8.07 to 8.55-8.73 and EC was also measured as 9.38-9.79 mS/cm. The height of the both plants increased and the new shoots were grown during experiments. The growth of *Bolboschoenus maritimus* was better. To conclude, lab-scale vertECO© wetland systems could remove nutrients from the brackish eutrophic sea water and *Bolboschoenus maritimus* showed better nutrient removal performance. The combined effect of plants and substrates was not considerably more effective than the effect of substrate uptake itself. As sorption sites will be saturated over time (especially for the PO_4^{3-}), the role of the plants might increase over time if managed properly through regular plant harvesting. Future designs can focus on enhanced nutrient removal and plant performance and beneficial use of harvested plants.

Abstract
The micropollutant is high effect and accumulate in the aqua system. The almost widely used 17α-methyltestosterone (MT) and 17β-Estradiol (E2) for Nile tilapia productivity and female hormone increasing. This study is focused on MT and E2 removal via the photocatalytic process using in-house PVDF membrane modified by nanomaterials (either 1%TiO_2 or TiO_2/α-Fe_2O_3). The membranes were characterized for water contact angle (WCA), morphology analysis, permeability and salt rejection. The membrane permeability results of PVDF, PVDF-TiO_2, and PVDF-TiO_2/α-Fe_2O_3 were 4.5 x 10^{-11}, 6.1 x 10^{-11} and 6.3 x 10^{-11} m/s.Pa, respectively. The optimum removal time with UV light is 20 min and 60 min for MT and E2, respectively. The MT removal is 100% removal performance for all membrane. The performance of E2 removal by PVDF, PVDF-TiO_2, and PVDF-TiO_2/α-Fe_2O_3 were 65%, 95%, and 72%, respectively. The addition of nanomaterials, both TiO_2 and α-Fe_2O_3, enhanced the water flux. However, the removal efficiency of E2 less than MT according to the chemical bond and structure of E2 is stronger than MT. The addition of α-Fe_2O_3 showed the high permeability but less removal performance consistent with the surface roughness which inhibited the catalytic activity.

Photocatalytic membrane (PMR); hormone; 17β-Estradiol (E2); 17α-methyltestosterone (MT); titanium dioxide (TiO_2); Hematite (α-Fe_2O_3)

INTRODUCTION

Endocrine-disrupting compounds (EDCs) are micropollutants and bioaccumulate that can cause widespread environmental. 17 α-methyltestosterone (MT) and 17β-Estradiol (E2) for Nile tilapia productivity and female hormone increasing. Conventional wastewater treatment technology is inefficient completely in the removal of hormone such as adsorption, biodegradation, bio-sorption (Tagliavini and Schäfer 2018; Vieira et al. 2021). It requires longer operational time and is less efficient. Nanomembrane filtration process and advanced oxidation processes (AOP) had been presented a high performance but high pressure and energy demand. Hence, the coupling technique and mechanism of membrane sieving and photocatalytic which can oxidize pollutants quickly and enhance the presence of irradiation light to improve process performance. The performance of the photocatalytic membrane system was investigated the MT and E2 removal at source to use for the surface water management around agriculture fish floating case and wastewater treatment plant effluent in Songkhla lake, Songkhla, Thailand.

MATERIALS AND METHODS

Synthesis of TiO_2 was carried out following methods published in previous studies (Bootluck et al., 2021). The TiO_2 powder was obtained after calcinated at 450°C for 2 h. α-Fe_2O_3 and Ti/α-Fe_2O_3 samples were fabricated by the hydrothermal method following the previous method (Bootluck et al., 2021). The preparation process of the in-house photocatalytic membrane was fabricated is shown in **Figure 1**. The control PVDF was prepared as following in-house fabricated and named PVDF, PVDF-TiO_2, and PVDF-Ti/α-Fe_2O_3 membranes. For the PVDF-TiO_2 used 1 wt% TiO_2 and was mixed with 0.1 wt% PVP and 17 wt% PVDF and dissolved in NMP under a magnetic stirrer for 5 h at 60°C (Subramaniam et al., 2020). PVDF-Ti/α-Fe_2O_3 membranes, either adding 1 wt% Ti/α-Fe_2O_3 and followed the previous method. Then, the homogeneous solution was sonicated for 30 min by sonication (GT sonic, China). The membrane casting was done on a glass plate using phase inversion method. The membrane was dried for 5 min at 70 °C and was stored in DI water until used.

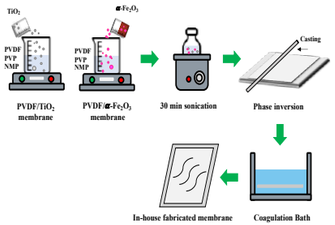

Figure 1. The schematic diagram of the fabrication process of photocatalytic membranes

Membrane surface and morphology were characterized by water contact angle (WCA) measurement and scanning electron microscope (SEM, SU 3900, Hitachi, Japan). The membrane permeability and salt rejection were test as following ASTM D4516 method (ASTM, 2002).
The 5 mg/L of MT and E2 concentration removal performance were test by the crossflow unit cell assembly for 3 hrs for with and without UV_{95W} condition. The photocatalytic kinetics were determined and the first-order rate constant (k) was calculated following Dzinun et al. (2015).

RESULTS AND DISCUSSION

The contact angle of PVDF, PVDF-TiO_2, and PVDF-TiO_2/α-Fe_2O_3 membranes are 84°, 78° and 71°, respectively. The WCA decreases when added TiO_2 and TiO_2/α-Fe_2O_3 which relatives with the increasing of permeability. The results of membrane permeability of PVDF, PVDF-TiO_2, and PVDF-TiO_2/α-Fe_2O_3 were 4. 5 x 10^{-11}, 6.1 x 10^{-11} and 6.3 x 10^{-11} m/s.Pa, respectively. The morphology showed two-layered the sponge-like structure and macro voids to carry the high-water flux. The water flux for 180 min operation, PVDF-TiO_2 membrane was the highest (573 LMH). PVDF-TiO_2 and PVDF-TiO_2/α-Fe_2O_3 membranes showed similar permeate flux. The results showed that the PVDF-TiO_2 membrane showed the highest flux, meaning water flux is not correlated to WCA.

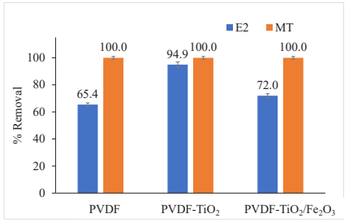

Figure 2. The hormone removal performance of PVDF, PVDF-TiO_2, and PVDF-TiO_2/α-Fe_2O_3 membrane.

From Figure2. the hormone removal of MT and E2 found that the E2 (82%) is less performance than MT (100%) due to the strong chemical bond of E2. The optimum time with UV light is 20 min and 60 min for MT and E2 removal, respectively. The kinetic degradation of MT and E2 are first-order reaction. There have rough spots on the surface membrane after adding TiO_2 and α-Fe_2O_3 catalyst, and the membrane pores of cross-section became wider upon catalyst but effect on its performance. However, the high pH is more OH ions available on the TiO_2 surface which it is easier to generate OH• and improves process efficiency.

Abstract
The purpose of this study is to apply a desalination battery as a method to remove NaCl in food wastewater and to improve the performance of a desalination battery by introducing a carbon-based electrode. Carbon felt(CF), graphite felt(GF), and carbon felt coated with functionalized MWCNTs(CNT-CF) were tested as target electrodes. MWCNTs were coated using the electrophoresis method. CF showed the lowest chloride ion removal performance, and the time required to achieve a chloride ion removal rate of over 85% was reduced by about 7.7 times for GF and 3.6 times for CNT-CF compared to CF.

Keywords
Carbon Felt; Carbon nanotubes; Chloride ion removal; Desalination; Electrode; Graphite Felt

INTRODUCTION

Food wastewater is one of the wastes inevitably discharged from human life, and the amount of it is increasing due to the increase in population and economic activity. Anaerobic digestion is being considered as a method for treating food wastewater [1]. However, a large amount of NaCl is contained in food wastewater, which reduces the stability of anaerobic digestion [2]. Desalination batteries can be a way to remove NaCl and store some of the energy used for NaCl removal. Desalinated battery has a section for desalination between the anode and cathode, and the cation exchange membrane and the anion exchange membrane are designed to form an interface with the desalination section. In desalination, sodium ions and chlorine ions in the desalination chamber are separated and transported to the anode and cathode. The electrochemical reaction during charging is as shown in Equations (1) to (3) [3].

Anode Part: $Na^+ + e^- \rightarrow Na(s)$ (1)
Desalination Part: $NaCl(aq) \rightarrow Na^+ + Cl^-$ (2)
Cathode Part: $2H_2O(l) \rightarrow 4H^+ + O_2(g) + 4e^-, H^+ + Cl^- \rightarrow HCl(aq)$ (3)

The electrochemical redox reaction on the surface of the electrode should be encouraged in order to improve battery performance. Large-surface-area oxide electrodes generally offer high catalytic activity [4]. Carbon materials can be thermally oxidized to increase their surface area and make them advantageous for use in aqueous solutions. Because of these advantages, research on CF and GF electrodes is in progress. One of them is to improve the electrochemical reaction by coating the carbon-based electrode with other materials. Carbon nanotubes are being studied as electrode coating materials and are characterized by high tensile strength, high electrical conductivity and large surface area [5].

In this study, multi-walled carbon nanotubes were attached to CF by electrophoresis, and it was named CNT-CF. In addition, CNT-CF was applied as electrodes to a desalination battery and their performance was compared with CF and GF.

MATERIALS AND METHODS

Preparation of electrodes

CF(CNF Co. Ltd., Republic of Korea) and GF(CeTech Co. Ltd., Taiwan) were thermally oxidized at 500 °C for 4 hours to improve surface wettability. MWCNTs (Sigma Aldrich) with a diameter of 10 to 20 nm and a length of 5 to 15 nm were added to a mixed solution of sulfuric acid and nitric acid (3:1) for impurity removal and functionalization. The functionalized MWCNTs were ultrasonically dispersed in ethanol to form a uniform suspension. 25 mg $ZnSO_4 \cdot 7H_2O$ was added into the suspension to improve the deposition rate and the adhesion of the MWCNTs to electrode [6]. Electrophoretic deposition was performed by applying a voltage of 30 V for 10 minutes. CF was used as coating substrates to connect to the negative potential, and the counter electrode was made of the same material as the substrate. The distance between the electrodes was maintained at 10 mm.

Assembly of the desalination battery module

The desalination battery is assembled with SWB2464 coin cell(4toone Co., Ltd., Republic of Korea), seawater battery housing kit(4toone Co., Ltd., Republic of Korea), anion exchange membrane(fumatech Co., Ltd., Germany), and desalination compartment. The desalination compartment is made of polycarbonate material and designed with an internal volume of up to 3.4 ml.

Electrode performance test

In experiments No.1 to No.3, 5,000 mg/L as Cl synthetic wastewater was prepared by adding 8.242 g of NaCl to 1 L of deionized water. The value of 5,000 mg/L as Cl refers to the concentration of chlorine compounds in effluents in 2017 and 2019 investigated by the Ministry of Environment of the Republic of Korea. 3 ml of synthetic wastewater was injected into the desalination compartment, and the compartment was separated with an anion exchange membrane before assembly. All of test electrodes were connected to the cathode compartment and an external voltage of 9 V was applied. Chlorine ion concentrations were measured by sampling samples in the desalination compartment at specific times.

Table 1. Experimental condition of desalination test by seawater battery

No.	Conc. (mg Cl^-/L)	External voltage (V)	Cathode materials	Initial cell voltage (V)
1	5,000	9	CF(3cm×3cm)	1.305
2			GF(3cm×3cm)	1.827
3			CNT-CF(3cm×3cm)	1.116
4	302		CF(3cm×3cm), CNT-CF(3cm×3cm)	1.218, 1.240

RESULTS AND DISCUSSION

When CF was used as the cathode electrode, 86.7% of chlorine ions were removed in 165.5 hours. As shown Fig. 2, the voltage change of the cell was divided into a phase in which the voltage rapidly increased(A-stage) and a phase in which the voltage increased slowly(B-stage). The A-Stage shows a sharp slope due to the adsorption behavior of sodium ions on the Na metal of the anode, and the stable slope at the B-Stage is due to the intercalation of sodium ions in the Na metal [7]. The chlorine ion removal rate in the A-Stage section showed a relatively insignificant tendency compared to the B-Stage.

Figure 3 shows the chlorine ion removal experiment by applying GF to the cathode electrode. During the operating time of 21.5 hr, the chlorine ion removal rate achieved 92.6%. By replacing the cathode electrode from CF to GF, the time required to achieve a chlorine ion removal rate of over 85% was reduced by about 7.7 times (165.5 hr → 21.5 hr). The better chlorine ion removal of GF than the CF can be explained by the difference in oxidation degree between the two electrodes. During the heat treatment process for use as an electrode, hydrophilic functional groups (C-O, C=O, etc) are created on the electrode surface [8],[9].

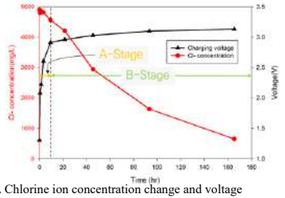

Figure 2. Chlorine ion concentration change and voltage change according to operating time of seawater battery using CF as cathode electrode

In Figure 4, a chloride ion removal experiment was performed using the CNT-CF electrode coated with MWCNT on the CF applied in Figure 1 as a cathode electrode. During the operating time of 45.5 hr, the voltage rose from 1 V to 3 V, and the chlorine ion removal rate reached 98.0%. This means that CNT-CF in Fig. 4 has an improved electrochemical redox reaction than CF in Fig. 2. This result can be explained by the difference in electrical conductivity between CF and MWCNT. The electrical conductivity of CF (PAN-based) is 588 S/cm, and the electrical conductivity of MWCNT is 104 to 105 S/m, so MWCNT has about 17 to 170 times the electrical conductivity of CF [10],[11].

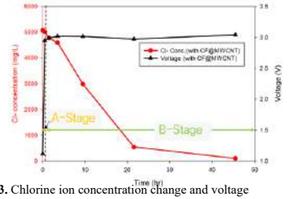

Figure 3. Chlorine ion concentration change and voltage change according to operating time of seawater battery using GF as cathode electrode

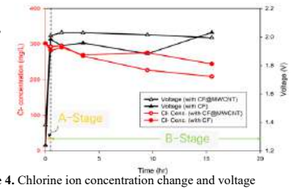

Figure 4. Chlorine ion concentration change and voltage change according to operating time of seawater battery using CNT-CF as cathode electrode

CONCLUSION

To improve the performance of the desalination battery, a carbon-based electrode was applied as a negative electrode. The electrodes used in the experiment were CF, GF, and CNT-CF, and GF took the shortest time when comparing the time required to achieve 85% chloride ion removal rate.

Comparing the performance of CNT-CF and CF, CNT-CF showed better performance, and similar results were obtained when CNT-CF and CF electrodes were applied to thermal power plant floor ash washing water. It was found that MWCNTs had a positive effect on the redox reaction rate of the electrode. In the future, the desalination of actual food wastewater will be tested and the interfering effect of other substances will be identified.

Abstract
Industrial development leads to the generation of effluents, wastewater and contaminated water. It is caused by increased demand for production of clothing and improving the quality of health. The organic dyes are a threat to aquatic ecosystems due to their carcinogenic and mutagenic properties which are harmful for the fauna living in contaminated water. Herein, the polymer inclusion membranes (PIMs) containing a cyclodextrin (CD) ligand which characterizes strong affinity for organic pollutants, seems to be a perfect material for wastewater treatment. The novel PIM containing CD ligand was studied for separation of organic pollutants from aqueous solutions. Influence of different parameters was studied to determine optimal conditions for removal of Acid Orange 7 (AO7) and Methylene Blue (MB). The driving force of dye transport across PIM was based on pH gradient and RF values were 97,6% and 96,5% for AO7 and MB, respectively.

Keywords
Cyclodextrins; Membrane Processes; Organic Dyes; Polymer Inclusion Membrane

INTRODUCTION

Recently, an increase in the concentration of various chemicals such as dyes, pharmaceuticals, detergents, pesticides in water and sewage has been observed. This is caused by the increased demand for the production of clothing and improving the quality of health, which also leads to the discharge of this type of substances with industrial or municipal wastewater as a result of dyes production, clothing colouring and washing clothes. Dyes as organic compounds are a threat to aquatic ecosystems due to their carcinogenic and mutagenic properties, which affects the health of the fauna living in contaminated water. In addition, it results in limited visibility, which disturb the functioning of the fishes (*Berradi et al. 2019*). The processes of photosynthesis under such conditions are inhibited and the production of oxygen in water is reduced. There are known some treatment methods for removal organic dyes from (waste)water: membrane separation, adsorption, advanced oxidation processes, photocatalysis, biological treatment. One of the simple, cost-effective and safe alternative for colour removal are membrane processes for instance with application of polymer inclusion membranes (PIMs). The PIMs are obtained as a result of mixing and immobilization of doped carrier together with plasticizer in polymer matrix. The doped carrier is responsible for recognition and transport of pollutant molecule/ion from source phase into feeding phase (*Ma et al. 2017*). Nowadays most studies focused on ion carriers which are applied in PIMs for separation of heavy metals from aqueous solutions, but only some consider application of organophillic carrier like cyclodextrins (CDs).
The CDs are group of macrocyclic oligosaccharide family composed mostly with 6, 7 or 8 glucose units, well known as α-, β-, and γ-CD respectively. These compounds are derived from cellulose through biocatalytic synthesis with specific cyclodextrin glycosyltransferase (CGTase), The most interesting ability of CDs is formation of inclusion complex with organic molecules like ibuprofen, this ability was applied in drug delivery. However, it seems a promising strategy to obtain separative materials containing CDs (*Jambhekar et al. 2016*).
The application of CDs for organic pollutants removal is promising but also problematic by reason of their high solubility in water due to carbohydrate core. In turn, the preparation of PIM with CDs is an issue due to their low solubility in organic solvents. On the other hand, the most research around CDs in PIMs focused mostly on metal ion removal. Therefore, the application of CDs in removal of organic pollutants from aqueous solutions is not fully checked field in spite of remarkably promising properties.
In this study, we analyzed the removal of organic dyes (AO7 and MB) from aqeous solutions using PIMs containing a perbenzylated β-CD derivative as the carrier. To evaluate the performance of organic dyes separation, we used the following parameters: the impact of the carrier concentration, the quantity of plasticizer in the membrane, the acidity of the source phase as well as receiving phase, and the feasibility of reusing the membrane.

MATERIALS AND METHODS

Reagents

Inorganic reagents, i.e., sodium chlorides (NaCl), magnesium sulphate ($MgSO_4$), hydrochloric acid (HCl) and sodium hydroxide (NaOH), potassium hydroxide (KOH) provided by POCh (Gliwice, Poland) and organic chemicals, i.e., crystalline β-Cyclodextrin, benzyl chloride, Methylene Blue, Acid Orange 7 were obtained from MERCK (Darmstadt, Germany); and cellulose triacetate (CTA), *o*-nitrophenyl octyl ether (*o*-NPOE) and chloroform were obtained from Fluka (Seelze, Germany).

Synthesis of the perbenzylated β-CD derivative and preparation of PIM

Native β-CD was dissolved in distilled water and then activated to form an oxyanion by 4M aqueous solution of potassium hydroxide (KOH). Benzyl chloride was introduced into the reaction mixture. The reaction mixture was heated at 65°C for 24 h. After cooling, the mixture was extracted with chloroform, then the organic layer was washed with distilled water. The organic layer was dried with anhydrous $MgSO_4$, then separated by filtration and concentrated. The synthesis protocol was slightly modified according to (*Bouzitoun et al., 2006)*.
PIM was prepared, according to previously designed protocol (*Zawierucha et al., 2022)*, from a chloroform solution containing: a matrix (cellulose triacetate (CTA)), a plasticizer (*o*-nitrophenyl octyl ether) and a carrier (perbenzylated β-CD derivative). The glass ring attached to the glass plate by a CTA-chloroform based adhesive was filled with the appropriate dosage of the organic solution. The mixture was left overnight at room temperature to evaporate the chloroform. The resulting membrane (Figure 1) was separated from the glass plate by wetting with cold water. The thickness of the membrane was measured with an ultrameter.

Transport studies

Transport studies were carried out in special two-chamber permeation vessels at room temperature. The membrane was placed between two chambers containing feeding and receiving phases. The feeding phases contained aqueous solutions (50 cm^3) of MB or AO7. Both of phases were continuously stirred at 600 rpm, whereas the sample were periodically collected. The concentrations of dyes in the samples were quantified by UV-VIS Shimadzu 2401 spectrophotometer.
The removal efficiency was described by the recovery factor (*RF*) as followed in equation:

$$RF = \frac{c_0 - c}{c_0} \times 100\% \quad (1)$$

where c_o and c are initial concentration of dyes in source phase and feeding phase at given time (mg/l).

RESULTS AND DISCUSSION

Kinetics of dyes transport through PIM

The kinetics of dye transport was analysed for the MB and AO7 through PIM containing perbenzylated β-CD derivative. The analysis was performed for changes of concentration in the feeding and receiving phase.

The kinetic curves on Figure 2 express exponential nature of relationship: c/c_0 in the function of time. The presented kinetic model is similar to primary transport proposed for supported liquid membranes (*Danesi et al. 1984)*.

Influence of initial concentration on transport through PIM

According to the Figure 3, the RF value is highly maintained in range 10-100 mg/l of AO7 for around 98%. The RF value for 500 mg/l was decreased to 92% and may be caused by precipitation of dye molecules on membrane surface or clogging of membrane pores.

Mechanism of dyes transport through PIM

The driving force of transport is based on pH gradient between two phases. The dyes are carried from feeding phase to receiving phase through formation of inclusion complex with CD inside PIM. The mechanism of transport is presented on Figure 4.

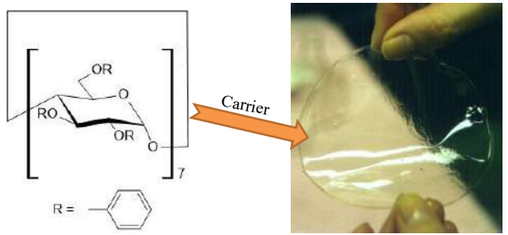

Figure 1. The structure of perbenzylated β-CD (the carrier) and the PIM with doped carrier.

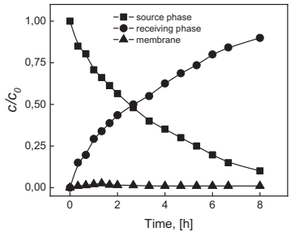

Figure 2. The profile of AO7 (100 mg/l) concentrations in source, membrane and receiving phases during the transport process across PIM.

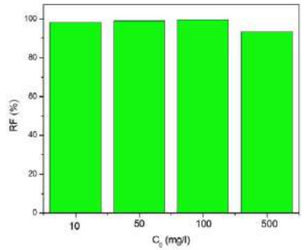

Figure 3. The RF profile depending on initial concentrations of AO7 in feeding phase.

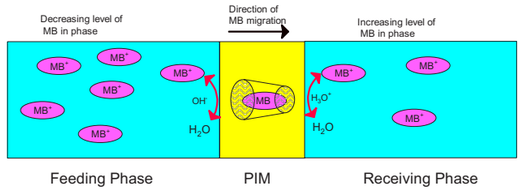

Figure 2. The mechanism of separation of MB through PIM containing perbenzylated β-CD carrier.

Abstract
Excessive deposition of reactive nitrogen in the environment has led to loss of biodiversity, eutrophication and acidification of ecosystems. Recently, bacteria capable of anaerobically metabolizing ammonium through the reduction of iron III, a biological process called Feammox, have been discovered. The formation of biofilms of Feammox bacteria in hollow-fiber membrane bioreactor (HFMB) was evaluated as an efficient and sustainable alternative for ammonium removal in from wastewater.

Keywords
Ammonium, biofilms, Feammox, HFMB, nitrogen, wastewater.

INTRODUCTION

Human activities coupled with the growth of industrialization have generated high levels of reactive nitrogen (Nr) pollution in the form of ammonium (NH_4^+) (Galloway and Cowling, 2002). Consequently, excessive Nr deposition in the environment has caused biodiversity loss, eutrophication and soil acidification (Yang et al., 2014).

Biological nitrogen removal is mainly based on the use of activated sludge, which corresponds to a heterogeneous set of microorganisms categorized as bacterial consortia (BC) (Yang et al., 2011). However, biofilm formation is more effective for biological nitrogen removal (Li et al., 2021). For example, hollow-fiber membrane bioreactors (HFMB) integrating a selective membrane and biological treatment based on biofilm formation of bacterial communities have been widely used for NH_4^+ treatment (Razaviarani et al., 2019; Wu et al., 2020).

In 2005, a bacterial process called Feammox, discovered in a forested riparian wetland soil in New Jersey (USA), was identified as capable of anaerobically metabolizing NH_4^+ through the reduction of ferric iron (Fe^{+3}) (Clément et al., 2005). In this context and based on the favorable growth conditions of Feammox bacteria, it is established that this biological process could have a significant impact on improving autotrophic nitrogen removal from wastewater, optimizing removal efficiency, reducing energy costs and organic carbon requirements of conventional nitrification-denitrification processes.

MATERIALS AND METHODS

The anaerobic sludge sample was obtained from the sewage system of a brewery treatment plant (IC) located in Santiago, Chile. The sludge sample inoculum was added to a Feammox pathway enriched medium, with sodium bicarbonate ($NaHCO_3$) or sodium acetate (CH_3COONa) at pH 7 and under anaerobic conditions (20 ± 2°C). Samples were monitored every 7 days for 28 days, measuring NH_4^+ and ferrous iron (Fe^{+2}). Cultures inoculated with pre-enriched bacterial consortia (EBC) were also evaluated under optimized growth conditions.

Pieces of 10 cm hollow-fiber (0.4 - 2.6 mm diameter) were incubated with 20mL of the culture medium inoculated with the sludge sample (after 28 days of growth), in a Petri dish, under anaerobic conditions, at 20 ± 2°C, for 10 days and analyzed by scanning electron microscopy (SEM).

RESULTS AND DISCUSSION

Figure 1 shows the results of the measurements obtained from the batch reactor treatment. Four samples were evaluated: IC sludge, Feammox selective medium and $NaHCO_3$ (Treatment. 1); IC sludge, Feammox selective medium and CH_3COONa (Treatment 2); EBC, Feammox medium and $NaHCO_3$ (Treatment 3); and EBC, Feammox medium and CH_3COONa (Treatment. 4). In all samples, Figure 1A [Fe^{+2}] and 1B [NH_4^+] were measured. Treatment 2 increases its concentration steadily, reaching a +Δ84.6 mg/L of [Fe^{+2}]. In Treatment. 2, a NH_4^+ removal % of 20.37% is obtained with respect to the initial [NH_4^+]. The degradation of CH_3COONa could release protons, reducing the pH of the medium, generating a favorable environment for the Feammox reaction (Xia et al., 2022), which would explain the positive results obtained with CH_3COONa. This is the reason why CH_3COONa is proposed as the most efficient carbon source for the Feammox process.

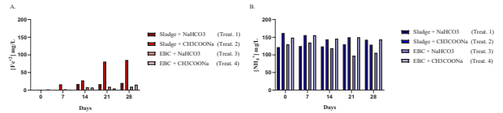

Figure 1. A. Fe^{+2} and B. NH_4^+ concentrations of the samples $NaHCO_3$ sludge (Treatment.1), CH_3COONa sludge (Treatment 2), EBC $NaHCO_3$ (Treatment 3) and EBC CH_3COONa (Treatment. 4)

In Figure 2, SEM images of the hollow-fiber samples are shown. The results show the formation of biofilm networks between Feammox bacteria on the fibers exposed to the sludge samples with $NaHCO_3$ and CH_3COONa. Working with biofilm formation is more convenient as it allows obtaining a higher biomass concentration, a denser sample structure and a higher resistance to shock loads (Hassard et al., 2015).

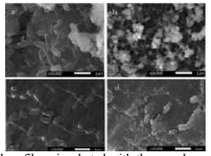

Figure 2. SEM images of hollow-fibers incubated with the samples a. $NaHCO_3$ sludge (Treatment 1), b. CH_3COONa sludge (Treatment 2), c. EBC $NaHCO_3$ (Treatment 3) and d. EBC CH_3COONa (Treatment 4).

These results would support the use of HFMB, based on biofilm formation, as an efficient method for Nr removal from wastewater.

Abstract
In this work, the removal of carbamazepine in an aqueous solution was performed using the Fenton process catalyzed with Fe-BC and Zn-BC. The research included synthesis of catalysts and optimization of pharmaceutical removal conditions using the *Definitive screening design* statistical method in order to achieve the maximum efficiency of the mentioned treatment. Both materials showed good catalytic performance in the applied treatment (~98%). Obtained effluents showed high toxicity inhibition percent (~80%), as well as mineralization measured as TOC~80%. The further step is characterization of effluents using ultra-performance liquid chromatography (UPLC)–high-resolution mass spectrometry (HRMS) method.

Keywords
biochar-based catalyst; degradation; Fenton; carbamazepine;

INTRODUCTION

Carbamazepine (CBZ) is classified as a persistent organic pollutant, because its removal efficiency in water treatment plants is about 10%. It is toxic even at concentrations below 100 mg/l. Therefore, there is a need to find an efficient technology for its removal from the aquatic environment.
The Fenton process is one of the most effective advanced oxidation processes and is used to treat water with a high content of complex organic matter, as well as other no biodegradable compounds. The use of Fenton's reagent increases the degradability of complex organic compounds in wastewater, which results in their conversion into organic compounds of low molecular weight, or complete mineralization, until the formation of carbon dioxide and water. Increasing attention is focused on the use of biochar as a catalyst in order to use sewage sludge as a resource, not the waste. Due to its low cost, large specific surface area and good stability, biochar is a promising material that can be compared with other carbon materials. It has been often applied as carrier to improve the performance of iron and other ions impregnated in the carbon matrix. In this work, the removal of carbamazepine was performed using the Fenton process catalyzed by modified biochars, Fe-BC and Zn-BC. The test included the synthesis of biochar and the optimization of the conditions for the degradation of CBZ, using the Fenton process, with varying doses of hydrogen peroxide, CBZ and prepared catalysts, as well as pH and reaction time.

MATERIALS AND METHODS

For the synthesis of biochar, the final sludge from the wastewater treatment plant in the settlement of Kovilj (near Novi Sad), Autonomous Province of Vojvodina, Republic of Serbia was used. The biochar preparation procedure was performed according to Chen et al. (2020). Impregnation with iron and Zn onto biochar was performed according to the conventional method (Iurascu et al., 2009; Azmi et al., 2014). A BET analyzer (AutoSorb iQ2) was used to characterize the synthesized materials in order to test the specific surface area. To optimize the process conditions, the statistical method of *Definitive screening design (DSD)*, was assessed in order to achieve the maximum efficiency of the applied treatment and the degradation of the selected pollutant. The tests were carried out by a series of experiments on JAR test apparatus (FC6S Velp scientific, Italy). The absorbance (A) was measured at a wavelength of CBZ λ_{max} = 285 nm. Determining the absorption maxima (λ_{max}) by recording the spectrum of the CBZ solution, as well as monitoring the change in absorbance during the experiments, was performed using a UV-VIS spectrophotometer. Toxicity of samples was tested with the Aliivibrio fischeri bacteria bioluminescence test according to protocol ISO 11348-3 (2007). The principal of the test is to measure the bioluminescence of the bacteria before and after the addition of test samples, compared to control, at different time rates, 5, 15 or 30 minutes. The mineralization of effluents was determined using TOC analyzer (liquiTOC II, Elementar, Germany) (SRPS ISO 8245:2007).

RESULTS AND DISCUSSION

The impregnation of the pristine biochar with Fe (III) (BET= 3.807 m^2/g) and precipitation with Zn (II) ions (BET= 104.7 m^2/g) influenced the increase of the specific surface areas of the pristine material (BET= 57.83 m^2/g). The basic scheme of the experiment, obtained by applying the DSD model with 5 numerical factors, consists of 12 experiments and 2 central points (Table 1).

Table 1. Matrix of experiment with achieved CBZ removal efficiencies

Sample	Removal efficiency (%)	
	Fe-BC	Zn-BC
1	78	79
2	87	85
3	88	58
4	84	79
5	1	81
6	88	85
7	83	87
8	7	90
9	0.2	95
10	79	85
11	79	88
12	88	93
13	96	96
14	96	98

The results of testing the efficiency of the Fenton process in the removal of carbamazepine are shown in Table 4, where the range of removal efficiency was established from 0.2% to 96% for Fe-BC, from 58% to 98% for the Zn-BC catalyst. The achievement of maximum and minimum removal efficiency in the Fenton process at different set of process conditions is observed, thus confirming the assumption that the drug removal process itself largely depends on the applied experimental conditions, as well as on the applied materials. During the experiment, very significant removal efficiency was observed in the Fenton process at a different set of process conditions, which established that the removal process itself depends on the applied experimental conditions and used catalysts. An exception exists in 3 experiments in the case of Fe-BC, when the efficiency was low (up to 7%).
Optimization diagrams of the Fenton process are shown in Figures 1 and 2. They give a clear insight into how the selected process parameters affect the dependent variable, i.e. drug removal efficiency. The statistical model within the Fenton process for Fe-BC suggests a high carbamazepine removal efficiency of 95.885% under the following optimal conditions: pH=5.5, drug concentration of 5.5 mg/l, catalyst concentration of 60 mg/l, hydrogen concentration -peroxide of 10.5 mM and a reaction time of 105 min.

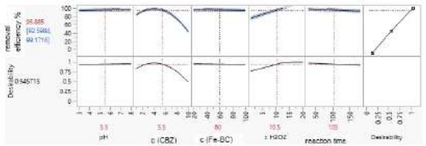

Figure 1. Optimization diagram of the Fenton process catalyzed by Fe-BC

Additionally, the statistical model within the Fenton process for Zn-BC suggests a high carbamazepine removal efficiency of 97.09% under the following optimal conditions: pH=5.5, drug concentration of 5.5 mg/l, catalyst concentration of 60 mg/l, concentration of hydrogen peroxide of 10.5 mM, while the reaction time is not proposed by the model, assuming that it does not have a large effect on the efficiency of the removal of the selected drug, under the investigated conditions (Figure 2).

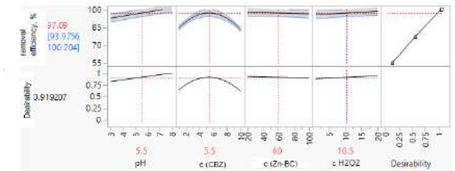

Figure 2. Optimization diagram of the Fenton process catalyzed by Zn-BC

It can be concluded that both biochars showed good catalytic performance under the applied conditions of the Fenton process. Toxicity measurements showed high inhibition percent (~85%) in both cases, pointing out on formation of toxic intermediates after Fenton reaction of 105 minutes. Further investigation will be conducted for longer reaction time, aiming on decreasing the effluent toxicity. Also, significant mineralization, measured as TOC, was achieved (~80%). The next step that will be implemented is the characterization of the obtained effluents after the optimal conditions using ultra-performance liquid chromatography (UPLC)–high-resolution mass spectrometry (HRMS) method.

WATER QUALITY AND QUANITY, FRESH WATER SOURCES SUITABLE FOR CREEK RIDGE INFILTRATION IN THE BRAAKMAN ZUID REGION (NL)

B.Letterie

Water Technology Research Group, HZ University of Applied Sciences, Edisonweg 4, 4382 NW Vlissingen the Netherlands (E-mail: *lett0009@hz.nl)**

Abstract

The Dow facility located in Terneuzen currently uses water of drinking water quality which is transported over a large distance. Dow want to use a water source closer by and not compete with drinking water. Dow needs ca. 400 Nm^3/y. Creek Ridge Infiltration can be used as a methodology to store water during the wet season and extract it during the dry season, with a 50% efficiency. The water quality and water quantity of the water source used for infiltration is key and needs to be examined. In this research several fresh water sources have been evaluated, both on quantity (1 mNm^3/y needed) and quality for infiltration, following local regulations. The results show that especially the quality of surface water is insufficient in the Terneuzen area, mainly caused by pesticides from agriculture. There is the need to pre-treat the water before infiltration, preferably using a NBS like a wetland (to be tested in a following up project). Also the water quantity available for infiltration shows great variation over the year, but also between the years, making is a necessity to consider the usage of several sources in the surroundings rather than focus on one source with the best quality.

Keywords

Water quantity, water quality, managed aquifer recharge, legislation, fresh water source

INTRODUCTION

The FRESH4Cs project focusses on the second Europe 2020 priority of sustainable growth, by demonstrating the provision of alternative and sustainable fresh water resources for lowland coastal regions. Traditional water resources are under pressure, and this problem is even more prominent in lowland coastal regions due to salinization of (near) surface waters. These same coastal lowlands drain vast amounts of water towards the sea at moments of water surplus (seasonal). Where water consumption has often been reduced to economic feasible levels, a second step in efficient water resource management is providing alternative and more sustainable resources, which is the focus of this project.

Dow is a partner in the FRESH4Cs project and the aim for Dow is to become resilient to climate change and independent of remote fresh water supply originating from the Biesbosch, 120 km away. Therefore Dow actively works on water savings, recycling and multi-sourcing. In 2008 the concept of a Robust Water System in the area of Zeeuws-Vlaanderen was initiated. It pursues collaborations with local governments and other end users in industry and agriculture to find regional solutions. DOW has invested over the past years in this robust water system for the region, not only in providing for its own water resources but also in aiding other regional water users.

In the current project there is an interest in exploring underground fresh water storage capabilities within the Braakman South region (cross-border Netherlands/Belgium). Excess rain precipitating in winter months, can be captured and temporarily stored for usage by agriculture and industry during periods of shortage. Dow would benefit from such a feasibility study, as it might provide solutions for its own water resources. Additionally, it will also strengthen Dow's cooperation with other regional water users that will benefit directly from the project (mainly farmers).

This report is written under work package 3 of the project, where Dow is preparing for investments, articulating the volumes and quality of water to be supplied to Dow and local farmers. In this report the water quality and water quantity of water sources in the area will be examined for suitability for infiltration. The ultimate goal is to find a suitable fresh water source for the infiltration of 1 Mm^3 annually during the winter months.

METHODOLOGY

In this chapter the methodology used to examine the suitability regarding both the water quality and the water quantity of the three potential fresh water sources will be described.

Isabellakanaal

The Isabellakanaal receives less fresh water from the Belgium polders since 2015 and therefore it is plausible that the chloride concentration of the Isabellakanaal has become too high over the past few years to be used for infiltration. Therefore the water quality was first tested on electrical conductivity (EC), a substitute for the chloride concentration.

For the duration of one year, starting on September 2020 until august 2021, the EC has been measured on a monthly basis on different locations along the Isabellakanaal starting at the Braakman and following the channel until past the Isabella gemaal, just across the Belgium border.

Leopoldkanaal

To determine the water quality parameters that are relevant for infiltration into the groundwater the Nota Grondwater is applicable (*Waterschap Scheldestromen, 2019*). The water quality of the Leopoldkanaal has been determined by the external laboratory Aqualab Zuid B.V., accredited conform NEN-EN-ISO/IEC 17025 (nl) under the number L387. The analysis have been performed conform NEN 6600-2, in compliance with the Nota Grondwater. The parameters that have been monitored have been discussed with the waterboard Waterschap Scheldestromen and are mostly in line with the Nota Grondwater. WSSS has agreed with deviating slightly from the Nota Grondwater regarding the list of pesticides and herbicides since the monitoring of the water quality regarding pesticides and herbicides was already ongoing for several years on the water coming from the Belgium Zwarte Sluispolder and the Isabellapolder by Evides, and measuring the same parameters on the Leopoldkanaal enabled us to make a solid comparison while still taking the major pesticides and herbicides into account.

Zwarte Sluispolder and Isabellapolder

Also for the Zwarte Sluispolder and for the Isabellapolder the water quality has been determined by Aqualab Zuid B.V. The water samples have been taken from the Evides basins whose are only fed by water coming from both polders. The same parameters have been analysed as for the Leopoldkanaal.

Of both the Zwarte Sluispolder and the Isabellapolder, an analysis has been done how much water would potentially be available for infiltration. The water of both polders comes together in a ditch and is discharged over the Boekhoute weir towards the Leopoldkanaal. The water from the Leopoldkanaal finally flows into the North Sea where it is mixed with the sea water.

To calculate the volume of water that flows over the weir data from the Boekhoute weir has been used (*Vlaanderen Waterinfo Kaartencatalogus*). The data provides information about the water level upstream of the weir and of the level of the weir itself, both TAW corrected. By using the Rehbock formula (Boiten *et al.*, 1995) the flowrate over the weir can be calculated. The data at the Boekhoute weir is logged every 15 minutes which makes it possible to calculate the volume that flows over the weir for every quarter of an hour. Finally the volume has been calculated on a monthly basis.

RESULTS AND DISCUSSION

In this chapter the results of the measurements of the water quality will be presented and compared with the thresholds mentioned in the Nota Grondwater. Also the calculated water quantities will be presented and discussed.

Water quality

The water quality of the Isabellakanaal, the Leopoldkanaal and the water from the Evides basins that comes from the Belgium Zwarte Sluispolder and the Isabellapolder has been measured and analysed. In the next subchapter the water quality analysis of the three possible sources of freshwater will be presented. The raw data and the processed data can be found in Appendix **¡Error! No se encuentra el origen de la referencia..**

Isabellakanaal

For the Isabellekanaal the water quality was first tested on electrical conductivity (EC), a substitute for the chloride concentration. In the Nota Grondwater, a threshold for chloride for infiltration in groundwater is stated of 160 mg/l. Also the Nota Grondwater states formula (1) and (2) for converting EC into the of concentration chloride in mg/l.

$$EC < 4mS/cm \ / \ Cl < 1000 \ mg/l: EC = (Cl + 188.5) / 286 \quad (1)$$

$$EC > 4mS/cm \ / \ Cl > 1000 \ mg/l: EC = (Cl + 450) / 360 \quad (2)$$

Using formula (1) it is determined that an upper threshold of 1.22 mS/cm can be used, all values below the threshold represent chloride concentrations lower than 160 mg/l. The results of the EC measurements at the different location is shown in Figure 1.

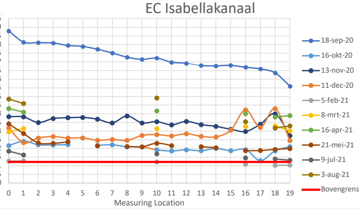

Figure 1: EC measurements Isabellakanaal

From Figure 1 it can be derived that only on February the 5th from location 10 to the Belgium border the EC was sufficiently low to meet the threshold for chloride of 160 mg/l. All other measurements show an exceedance of the norm for chloride. This would mean that the Isabellakanaal can only provide fresh water for infiltration during a very limited timeframe of the year.

Leopoldkanaal

The results of the analysis of the water quality of the Leopoldkanaal are shown in Table 1

Table 1: Results water quality analysis Leopoldkanaal

* Only for biological agriculture
**If the sum is exceeded, a threshold of 0.1 µg/l for the individual substances are applicable

The chloride concentration of the Leopoldkanaal is mainly in compliance with the threshold of 160 mg/l as described in the Nota Grondwater. During the infiltration the EC will be continuously monitored and when the threshold is exceeded, the infiltration will be stopped if water the Leopoldkanaal would be used.

For the metals, cupper exceeds the upper limit in two of the six measurements, and manganese is structurally to high. For both cupper and manganese, the norm is only applicable if the water will be used for biological agriculture. Since it is assumable that one of the potential farmers will practice biological agriculture, it is desirable that both cupper and manganese meet the threshold mentioned in the Nota Grondwater if water of the Leopoldkanaal would be used for infiltration.

Also for the total sum of pesticides, the values structurally exceed the threshold of 0.5 µg/l. Conform the Nota Grondwater, the individual pesticides have been analysed and it was concluded that 2,6-Dichlorobenzamide (BAM), Glyphosate (commonly used in Roundup and nowadays also in other brands) and Aminomethylphosphonic acid (AMPA, a breakdown product of glyphosate) exceed the threshold of 0.1 µg/l for all analysis. For infiltration the pesticides are too high if water from the Leopoldkanaal would be used.

For the polycyclic aromatic hydrocarbons (PACs) phenanthrene exceeds the threshold in three out of 6 analysis. Phenanthrene is released by burning hydrocarbons like natural gas and gasoline, and is considered to be carcinogenic. Also one analysis showed an exceedance of fluoranthene. For both phenanthrene and fluoranthene the limit for drinking water is 0.1 µg/L (*RIVM Zoeksysteem van stoffen, 2022*). It can be assumed that there is no health risk involved when water from the Leopoldkanaal is used for infiltration, but to avoid accumulation of the PACs in the groundwater the limit as described in the Nota Grondwater will be followed meaning that the values for PACs are too high for infiltration when water from the Leopoldkanaal would be used.

Zwarte Sluispolder and Isabellapolder

The results of the water quality analysis of the Zwarte Sluispolder and the Isabellapolder are show in Table 2.

Table 2: Results water quality analysis Zwarte Sluispolder and Isabellapolder

* Only for biological agriculture
**If the sum is exceeded, a threshold of 0.1 µg/l for the individual substances are applicable

The concentration of chloride meets the requirement of 160 mg/l. For cupper some measurements exceed the threshold, as well as for manganese. Although this only applies for biological agriculture, it is desirable that both cupper and manganese meet the threshold mentioned in the Nota Grondwater if water of the Belgium polders would be used for infiltration.

Also for the total sum of pesticides, the values mostly exceed the threshold of 0.5 µg/l. Conform the Nota Grondwater, the individual pesticides have been analysed and it was concluded that BAM, Glyphosate and AMPA exceed the threshold of 0.1 µg/l for most of the analysis. For infiltration the pesticides are too high if water from the Belgium polders would be used for infiltration.

Comparable with the Leopoldkanaal, also the PAC phenanthrene exceeds in many of the measurements the threshold mentioned in the Nota Grondwater.

Water quantity

The volume of the water flowing from the Zwarte Sluispolder and the Isabellapolder over the Boekhoute weir has been calculated on a monthly basis. The results are show in Table 3.

As is shown in Table 3 there are huge differences in the volume that flows over the weir between the different months in one year, but also between the various years. In 2021 21M m^3 was discharged to the Leopoldkanaal, while in 2018

s flown over the weir at all, while in the month March alone more than 6M m^3
d flow over the weir, more in one month than in the entire year of 2018.

CONCLUSIONS

The water EC of the water of the Isabellakanaal shows values varying from 8 mS/cm to 1 mS/cm. However, the measurements show that only for circa six weeks in one year time the values were under the threshold of 1.22 mS/cm representing the chloride concentration of 160 mg/l. From these measurements it can be concluded that the water of the Isabellakanaal contains a to high chloride concentration to be used as a reliable source of fresh water for infiltration into the groundwater.

The water of the Leopoldkanaal showed to be fresh enough for infiltration. However, the metals cupper and manganese exceed the threshold for infiltration, 2.4 µg/l and 31 µg/l respectively, when biological agriculture would be performed. Also the total sum of pesticides exceeds the threshold of 0.5 µg/l with the individual pesticides BAM, glyphosate and AMPA exceeding the threshold of 0.1 µg/l. Finally the PACs phenanthrene and fluoranthene also exceed the threshold for infiltration of 0.003 µg/l. The water quality of the Leopoldkanaal is therefore insufficient for infiltration in the groundwater.

The water of the Zwarte Sluispolder and the Isabellapolder seems slightly better than the water of the Leopoldkanaal, however also cupper, manganese, BAM, AMPA, glyphosate and phenanthrene exceed the thresholds mentioned in the Nota Grondwater. The water of the polders is of a slightly better quality then the water of the Leopoldkanaal, however the substance mentioned above exceeding the Nota Grondwater make this water, not suitable for infiltration.

The water quantity of the Zwarte Sluispolder and the Isabellapolder available for infiltration shows variations over the months in one year, but also between the various years. To have access to a source that can supply a constant amount of water, the water from the Zwarte Sluispolder and the Isabellapolder can provide a substantial part of the water, but it cannot be guaranteed that the water will be available all the time.

Seen the varying effect of infiltrating water of different quality into the groundwater as mentioned above, it cannot directly be concluded that the infiltration pilot has positively or negatively changed the quality of the groundwater. It should be noticed that the pilot was small scale, and only has occurred for a period of one year. To gain more insight in the effect of the infiltration pilot, a longer period of experimenting for at least 5 years with additional monitoring is advised to be able to draw conclusions regarding water quality effects of infiltration on the groundwater quality.

RECOMMENDATIONS

Since the infrastructure of Evides that is already installed to transport the water of the Zwarte Sluispolder and the Isabellapolder to the basins, and the water quality seems the most suitable, the water from the Belgium polders is the most preferred option for infiltration. However, the quantity is not always adequate for continues infiltration. Therefore a second water source may be considered. Since the chloride concentration of the Leopoldkanaal is much lower than the Isabellakanaal, and mostly in compliance with the Nota Grondwater, the Leopoldkanaal seems most suitable as a second water source.

The quality of both the water from the Belgium polders and from the Leopoldkanaal do not meet the requirements of the Nota Grondwater for all the substances. Therefore it is recommended to do research towards suitable technologies to treat the water in the most cost and energy efficient way. During the course of this project, the follow up project Aquatuur has been initiated where several constructed wetlands , whether or not combined with activated carbon filters, will be tested on removal efficiencies of the substances found in this research that now exceed the thresholds of the Nota Grondwater.

Since the water can be transported using the Evides infrastructure, it would be beneficial to discuss the options, possibilities, challenges and limits of the infrastructure with Evides. Also the management of the basins, possibilities to store additional water for infiltration in the basins and monitoring possibilities could be discussed with Evides as well as the common interest Dow, Evides and local farmers would experience for infiltration additional water that later can be extracted.

The VMM controls the level of the Boekhoute weir, and decides when the weir will be lowered or raised, in consultation with the owners of the Zwarte Sluispolder and the Isabellapolder. Therfore it is also recommended to start communications with these stakeholders to discuss the possibilities of pumping more water from the polders, and measures that allow more extraction without changing the groundwater level in the polders. The ideal situation would be that all the water that in the current situation flow over the Boekhoute weir is used for infiltration via the Evides infrastructure, including the basins.

As a design for the extraction of the fresh water source, infrastructure needed to transport and pump the water to the infiltration location and after extraction of the groundwater to the water consumers, a schematic overview is suggested in Figure 2.

Use of a packed-bed biofilm reactor to achieve rapid formation of anammox biofilms for high-rate nitrogen removal

Abstract
Anammox (AMX) is an efficient and carbon-saving process for biological nitrogen removal; however, the long start-up period hinders its application in wastewater treatment. In this study, an innovative packed-bed biofilm reactor (PBBR) was developed for the rapid enrichment of AMX biofilms. With a greatly reduced fluid turbulence in the PBBR, the attachment and growth of AMX biofilms were found to be accelerated and the specific AMX biofilm formation rate was 60% faster than that in the conventional moving-bed biofilm reactor and the nitrogen removal capacity of the PBBR increased rapidly from 77.6 to 876.8 mg N/(L·d) in 2 months.

Keywords (maximum 6 in alphabetical order)
Anammox, autotrophic nitrogen removal, biofilms, start-up, wastewater treatment

INTRODUCTION

Fluid turbulence and mechanical collision between biocarriers are the main detrimental factors that restrict the biomass attachment to the carriers. The successful start-up of Anammox (AMX) bioreactors commonly requires 150–500 d (Yu et al., 2013; Zekker et al., 2013). In this study, a new bioreactor configuration, packed-bed biofilm reactor (PBBR), in which plastic carriers were tightly packed in the bioreactor, was developed for the rapid start-up of AMX biofilm reactors. With the significantly reduced fluid turbulence and no mechanical collisions between the biocarriers, the PBBR provided a more favorable condition for AMX biofilm formation and growth. Besides, the AMX biofilm pre-acclimated in the PBBR was found to have a much higher nitrogen removal capacity and more stable nitrogen removal performance in the practical wastewater treatment than the AMX biofilm enriched in the conventional moving-bed biofilm reactor (MBBR).

MATERIALS AND METHODS

A column-type reactor made of polymethyl methacrylate with a height of 50 cm, diameter of 8 cm, and working volume of 2.5 L was used. The PBBR column was filled with 2 L of commonly used plastic K1 carriers (AnoxKaldnesTM, Veolia, Sweden). The top of the biocarriers was capped with a coarse screen to keep the carriers tightly packed in the PBBR. Experimental studies were conducted to investigate the biofilm development and the nitrogen removal performance of the PBBR system.

RESULTS AND DISCUSSION

Rapid AMX biofilm formation in the PBBR

The confocal laser scanning microscopy (CLSM) was used for monitoring and visualization of biofilm development in the PBBR (Fig.1). Different from the suspension in the conventional MBBR (> 30/s), biocarriers in the PBBR would experience a much lower shear intensity (< 1/s) during its operation. With a greatly reduced fluid shear in the mild flow of PBBR, biomass would settle on the biocarriers and readily colonize on the carrier surface. Under the nearly quiescent fluid environment, the rate of AMX biofilm formation in PBBR was significantly promoted, and the biofilm biomass content in the bioreactor rapidly increased to 4,047 ± 333 mg VSS/m^2 after 100-d acclimation, with an average biofilm thickness of 182.5 ± 44.1 μm. In comparison with the conventional MBBR, the doubling time of the AMX biofilm in the PBBR was greatly shortened from 34.0 d to 21.7 d. The PBBR which can effectively facilitate the formation and growth of AMX biofilms on the biocarriers can be used as a source and supplier of healthy AMX biofilms.

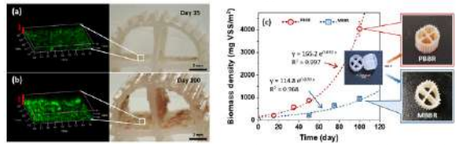

Figure 1. Biofilm formation in the PBBR: CLSM and stereoscopic images of the enriched AMX biofilms on (a) day 35 and (b) day 100; (c) biomass density and biofilm growth on the K1 carriers in the PBBR (vs. the MBBR).

Nitrogen removal performance of the PBBR

In addition to being an excellent reactor for AMX biofilm enrichment, the PBBR also showed an excellent autotrophic nitrogen removal performance. The nitrogen removal capacity slowly increased from the initial level of 77.6 to 106.0 mg N/(L·d) during Stage I (Fig. 2). In Stage II, with the adjustment of the feeding scheme, the free ammonia (FA) and free nitrous acid (FNA) contents in the PBBR were maintained at a low level by decreasing the exchange ratio and extending the hydraulic retention time in operation. Maintaining a low FA (< 2.7 mg/L) and FNA (< 5.8 μg/L) concentrations in the early stage was found to play a critical role in the AMX biofilm development, particularly when the biofilm was thin (<100 μm). As the biofilm thickened, the AMX bacteria embedded in the thick biofilm were well-protected from FA and FNA, and the biofilm became more robust against inhibitors in the suspension. Overall, by using the optimized operating strategy for the PBBR, the AMX biofilm growth was accelerated and the nitrogen removal capacity of the PBBR could increase rapidly from 77.6 to 876.8 mg N/(L·d) in 2 months, significantly shortening the start-up period of the AMX-based bioreactors.

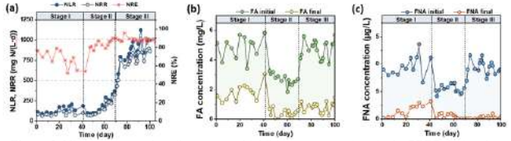

Figure 2. Nitrogen removal performance and inhibitor concentrations in the PBBR during the experimental period: (a) nitrogen loading rate (NLR), nitrogen removal rate (NRR), and nitrogen removal efficiency (NRE); (b) FA concentration at the beginning and the end of each SBR cycle; and (c) FNA concentration at the beginning and the end of each SBR cycle.

Abstract
The Monteagudo WWTP faces a major challenge during four months of the year when a temporary agro-industrial discharge increases the average treated load from 2500 equivalent-inhabitants to six times that amount. To address this issue, a study to test the feasibility of pure oxygen as an alternative to increasing the volume of the IFAS process was conducted. The study was performed from 2017 to 2022, during which the use of pure oxygen was tested and subsequently verified. The results of the study showed that the use of pure oxygen effectively increased the capacity of the WWTP's treatment process reaching removal values up to 9 kgCOD/m^3/d. This approach not only improved the capacity to handle temporary industrial discharge but also avoided the need for an important investment in the expansion of the WWTP. The treatment in question is currently applied on an annual basis during the season of agro-industrial discharges.

Keywords
IFAS; MBBR; pure oxygen; temporary industrial discharge

INTRODUCTION

The Monteagudo (Navarra) Waste Water Treatment Plant (WWTP) is responsible for treating the discharge of an average of 2500 equivalent inhabitants throughout most of the year. However, during the four months of August to November, the treated load is significantly increased to 15000 eq-inhabitants due to a temporary agro-industrial discharge. This presents a significant challenge for the WWTP in terms of maintaining the effectiveness of the treatment process. The treatment plant consists of Integrated Fixed-film Activated Sludge (IFAS) as biological process, followed by a trickling filter and final lagooning. The volume of the biological process was designed for the usual load, having difficulties during the high load period to guarantee the quality of the treated water.

An alternative method for increasing the capacity of the biological process is to utilize liquid oxygen injection in place of traditional aeration. This approach relies on the ability to transfer oxygen to microorganisms at a significantly higher rate. While aeration using air bubbles can transfer a maximum of 1500-2000 mgO$_2$/m^3/day, the use of pure oxygen can transfer up to 7500-9000 mgO$_2$/m^3/day. According to Skouteris *et al.* (2020), pure oxygen achieves faster treatment rates at higher biomass concentrations and shorter hydraulic retention times (HRT). The WWTP receives up to 1800 kg/day of COD in 800 m^3/day during peak months, which requires more than 600 kgO$_2$/day. Given the volume of the IFAS is 135m^3, the necessary oxygen transfer rate (OTR) is estimated to be more than 4000 gO$_2$/m^3/day. Therefore, replacing air with pure oxygen could expand the WWTP capacity to effectively treat the received load. Furthermore, the use of pure oxygen also increases its diffusion in the biofilm of moving bed-based processes, thus it would be possible to increase the attached biomass (Salvetti *et al.*, 2006).

The current study shows the experimental research carried out on a real WWTP during a high load period, with the aim of evaluating the effects of replacing the electrical consumption of blowers through the utilization of pure oxygen injection. The assessment will cover the examination of the treatment capacity, the quality of the final discharge and the energy and consumable costs.

MATERIALS AND METHODS

Influent water and operating parameters.
Table 1 summarizes the characteristics of the influent water at average and high load. **Table 2** shows the expected operating parameters in each of the seasons.

Pure oxygen injection equipment and monitoring.
Exclusive technology from Nippon Gases was installed, including specific injection equipment, a cryogenic tank and control panels. Additionally, the MiruGas® system was implemented for process remote monitoring, automation and control. This APC tool is specifically designed for the operation of biological processes. Through its calculation algorithm for Oxygen Utilization Rate (OUR - gO$_2$/m^3/d), the tool is capable of continuously monitoring microbial activity (Irizar *et al.*, 2009). Additionally, other key variables including water flow, gas flow, dissolved oxygen and turbidity at the outlet, were also tracked. During the testing period, an intensive analytical monitoring was carried out to verify the performance of the pure oxygen application.

RESULTS AND DISCUSSION

During the high load experimental period shown in the following graphs, the operating conditions of blowers together with the pure oxygen were changed until the combination that managed to treat the entire load at minimum cost was obtained: finally, a fixed blower input was established, being the injection of pure oxygen regulated (ON-OFF control) by the Dissolved Oxygen (DO) value.

Figure 1 shows the flow rate and the organic input load. Typical values were ranging between 1200 and 1500 kg COD/day, which are up to 5 times greater than the load for the rest of the year. **Figure 2** shows the COD concentration values at the inlet of the WWTP, at the secondary clarifier, and the final outlet after the trickling filter. Most of the COD removal occurs in the IFAS process with pure oxygen. The trickling filters have acted as a refining process. The best results in terms of water quality were obtained during the last part of the period, when the sludge was already acclimatised to pure oxygen, and the air and oxygen configuration was optimal. This configuration has been repeated in subsequent years. It has been proved that the correct application of pure oxygen in moving bed processes achieves significant improvements in the suspended solids, facilitating their settling and significantly reducing the COD of the output water associated with suspended solids.

It is important to find the optimal balance between both air/oxygen systems, as an excess of air can lead to an undesired stripping of the injected oxygen bubbles. On the other hand, a minimum but continuous supply of air is recommended to ensure agitation. This saves a lot of cryogenic oxygen consumption while still achieving high Oxygen Transfer Efficiency (OTE) values, which are impossible to achieve with air bubbles alone. The volumetric load that the expanded IFAS process was capable of treating with pure oxygen and proper operation and control is shown in **Figure 3**, reaching values of up to 9 kgCOD/m^3/d. With this data, it can be concluded that excellent process efficiencies and greater stability were achieved. The operational cost comparison of this configuration versus the amortisation and operating cost of the increased IFAS volume and blowers clearly showed the convenience of pure oxygen injection considering 4 months campaigns. With the implementation of pure oxygen, NILSA had two benefits: it required no fixed installation, thus eliminating risk of a costly investment in case of company closure. Secondly, was ready for use when needed and avoided the need for major construction work in time for the following season. Additionally, for Nippon Gases, this presented a chance to evaluate and enhance their new special injection equipment for moving bed processes.

Table 1. Characteristics of the influent water at average load associated with most of the year, and the high load expected between August and November

Parameter		AVERAGE	HIGH
Flow	m^3/d	**500**	**800**
TSS	gSS/m^3	250	500
COD_{total}	gCOD/m^3	600	2250
$COD_{soluble}$	gCOD/m^3	303	1655
BOD_5	gCOD/m^3	400	1595
$COD_{T\ inert}$	gCOD/m^3	50	80
Resulting loads			
COD load	kgCOD/d	300	1800

Abstract
OPFRs are emergent, toxic, and persistent pollutants that can easily diffuse in water, and that are only partially removed in wastewater treatment plants. Ligninolytic white rot fungi (WRF) can constitutively, and co-metabolically degrade a series of contaminants through non-specific extracellular enzymes and a versatile intracellular system. An initial screening for evaluating the ability of six different WRF and one non- ligninolytic fungus to degrade TEP, TBP, TCEP and TBEP is reported. WRF showed to be better degraders than *A. niger*, which can grow in the medium but not degrade OPFRs. TEP was not removed at all, while only 47% of TCEP could be removed by *G. lucidum* under nutrient limiting conditions. TBP and TBEP were completely degraded by *G. lucidum*, *P. sanguineus* and *T. versicolor* after 3 days. We theorize that OPFRs with larger structures are more easily degraded as it is easier for the fungi to take radicals of them. Biodegradation was the main mechanism of OPFRs removal, but its contribution depends on each fungus and each contaminant.
Keywords: emerging pollutants, flame retardants, fungal degradation, laccase, removal.

INTRODUCTION

Organophosphate flame retardants (OPFRs) are alkyl esters of phosphoric acid which are used as additives in a variety of commercial products due to their ability to act as flame retardant barriers. These high-production-volume compounds are not chemically bonded to their host materials and can easily diffuse in water compartments, being only partially removed in wastewater treatment plants (WWTPs) (Reemtsma et al., 2008). Bioremediation progressively appears as an appealing degradation method for persistent contaminants as it is simple, efficient and economically feasible.
The microbial degradation of some OPFRs has been studied (Dunyu et al., 2021). However, it implies the need for an adaptation period for bacteria to efficiently degrade the contaminant and a substrate's concentration "response threshold", below which bacteria cannot degrade the contaminant (Chaudhari et al., 2012). Ligninolytic white rot fungi (WRF) can overcome these concerns as they can constitutively, and co-metabolically degrade a series of contaminants through non-specific extracellular ligninolytic enzymes and a versatile intracellular system.
The present work reports an initial screening for evaluating the ability of six different WRF and one non- ligninolytic fungus to degrade four OPFRs, known to be soluble in water and usually detected in WWTPs effluents. Additionally, performance of two chosen fungi was further studied in the degradation of a well-degraded contaminant, to elucidate the contributions of physical adsorption and biodegradation to this removal. As a part of an ongoing project, it is expected that the results of this work pave the way for deeper studies on the degradation of soluble OPFRs through WRF.

MATERIALS AND METHODS

Four different OPFRs were tested: triethyl phosphate (TEP), tributyl phosphate (TBP), trichloro ethyl phosphate (TCEP) and tributoxy ethyl phosphate (TBEP). Six WRF: *Ganoderma lucidum, Pleorotus ostreatus, Phanerochaete velutina*, *Pycnoporus sanguineus*, *Trametes versicolor,* and *Trichoderma viride* and one non-ligninolytic fungus (*Aspergillus niger,* as we intend to degrade real wastewaters with elevated COD in the future) were tested. Pellet fungal biomass was used in all cases.
For the initial screening, 250 mL Erlenmeyer flasks with 50 mL of maintenance medium were used. The medium was spiked with a mixture of the four OPFRs at a concentration of 10 ppm for each compound and inoculated with pellets equivalent to 3.5 g/L of dry biomass. Experiments were conducted for 15 days, in a dark controlled environment at 25ºC, with continuous shaking (135 rpm).
Duplicates were performed for each fungus. Samples were taken at t_0 and after 3 days of experiment, to evaluate immediate degradation. Afterwards, 3 g/L of glucose were added, and final samples were taken at day 15 to assess fungal performance under nutrient-limiting conditions. To assess the contribution of each degradation mechanism, *Ganoderma lucidum* and *Trametes versicolor* were inoculated in maintenance medium spiked with TBP at 10 ppm. In this case, ~3.5 g/L of dry biomass of heat-killed pellets were inoculated to evaluate physical adsorption. Experiments were conducted in triplicate for 7 days, in the same environmental conditions as before. Samples were taken at t_0 and after 3 and 7 days of experiment. TBP concentrations were quantified for each experimental time.

RESULTS AND DISCUSSION

Initial fungal screening

T. viride and *A.niger* were the least suitable candidates to remove OPFRs, thus showing that ligninolytic fungi have a better degradation capacity in this case. TEP was the most recalcitrant compound because no degradation was detected. TCEP is also very difficult to remove, with *G. lucidum* being the only fungus able to remove 47% of the contaminant, only under nutrient limiting conditions, which would indicate that the enzymes involved in this degradation may be different than the ones that degrade TBP or TBEP. These two last contaminants were easily removed by *G. lucidum, P. sanguineus* and *T. versicolor*, which were able to remove 100% of the contaminants after 3 days of treatment. However, *P. sanguineus* and *T. versicolor* would be more efficient in this specific case, as they are able to remove the same amount of TBP and TBEP as *G. lucidum* but with ~50% less of biomass (as measured by final dry weight determination). By looking at each of the contaminant's structure, we theorize that WRF degrade OPFRs by taking radicals of them, which would explain why contaminants with larger structures are more easily degraded. Further research into specific enzymatic activities and transformation products should be carried to validate our hypothesis.

Results of control experiment with thermal inactivated biomass after 3 days, showed that adsorption contributed to 31% of the removal for *G. lucidum,* and 21% for *T. versicolor.* This parameter was maintained until the end of the experiment, which shows that there is no desorption of the contaminant afterwards. As for the results, we can conclude that biodegradation is the main mechanism of OPFRs removal. Nevertheless, the contribution of adsorption as a removal mechanism will depend on each fungus and each contaminant, so further research is necessary.

Abstract
Emerging contaminants such as pharmaceuticals and personal care products (PPCPs) have increased their use during the COVID-19 pandemic. Nature-based solutions, such as biofiltration are a good alternative for their removal. The use of hazelnut shells and its biochar is a cheap support material. Thus, this work is focused on the evaluation of the adsorption processes within biofiltration, optimizing variables for the removal of paracetamol, amoxicillin and triclosan. Biochar was produced from 3 different particle sizes. The removal process was evaluated in columns continuously until saturation. Results with biochar reported removals up to 100% for the 3 contaminants, optimizing the parameters of adsorbent dose (0.5-12 g/L) and agitation time (5-180 minutes). The use of smaller particle sizes (<355 µm) showed higher removals at lower doses of material (74-100%, 2 g/L). The biochar significantly improved the removal up to 200%, being its use is recommended at ratios 1:0.25 with hazelnut shells.

Keywords
Adsorption, amoxicillin, biochar, paracetamol, superficial area

INTRODUCTION

Nature-based solutions, such as biofilter-based technologies have a biotic component (plants, earthworms and/or microorganisms) and a support medium. The latter is a fundamental part of these technologies and will favor the adsorption and biodegradation (support biotic component) processes to be carried out in the emerging contaminants removal (Deng et al., 2021). In these technologies, adsorption has proven to be highly effective in removing emerging contaminants but conventional support materials, such as gravel, can account for up to 50% of the investment cost. Various materials have been studied for this purpose, such as zeolite, sand, construction waste, activated carbon, among others (Chang et al., 2019; Thuptimdang et al., 2021; Wang et al., 2013). Activated carbon as an adsorbent has been highlighted, but its investment costs are high (~21 USD/kg). For this, the use of organic residues is an alternative that benefits this type of technology as it is sustainable, economical, and effective. These have functional groups that benefit interactions with contaminants, as well as being easily modifiable to biochar, benefiting their porosity and surface area for the contaminant's removal (Maleki & Mao, 2022; Mohanty et al., 2018).

In recent times, due to the COVID-19 pandemic, drug consumption and use of personal care products has been on the rise. These can cause negative effects on human and animal health when discarded into the environment, causing alterations in the endocrine system and antibacterial resistant pathogens (García-Gómez et al., 2011). This study proposes the use of hazelnut shell and its biochar to study their potential use in support media, evaluating their ability to remove 3 emerging contaminants: paracetamol, amoxicillin and triclosan.

MATERIALS AND METHODS

Adsorbent material

Hazelnut shells were crushed, sieved, and divided into 3 granulometries: large (<2 mm and >600 µm), medium (<600 µm and >355 µm) and small (<355 µm and >150 µm). For biochar generation, approx. 15 g of hazelnut shell was placed in a 50 mL crucible with a lid, which was inserted into another 150 mL crucible. The smallest was covered with sand to reduce the entry of air into the sample. Crucibles were introduced into the muffle with a heating rate of approximately 20 °C/min, up to a temperature of 900 °C.

Experimental model

Adsorption was evaluated with different doses of adsorbent for each size: between 1 and 64 g/L for hazelnut shell and 0.5 a 12 g/L for biochar. These tests were carried out separately for each contaminant, for concentrations of 20 ppm in 20 mL of solution. The solutions were added to beakers covered with aluminum foil which were installed on an orbital shaker at 150 rpm for 1 hour. After contact time, the samples were centrifuged and filtrated. The concentration of each contaminant was determined before and after the tests, thus determining the percentage of removal. After selecting the most favorable working point, the optimal stirring time (between 5-180 minutes) for the adsorbent dose determined for each particle size was evaluated. Finally, the removal percentages were determined through the same procedure mentioned.

For the continuous test, to determine the optimal proportion of biochar and shell necessary in a continuous process, the rupture curves were carried out in 10 x 0.8 cm columns. 20 ppm of each contaminant was evaluated, using a flow rate of 9.3 m^3/m^2d. The evaluated shell:biochar ratios were 1:0, 1:3, 1:1, 3:1, 0:1.

Analytical method

For determination of the concentration of each contaminant, ultraviolet visible light spectroscopy (UV-Vis) was used through Hanon i5 UV-Vis Spectrophotometer with 1 cm wide quartz cells. The respective calibration curves were generated at wavelengths of 243, 228 and 292 nm for paracetamol, amoxicillin and triclosan, respectively.

RESULTS AND DISCUSSION

For the tests only with hazelnut shell, the removals of none of the contaminants exceeded 27% for the ranges evaluated, this value being reached only by the smallest sizes of adsorbent in the removal of paracetamol. In the case of biochar, removals increased significantly. For example, removal was 86% for triclosan with biochar from a large shell size. In any case, smaller sizes of the material required lower doses, reaching removals of 100% paracetamol, 98.7% triclosan and 73.7% amoxicillin with only 2 g/L of adsorbent in 1 hour of contact. The greater superficial area that this material has, agrees with the high removals at low doses and times.

Regarding the continuous process, amoxicillin columns were the first to saturate (5 days). It is possible to relate the shortest saturation time with the adsorption capacity of the adsorbent. The ratios of 1:1 and 1:3 showed similar results, reaching a C/C_0 for paracetamol on the 9th and 10th days of operation, respectively. Although a greater amount of biochar can allow a longer operating time for this type of filter, it is preferred to accompany the material with a certain percentage of shell. This since it generates a similar operation and allows a more economical replacement of adsorbents, requiring less treatment for the hazelnut shell for its use compared to biochar.

Table 1. Comparative removal percentage of amoxicillin, paracetamol and triclosan through biochar of different particle sizes with an adsorbent dose of 2 g/L

	% Removal	
Contaminant	Large particle size	Small particle size
Amoxicillin	13.69	73.65
Paracetamol	18	100
Triclosan	16.51	98.70

Abstract
Wastewater treatment plants (WWTPs) play a crucial role in protecting the environment and public health by removing pollutants. However, the energy consumption of these facilities can be significant, making it important to evaluate their energy efficiency. To date, a comprehensive methodology for energy audit at WWTP is still missed. This paper provides an overview of the methodologies currently used for evaluating the energy efficiency of WWTPs highlighting their advantages and limitations. The information will be useful to guide future research on this topic helping WWTP utilities to reach the energy audit goals in accomplishment of EU directives. The present overview pointed out that the obtained findings from benchmarking are often limited and fragmented and energy evaluation based on data envelopment analysis (DEA) depends on the selection of proper parameters. Consequently, further investigations are advised to develop standard procedures for data acquisition and online monitoring.

Keywords
Benchmarking; Energy efficiency; key performance indicator (KPIs); methodology; wastewater treatment plants (WWTPs)

INTRODUCTION

The main priority at wastewater treatment plants (WWTPs) is the attainment of high quality of treated effluent ensuring high effective removal of pollutants and protecting the environment and public health. However, WWTPs consist of energy-consumptive stages and the energy consumption mainly depends on the implemented technologies, on the plant size (in terms of population equivalent) and on the differences on target effluent quality among several countries (Gu et al. 2017). For instance, in medium and large WWTPs with conventional activated sludge (CAS), the aeration is the highest energy-consuming component (~60% of the total electricity consumption) as shown in Figure 1. As whole, the specific energy demand in WWTPs might decrease with the increase of inflow volume while it might increase with increasing concentration of pollutants in the influent (measured in terms of COD, BOD_5, and nitrogen) (Gu et al., 2017).
Therefore, the optimization in terms of removal efficiency and energy savings is essential to ensure the WWTPs performance that is both environmentally sustainable and economically viable (Sabia et al., 2020).
As recently advised by the European Commission, further efforts are needed to decrease the energy consumption in the wastewater sector which accounts for ~0.8% of the total energy use in the EU. In this regard, energy audit of WWTP could help to identify the significant energy consumers (such as processes and equipment) including the evaluation of the needed maintenance practices and their lifespan. However, further investigations are required to develop a comprehensive methodology for energy audit at WWTP (Sabia et al., 2020).

The aim of the present article is to provide an overview of the methodologies available in literature to assess the energy efficiency of WWTPs highlighting their advantages and limitations. The information will be useful to guide future research on this topic helping WWTP utilities to reach the energy audit goals in accomplishment of EU directives.

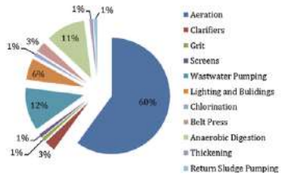

Figure 1. Percentages of energy use related to different compartments of CAS system (Gu et al., 2017).

METHODOLOGIES OVERVIEW

Table 1 provides a brief survey of main available methodologies to assess WWTPs energy performance. As a whole, they can be categorized in a) benchmarking; b) energy management tools; c) decision support tools.
The former, benchmarking, represents the first analysis aimed at understanding the energy consumption at WWTPs and it is based on Key Performance Indicator (KPI). Among the most reliable water-energy indexes, the total energy consumption (kWh) could be related to the treated wastewater volume (kWh/m^3), the plant size expressed as served PE per year (kWh/PE*y), and the amount of COD removed (kWh/kg COD). Several studies have performed the energy benchmarking using different KPIs. For instance, ENERWATER is an energy benchmarking model based on identification of KPIs that reflect the operational efficiency. While other studies have been performed by linearly aggregating the KPI values using the weights derived by Factorial analysis (F.A.) and consequently calculating the Global Energetic Index (GEI) in order to obtain a single indicator (Sabia et al., 2020).
However, the obtained findings from benchmarking are often limited and fragmented since they are strongly influenced by characteristics of treated wastewater and data are locally collected showing some differences at different geographical areas.
Among energy management tools, data envelopment analysis (DEA) is a mathematical programming technique that allows the analysis of processes that involve various inputs (e.g., costs for energy, waste management, and chemical) generating several outputs (amount of TSS, COD and BOD removed) (Hernández-Sancho et al., 2011). Moreover, DEA output could be related to environmental impacts in the framework of life cycle assessment (LCA) providing a broader performance evaluation of WWTPs.
Lastly, limited studies have been performed in order to develop decision support tools which could help WWTP managers to identify all possible strategies and actions for the optimization.

Table 1. Overview of methodologies for the evaluation of energy efficiency.

Methodology	Description	Limitations	References
KPI based on volume of treated water, PE, COD removed, BOD removed , TN removed, TSS removed	Determines evaluation of energy performance through a specific energy consumption and by using a set of indicators.	KPI for volume and PE assumes that the pollutant concentration are constant; KPI for COD, BOD, TN, TSS neglects the volume of WW and the other pollutants to be treated.	(Vaccari et al., 2018), (Di Fraia et al., 2018), (Zaborowska et al., 2017)
GEI (Global Energetic Index)	Was performed by linearly aggregating the KPI values using the weights derived by factorial analysis	Small number of WWTPs for the development of this methodology.	(Sabia et al., 2020)
EI (Energy Intensity)	A novel approach to evaluate the influence of the aging factor on energy use in WWTPs.	Are evaluated the economic cost of the energy used rather than the quantity of energy consumed in WWTPs.	(Longo et al., 2016)
ENERWATER	Standard method and online tool for assessing and improving the energy efficiency of wastewater treatment plants	The availability of data observation should be large to be representative of all the European WWTPs.	(Longo et al., 2016), (Longo et al., 2019)
DEA (Data envelopment analysis)	Non-parametric model, that calculates rather than estimates, the frontier using programming techniques. Widely applied for eco-efficiency assessment.	Not robust, no allowance for stochastic factors, heterogeneity across units of assessment not considered.	(Hernández-Sancho et al., 2011), (Lorenzo-Toja et al., 2015)

CONCLUSION AND FINAL REMARKS

WWTPs energy consumption depend on several factors including influent flowrate, pollutant load, WWTP size, type of the treatment technologies implemented. COD, suspended solids, nitrogen and phosphorus are the main parameters that influence the energy consumption and the treatment efficiency. Assessing the energy efficiency of WWTPs is essential to reduce the energy consumption and operational costs meanwhile improving the environmental sustainability and optimizing WWTPs performance. Benchmarking based on single KPI is suitable for WWTPs operated at similar conditions (e.g., same installed technologies). However, findings are strongly related to wastewater characteristics. Findings obtained by applying DEA depend on the proper selection of input and output variables. Further investigations should address the development of standard procedures for data acquisition and collection and the implementation of online monitoring.

Abstract
An experiment was carried out to check the effectiveness of ammonium nitrogen removal from synthetic wastewater using the activated sludge method and a structure supporting biofilm settling. The cleaning process was carried out in 6 cylinders with a capacity of 4 liters. Three of them were filled with synthetic sewage with a composition similar to domestic sewage. In addition, an increased dose of ammonium nitrogen was used in 3 cylinders. The hydraulic retention time was set at 36 hours. The most optimal conditions for microorganisms were provided by constant temperature of the wastewaterand aeration. Four cylinders are equipped with a specially prepared insert made of plastic, which largely contributed to better contact of activated sludge with synthetic sewage. The other two unfilled cylinders were treated as a comparative level. In the first group of cylinders, the reduction of ammonium nitrogen remained at the level of 58.51 - 77.96%. However, in the second group, the efficiency of purification processes was much lower and the average ranged from 27.64 to 33.43%.The final comparison of the cleaning effects in each of the cylinders shows that the increased content of ammonium nitrogen does not inhibit the process, but only slows it down.
Keywords
activated sludge, ammonium nitrogen, wastewater treatment

INTRODUCTION

Wastewater characterized by a high content of ammonium nitrogen comes from, among others, Motor Rest Area facilities. These facilities very often do not have a local wastewater treatment plant, due to the fact that previous experience in the wastewater management sector in Motor Rest Area facilities indicates serious operational problems during biological wastewater treatment. The main reason for the failure of the biological treatment of this type of wastewater is the too high content of ammonium nitrogen, significantly exceeding the range of concentrations of this pollutant in typical domestic wastewater, which ultimately leads to the inefficiency of the treatment systems. Therefore, measures were taken to check the level of ammonium nitrogen reduction in wastewater heavily loaded with this pollutant using the activated sludge method.

MATERIALS AND METHODS

The test stand was equipped with 6 cylinders with the same capacity of 4 liters. Activated sludge was obtained from the Municipal Sewage Treatment Plant located in the city of Świdnica (Poland)., Each of the cylinders was filled with activated sludge to the level of 1.5 liters. The remaining capacity was supplemented with specially prepared synthetic sewage, according to the source [1,2,3,4]. Each cycle required a freshly prepared synthetic wastewater just before the end of the hydraulic retention time, so the synthetic sewage was prepared on an ongoing basis due to the risk of putrefaction caused by the presence of nutrients in the recipe. For this reason, the parameters of synthetic wastewater did not differ much from each other. Monitoring of wastewater quality was carried out during each cycle.
The cylinders were divided into two groups. The first of the three were flooded with sewage of the basic composition. The remaining cylinders (the second group) received wastewater with an increased concentration of ammonium nitrogen. The concentration level was determined on the basis of literature, but also own research of wastewater from Motor Rest Area facilities. In addition, in each group of cylinders, two of them are equipped with a proprietary fluid bed made of plastic.
Each of the cylinders was equipped with an aeration system, and the aeration time was set at 12 hours, as well as the rest time, which was also 12 hours. The hydraulic retention time of sewage was set at 36 hours.

Wastewater samples for testing were taken at the beginning of each cycle in the 1st hour, the second batch was taken in the 2nd hour to control the treatment process. The third batch of samples taken in he 36th hour represented the end of each cycle. The test results obtained from the last batch of samples were compared to the initial one, which was the reference point. Thanks to this, it was possible to assess the level of ammonium nitrogen reduction.

RESULTS AND DISCUSSION

The used filling of the cylinders improved the cleaning process by deposition of biofilm in the free spaces of the material. In the cylinders in which the filling was present throughout the experiment, it supported the growth of biomass. This is due to the better contact between wastewater and activated sludge, and consequently faster reduction of ammonium nitrogen. This is evidenced by the better efficiency of cleaning in filled cylinders. The first three cylinders, where the composition of synthetic sewage was similar to the composition of domestic wastewater show a greater range of ammonium nitrogen reduction in the range of 58.51-77.96%. However, the last three, to which wastewater representing higher concentrations was delivered, were worse at reducing ammonium nitrogen in the range of 27.64-33.43%. Due to the fact that the first three cylinders shown in the diagram show a wider range of reduction, it is concluded that the purification process is much more intensive at lower concentrations of ammonium nitrogen. On the other hand, the results of the experiment prove that, contrary to the thesis adopted so far, that the processes of nitrogen transformation are inhibited by the concentration of ammonium nitrogen equal to 150 mg NH_3/dm^3 [5], but even at high concentrations (used in the experiment), deviating from the norm assigned to domestic sewage, there is still reduction, and the purification processes are not inhibited, but only slowed down.

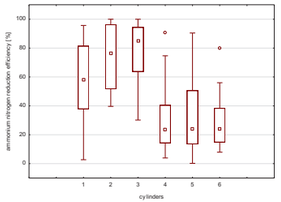

Figure. 1. Reduction of ammonium nitrogen in the cylinders at HRT of 36 hours.

Abstract
Nowadays, contamination is observed in almost all sources of available water bodies. A fundamental environmental challenge is the so-called emerging contaminants (EOCs) previously not known to be significant in freshwater. EOCs appear from products typically used in everyday life, including persistent organic pollutants, veterinary medicines, pharmaceuticals, and personal care products. These EOCs are gaining notable prominence in water remediation research because they possess an intricate molecular nature and are very hard to detect and remove.
This talk will present a new pectin-based adsorbent to simultaneously remove heavy metals and antibiotics. We will show that by changing the traditional way to crosslink pectin, we can adsorb big quantities of Zn2+ and tetracycline. We will discuss the application of pseudo first- and second-order models to understand the adsorption kinetics and the Langmuir isotherm model to describe adsorption onto pectin.

Keywords (maximum 6 in alphabetical order)
Adsorption; Pectin; Tetracycline; Water Remediation, Zinc

INTRODUCTION

Access to clean water for human consumption is becoming a significant challenge worldwide because around 14000 people die daily because of water pollution[1]. Water contaminants are classified into different groups regarding their nature: organic, inorganic radioactive, suspended solids, pathogens, and nutrient contaminants. In particular, heavy metals can reach water via natural sources such as volcanic eruption or anthropogenic activities like mining, causing different diseases by bioaccumulation in the target organs. Each metal type has different target organs and an accumulation limit before being fatal for the individual. On the other hand, antibiotics can only reach aquatic media from human activities (hospitals, domestic or veterinary uses). These contaminants are present in the water bodies of numerous countries in the range of ng/L to µg/L. The problem created by antibiotics is the coexistence of antibiotics and bacteria in the aquatic media, dramatically elevating the probability of developing antibiotic resistance genes by these bacteria, resulting in a public health issue[2].
The principal problem with these pollutants is that they escape from the methods used in most wastewater treatment plants. Different strategies have been developed to overcome this problem; the most popular are chemical precipitation, coagulation/flocculation, ionic interchange, or membrane technologies. Among them, we chose bio-sorption because it is a convenient method, as it is metabolically passive, does not need any external energy (cost-effectiveness) and is sustainable.
In this work, we have used citrus pectin to develop an adsorbent with the abovementioned characteristics. Pectin is discarded from the juice industry and can be isolated by green extraction methods. Pectin has been used as an absorbent of heavy metals when it is cross-linked with Ca^{+2} [3]. However, in this work, we will present a new cross-linking system based on lanthanides. We will show in this talk that we can adsorb heavy metals and antibiotics simultaneously.

MATERIALS AND METHODS

Materials: Pectin with low DE (9.9%) was gently delivered from Herbstreith & Fox. Glycerol (≥ 99%), calcium chloride anhydrous granular (≥ 93%), europium chloride hexahydrate (99.99%), tetracycline, and Zinc solutions were purchased from Merck.
Film preparation and dual cross-link: 3 wt% of LM pectin was dissolved and stirred in Milli Q water and 6 wt% of glycerol solution at 70 C and consequentially casted into a petri dish at room temperature to obtain thin film hydrogel membrane. Hydrogel crosslinking was performed in two steps exploiting the batch method; firstly into a 500 ppm of Ca^{2+} solution for 40 min (LMP-Ca). Therefore, the LMP-Ca hydrogel was washed with Milli Q water and secondly cross-linked with Eu^{3+} solution at the same conditions (LMP-Ca+Eu). Both the hydrogels cross-linked only with Ca^{2+} (LMP-Ca) and those cross-linked with the dual system (LMP-Ca+Eu) will be used to analyse the adsorption capacity against heavy metals and antibiotics.
Batch adsorption experiments: Kinetic adsorption experiments, were performed at fixed initial concentration of 150 mg/L for Zn^{2+}, 50 mg/L for TC, and 30 mg/L for TC/Zn^{2+} simultaneous removal. Metal ion concentration a specific time (C_t) were measured by an inductively coupled plasma atomic emission spectrometer (ICP-AES) (Horiba Yobin Yvon Activa), whereas the tetracycline concentration was determined by UV-Vis spectra. We measured the heavy metal concentration at different times ranging from 10 min to 24 h. The adsorbent dosage was fixed to 2.5 g/L, and a constant pH = 7 was kept for all the experiments.
C_t were measured by an inductively coupled plasma atomic emission spectrometer (ICP-AES) (Horiba Yobin Yvon Activa), whereas the tetracycline concentration was determined by UV-Vis spectra. Aliquots were taken at a specific time and were used to measure the C_t. The adsorption capacity (q_t) (mg/g) was calculated as follows:

$$q_t = \frac{C_0 - C_t}{d} \quad (1)$$

where C_0 and C_t represent the initial and after soaking concentrations of a given pollutant (mg/L), respectively and d is the adsorbent dose (g/L).
The removal efficiency (R%) was calculated as follows:

$$R\% = \left(\frac{(C_0 - C_t)}{C_0}\right) \times 100\% \quad (2)$$

RESULTS AND DISCUSSION

Figure 1 shows the calcium (a), europium (b) and calcium-europium (c) uptake capacities of LM-pectin films determined by ICP-AES. These kinetic experiments allow determining the cross-link density of these films after 40 minutes. The sorption of Eu^{3+} (Fig 1b) was fast in the first 30 min. After that, it proceeded at a relatively slower rate and finally reached equilibrium after ~200 min. The same behaviour is observed using calcium as a crosslinking agent (Fig. 1a). In addition, Fig. 1c shows the kinetic when the pectin is cross-linked with calcium and then with europium. In this last case, the crosslinking is even more effective than that produced only with Eu^{+3}. In pure water with pH of 7, LM-pectin has a large number of negative centres, because pKa of pectin is about 3.5. The degree of esterification has a crucial importance for an electrostatic interaction between pectin and ions. The low degree of esterification causes a high available number of acidic groups, which can bind with a higher amount of cations. Thus, the lower the degree of esterification of pectin, the higher number of junction zones. Therefore, the formed film is stable.

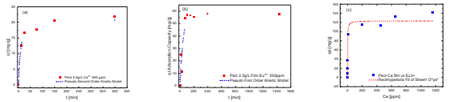

Figure 1. Adsorption kinetics of LM-pectin cross-linked by Ca^{2+} (a), Eu^{3+} (b) and with the dual system (Ca^{2+} and Eu^{3+}).

The adsorption kinetics was investigated for tetracycline (TC). The experiments for the effects of contact time were carried out at varying contact times ranging from 10 min to 1500 min at an adsorbent dose of 2.5 g/L, at room temperature (25 °C), and pH = 7. Optimization of contact time is essential for the adsorption studies to ensure complete equilibrium between the film and TC. Fig. 2 shows the effect of the contact time of the pectin cross-linked with Eu^{3+} film and TC. It was found that TC removal was fast during the first 100 min reaching the equilibrium after ~500 min. This may be because, in the initial stage, adsorption sites are highly available, but over time, there is a depletion of the adsorption sites. Fig. 2b shows the amounts of removal rate corresponding to the different equilibrium concentrations. The results showed that the percentage of tetracycline removed is maximum (68 %) at 10 ppm of TC. It is also expected to increase at lower concentrations of TC in water.

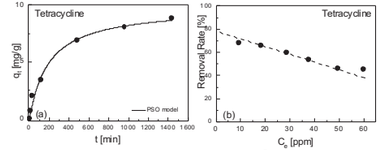

Figure 2. Adsorption kinetics of pectin cross-linked with Eu^{3+}. Initial tetracycline concentration was 50 mg/L and pH 7. Dashed line represents the fitting using the PSO model.

Fig. 3 shows the kinetic experiments (a) and the removal rate (b) for adsorption of tetracycline on pectin films cross-linked with the dual system (Eu^{3+} and Ca^{2+}). The adsorption capacity of TC is higher for the dual crosslinking system. The q value for the TC removal is 57% higher for the dual system (14 mg/g) than the Eu^{3+} cross-linked film (8 mg/g).

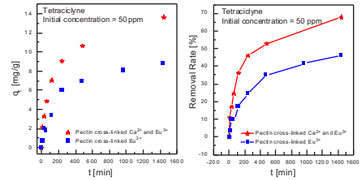

Figure 3. Adsorption kinetics (a) and removal rate (b) of pectin film cross-linked with the dual system (black points) and cross-linked only with Ca^{2+}. Initial tetracycline concentration was 50 ppm, pH = 7 was fixed using a HNO_3 solution and the dose was 2.5 g/L.

Finally, Fig. 4 shows the kinetic experiments (a) and the removal rate (b) for adsorption of the two pollutants (tetracycline and Zinc) simultaneously. The removal rate is very high in both cases as seen in Fig. 4b.

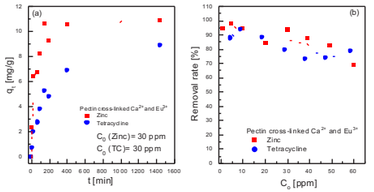

Figure 4. Adsorption kinetics (a) and removal rate (b) of pectin film cross-linked with the dual system (black points). Initial concentration was 30 ppm for tetracycline and for Zinc respectively. pH = 7 was fixed using a NaOH and HNO_3 solutions. The dose was 2.5 g/L.

In conclusion, we have shown a novel way to crosslink pectin with a low degree of methoxylation via Eu^{3+}. Moreover, we can use a dual crosslinking system of Eu^{+3} and Ca^{2+}. With this strategy, we can reach remarkable pharmaceuticals and heavy metals adsorption.

Abstract
The development of UV LEDs in the past decade has led to significant research in water disinfection. The possible synergy between multiple wavelengths in the UV range has been widely debated. Some researchers have concluded the existence of synergy, while others have discarded it. This study analyses the use of three UV light sources with different wavelengths (265, 275, and 310 nm) on the inactivation of *Escherichia coli* bacteria. A fixture to accommodate up to 8 high power light sources has been designed and used in the tests. This study proves that combinations of 310 nm with 265nm or 275 nm devices present a significant synergy. The observed synergistic effect has been correlated to the emission spectra of the respective LEDs to elucidate the possible mechanism of inactivation in combination.
Keywords
E. coli; disinfection; spectrum; synergy; ultraviolet light; wastewater

INTRODUCTION

There exists a controversy on the possibility of a combination of wavelengths and its resultant effect on different applications [1,2]. In all the studies on synergy so far, authors have had little to no control over the light sources used. In the author's opinion, factors like emission spectrum, type of device, and contribution of each wavelength, when combined, plays a key role in comprehensively evaluating possible synergistic effect between multiple wavelengths for the inactivation of microorganisms. This study attempts to fill these knowledge gaps and take advantage of establishing complete control over the light source to study its resulting effect on the inactivation of *E. coli K12*.

MATERIALS AND METHODS

The LEDs used in this study result from extensive market research and characterisation, thus enabling a good understanding of its behaviour. 13 possible combinations of the wavelengths on the fixture, as seen in figure 1 (a-d), have been studied. Experiments have been conducted in a single pass flow type system (figure 1e) at two different intensities to estimate the overall UV dose response.

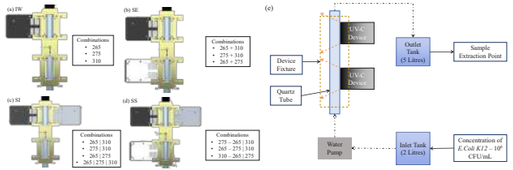

Figure 1. Combinations on UV fixture – (a) Individual wavelengths (IW), (b) Sequential Mode (SE), (c) Simultaneous Mode (SI), (d) Sequential + Simultaneous Mode (SS), and (e) Experimental set-up

RESULTS AND DISCUSSION

Individual disinfection experiments in a single pass, at a flow rate of 2 L/min and contact time of 0.753 seconds, confirmed the 265 nm light source to be most effective in the inactivation of E. coli (2.793 ± 0.173 log units), while the 310 nm led to the lowest disinfection (0.0003 ± 0.00008 log units). Due to the similar inactivation mechanism of wavelengths in the 250-280 nm range, the observed log reduction for 265 nm and 275 nm (2.448 ± 0.244 log units) were similar within the experimental error. Also, resulting from a different inactivation mechanism, the 310 nm light source was ineffective in a single-pass system due to short contact time. When a combination of the three wavelengths was used, an average log reduction of 5.408 ± 0.314 was observed. Under combined irradiation experiments, the average log reductions were similar to the sum of individual log reductions of the respective wavelengths for combinations of 265 nm and 275 nm attempted. For combinations involving the use of 310 nm, a possible synergistic effect was seen.

Table 1. Synergy of inactivation at 50% and 100% dose with error representing the 95% confidence interval obtained by t-student analysis. (LRV – Log reduction value)

UV	At 50% Dose		At 100% Dose	
Combination	Theoretical LRV	Actual LRV	Theoretical LRV	Actual LRV
265|275	2.640 ± 0.091	2.722 ± 0.088	5.241 ± 0.092	5.281 ± 0.038
265|310	1.514 ± 0.035	1.781 ± 0.124	2.794 ± 0.053	2.944 ± 0.047
275|310	1.127 ± 0.084	1.850 ± 0.141	2.448 ± 0.075	3.047 ± 0.157
265|275|310	2.641 ± 0.091	2.801 ± 0.071	5.242 ± 0.092	5.408 ± 0.115
265+275	2.640 ± 0.091	2.783 ± 0.109	5.241 ± 0.092	5.231 ± 0.076
265+310	1.515 ± 0.035	1.772 ± 0.086	2.794 ± 0.053	2.945 ± 0.085
275+310	1.127 ± 0.084	1.277 ± 0.059	2.448 ± 0.075	2.647 ± 0.119

To further evaluate the synergistic effect of the wavelengths, a robust statistical analysis using three different techniques has been conducted. T-student, ANOVA, and Codified ANOVA (2 factor, 2 level) analysis showed significant synergy for the combinations highlighted in blue in Table 1. This is mainly due to the emission spectra of the 310 nm LEDs, wherein about 26% of the light emission occurs after 320 nm. In this range, the inactivation shifts to another mechanism leading to a synergistic effect [3].
Finally, the electrical energy per order of inactivation has been calculated to evaluate if the synergistic effect is energy efficient as well.

Abstract

The NATURE project (https://www.natureproject.eu/) aims to explore the use of nature-based solutions (NBS), especially wetlands, as management option for reducing the presence of antibiotics (ABs) and antimicrobial resistance (AMR) at the river catchment scale, from wastewater treatment to estuarine areas in four countries (Denmark, Spain, Portugal, and Mali). The results show the presence of several classes of ABs (fluoroquinolones, lincosamides, macrolides, sulfonamides, and rifamycin) and AMRs in wastewater and surface water samples, but their concentration and abundance were highly variable (ranging from 4 to 760 ng/L). Overall, our study demonstrate that the implementation of NBS at different river catchment levels (wastewater treatment, river stream or estuarine area) can improve the attenuation of ABs and AMR from 30 to 50%, in comparison to a reference approach without vegetation.

Keywords

Antibiotics; ecosystems; nature based solutions; removal; constructed wetlands; saltmarshes.

INTRODUCTION

Antibiotics (ABs) have been found in 2/3 of the world's rivers and experts expect a 65% increase of drug concentration in water by 2050. Once in the environment, ABs can promote antimicrobial resistance (AMR) which creates resistant microbial strains posing a risk to ecosystems and human health (Murray, Ikuta, et al., 2022). AMR is already responsible for an estimated 33,000 deaths per year in the EU and costs €1.5 billion per year in healthcare costs and productivity losses. The NATURE project (https://www.natureproject.eu/) aims to explore the use of nature-based solutions (NBS), especially wetlands, as management option for reducing the presence of ABs and AMR at the river catchment scale, from wastewater treatment to estuarine areas in four countries (Denmark, Spain, Portugal, and Mali).

RESULTS AND DISCUSSION

The results show the presence of several classes of ABs (fluoroquinolones, lincosamides, macrolides, sulfonamides, and rifamycin) and AMRs in wastewater samples, but their concentration and abundance were highly variable(ranging from 4 to 760 ng/L), at least in small decentralized wastewater treatment NBS monitored in Denmark (10 to 100 PE). Trimethoprim was the most abundant AB in the pre-settled wastewater from Denmark, whereas in the case of the Spanish site, clindamycin and azithromycin were the most abundant compounds in secondary treated wastewater effluents. The main results achieved so far demonstrate that the use of NBS as secondary or tertiary wastewater treatments results in a greater removal of ABs and AMR than conventional wastewater treatment solutions. For example, average removal of identified ABs and AMR (intI1 and sul1) in conventional tertiary wastewater treatment was of 40% and 1.5 log units, whereas these removals increased up to 70-80% and 2-3 log units by using NBS, respectively. Similarly, the renaturalization of river streams has been observed to enhance the attenuation of antibiotics by 30-40%. Several micropollutants have been detected in water of a Portuguese river estuary, all at low amounts (concentrations lower than 5 ng/L except for trimethoprim, which was detected up to 100 ng/L). However, the most abundant compounds were anti-inflammatory and analgesic compounds (up to 2,700 ng/L for acetaminophen). The potential of the estuarine saltmarsh to remove these pollutants is being evaluated. Results from Mali indicate that hospital wastewater effluents discharging into the Niger river are a very important source of ABs, reaching concentration levels greater than 30,000 ng/L (ciprofloxacin and acetyl-sulfamethoxazole). Therefore, we expect that the implementation of NBS at these sites would aid to reduce the impact of ABs and AMR into the Niger river.

CONCLUSIONS

Overall, the results demonstrate that the implementation of NBS at different river catchment levels (wastewater treatment, river stream or estuarine area) can improve the attenuation of ABs and AMR.

Abstract
Wine making is a water-intensive industry, with an estimated water footprint of up to 1,000 L per 1 L of wine. Most of the footprint is associated with irrigation, which essentially narrows the opportunities for circular water management to wineries. The water used by wineries, however, becomes highly contaminated with sugars, alcohols, carboxylic acids, etc. The organic loads of winery wastewater (WWW) are not only high, but also extremely fluctuating, e.g. chemical oxygen demand can vary by multiple orders of magnitude throughout a year. Wineries have limited possibilities to dispose the wastewater legally. An investment into their own wastewater treatment plant is frequently too high for the often family-owned small and medium wineries, therefore they are dependent on external facilities whose services are costly. Given these challenges and the growing legislation pressure, there is an increasing demand for cost-effective, robust and compact wastewater treatment technologies that would allow for water reuse and/or secondary products. One such technology, which is investigated in this work, is a combination of evaporation and stripping. Laboratory tests with real WWW from the Czech Republic have shown that the original wastewater volume can be reduced by 90 % using evaporation with the ethanol yield being virtually 100 % in the distillate. The distillate can be further processed in a stripping column to obtain recycled water with over 99.99 wt.% purity, with ethanol being either recovered or discarded based on the market situation. It was also demonstrated that the storage period affects the technology performance, therefore the storage time can be optimized to achieve specific technological goals. These promising results confirm that the innovative technology configuration has the potential to not only be competitive against the conventional WWW treatment technologies, but also redefine the water management in wineries by turning what was originally a waste stream into usable and/or marketable products.

Keywords
Circularity; ethanol; evaporation; stripping; wastewater recycling; winery

INTRODUCTION

Wineries produce significant amounts of wastewater, with an estimated specific winery wastewater (WWW) production of 0.5–14 L per 1 L of wine (Ioannou et al., 2015). The main contaminants are ethanol, organic acids (mostly acetic acid) and unfermented sugars (glucose, fructose) (Malandra et al., 2003). These can result in chemical oxygen demand (COD) over 100,000 mg/l particularly in the vintage period (grape crushing), during which the wastewater is extremely difficult to treat (Mosse et al., 2011). Given the limitations of the conventional technologies (high capital cost and spatial footprint, low turndown ratio), there is a number of emerging technologies which have been of research interest and allow not only for WWW treatment, but also water management circularity. The three most prominent are membrane bioreactor, reverse osmosis and evaporation (Miklas et al., 2022b), the last of which is the subject of this study. As the authors previously revealed, there have been limited research efforts targeting ethanol, despite it being the primary contaminant. This creates an apparent research gap to assess the possibilities of 'closing the loop' using an evaporation process. This is complemented by an investigation of the effect of storage prior to treatment, as storage time affects the composition of the WWW and can thus be used to optimise the process.

METHODOLOGY

The methodology consists of two parts:
a) simulated storage (Figure 1),
b) operating test (Figure 2).

In both parts, analytical chemistry methods are used to determine COD and concentrations of ethanol, acetic acid, glucose and fructose. COD was measured photometrically using COD cell test, fructose and glucose was determined by high-performance liquid chromatography, ethanol by gas chromatography with flame ionization detector, and acetic acid by ionic chromatography.

WWW samples for this research are taken from a winery in South Moravian region in the Czech Republic during the critical period of the vintage season and analysed at biweekly (14 days) intervals for 1 month (see Figure 1) before the follow-up testing takes place.

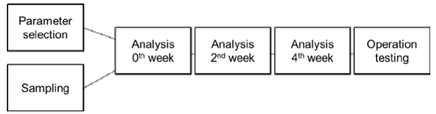

Figure 1. Methodology of the storage period investigation.

The operating test consists of two steps: evaporation in a multi-stage flash evaporator with nominal heat output of 40 kW and air stripping in a small-scale column (700 mm tall, 100-mm diameter) as shown on Figure 2.

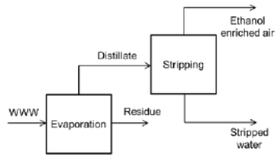

Figure 2. Operating test sequence.

The methodology allows for three key results: a) the effect of storage time effect on contaminant levels, b) volume reduction capabilities and product purities from the proposed process configuration, c) the relationship between the two to determine strategy for operation testing, including a potential chemicals dosage.

RESULTS AND DISCUSSION

The sample was taken on October 7th, 2022 and the first test was carried out immediately. The sugars' concentration was already negligible as alcohol fermentation had probably already converted them to ethanol. The COD value was relatively high (8,310 mg/l) and only slightly decreased over the 4-week period. Ethanol concentration, on the other hand, decreased significantly from 3.914 g/l to 1.890 g/l. The related acetic acid formation was evident as its concentration increased from 0.649 g/l to 3.733 g/l during the monitoring period. The ethanol and acetic acid concentrations can be seen on Figure 3.

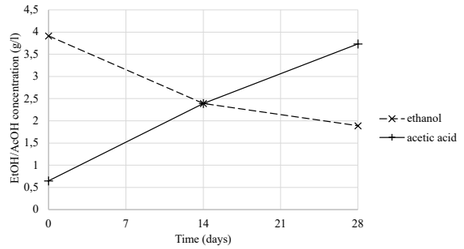

Figure 3. Ethanol and acetic acid concentration over the storage period.

During WWW storage, sugars are first transformed to ethanol during alcohol fermentation, followed by acetic fermentation consuming ethanol to form acetic acid. During evaporating, the volatility of ethanol makes it concentrate in the distillate, while the concentration of acetic acid is significantly lower and sugars are to be found exclusively in evaporation residue. The stripping column effectively separates ethanol from water, but the presence of acetic acid contaminates both potential products (ethanol solution and stripped water).

The evaporation test started with 182.5 L of WWW, which was circulated in a closed loop until a volume reduction of 90 % was achieved (less than 20 L as the evaporation residue). Figure 4 shows the difference between the distillate and residue.

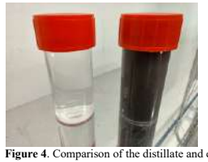

Figure 4. Comparison of the distillate and evaporation residue.

Based on the storage period investigation, sodium hydroxide was dosed during operating tests to stabilize acetic acid in the evaporation residue, which eliminated the distillate contamination. This has proven to be successful as the distillate contained only 8.8 mg/l of acetic acid. Simulation results (see Figure 5) show that the concentration would be 200 times higher without NaOH. Also, once around 50 % of the WWW is evaporated, basically no ethanol is left in the residue.

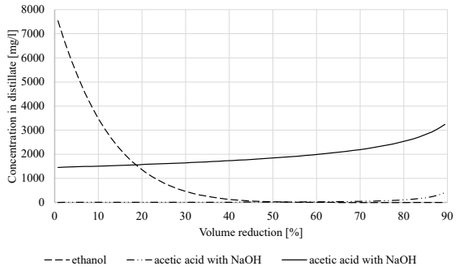

Figure 5. Simulation results from a model validated by the evaporation test.

The stripping test was carried out with extremely dry air, which resulted in an underwhelming ethanol removal of around 15 % per pass. The previous experiment with ambient air suggests that the removal can be close to 50 % (Miklas et al., 2022a), potentially resulting in sub-100 mg/l ethanol concentration and allowing for a more meaningful water reuse. This is the point for future validation and/or other technology consideration (e.g. membrane distillation).

CONCLUSION

The presented work expanded the opportunities for circular water management in wineries by demonstrating the potential of evaporation coupled with stripping as a means to obtain clean water and ethanol. Results suggest that up to 90 % of WWW can be recycled using the technology, with the possibility to recover ethanol as a by-product. The effect of storage period on the technology performance was also investigated. It is advisable to process WWW as soon as possible (sugars dominance) if water recycling is the main priority, as this leads to the lowest distillate contamination. If ethanol recovery is desirable, a prolonged storage period can be beneficial. Very long storage periods are related to acetic acid formation, which is mostly undesirable. However, the acid stabilization using sodium hydroxide can prevent distillate contamination and potentially leads to the recovery of sodium acetate as an additional product.

Lab Scale Study of Wastewater Treatment using Nano-bubble Aeration in the Activated Sludge Process

M. Mohamed, M.I. Kizhisseri, M. Sakr, M. Maraqa, M. Hamouda

* Department of Civil and Environmental Engineering, United Arab Emirates University, Al Ain, UAE
(E-mail: m.mohamed@uaeu.ac.ae)*

Abstract
The most widely used method in municipal wastewater treatment is activated sludge process (ASP). For an ASP system, oxygen level in the aeration tanks is a critical factor in improving the removal efficiency of organic matter. Nano-bubbles are expected to be effective in increasing the levels of oxygen in comparison with conventional macro-bubbles used for aeration. This study aims to determine the feasibility of using nano-bubble aeration to replace macro-bubble aeration in a conventional ASP system. In this study, a hybrid method of aeration in which a nano-bubble generator and ultrafine diffusers with compressed air were operated intermittently to generate nano-bubbles. Two identical ASP systems; one with nano-bubble and the other with macro-bubble were tested. The treatment efficiency was determined by measuring the COD of the influent and effluent samples. Results indicate that nano-bubble aeration has a great potential in enhancing the biological treatment efficiency of ASP wastewater treatment systems.

Keywords
Activated sludge process, aeration, bubble size distribution, nanobubbles, wastewater treatment.

INTRODUCTION

The major biological processes prevalent in the Middle East region for municipal wastewater treatment are found to be the conventional activated sludge process and membrane bioreactor. At domestic WWTPs in the UAE, wastewater is treated to tertiary level to produce treated effluent (Statistics Centre - Abu Dhabi, 2015, 2018). A major challenge encountered in the ASP wastewater plants is attributed to power consumption during the aeration process of the activated sludge system. Usually, aeration in activated sludge systems is achieved by bottom diffusers. The efficiency of diffusors of macro bubbles is very low and ranges between 6-30%, which results in huge quantities of air that needs to be pumped to achieve the required treatment level. A critical factor in enhancing the efficiency of wastewater treatment is the transfer of oxygen in water. The aerobic biodegradation capacity is related to the growth of site specific microorganisms, which is significantly affected by the oxygen content in water (Song and Katayama, 2010). Thus, there is a need to improve oxygen transfer in the aeration tanks of activated sludge system not only to cut down on energy consumption but also to reduce the carbon footprint associated with the process.

Conventional techniques can produce macro-bubbles with diameters of millimetres or centimetres. Macrobubbles stay in water for short times and are inefficient for oxygen transfer process, leading to a small zone of influence and low activity of aerobic microorganism (Agarwal et al., 2011). An effective technique for increasing the oxygen transfer in water would be MNBs injection compared with the traditional technologies with macrobubbles (H. Li et al., 2013). Microbubbles with 30 μm radius were first found by Turner (Turner, 1961) in water and they were found to exist for long periods of time. Nanobubbles stay in water for longer periods and their stability can be attributed to electrically charged liquid–gas interface, which creates repulsion forces that prevent the bubble coalescence (Ushikubo et al., 2010). MNBs are tiny bubbles with diameters on the order of micrometers and nanometers, showing great potential in environmental remediation (H. Li et al., 2013).

Application of MNBs has drawn recent interest in various environmental applications due to its special characteristics, such as large specific surface area, negatively charged surface, long residence time in water, high mass transfer efficiency, and the generation of highly reactive free radicals (H. Li et al., 2013). (H. Li et al., 2013) showed that MNBs would greatly enhance bioremediation by accelerating oxygen transfer process. Enhanced aerobic degradation technologies aim mainly on increasing oxygen levels which can increase biodegradation rates by several orders of magnitude (Mohamed et al., 2010; Mohamed and Hatfield, 2011). These technologies operate by providing a supply of oxygen, which becomes available to bacteria (Mohamed, 2011). Micro and nano bubbles have been in use for various environmental engineering applications in the past twenty years because of various characteristics they possess (Movahed and Sarmah, 2021; Xia and Hu, 2018; Yang et al., 2017).

Based on the differences in their sizes, bubbles were categorized as macrobubbles, microbubbles (MBs), and sub-micro or nano bubbles (NBs) for conventional or big bubbles, fine bubbles, and ultrafine bubbles, respectively (Agarwal et al., 2011; Pérez-Garibay et al., 2012). Garibay et al. (Pérez-Garibay et al., 2012) employed the term conventional bubbles to describe the bubbles with sizes ranging between 600–2500 μm. In 2017, Temesgen et al. (2017) suggested the size boundaries of the MBs, with a minimum size of approximately 10 μm, while the maximum size suggested was 100 μm; and the diameters below 200 nm represent the NBs. The bubble size ranges and their associated properties can be summarized as shown in Figure 2. The most typical tools used for measuring the size and size distribution of the MBs and NBs are the laser-diffraction particle-size analyzer (Agarwal et al., 2011), atomic force microscope (Parmar & Majumder, 2013), and image analysis (Kim et al., 2012). The size and size distribution of the MBs and NBs are affected by the design and operation conditions. Kim et al. (2012) demonstrated that the size and fraction of the MBs mainly depend on the pressure differences across the nozzle system such as higher pressure would produce smaller bubbles because of an increase in air density and at pressures above approximately 3.5 atm, the sizes of the MBs were almost constant.

As MNBs have higher surface area/volume ratio as compared to macro air bubbles and they tend to reside longer before they burst on the liquid surface (Sakr et al., 2022). Thus, we hypothesized that nanobubbles (NBs) will be more efficient to use than macro air bubbles, leading to reduced pumping volume to the reactor and a consequent cut down on the pumping cost. To test our hypothesis, we carried out lab-scale experiments to characterize NBs size and size distribution which leads to optimization of operating conditions with respect to NBs size.

This study aims to determine the feasibility of use of nanobubble aeration to replace macro bubble aeration in a pilot-scale conventional ASP system. The process was evaluated by its capacity to reduce the soluble organic matter at increased loading rates, as well as the DO levels of the aeration tank.

MATERIALS AND METHODS

The study involved the construction of lab-scale activated sludge systems and experiments on biological treatment of wastewater. Two identical ASP systems were operated; one with nanobubble aeration and the other with macro bubble aeration, and tested as bench scale systems for treating 60 liters of wastewater per day. The schematic of experimental set up is shown in Figure 1.

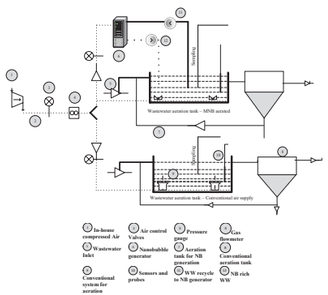

Figure 1. Experimental set-up of the bench-scale activated sludge process systems

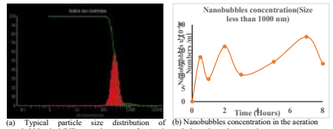
Domestic wastewater after primary settling and return activated sludge (RAS) were collected from the nearest municipal wastewater treatment plant (WWTP), Al Saad WWTP in Al Ain, United Arab Emirates. The primary settled wastewater was stored in a tank, and pumped into the aeration tank, which is also activated with RAS from the sludge settling tank (Figure 1). Experiments were conducted with a hydraulic retention time(HRT) of 8 hours, mixed-liquor suspended solids of 2000-3000 mg/L and RAS circulation of 20%. These operating conditions were as close as the conditions at Al Saad WWTP. The MNB aeration system differed from the conventional system only on the air delivery system. The wastewater was aerated at constant air flowrate using in-house compressed air, to keep the oxygen level above 2 mg O_2/L. In this study, for the MNB aeration ASP system, nanobubbles were produced by a nanobubble generator (N2BG, Newmantech Co. Ltd., Korea) in addition to compressed air introduced into the aeration tank through ultrafine diffusers. In N2BG generator, air was injected to a cylinder inside the generator along with the wastewater, and thus nanobubbles are generated in the liquid. The macro bubbles for the experiments were produced by air compressor and induced into the system through a pipe with inner diameter of 5mm. In both the systems, the air inflow rate was kept same to ensure the similar condition. The treated water was transferred to the sedimentation tank, where the sludge was allowed to settle. The RAS was pumped to the aeration tank (sludge return) from the sedimentation tank. For each experiment run, the continuous flow ASP systems were run for 8 hours and required measurements were made.

The online measurements in the aeration tanks included temperature, pH, dissolved oxygen levels and TDS levels. In addition, chemical oxygen demand (COD) was analyzed at regular intervals from the beginning of the experiment to the end of the experiment run. The COD was analyzed to assess the effectiveness of treatment in removing organic compounds. The bubble size distribution, dissolved oxygen levels, and zeta potential were analyzed at regular intervals to understand the change in DO transfer efficiency of both the types of aeration.

RESULTS AND DISCUSSION

The quantity and size of the MNBs affect their mass transfer efficiency. Larger amounts of the NBs result in larger total surface area and increases the mass transfer flux from bubbles to solution, and smaller bubble size results in higher internal pressure and larger specific area. Analysis results showed that the hybrid method followed for nanobubbles generation for the experiments was successful in generating nanobubbles. MRB's NANOTRAC Wave II Particle Analyzer (Germany) was used to analyze the MNB characterization and bubbles distribution at regular intervals. Nanoparticle analyzer results showed that the microbubble generator produced a good concentration of bubbles with the diameter size in the range 10 -500nm. Also, the zeta potential values showed relative stability of the bubbles. The particle distribution curve obtained for a case of 1hr NB aeration is shown in Figure 2 (a). The trend of the concentration nanobubbles present in the aeration tank because the NB generation is depicted in the Figure 2 (b). It showed that a high concentration of the nanobubbles of the order of the 10^{-} 8 numbers/ml were maintained throughout the experiment run. However, it was noted that the concentration of nanobubbles reached a peak immediately after the run of nanobubble generator (N2BG, Newmantech Co. Ltd., Korea). However, when the samples from aeration tank with conventional aeration were analyzed, no significant concentration of NBs were detected.



(a) Typical particle size distribution of nanobubbles in MNB aerated system, after (at 1 hr)

(b) Nanobubbles concentration in the aeration tank throughout the operation

Figure 2. Properties of the nanobubbles generated in the aeration tank

The average values of characteristics of wastewater influent into the aeration tanks are measure as shown in the Table 1.

Table 1. Characteristics of wastewater used for the experiments

Characteristics of influent to aeration tank	Values
pH @ 25°C	7.3
COD (mg/L of O_2)	185
Conductivity (μS /cm)	1385
Total dissolved Solids (mg/l)	2663.5
DO (mg/l O_2)	0.97
Temperature	20.2 ° C
Nanobubbles concentration (< 1000nm)	Not Detected

In the NBs based ASP system, the concentration of DO showed a rapid increase in first 30 minutes, which was high when compared with DO values of the conventional aeration (Figure 3). The average DO during the first 30 minutes increased by more than 4 mg/l while it was only about 2.5 mg/l by conventional aeration. The concentration of dissolved ozone increased along with the time initially, and remained relatively constant after 2 hours of operation.

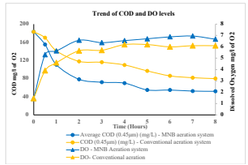


Figure 3. Dissolved oxygen and COD changes with time.

The treatment efficiency was determined by measuring the COD of the influent and effluent samples. The concentrations of COD in different times showed significant differences. The values of CODs of the effluent from aeration tanks at regular time periods of treatment is shown in Figure 3. The removal efficiency values were calculated relative to the concentration COD in the influent to the aeration tank. It was noted that the COD removal was more efficient throughout the operation. Most of the COD removal was achieved within 6-7hrs of operation in both the systems. The performance of MNB aerations system exceeded the conventional system at all times of the experiment run, and achieved a COD removal of about 72% in comparison to an average COD removal of 56%. Another significant observation was that a quick COD reduction occurred in the first 1-2 hrs of NB aeration, and this could be because of oxidation ability of nanobubbles to produce better oxidation effect, but the efficiency is limited by the quantity of oxygen transfer. Also, the observed overall improved efficiency of NB system could be because of their ability to maintain electron acceptors for microorganisms for their metabolic, and longer life in water system contributing to oxygen transfer efficiency.

CONCLUSIONS

In this study, application of nano bubble aeration in biological wastewater treatment as an efficient aeration technique for organic removal is proposed. The initial results showed significant increase in DO transfer capacity and COD removal efficiency for nanobubble aeration. Therefore, the nanobubble aeration has a great potential in enhancing the biological treatment efficiency of ASP wastewater treatment plants.

Abstract
Digestate sludge coming from the anaerobic digestion (AD) plants is a rich source of nutrient that can be used for agriculture. However, due to the presence of emerging contaminants, and among them pharmaceuticals, a post- AD treatment would be required. In this research four treatment including RO, ozonation, adsorption and UV-based AOP were compared in terms of efficiency and cost for pharmaceutical removal. The highest removal efficiency was obtained with the RO treatment followed by O_3, activated carbon and UV/H_2O_2. However, by considering the cost, ozone treatment seems to be the most cost-effective post-AD treatment.

Keywords
Pharmaceutical removal; advanced oxidation; Digestate

INTRODUCTION

Organic waste represents an average of 46 % of global waste, resulting in GHG emissions that poses a serious climate change thread (Worldbank.org). Anaerobic digestion (AD) can contribute to recover valuable renewable energy and nutrients from multiple organic waste streams. However, the use of active pharmaceutical compounds including antibiotics and hormones for animal farming limits the direct application of food-processing digestate. As such, there is a need for cost-effective solutions for the removal of pharmaceuticals from digestate.

MATERIALS AND METHODS

Food processing digestate was collected from a biogas plant in Malta. Four methods (RO, ozonation, adsorption and UV/H_2O_2) were evaluated in terms of efficacy for pharmaceutical removal. In all the experiments, the digestate supernatant was spiked with a final concentration of 10 mg/L salicylic acid (SA) as a surrogate for pharmaceutical compounds. The four treatments were conducted as following:

For filtration via reverse osmosis (RO), a cross-flow RO membrane unit coupled with Diaphragm Booster pump (OsmoPure, model 75) was used. The ozone treatment were carried out in a plexiglass bubble column reactor with the capacity of 2.7 L equipped with stirrer and diffuser. Adsorption experiments were conducted in 250 ml glass stoppered bottles by using acid-washed steam-activated powder of activated carbon (AC) (DARCO@G-60) in different ratio of AC:DOC. The UV and UV/H_2O_2 treatments were done using a PearlLab beam device, and adding certain amount of H_2O_2.

The reported capital and operational cost (CAPEX and OPEX) of the four treatment were compared to find the most cost-effective treatment.

RESULTS AND DISCUSSION

Figures 1a to 1d show the results of the four experiments:

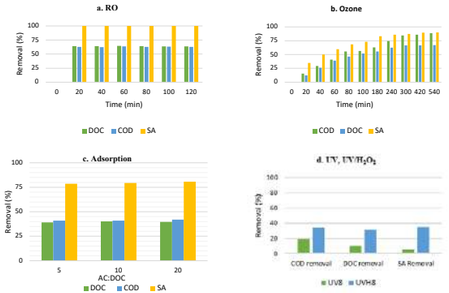

Figure 1. COD, DOC and SA removal efficiency from the digestate during (a) RO, (b) ozone, (c) adsorption, and (d) UV and UV/H_2O_2 treatment (UV8 is UV experiment in 8 hours and UVH8 is the same experiment by adding H2O2).

In the RO system, the flux remained constant (32.1 LMH) in the two-hour experiment, meaning that no fouling occurred. Data obtained from Figure 1a shows a similar removal efficiency for all the samples collected every 20 min, which again confirms that the RO treatment can produce a permeate free of SA without fouling despite the complex matrix and high load of organic matter.

In ozone treatment, SA removal of 83 % was achieved after 180 min (Figure 1b). However, as the key parameters (COD, DOC) were still high (with COD:DOC ratio of 3.7), the experiment continued for 540 min. SA removal did not show any significant changes after 180 min, also full mineralization did not happen even after 540 min. These can be related to the higher refractory compounds in the matrix that cannot be oxidized under this operational condition.

Results for the adsorption experiment in figure 1c shows a maximum of 35% DOC removal. Yet, almost 80 % of SA was removed after 2 hours in all AC:DOC ratios. The high removal of SA is likely due to its hydrophobic nature. K_{OW} for SA is 2.26 which indicates its affinity to attach to the floc, particles and adsorbed by activated carbon.

In UV treatment, the UV-LED machine offers intensities that are lower than what has previously been used for the treatment of pharmaceuticals and organic materials, even for simpler and less concentrated matrices. Therefore, this system cannot handle an organic load higher than 150 mg/L of COD per 272.9 µW/cm². As shown in Figure 1d, less than 6 and 36% of SA was removed after 8 hours treatment with UV and UV/H_2O_2, respectively. The higher removal efficiency by adding H_2O_2 is contributed to the formation of active OH radicals.

Table 1.1 shows the capital, operational and maintenance cost related to the four treatment reported in pervious researches for advance wastewater treatment in view of water reclamation and reuse (McGivney & Kawamura, 2008; Plumlee et al., 2014).

Table 1. CAPEX and OPEX of the four treatments

Treatment	CAPEX ($M/MGD*)	OPEX and maintenance ($M/MGD)
RO	7.14 (a)$^{-0.22}$	0.44 × (a)$^{-0.13}$
Ozone	2.26(a)$^{-0.54}$	0.0068(a)-$^{0.051}$
Activated carbon (AC)	3.03 (a)$^{-0.54}$	0.085 (a)$^{-0.16}$
UV/H_2O_2	0.474 (a)$^{-0.056}$	0.038 (a)$^{-0.052}$

*Million US dollars per million gallons per day of treated flow. a: Plant capacity in MGD

As the table shows, the cost related to the four treatment is in the following order:

Capital cost: UV/H_2O_2<O_3<AC< RO

Operation and maintenance cost: O_3<UV/H_2O_2< AC<RO

Although RO leads to full removal of pharmaceutical compounds, by taking the cost into account, ozonation seems to be the most cost-efficient treatment for pharmaceutical removal from digestate.

Abstract

Direct greenhouse gas (GHG) emissions due to methane stripping from AnMBR effluents is still a key issue that limits the full-scale application of this technology. Degassing membrane (DM) technology has been extensively applied in several industries for dissolved gasses removal/recovery from liquid streams. In this study, the performance of three different DM systems are compared at different operational conditions, such as liquid flow rate (Q_L), operating temperature, and diving force intensity (i.e. transmembrane pressure, TMP). Overall, the highest methane recoveries (up to 50%) were achieved when operating at low Q_L (200-250 L/h) and high TMPs (0.6-0.8 bar). However, the estimated overall mass transfer coefficient was significantly hindered as the Q_L was increased.

Keywords
Anaerobic effluent; AnMBR; Degassing membrane; Dissolved methane recovery.

INTRODUCTION

Anaerobic systems are an excellent alternative for sustainable municipal wastewater treatment. However, effluents with a significant concentration of dissolved methane are produced. Methane losses in anaerobic effluents can reach up to the 80% of the overall production when operating at low temperatures (under 15ºC) (Giménez et al., 2014), resulting in dramatic reductions in process feasibility. Additionally, methane emissions produce a significant environmental impact due to the high global warming potential of this gas (more than 25 times than CO_2) (EPA 2022), representing a key limitation for the applicability of anaerobic processes at full-scale.

Degassing membrane (DM) technology is a promising alternative for dissolved methane capture from anaerobic effluents, boosting the applicability of high-rate anaerobic treatment (e.g. municipal wastewater) at ambient temperature. However, further work is needed to minimize membrane resistance in order to maximize methane recovery while minimizing total costs.

This work aims to evaluate the potential of three DM technologies for dissolved methane recovery from AnMBR effluents, i.e. non-porous polydimethylsiloxane (PDMS) membranes, non-porous polymethylpentene (PMP) membranes, and porous hydrophobic polypropylene (PP) membranes. Different operational conditions (e.g. treatment flow rate (Q_L), operating temperature, and transmembrane pressure (TMP) applied as driving force) are evaluated in order to maximize energy recovery and reduce greenhouse gas (GHG) emissions.

MATERIALS AND METHODS

Figure 1 shows a picture of the pilot plant used in this study, which includes Three parallel commercial DM systems for recovering the methane dissolved in the effluent from a pilot-scale AnMBR system: i.e. non-porous PDMS membranes (PERMSELECT ®, MedArray Inc. USA), non-porous PMP membranes (Separel ®), and porous PP membranes (3M™ Liqui-Cel™). Table 1 shows different characteristics of the membranes used.
By way of example, results from the performance of the PDMS unit are presented in this abstract. This unit was operated in shell-side mode to avoid lumen clogging problems, applying vacuum in the lumen side to generate the driving force necessary for gas recovery.

RESULTS AND DISCUSSION

Fig. 2 shows the methane recovery efficiencies reached in the PDMS DM unit at different TMP and Q_L. The highest methane recovery efficiencies were reached when applying low Q_L since low flow rates results in high contact times between liquid and membrane (i.e. high hydraulic retention times). On the other hand, methane recovery raised as TMP was increased since raising the driving force in the system resulted in a greater flux of gas through the membrane, enhancing thereby methane capture efficiency.

The global mass transfer coefficient (K) was evaluated to determine the effect of the studied operating conditions (Q_L and TMP) on the total system resistance (see Fig. 3). The estimated K indicated that increasing liquid flow rate significantly hindered the mass transfer efficiency. This was related to the liquid velocities reached in the DM unit, which could favour the generation of dead zones causing undesirable effects on K. Moreover, this effect may be amplified when operating at shell-side mode since the fibres may suffer some kind of shakings, deforming, and compression, reducing overall effectivity. On the other hand, increasing the TMP resulted in beneficial effects on K. This was attributed to a possible increase in membrane permeability as the operating driving force was raised. Consequently, operating the DM unit at moderate Q_L and high TMP could be recommended to boost the methane recovery efficiency of PDMS membranes.

CONCLUSIONS

Methane recovery was maximized at high TMP and low Q_L. Maximum methane recovery efficiencies of around 50% were achieved when operating at 0.8 bar and 200 L/h. Increasing TMP resulted in an improvement on K, whilst increasing Q_L results in unfavourable effects on methane recovery due to reduced K values.

Abstract
Aerobic granular sludge technology was used for treating wastewater from a hospital for 150 days. The abrupt changes in the influent characteristics did not significantly affect the organic matter and nutrients removal. The granular conformation suffered modifications in settle ability and size, but the granular shape was never compromised by the influent nature. The capability to remove pharmaceuticals was linked to absorption-desorption processes over the operation. Cyclophosphamide, triclosan, naproxen and ketoprofen were removed with success, diclofenac and carbamazepine had oscillation in removal ratios and, trimethoprim could remove until day 60. The study of microbial populations of bacteria, archaea, and fungi supported the variations in performance because the diversity increased notably at day 60. The fungi and PAO organisms were depleted from day 120 to day 140 linked with higher toxics loads in influent, but later they proliferated again.

Keywords
Aerobic granular sludge; hospital effluent; microbial ecology; pharmaceuticals; wastewater.

INTRODUCTION

Environmental pollution by pharmaceutical compounds (PhCs) is become a problem that concern the regulatory agencies since these chemical compounds negatively affect to aquatic wildlife generating neuroendocrine problems and mutagenic effects, as well as the depletion of quality of water by exposure at small doses, which are bioaccumulative and persistent even at low concentration. The consumption of PhCs has increased drastically for human health and veterinary control worldwide. Hospital activities have been pointed out as a relevant source of pharmaceutical compounds via wastewater discharges due to the use of PhCs, even those that are not commonly dispensed. In most countries, hospital discharges without previous treatment are introduced into urban wastewater networks and are treated together with other effluents. This fact entails less efficiency for removal PhCs on WWTPs, it will trigger the release of these compounds to receiving water bodies. WWTPs located in Spain usually encompass exclusively primary and secondary treatments, with biological treatment based on conventional activated sludge, while other technologies are rarely applied. Wastewater treatment plants appear unequipped to remove effectively remove PhCs because they were designed to biodegrade carbon, nitrogen, and phosphorous.

Different wastewater technologies have been analyzed to determine the efficiency to remove PhCs. Díaz-Garduño et al., 2017 showed a deep study of WWTPs located in southern of Spain taking into account different real scenarios. They compared effluents after photobiotreatment based on microalgae and effluents after multibarrier treatment. Results showed that the most effective way was multibarrier treatment. However, the high economic and energy costs are a big disadvantage. Aerobic granular sludge (AGS) technology is postulated as an alternative energetically sustainable, which is extremely resistant to drastic changes in the characteristics and loads of influents. This distinctive is marked by the compact biofilm in spherical conformation, encouraged by shear force in circular and continuous movement. The tridimensional matrices allow the co-existence of aerobic-anoxic-anaerobic niches to promote diverse metabolic pathways both for organic matter and inorganic nutrients and for the various needs to degrade PhCs. This technology has been tested using simulated hospital wastewater (Muñoz-Palazon et al., 2022), but the microbial load and changes in the influent characteristics are key aspects to evaluate the capability of treatment of AGS. In this research, we have studied the capacity of AGS to remove, degrade and transform pollutants from real hospital wastewater.

MATERIALS AND METHODS

Determination of physic-chemical parameters

The BOD_5, COD, inorganic nitrogenous ions (NH_4^+, NO_2^- and NO_3^-) and phosphate ion (PO_4^{3-}) were measured in duplicate. The granular properties were analysed by mean size and settling time using n=35±5 pieces. The samples of effluent and influent were subjected to solid phase extraction and eluted in methanol. The pre-concentrated samples were used to measure PhCs using UHPLC 1260 Infinity II - 6470 LC/TQ.

Biological studies

Then, DNA from biological samples was extracted and was used to quantify the absolute number of genes through qPCR and to identify the bacterial, archaeal and fungal communities by means of massive parallel sequencing(Muñoz-Palazon et al.,2022). The pipeline of raw bioinformatic data from Illumina was done using mothur software.

Statistical studies

Analyses of diversity were calculated with PAST. SIMPER analyses were done to evaluate the contribution to dissimilarities among periods and PERMANOVA to analyse the significance of variables. The treated bioinformatic data were employed to calculate analysis based on compositional statistics (PCA and Expected effect size). Multivariate analyses were done to link microbial communities and performance.

RESULTS AND DISCUSSION

The AGS operated in sequential batch cycles showed robustness during the whole experimentation time (150 days), because great changes were detected in the influent in terms of composition, loads and toxic substances. Despite oscillations in COD concentration (Figure 1A), the removal ratio was higher than 70% since operational day 50. In terms of inorganic nutrients, the total nitrogen removal achieved values of 91% of removal ratio, and until 52% of phosphate removal (Figure 1B). The biomass granular changed their size and decrease their settle ability but the conformation was not compromised (Figure 1C, 1D).
Related to PhCs, the trend could not be defined because the results pointed out a bioadsorption-desorption processes related to their attachment to granular biomass. Although, AGS demonstrated high capacity to retain and/or removal these PhCs and not release them in discharges. The most abundant PhCs received in hospital sewage were trimethoprim, carbamazepine, naproxen and diclofenac, followed by ketoprofen. Both cyclophosphamide and triclosan had the lowest concentration. The removal ratio of all PhCs is shown in Figure 2, where it is observed higher ratios for naproxen, cyclophosphamide, triclosan and ketoprofen.

In terms of microbial population, continuous changes were detected over the operation, because the real wastewater from the hospital supposed a relevant load of external microorganisms within the system. In fact, this event was more notorious between days 60 and 140, depending on the domain, as could be in the absolute quantification genes of interest, especially highlighted for PAO and *Fungi*. In general, *Donkdonella*, *Thauera* and *Hyphomicrobium* were the most ubiquitous bacteria (Figure 3). *Nectriaceae* and *Trichosporonaceae* were the most abundant fungal phylotypes and *Bathyarchaeaota* and *Euryarchaeaota* phyla as the most abundant archaeal OTUs.

Abstract
In this study, the efficiency of a scale inhibitor, the diethylene triamine penta (methylene phosphonic acid) (DTPMPA) has been investigated. The results obtained showed that DTPMPA can inhibit $CaCO_3$ formation in solution and on a metallic surface at very low concentration in solution. A hydrophobic sol-gel film has been developed and presented interesting scale inhibition properties.

Keywords
Electrochemical quartz crystal microbalance; fast controlled precipitation; Scale inhibition; Sol-gel coating

INTRODUCTION

Scaling phenomenon, principally formed by calcium carbonate $CaCO_3$, leads to technical and economic problems in industry. Environmental and health issues lead laboratories to seek new methods of detection to determine and to quantify the calcium carbonate $CaCO_3$ crystals in water.
The aim of this study is to develop a new hybrid sol-gel coating able to inhibit scale formation. An inhibitor, namely diethylene triamine penta (methylene phosphonic acid) (DTPMPA) will be impregnated at the surface of the sol-gel coating. Firstly, the scale inhibition properties of DTPMPA, on the nucleation/growth processes of $CaCO_3$, have been studied in bulk and on a metallic surface using fast controlled precipitation and electrochemical quartz crystal microbalance respectively. Secondly, the scale inhibition properties have been studied when a sol-gel coating has been applied to the metallic surface. The evaluation of its antiscale effectiveness has been followed by quartz crystal microbalance.

MATERIALS AND METHODS

Fast controlled precipitation

The fast controlled precipitation (FCP) method is based on the moderate degassing of CO_2 gas dissolved in water, which generates an increase of pH leading to the $CaCO_3$ precipitation. This method is generally used to evaluate the efficiency of scale inhibitors (Peronno 2015). The precipitation time and the crystal growth kinetics were followed by measuring simultaneously the pH and resistivity of the solution over time.

Electrochemical quartz crystal microbalance (EQCM)

The electrochemical quartz crystal microbalance (EQCM) was performed to measure the mass change of $CaCO_3$ deposited on an active surface and to assess the scaling rate in the absence and presence of inhibitor (Gabrielli 1998). The working electrode, a 5 mm diameter gold disc deposited in a quartz crystal resonator, was adapted in a submerged impinging jet cell. The electrochemical potential was maintained at -1 V/SCE, corresponding to the reduction of the dissolved dioxygen. The formed hydroxyl ions increased the local pH near the electrode surface up to 11.2 and if no chemical reaction contributed to the consumption of OH^-, it leads to $CaCO_3$ precipitation. The current and the frequency change Δf as function of time were recorded simultaneously. The frequency change Δf of the quartz resonator was proportional to the mass change (Δm), due to the $CaCO_3$ deposition on the working electrode, according to Sauerbrey equation (Eq. 1) (Gabrielli 1998, Cheap-Charpentier 2018):

$$\Delta f = -K_S \Delta m \quad (1)$$

Quartz crystal microbalance (QCM)

Finally, a quartz crystal microbalance (QCM) was used to measure the mass of $CaCO_3$ deposited on the surface of the electrode and to follow its kinetic of growth, scale particles being generated by the FCP method. The mass deposited was measured over time according to Sauerbrey equation typically at 9 MHz, 1,22 ng mass change corresponds to 1 measured Hz. Different metallic surfaces (aluminum alloy, stainless steel) were used in this study, with or without sol-gel coating.

The synthesis of the sol-gel coating

The procedure used for the synthesis of mesoporous silica films was similar to the earlier procedure described by Zhao et al. (D. Zhao 1998). Various formulations were tested according to the nature of the precursors to study their different characteristics (hydrophobicity, roughness ...) and then, to evaluate their anti-scaling action. The precursors used are: Tetraethylorthosilicate (TEOS), 3-(Trimethoxysilyl)propyl methacrylatele (MEMO) and Methyltrimethoxysilane (MTEOS). Two sol-gels were tested here: S1 (TEOS:MEMO) and S2 (TEOS:MTEOS).

CHARACTERIZATION OF THE SOL-GEL LAYER BY SEM

The sol-gel layer S2 deposited on a gold surface has been characterized by scanning electronic microscopy (SEM) and its thickness is about 0.5 µm (Figure 1).

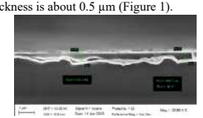

Figure 1. SEM image of the sol-gel S2 (TEOS: MTEOS) deposited on the gold electrode.

The hydrophobicity of the film was determined by determining the contact angle for the sol-gel films S1 and S2 (Figure 2).

Sol-gel	S1 (TEOS:MEMO)	S2 (TEOS:MTEOS)
Contact angle (°)		

Figure 2. Contact angle for the sol-gel films S1 and S2.

The addition of precursors with methyl groups (MTEOS) increases the hydrophobic character of the film. This is shown by the increase of the contact angle in the sol-gel S2.

RESULTS AND DISCUSSION

Evaluation of the effect of the inhibitor in solution by FCP

To determine the inhibition effect of the DTPMPA towards $CaCO_3$ precipitation in solution, the tests were carried out using FCP method.

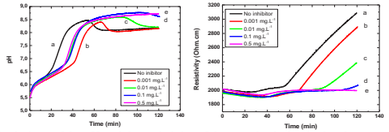

Figure 3. Evolutions of the pH and the resistivity of the tested solution in the absence and presence of DTPMPA: (a) 0 (b) 0.001, (c) 0.01, (d) 0.1 and (e) 0.5 $mg.L^{-1}$ at 30 °C, hardness 25 °F (containing initially 100 $mg.L^{-1}$ Ca^{2+}).

Without inhibitor, during the first nucleation phase, the pH increases until a maximum value that marks the time of precipitation (T_p), before decreasing until a constant value, which indicates the re-establishment of the chemical equilibrium. The resistivity-time curve exhibits an increasing slope that indicates a homogeneous precipitation stage. The precipitation time increases from 57 min without inhibitor to 86 min with 0.01 ppm of inhibitor until a total inhibition for 0.5 ppm of DTPMPA (Figure 3). The results show that DTPMPA can inhibit efficiently the $CaCO_3$ formation at very low concentration.

Evaluation of the effect of the inhibitor on a metallic surface by EQCM

To facilitate the comparison between the different experiments, the current is normalized by I_0, the initial reduction current. The scaling time, t_s, is defined as the intersection of the tangent at the inflexion point of the curve I/I_0 vs time and the time axis. The scaling rate, r_s, is determined according the slope of the linear part of the falling current. A low value of the residual current (I/I_0 close to 0) indicates that the $CaCO_3$ layer formed on the metallic surface is insulating and compact (Figure 4, right).

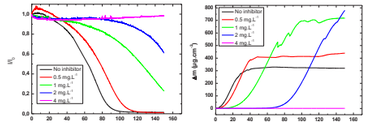

Figure 4. Evolutions of the relative current and the deposited mass of the tested solution in the absence and presence of DTPMPA, T = 30 °C, hardness 25 °F, E = -1 V/ECS.

The $CaCO_3$ deposit progressively covers the entire surface of the metal, then isolates it from the water, avoiding the electrochemical formation of scale. The mass increases over time with the surface coverage and the corresponding slope gives a comparative idea of the scaling rates in the absence and presence of DTPMPA. Without inhibitor, the mass does rapidly increase until its stabilization which corresponds to the full coverage of the electrode surface.
With inhibitor (Figure 4, right), a decrease of the slope and an increase of the scaling time is observed, indicating that inhibitor delays the formation of scale. For [DTPMPA] at 1 and 2 ppm, the scaling rate decreases but the mass continues to increase, this is due to the porosity created in the layer of scale by the inhibitor. For [DTPMPA]=4 ppm, no change in mass and current is observed, showing an absence of scale deposition on the electrode surface. This corresponds to a total inhibition of scale.

Study of the sol-gel coating

A hybrid sol-gel layer was deposited onto a metallic electrode to evaluate its anti-scaling by QCM (Figure 5).

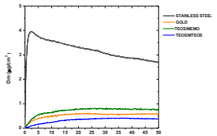

Figure 5. Curves of the evolution of the deposited mass according to the nature of the surface

The mass of scale deposited on stainless steel is twice as high as the one measured on the sol-gel layer made from TEOS and MEMO. To improve the scaling effect, the hydrophilicity of the sol-gel layer was measured by modifying its composition using MTEOS with methyl groups. This layer efficiently inhibits scale formation.

CONCLUSION

The DTPMPA inhibits perfectly the scale formation in solution and on a metallic surface. By controlling the hydrophilicity of the sol-gel coating, this film presented very interesting anti-scaling properties. To totally inhibit the scale formation, the impregnation of the inhibitor on the surface of the hybrid sol-gel coating will be performed. This approach, maintaining the inhibitor attached to the surface, is very important to preserve the water quality.

Abstract
Cellulose can be recovered from sewage to develop valuable bioproducts. This study aims to assess the suitability of biochar produced via carbonisation from recovered cellulose as an absorbent for pollutants removal. 3 types of biochar were tested: 100% cellulose, 50% cellulose-50% straw and 50% cellulose-50% wood. Despite the physical characterization showed that the mix with wood had the higher surface area, adsorption test revealed that it had the lower absorption capacity. The most satisfactory results were obtained with 100% cellulose and will be verified by the analysis of the biologically activated biochar.

INTRODUCTION

Wastewater contains a huge number of substances with the potential to be transformed into raw materials for bio-based products. Cellulose from toilet paper is one of the most relevant representing between 40 and 50% of the total suspended solids in several countries (Liu et al., 2022). In this context the INTERREG-WOW! project aims to recover that cellulose to produce activated biochar to be used as a substrate for additional treatment for the removal of pollutants (e.g. in Constructed Wetlands (CW)). Cellulose from Ede wastewater treatment plant (WWTP) influent (The Netherlands) was collected and dried by Cirtec B.V. (Khan et al., 2022) and pre-processed by Klimafarmer who obtained 3 types of non-activated biochar: 100% cellulose, 50% cellulose-50% straw and 50% cellulose-50% wood. The main target of this study was to assess their pollutants adsorption capacity to choose the most suitable for the application as additional treatment step.

MATERIALS AND METHODS

Physical characterization of biochar

Material characterization was performed by 3P INSTRUMENTS. Density was determined by Helium pycnometry following DIN 66137-2. BET surface area and micropore analysis were performed with CO_2 at 273 K.

Evaluation of the adsorption capacity

Biochar preparation for analysis. As absorption capacity is dependent on the particle size, to make an adequate comparison, the material was crushed and washed obtaining three different fractions (Fig. 1): pellets, 100-500 µm and powder below 100 µm.

Figure 1. Fractions of 100% cellulose biochar. a) pellets, b) 100 - 500µm c) powder <100µm.

Batch mode test. This is the most common setup for kinetics experiments. In this study brown-glass bottles containing 1 g/L of biochar were used and filled with 250 mL of a solution of 5 mg/L of indigo carmine (model compound) in ultrapure water and placed on a shaking table for 10 days.

Continuous mode test. As an alternative to conventional lab-scale columns systems that needs several months to reach the saturation, a rapid small-scale columns (RSSCs) system was used for this work. The equipment had two columns operated in parallel with 10 mm of internal diameter and filled with 400 mg of biochar, obtaining 0.8 mL of bed volume. They were fed from a storage tank containing a 5mg/L solution of indigo carmine at a flow of 10 mL/min.

RESULTS AND DISCUSSION

Materials Characterization

Results obtained from biochar characterization showed that Helium density was similar for all of them. The main difference was the BET surface area. 50% cellulose-50% wood has the best conditions regarding adsorption, with 280 m^2/g while 100% cellulose and 50% cellulose-50% wood have 211 and 249 m^2/g respectively, thus the mix of cellulose with other conventional sources of biochar entailed an increase in the area, that could improve the adsorption capacity.

Adsorption capacity

The profiles of indigo carmine adsorption for the fraction between 100-500 µm of each non-activated biochar is presented in Figure 2. From the material characterization, the 50% cellulose-50% wood biochar was expected to present a higher adsorption capacity. Nevertheless, this material showed the lowest one in all cases. In batch, 50% cellulose-50% straw showed slightly better yield (10% higher) than 100% cellulose. However, in continuous 100% cellulose took longer to reach saturation. In powder, it was the most evident reaching the 80% of saturation after 32, 80 and 101 BV for the mix of wood, the mix of straw and pure cellulose respectively.

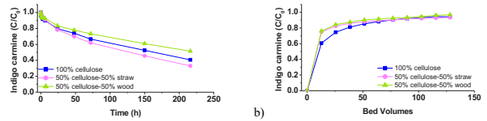

Figure 2. Adsorption of the indigo carmine by the 100-500µm fraction of each biochar mix in a) batch mode b) continuous mode.

This first assessment with non-activated biochar showed that 100% cellulose had great potential as an adsorbent. The next step will evaluate the surface changes due to the biological activation of the material and will verify if 100% cellulose is the most suitable biochar for CW substrate.

ACKNOWLEGMENTS

Abstract
The aim of this work was to investigate the effect of mid-temperature alkaline pre-treatment with NaOH on waste activated sludge (WAS) disintegration and methane yield (Y_{CH4}) increase. The use of a small dose of 16 g NaOH/kg TS and 30 minutes of heating at 60°C allowed to obtain the average degree of sludge disintegration of 29% and Y_{CH4} increase of 30%. The obtained results varied significantly during the year. The highest Y_{CH4} increase (71%) was achieved in summer when the raw WAS Y_{CH4} was the lowest. Changes in WAS Y_{CH4} were correlated to its composition, which was noticed in extracellular polymeric substances (EPS) formation.

Keywords
alkaline pre-treatment; extracellular polymeric substances; methane potential; waste activated sludge disintegration

INTRODUCTION

During the wastewater treatment processes significant amounts of sewage sludge are formed and must be disposed of. Nowadays, the most common method used for sludge treatment is anaerobic digestion (AD), where the mass of sludge is reduced and energy is recovered in form of biogas (methane). Increasing the efficiency of biogas production to achieve energy self-sufficiency in a municipal wastewater treatment plant (WWTP), and even to become an energy producer, is recently one of the key aims for WWTP operators.

An effective way to increase biogas production at WWTP is the co-digestion of sewage sludge with agro-industrial waste (Budych-Górzna et al., 2016). Case studies of co-digestion of biosolids with organic wastes at full scale showed that the use of co-digestion could overcome significant economic challenges including higher methane yield (Y_{CH4}), more efficient digester volume utilization, and reduced biosolids production (Shen et al., 2015). However, the use of co-digestion is possible only if the WWTP has an excess volume of digesters. Otherwise, the focus should be on increasing the production of biogas from sludge generated at WWTP and improving its degradation rates, allowing full-scale plants to reduce the size of digesters (Souza et al., 2013). One way to achieve this is to enhance the digestibility of waste activated sludge (WAS) via a variety of pre-treatment methods (e.g. Zhen et al., 2017).

Microorganisms responsible for aerobic wastewater treatment tend to aggregate by forming flocs, biofilms, and granules thanks to extracellular polymeric substances (EPS). EPS are the predominant constituents of activated sludge and represent up to 80% of its mass (Tian et al., 2006). The EPS matrix may serve as a multipurpose functional element of microbial communities, including adhesion, protection, structure, recognition, and physiology. The temperature, rather than wastewater composition, significantly influences the content and chemical constituents of different EPS fractions (Zhang et al. 2015). Although EPS are essential for proper activated sludge functioning, they have a negative impact on the AD process (Peng et al., 2020).

Alkaline pre-treatment (APT) is relatively simple to implement in the full-scale WWTP (Zhen et al., 2017) because it does not require sophisticated devices and it is easy to operate. Among the alkaline reagents, NaOH was found to be the most effective in sludge solubilization and enhancing biogas production. The combination of APT together with mid-temperature (<100°C) conditions could potentially lead to an even doubling of methane production (Liu et al., 2019). Toutian et al. (2021) recommended keeping alkali dosage during ATP below 80 mg NaOH per g TS of WAS.

The aim of this work was to investigate the effect of mid-temperature (60°C) APT with NaOH on WAS disintegration, EPS composition, and methane yield changes during the yearly operation of WWTP. Low alkaline doses were chosen to lower potential operational costs, eliminate the need for pH correction, avoid salinity increase and enable potential implementation at the industrial scale.

MATERIALS AND METHODS

Mechanically thickened WAS for batch tests was collected in different months from the Central WWTP (1,200,000 people equivalent, Poznan, Poland). Portions of 1.5 kg of WAS diluted to 5% TS were put into 2 L beakers with a mechanical agitator (140 rpm) and doses of NaOH were added. The initial dose of 2 mL 30% NaOH/L (i.e. 16.0 g NaOH/kg TS) was chosen according to the previous studies (Budych-Górzna et al., 2021, Komorowska-Kaufman et al. 2022). Tests were carried out in temperatures of 20°C and 60°C, with a time of 30 minutes. The pH and temperature were measured every 5 minutes. Soluble chemical oxygen demand (SCOD) was analysed in all samples to calculate DD according to the equation presented by Kim et al. (2013). Basic wastewater sludge parameters were measured according to APHA (2017).

Y_{CH4} was measured in triplicates with a blank sample with Automatic Methane Potential Test System (AMPTS, BPC Instruments AB, Sweden). The inoculum (I) was taken from a full-scale AD mesophilic reactor. The WAS without pre-treatment (WAS_o), after APT (WAS_A) and after mid-temperature APT (WAS_{MA}) were used as a substrate (S). The AD batches lasted 21.5 days at a temperature of 36°C, the I/S ratio was equal to aprox.1.

From WAS, three fractions of EPS were extracted: soluble (SOL), loosely bound (LB), and tightly bound (TB) (Pellicer-Nàcher et al., 2013). The total quantity of extracted EPS was expressed as TOC and measured with an Elementar High TOC (Shimadzu TOC-L, Japan).

RESULTS AND DISCUSSION

The characteristics of WAS used in batch tests were as follows: TS=4.9±0.2%, VS=78.7±1.0% TS, COD=57000±13130 mg/L, SCOD=231±88 mg/L, pH=6.9±0.2, N-NH_4=17.3±14.8 mg N/L, and soluble TP=55.1±10.9 mg P/L. All reagent doses increased the sludge pH to about 10.0, although after dosing 16 g NaOH/kg TS after approx. 30 min it decreased to 8.7 in 20°C and to 7.6 in 60°C, so no pH correction prior AD process was needed. APT with an initial dose at 20°C caused DD of 4.6±1.4%, additional implementation of heating (60°C) allowed to achieve DD of about 28.6±7.8%. It was noticed that obtained DD varied depending on the quality of the raw WAS. The less biodegradable during AD it was, the higher DD was achieved for the same process conditions. Therefore, for comparison of the disintegration process, WAS was seasonally collected in a sufficient amount for the necessary trials. The use of heating alone resulted in a reduction of the obtained DD in relation to the value after APT with an initial NaOH dose at 60°C by 4.8-18.5%. On the other hand, the use of heating and a high dose of 64 g NaOH/kg TS resulted in a 3.0-4.9% higher DD compared to that achieved in the process with a low dose. This confirms the validity of using a lower dose of the alkalizing agent.

The DD was not the main factor influencing the increase in methane production in the 21.5-day AD trials. The Y_{CH4} of raw WAS turned out to be the most important (Fig.1). If its value was over 210 NmL CH_4/g VS, which is close to the maximum value for WAS, the use of APT increases methane production only by a few percent. Kim et al. (2013) achieved maximum Y_{CH4} after disintegration with 0.1 M NaOH at 75°C (191.4 NmL CH_4/g VS). When Y_{CH4} of raw WAS was lower, the use of any disintegration method greatly increased methane production. In samples from summer, the increase in Y_{CH4} obtained with the low-dose mid-temperature APT was as high as 70.7%.

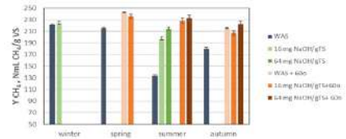

Figure 1. Changes in raw and pre-treated WAS during the year.

Similar conclusions were reached by Toutian et al. (2020) showing that thermal APT led to a higher biogas yield increase in summer (+42%) and a lower increase in winter (+3%). In the examined samples of raw WAS (Fig.1), COD was similar, although differences in the amount of EPS were noticed (Fig.2). The concentration of TB EPS was the highest in the June sample of WAS. Disintegration turned them into SOL EPS, resulting in an amount almost twice higher than in the other samples. Li et al. (2022) indicated that after EPS layer delamination, the Y_{CH4} in AD increased by 32.2% compared to the raw WAS.

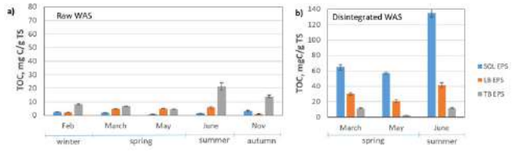

Figure 2. EPS concentration measured as TOC in raw WAS (a) and in WAS after disintegration with mid-temperature alkali pre-treatment with 16 g NaOH/kg TS and 60°C (b).

CONCLUSIONS

It was indicated that a low dose of 16 g NaOH/g TS and mid-temperature (60°C) was sufficient to achieve a significant DD of up to 45%. However, the DD under the same conditions depended on the properties of the raw WAS, which varies throughout the year. In addition, the methane production increase is not proportional to the achieved DD. It depends mainly on the Y_{CH4} of raw WAS, which was found to be correlated to the content of various EPS forms. The lowest raw Y_{CH4} for WAS was noticed in a summertime, and it was recommended to use during that period of a year heat pretreatment with alkaline addition. In many cases, in summer there is excess heat at the WWTP from combined heat and power units for which there is no direct application. Whereas, during winter, excess heat is often used for heating purposes of digesters and other facilities. It was indicated that during that period, solely alkaline is sufficient to boost Y_{CH4}. It is concluded that in order to best use energy and resources, the pretreatment should be adapted to seasonal changes in WAS. Overall economic and energy balance will be carried out to find best-case scenarios.

Abstract (max: 150 words)
Plastics and their degradation products are almost everywhere nowadays, even in traditional waste streams. These streams can be treated by multiple technologies, such as purple phototrophic bacteria (PPB). Current knowledge on PPB and plastic interaction is scarce. The study aimed to investigate the impact of plastic degradation compounds (PDCs) on the metabolism of PPB. Batch tests were performed on 100mL flasks under an irradiance of 160 ± 10 W/m^2 in the presence of butyric acid at different concentrations of PDCs (1, 2.5, and 5 gCOD/L), composed of half ethylene glycol and half terephthalic acid. Results indicate that PPB can tolerate PDCs concentrations of up to 5 gCOD/L without significant adverse effects on growth and activity but with a slight lag phase at higher concentrations simultaneously with EG consumption. Further research is needed to understand the upper tolerance limit for PDCs and their long-term effects on the bacteria.

Keywords (maximum 6 in alphabetical order)
Purple Phototrophic Bacteria; Plastic Degradation Products; Polyethylene terephthalate

INTRODUCTION

A significant quantity of non-biodegradable plastics is being used daily, such as polyethylene, polypropylene, and polyethylene terephthalate (PET); e.g., in Europe, more than 50 million metric tons of plastic is consumed every year. These plastics pose a significant environmental impact. This has led to unprecedented concerns about plastic pollution and a growing need for solutions to manage plastic waste and alternatives to traditional plastics [1]. These plastics often find their way into various aquatic environments, including oceans, rivers, and lakes, and can ultimately flow into crucial natural water sources. Furthermore, the presence of these compounds can have a detrimental impact on wastewater treatment plants by clogging filters and reducing the efficiency of the biological treatment processes [2].

Purple phototrophic bacteria (PPB) are a diverse group of organisms with a wide range of metabolic capabilities, including the ability to grow aerobically and anaerobically and utilize carbon-based organics as energy and carbon sources. They can also store carbon as polymers called polyhydroxyalkanoates (PHAs), fully biodegradable biopolymers with thermoplastic properties that are useful as a sustainable alternative to traditional plastics in multiple applications. In addition, PPB have also been shown to consume hydrocarbons and aromatic compounds. As such, PPB have been the subject of considerable study in recent years for their potential use in the bioremediation and biodegradation of multiple substrates [3-4].

This study aims to investigate the impact of plastic degradation compounds (PDCs), which includes Ethylene glycol (EG) and the aromatic compound terephthalic acid (TPA), derived from the degradation of PET, on the activity and growth of PPB. Studies have yet to be made with the PPB metabolism on the presence of such compounds despite their significant presence in our daily lives and on waste streams that PPB can treat. By understanding the influence of these compounds on the metabolism of PPB, we hope to gain insights into the potential toxicity to these microorganisms so crucial in the future of waste treatment. With further research, PPB are another valuable tool in the bioremediation of plastic pollution and for developing sustainable alternatives to traditional plastics.

MATERIALS AND METHODS

Origin of Culture. The culture used for the batch tests was selected in a continuous Sequence Batch Reactor (SBR) with a working volume of 4.2 L. The reactor was submitted to cycles of 24 hours, fed once per cycle with all the nutrients required using butyric acid as the organic carbon source and $NaCO_3$ as the inorganic carbon (IC) source. The end of the cycle was characterized by an IC famine phase that lasted from 3 to 5 hours. The reactor was continually illuminated with four halogen lamps with a Visible light cut filter, allowing only the Infrared wavelength to pass to the inside of the reactor, giving an approximated volumetric irradiance of 2.25 W/L.

Batch Tests. The batch tests were operated with an initial working volume of 100 mL under an irradiance of 160 ± 10 W/m^2 after the Visible light cut filter in a 150-rpm shaker with a temperature of 34 °C ± 2ºC and with the initial pH fixed at 6.6. The inoculum of each flask started with an optical density (OD) of 0.067 ± 0.002. All flasks were fed with 8.4 mmol/L of carbonate, 10.71 mmol/L of ammonia, 10.02 mmol/L of phosphate, 0.11 mmol/L of sulfate, and a standard mineral solution. In the study, three different concentrations of PDCs were examined, all with the same molar ratio of EG to TPA of 1:1. The concentrations were 1, 2.5, and 5 g COD/L, and the experiments were performed in the presence of butyric acid at 2 gCOD/L, the sole organic source in the origin reactor, to evaluate the activity of the PPB culture. Two control conditions were also evaluated: one in which only butyric acid was present at 2 gCOD/L and the other in which a combination of EG and TPA was present at a total concentration of 1 g COD/L. A spike of butyric acid and carbonate to reach 2 gCOD/L and 8.4 mmol/L in the flasks, respectively, was introduced at 1.7 days post-inoculation to prevent the culture from reaching a starvation phase. On the 4th day, except for PDCs control, all flasks were reinoculated to restart to the initial condition. Each condition was carried out in triplicates.

RESULTS AND DISCUSSION

The experiment started at a low biomass concentration hence with a colorless solution. Throughout the study, with the increase of biomass concentration, followed by the OD (Figure 2. A), the flasks acquired the typical reddish color specific to PPB culture enrichment and prominent absorption peaks at 805 and 865 nm, corresponding to the presence of bacteriochlorophyll a.

The results indicate that the butyric acid consumption rate was similar in the control (Figure 1. A) and the condition with 1 g COD/L of PDCs. (Figure 1. C) However, as the concentration of PDCs increased on conditions 2 and 3 up to 2.5 and 5g COD/L (Figure 1. D and E), there was a noticeable reduction in the butyric acid consumption rate on the first day, a 30% reduction in 5 g COD/L of PDCs condition. No increase was seen in EG or TPA consumption to compensate for this reduction, indicating the existence of a lag phase at these concentrations. After the butyric spike, the consumption of butyric acid increased in the conditions with higher concentrations of PDCs, namely at 2.5 and 5 g COD/L of PDCs (Figure 1. D and E, black arrow) when compared with the butyric control (Figure 1. A). This suggests that PPB required some time to adapt to PDCs at higher concentrations but did not seem to affect the overall activity of butyric consumption.

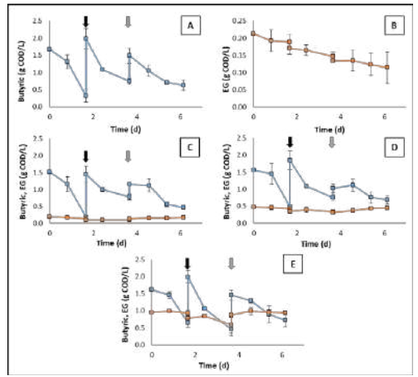

Figure 1. Evolution of butyric or EG concentration trough time for each condition. For each data point the average of triplicates is represented with the correspondent standard deviation. A – Control with butyric only (1 gCOD/L). B – Control with PDCs at 1 gCOD/L (TPA not shown). C – Condition 1: started at 1 gCOD/L of PDCs and 2 gCOD/L of butyric. D - Condition 2: started with 2.5 gCOD/L of PDCs and 2 gCOD/L of butyric E – Condition 3: started at 5 gCOD/L and 2 gCOD/L of butyric. Black and grey arrows showing the time of butyric spike and reinoculation respectively.

The PPB demonstrated the capability to consume EG, particularly in the control flasks containing only PDCs (EG and TPA) as sole organic source (Figure 1. B) and at 5 g COD/L of PDCs (Figure 1. E). EG maximum consumption of 109 mg COD/L.d was achieved at the highest concentration of PDCs. This was also associated with the highest biomass concentration suggesting that, in addition to the butyric acid, the extra carbon from EG might be used for growth (Figure 2 B). The growth rate seems not to be affected by the presence of the PDCs in the medium, except for a higher hindrance on growth at the beginning of the test at higher concentrations of PDCs, namely 2.5 and 5 gCOD/L as we have seen with the butyric acid uptake, being both related (Figure 2. A).

TPA was not consumed at a measurable rate without acclimatization or pre-selection of bacteria. This may be due to the aromatic nature of TPA and the metabolic requirements it poses (results not shown). Further research is needed to fully understand the upper tolerance limit for PDCs and the potential long-term effects on the bacteria.

Conclusion. Overall, the results suggest that PPB can tolerate concentrations of PDCs up to 5 g COD/L without significant negative effects on growth and activity, except for a slight lag phase at the beginning of the test at higher concentrations. The capability of PPBs to consume EG without previous adaptation is worthy of notice. This study demonstrated promising results relating PPB and plastic tolerance and their great potential for plastic bioremediation. Gradual acclimatization of PPB to PDCs will be further tested to increase the capacity of PPB to consume PDCs and evaluate their use for PHA production.

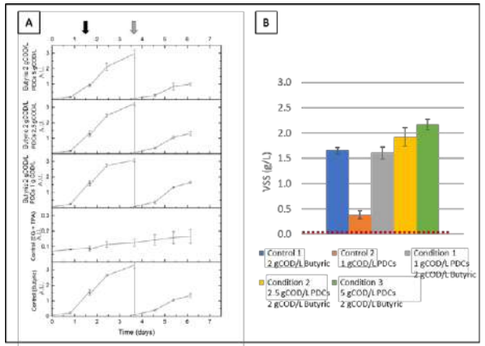

Figure 2. Growth of PPB at the different conditions and controls. A – Evolution of optical density at different conditions, average of triplicates with standard deviations. Black and grey arrows correspond to the time of butyric acid spike and reinoculation, not applying to PDCs Control. B – VSS values at the end of the first inoculum (grey arrow on Figure 2. A), average values from triplicates with standard deviation. Red dashed line showing the initial value of VSS in day 0.

Abstract
The proper management of meat brines is associated to high costs for the meat processing industries. Consequently, exploring alternatives for their valorisation is essential to increase the competitiveness and circularity of the meat sector. In that sense, this study proposes the valorisation of meat brines for the production of volatile fatty acids of industrial interest by means the application of anaerobic fermentation coupled with electrodialysis.

Keywords
Anaerobic fermentation; brines; electrodialysis; meat industry; organic acids

INTRODUCTION

The meat industry is one of the pillars of the food sector in Europe and the main industry of the agri-food sector in Catalonia with a turnover of 8,453 M€. During the preparation of processed products such as fuet and cured ham, the meat processing industry generates large volumes of high salinity wastewater (brines) due to the use of sodium chloride as preservative agent. Considering the high environmental impact which could cause their discharge in water bodies, brines must be properly managed by food industries either on-site or through external management companies. The current management costs for brines (up to 100€/m^3) are forcing companies to explore alternative processes oriented not only to treat them properly, but also valorise them with the purpose of approaching the circular economy model. To address this challenge, this study proposes the valorisation of high salinity wastewater generated in the meat processing industry to produce volatile fatty acids (VFAs) of industrial interest. The proposed technological approach is based on the application of a fermentation process under anaerobic conditions using mixed microbial culture as inoculum combined with electrodialysis as a suitable technology to recover the VFAs in the permeate and concentrate the salts in a more reduced volume.

MATERIALS AND METHODS

Acidification batch test were conducted to identify the optimal operating conditions to maximize the production of VFAs during the valorisation of 2 types of brines generated in the meat processing industries (Brines A-fuet production (λ: 107 mS/cm) and Brines B-cured ham production (λ: 220 mS/cm)) and a mixture 50:50 (vol.) of Brines A and B. The inoculum used for the batch test was enriched in acidogenic microorganisms in an anaerobic fermenter of 10 L operated in continuous mode under an HRT of 6 d and fed with saline wastewater (λ: 35 mS/cm). The test were carried out in 200 mL bottles during a period of 7 days at 37°C, evaluating the influence of the inoculum-substrate ratio for each type of brine to simulate an HRT of 3 and 6 days. The production of VFAs (acetic, propionic, butyric, iso-butyric, valeric, iso-valeric and 4-methylvaleric acid) was monitored periodically by the analysis of samples from the liquid phase by means of Gas Chromatography.

The effluent obtained in the anaerobic fermenter (Figure 1) was subsequently treated in an electrodialysis unit in order to evaluate its potential to separate the VFAs produced during the valorisation of brines and the salts, trying to maximise their recovery in the permeate.

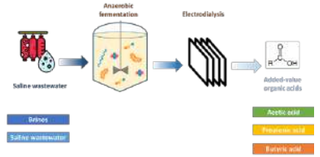

Figure 1. Production of volatile fatty acids from meat brines.

RESULTS AND DISCUSSION

The results obtained during the acidification batch test show the conductivity of the brines significantly affects to the percentage of acidification, ranging from 30% for Brine B to 80% from Brine A. In addition, higher HRT are associated to higher percentages of acidification. Figure 2 shows the composition of the VFAs produced during the anaerobic fermentation depends not only on the initial composition of the brines, but also on the operating conditions applied during the anaerobic fermentation.

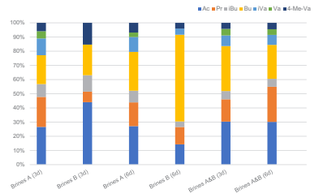

Figure 2. Composition of volatile fatty acids produced during the valorisation of meat brines.

The application of the electrodialysis allowed to efficiently recover (up to 95%) the volatile fatty acids produced during the anaerobic fermentation in the permeate and concentrate the salts (mainly sodium chloride) in a more reduced volume (~30% of the initial volume).

Abstract
Characteristics of activated carbon from banana peel and its adsorptive performance on diclofenac were studied to evaluate the potential of using banana peel as low-cost adsorbent as an alternative to conventional activated carbon for removal of micropollutants. Equilibrium was reached after 1000-1500 min and adsorption capacity was 93mg.g^{-1}. The kinetics were best fitted with a pseudo-second-order model indicating chemisorption and multiple diffusion steps. The adsorption isotherm was best fitted with Langmuir corresponding to homogenous sorption. Increasing pH from 6 to 10 caused gradual reduction in the adsorption capacity as electrostatic repulsion occurred due to both negative charge of diclofenac and activated carbon. This new adsorbent could be comparable with other adsorbent in previous studies. Based on the result, activated carbon produced from biowaste can be relevant to improve the wastewater treatment while preventing the negative side effect of using conventional activated carbon.

Keywords
Activated carbon; adsorption; banana peel; diclofenac; low-cost adsorbent

INTRODUCTION

The presence of persistent micropollutants cause a negative effect on aquatic organisms and human health. One of the reasons for their occurrence in environment is inefficient processes in conventional wastewater treatment plants (Carvalho et al., 2022). Pharmaceutical compounds are the subject of attention because of their intrinsic biology activity which can lead to fetal consequences. For instance, diclofenac (DCF) seems to be the compound with the highest acute toxicity among non-steroidal and anti-inflammatory drugs (Nadour et al., 2019). A concentration of several ng.l^{-1} DCF can change the cellular in the bronchi and kidney of rainbow trout (Zyłła et al., 2019). DCF has been detected in the Asian, European and American continents between 1998 and 2020 in the surface waters, raw and treated sewage in the water treatment plant with a wide range of concentrations from 0.04 ng.l^{-1} to 11 mg.l^{-1} (Carvalho et al., 2022).

Adsorption process with high dose activated carbon or combination with advanced wastewater treatment method might improve removal of micropollutant (Guillossou et al., 2019). Due to the large amount of activated carbon (AC) demand, using activated carbon produced from non-renewable sources such as coal, or lignite causes environmental pollution and enhances greenhouse gas emission (Hagemann et al., 2020). Hence, replacing fossil feedstocks of AC with sustainably and locally low-cost waste would contribute to waste management, circular economy, and removal of emerging contaminants. In this context, AC from banana peels may be a relevant alternative for water treatment. AC from banana peel was used for treatment of the methylene blue or heavy metal (Maia et al., 2021; Thuan et al., 2016), but its application to remove DCF has been little studied and the mechanisms involved remain poorly understood. Therefore, the objectives of this study are to: (i) investigate the adsorption characteristic by using kinetic, isotherm and intra-particle modelling, (ii) investigate the mechanisms involved by evaluating the effect of pH on adsorption in link with the change of activated carbon's characteristics.

MATERIALS AND METHODS

Activated carbon production

Banana peels were cut into 3 pieces around 4cm and washed with distilled water and dried at 105°C for 24h. They were ground into pieces from 254µm-2mm. Activated carbon was produced under chemical activation at impregnation ratio 1:1.5 (Banana peel: H_3PO_4, w:w) and kept overnight at room temperature. The material was placed in a muffle furnace with heating program for 4h at 200 °C followed by 2h at 500 °C. After the pyrolysis, it was washed with NaOH solution (1mol.l^{-1}) and then with distilled water up to pH 7. The obtained material was dried at 105°C for 14h and then it was sieved to gather particle with size from 75µm to 106µm and stored for characterization and adsorption tests. Commercial activated carbon Norit SAE 2 was used for comparison purposed as it has been proven to effectively remove the majors micropollutants (NORIT SAE SUPER, 2023).

Activated carbon characterization

Size distributions were determined by the Granulometer Malvern M3000. For the size distribution in volume, D10, D50, D90 of AC from banana peel were 7.32µm,73.6µm and 141µm respectively. In addition, commercial AC contained D[v,0.1] 4.24µm, D[v,0.5] 26.86µm and D[v,0.9] 136.41µm. The size distribution in number of both activated carbon were similar with small particle below 11µm.
Zeta potential of AC was measured by Malvern zetameter (Nano Zetasizer). Suspensions of 0.025g of AC in 200mL of 0.01M NaCl under different initial pH (2,3,4,5,6,7,8,10) were submitted to orbital shaker at 150rpm for 24h to reach equilibrium and measure the zeta potential.

Adsorption studies

The batch experiments (in triplicate) were carried out at 20°C by using a Jar test for constant agitation at 150rpm. Samples were filtered by a 0.45µm nylon membrane and DCF concentrations were determined by a UV-VIS spectrophotometer at 274nm.
The kinetic study was conducted to know the contact time effect on adsorption. Tests were conducted with 100mg.l^{-1} DCF solution and 0.5g.l^{-1} of AC. The pseudo-first-order, pseudo-second order, and intraparticle diffusion models were adjusted (Table 1).
Isotherm shows the relationship between the equilibrium concentration of the analytes (Ce) and the adsorbents uptakes (q_e) and it can provide insights into the nature of the biosorption phenomenon (Li et al., 2019). Equilibrium isotherms were obtained after 24h at different DCF concentrations from 1 to 10 mg.l^{-1} with 0.2 g.l^{-1} of AC. Langmuir, and Freundlich models were fitted (Table 1)
Effect of pH. The solution pH effect on the amount of DCF adsorbed was evaluated after 22h with 0.5g.l^{-1} of the adsorbent in 100mg.l^{-1} DCF solution with pH 6,7,8,9 and 10.

Table 1. Adsorption kinetic and isotherm model used

Model	Non-linear form	Linear form	Phenomena
Pseudo-first order	$q_t=q_e(1-e^{-k_1 t})$	$\log(q_e-q)=\log q_e-\left(\frac{k_1}{2.303}\right)t$	Physisorption
Pseudo-second order	$q_t=\frac{k_2 q_e^2 t}{1+k_2 q_e t}$	$\frac{t}{q}=\frac{1}{k_2 q_e^2}+\left(\frac{1}{q_e}\right)t$	Chemisorption
Intraparticle diffusion	$q_t=K_{id}t^{\frac{1}{2}}+C_e$		Mass transfer
Langmuir	$q_e=\frac{q_m K_L C_e}{1+K_L C_e}$	$\frac{C_e}{q_e}=\frac{1}{K_L q_m}+\frac{C_e}{q_m}$	Homogeneous
Freundlich	$q_e=K_F C_e^{\frac{1}{nF}}$	$\ln(q_e)=\frac{1}{n}\ln(C_e)+\ln(K_f)$	Heterogeneous

RESULTS AND DISCUSSION

Adsorption kinetic

Fig. 1a showed that the speed of adsorption was very fast in the early stage (0min- 90min) and reached equilibrium at 1000-1500 min. The experimental maximum adsorption capacity was 93mg.g^{-1}. Pseudo-second order model was the best fitted to experimental data with R^2=0.999 (Fig. 1b). This model indicated that the adsorption could be controlled by a chemisorption process that occurred with electrons sharing between molecules of DCF and AC's surface group. Moreover, experimental kinetic data was plotted by using intraparticle diffusion modelling in Fig.1c. It might be not rate-limited step in this process but it might involve multi stage adsorption where the initial stage (1st linear section) occurred (0-90 minutes) and represented the external mass transfer resistance involving the particle's surface. The second step (2nd linear section) (90-600 min) indicated a more gradual adsorption, characteristic of the adsorbate transport through the adsorbent inner surface. Finally, the third stage (3rd linear section) (600-3060 min) represented to the adsorption equilibrium.

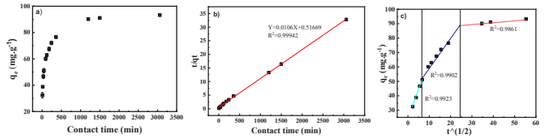

Figure 1. (a) Kinetic adsorption curves; (b) Pseudo-second order model of kinetic study and (c) Intraparticle diffusion kinetic plot

Isotherm study

Experimental data were fitted with Langmuir and Freundlich model with R^2 of 0.9901 and 0.9644 respectively (Figure 2a). K_L (Langmuir) and 1/n (Freundlich) values are 0.9572 and 0.593 below 1, so the diclofenac adsorption was favourable in the adsorbents of activated carbon from banana peel. These results suggested that the diclofenac adsorption took place onto a homogenous surface

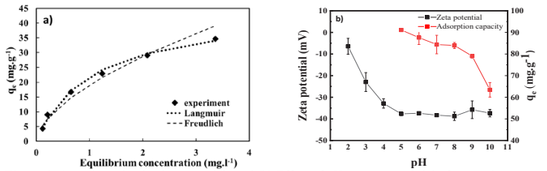

Figure 2. (a) Adsorption isotherm models and (b) Effect of pH on zeta potential of AC and resulting DCF adsorption capacity

Effect of adsorption pH

Fig. 2b showed about zeta potential of AC from banana peel with different pH. Within the pH range in which the adsorption capacity was evaluated, the activated carbon was negatively charged. Indeed, when the suspension alkalized, the particle tended to have more negative charge and zeta potential reach a plateau value of -40mV from pH 5 to 10. Concomitantly, adsorption capacity gradually decreased when increasing the pH from 6 to10 possibly due to an increase number of deprotonated species (-COO and O-) of DCF (pKa= 4.15) inducing electrostatic repulsion at high pH between negative charges of DCF and AC.

Comparison with commercial activated carbon

The commercial activated carbon adsorption capacity was 195mg.g^{-1} thus well above that of the banana peel AC (93mg.g^{-1}). However, the banana peel AC showed comparable adsorption capacities than other alternative adsorbent such as activated carbon tea waste (91.2 mg.g^{-1}), coco shell (63.47 mg.g^{-1}) (Malhotra et al., 2018, Saucier et al., 2015) and thus represent a potentially sustainable alternative.

Abstract
Concentration polarization (CP) is the major drawback in reverse osmosis (RO) system for brackish/seawater desalination. The present study aims to understand the effect of induced shear stress and enhanced flow dynamics on CP. We have numerically modelled the salt precipitation and CP with CFD, and for turbulent flow additional eddy viscosity and RSM equations are added in the solver. In case of turbulent flow CP is significantly reduced at the membrane surface, which may increase the longevity and overall performance of the membrane.

Keywords
CFD, concentration polarization, Roto-dynamic RO system, Turbulence Modelling.

INTRODUCTION

Today, RO filtration is the most used technology in the world for desalination. However, conventional spiral would RO modules (SWRO), face operational difficulties such as CP, which increases the internal friction and cause decline of permeate flux. Study [1-6] shows that cross flow increases the shear rate over the membrane, enhances the mass transfer coefficient and reduces the mineral concentration over the membrane. Dynamic filter [1-10] creates several wave forms that assist increasing cross flow, shear and mixing along the membrane surface which ensure the lower accumulation of solute and reduce the species transfer towards the permeate out. Such dynamic filter also disjoints the drop in pressure and shear rates. The performance analysis of roto-dynamic system proposed by Chaudhuri et al. [4] is considered for the present study, have a spinning disk over the membrane surface which creates axisymmetric flow structure, which enhances the shear and species transport over the membrane. The flow dynamics and precipitation rate [11-12], depend on feed concentration of salts, feed pressure and nature of flow (i.e., laminar/Turbulent) over the membrane surface. The CP is analysed for low and high shear region along the membrane surface at different feed pressure and spinning speed of rotor, which changes the flow patterns and concentration profiles as flow changes from laminar to turbulent.

METHODS AND RESULTS

To establish the numerical frame-work, we have used Ansys (fluent) as CFD solver for simulation of fluid flow, species transport, salt precipitation, and CP. We have used multiple UDFs to imposed different boundary and initial conditions.

Performance of roto-dynamic RO system in turbulent regime: Turbulence modelling and measurement of the turbulent flow along with species precipitation over the porous membrane is of great challenge. Therefore, first we stabilised the turbulence model used for the analysis (i.e., SST-Kω and RSM) in Ansys (fluent), validated with the existing experimental results of Poncet et al. [13], for non-dimensional velocity profile along the radial and azimuthal direction at different cross flow as shown in figure2.

The referred flow cavity [13] consist of a fixed disk (the stator) and a smooth rotating disk (the rotor). A fixed shroud encloses the cavity. The rotor and the central hub attached to it rotate at the uniform angular velocity Ω. The mean flow is mainly governed by three control parameters: the aspect ratio G, the Reynolds number (Re) based on the outer radius of the rotor, and the flow-rate coefficient C_w, defined as follows:

$G = h/R_2$; $R_e = \Omega R_2^2 / \nu$,$C_w = Q / \nu R_2$
where ν is the kinematic viscosity of water and Q is the imposed throughflow.

Table 1. Geometrical Parameters

Description	Symbol	value	unit	Source
Inlet Radius	R_1	38	mm	[13]
Outlet Radius	R-R_2	3	mm	[13]
Membrane to disk height	h	9	mm	[13]
Outer Radius	R_2	250	mm	[13]

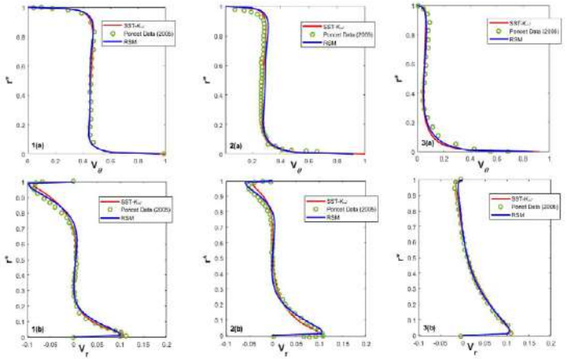

Figure 2. Mean velocity profiles for Re = 4.15 ⨯ 10^6, G = 0.036 at r* = 0.44 for SST-kω, RSM model and experimental data from poncet et al. [13], (1) C_w=0, (2) C_w=2579, (3) C_w = 5159.

This validated turbulence model is then used, to simulate the turbulent flow combined with the concentration polarization and particle precipitation behavior of salt in rotor-dynamic system. The dimensional specifications of rotor-dynamic system are taken same as rotor-stator cavity [Table 1] with same Reynolds number of 4.15 ⨯ 10^6. However, the stator is now being replaced with a porous membrane and a high pressure of 70 Bar with seawater salinity are applied as feed to simulate the CP of salt over membrane.

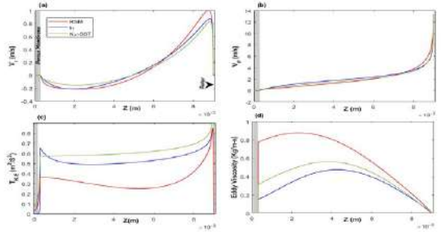

Figure 3. (a) Radial velocity, (b) Tangential velocity, (c) Turbulent kinetic energy and (d) Eddy viscosity profile along the domain perpendicular to membrane surface.

The high turbulent kinetic energy and turbulent viscosity over the membrane can be seen in the results (figure 3), which induces a high shear and recirculation over the membrane, increasing the transport of salt species.

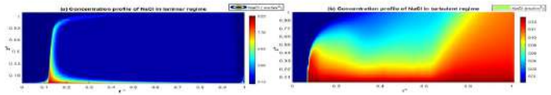

Figure 4. Concentration Polarization (CP), of NaCl over RO membrane in (a) laminar and (b) Turbulent flow.

In figure 4(a), we can see a pick in concentration near inlet of laminar flow due to presence of stagnation point. But, as we increase the rotor speed, due to the flow dynamics no such point exists in turbulent flow regime (figure 4(b)). Another important point is the concentration value over the membrane, as discussed, due to high turbulent kinetic energy, strain rate and eddy-viscosity the concentration polarization (CP) value is very less in case of turbulent flow.

CONCLUSION

Turbulence modelling equations is performed to study the CP of RO membrane during seawater desalination in turbulent regime after validating the model with the existing literatures.

The study shows that, it is possible to significantly reduce the CP propensity of the RO membrane, by maintaining a high shear and diffusion rate over the membrane with dynamics of fluid. Therefore, we can conclude that turbulent flow could be very beneficial for roto-dynamic system in order to mitigate the CP of desalinating membranes by enhancing the flow structure over the membrane.

Abstract
This work describes the sequential coupling of Fenton and aerobic biological process to treat pulp bleaching wastewater. Focus was put on the removal of chemical oxygen demand (COD) and adsorbable organic halides (AOX), under two treatment setups: Fenton followed by biological process; and biological followed by Fenton process. Aerobic biological treatment was performed in 2 L batch bioreactors, at room temperature, for 48 h. Fenton experiments were performed in 0.5 L batch reactors, using hydrogen peroxide as oxidant and Fe^{2+} as catalyst. Under optimal operating conditions, sequential treatment by Fenton followed by biological process yielded global removal of 71.9 % of COD and 89.6 % of AOX. The inverse sequence (biological followed by Fenton process) yielded global removal of COD and AOX of 82.6 % and 89.5 %, respectively.

Keywords
AOX; COD; process optimisation; pulp bleaching wastewater; response surface methodology.

INTRODUCTION

Aerobic biological wastewater treatment is based on the oxygen-assisted degradation of organics by microorganisms, yielding biomass, carbon dioxide, and water, among others (Suhr, Klein, et al., 2015). It is broadly used due to its lower cost, simpler operation, and less secondary pollution, when compared with physical and chemical technologies (Crini and Lichtfouse, 2019). Nonetheless, it is widely accepted that the toxic and recalcitrant nature of some industrial wastewaters render biological processes insufficient for pollution abatement (Hubbe, Metts, et al., 2016). Fenton process is a feasible alternative, known for its fast and effective abatement of recalcitrant pollution from wastewaters. It is based on the catalytic (Fe^{2+}) dissociation of H_2O_2 into •OH radical, which is a strong and non-selective oxidant (Brink, Sheridan, et al., 2017). For some wastewaters, the combination of these processes may be more efficient than the single application of any of them.

This work aimed to study the coupling of both processes: aerobic biological and Fenton, to maximise the global treatment performance in chemical oxygen demand (COD) and adsorbable organic halides (AOX) abatement. The goal was to address a major issue in this field of research: how to implement a setup in wastewater treatment plants that effectively reduces recalcitrant compounds, without compromising the effectiveness of conventional bioprocesses.

MATERIALS AND METHODS

Pulp bleaching wastewater served as case-study in this work, showing high levels of COD and AOX. The latter are recalcitrant compounds of environmental hazard. Wastewater was sampled at a pulp mill, after the first bleaching stage with ClO_2, which is the stream with higher concentration of AOX. Biocatalyst used in the bioprocess consisted of aerobic sludge collected at the wastewater treatment plant of the same mill. Two treatment setups were studied: (i) Fenton followed by aerobic biological process (activated sludge), and (ii) aerobic biological process followed by Fenton.

Fenton followed by biological process

Fenton process was carried out in 0.5 L batch with 6.0 mM of Fe^{2+} (as $FeSO_4.7H_2O$), 139 mM of H_2O_2 (30 % w/v), and treatment time (t) of 10 min. These operating conditions aimed to maximise AOX removal, as described elsewhere (Ribeiro, Marques, et al., 2020), since Fenton process is especially suitable to remove recalcitrant compounds. Wastewater temperature (T) and pH were set at 60 ºC and 2.48 ± 0.20, respectively, which are the values at which this wastewater stream is usually generated at this mill. At the end of treatment, wastewater samples were collected for determination of COD and AOX. The remaining wastewater was neutralised to 6.5 < pH < 7.5 with 9 M NaOH and proceeded for biological treatment. Nutrients N (as NH_4Cl) and P (as KH_2PO_4) were added to ensure COD:N:P of 100:7:1. Initial load of volatile suspended solids (VSS) of 3.60 $g \cdot L^{-1}$ was used according to preliminary tests. Preliminary experiments were also performed under different dilutions of the wastewater, showing that the biological sludge was able to cope with the Fenton by-products and the remaining recalcitrant compounds (Ribeiro, Morim, et al., 2021). Therefore, in this work, biological process was conducted directly on the Fenton-treated wastewater in 2 L glass reactors – 1.6 L of working volume, including wastewater, sludge, and micronutrients – under 400 rpm magnetic stirring, at room T, for 48 h.

Biological process followed by Fenton

In this treatment setup, aerobic biological treatment of raw wastewater was performed under similar conditions to those described for the inverse treatment sequence. Afterwards, biologically treated wastewater was centrifuged to remove the sludge, and reacidified to 2.5 < pH < 3.0 using a 32.5 % (v/v) HNO_3 solution. This procedure was adopted to perform Fenton process at the most favourable pH range (Ribeiro and Nunes, 2021). Response surface methodology (RSM) was used to find the optimal operating conditions of Fenton process, aiming to maximise the removal of AOX after the biological abatement of readily biodegradable compounds. Central composite experimental design was used to plan the experiences (Rodrigues and Iemma, 2015). The factors studied were the concentration of H_2O_2 (in the range 150 – 450 mM) and Fe^{2+} (4 – 10 mM), plus the treatment time (25 – 65 min). Three repetitions of the central point were performed, totalling 17 assays. Experiments were run at room T, to simulate what would happen at full-scale. After the established time for each experiment, samples were collected and immediately quenched with sodium sulphite.

Analytical methods

AOX content was quantified following EN 16166:2012, ISO 9562:2004 and EPA Method 1650C. COD and VSS were measured following Standard Methods 5220D and 2540E, respectively (Greenberg, Clesceri, et al., 1999). To support RSM analysis of the Fenton trials, four mathematical models were fitted to the experimental data: linear and second-order polynomial equations, with and without the terms describing the interaction between factors. 95 % confidence level was adopted.

RESULTS AND DISCUSSION

Fenton followed by biological process

Fenton process removed 50.2 % of COD and 65.0 % of AOX from the raw pulp bleaching wastewater (Figure 1). These results showcase the efficacy of Fenton process on the removal of recalcitrant compounds. The observed decrease in COD was in accordance with the observations of Van Aken et al. (2013), who reported 67 % COD removal from graphical industry wastewater under oxidant dose ranging 0.2 – 2 $g_{H2O2} \cdot g^{-1}_{COD}$ (in this work, 1.78 $g_{H2O2} \cdot g^{-1}_{COD}$ were used).

Biological treatment removed 37.3 % COD and 41.8 % AOX from the already Fenton-treated wastewater, leading to global removal from the coupled treatment of 71.9 % COD and 89.6 % AOX (Figure 1). These results highlight the advantage of coupling the treatments, achieving much higher removal of pollutants than by any of the processes applied individually. In a comparable work, Li et al. (2023) studied the sequential conjugation of Fenton process followed by activated sludge applied for treatment of mixed wastewater from different industries. The authors reported a maximum contribution of 20.9 % from Fenton process to the COD removal. Conversely, biological treatment contributed the most to the removal of the targeted pollutants, showing that its coupling with Fenton process may be especially suitable when recalcitrant compounds are found in the wastewater.

Biological process followed by Fenton

In this treatment setup, activated sludge removed 36.4 % of COD and 20.2 % of AOX. The removal of COD by biological treatment was similar between treatment setups, whilst the removal of AOX was about half of the value achieved under the inverse sequence. This suggested that the AOX compounds remaining in the wastewater after Fenton process may have been converted into less recalcitrant and more easily biodegradable compounds. When biological process is applied first, the recalcitrant nature of the raw wastewater is stronger and AOX removal is hindered.

The biologically treated wastewater was then subjected to Fenton process, which was optimised. Second-order quadratic model without interaction terms was selected as the best-fitting one, after checking the normality and randomness of the residuals, and analysing R^2 and adjusted R^2 (Rodrigues and Iemma, 2015). Lack-of-fit test for the two models (COD and AOX removal) yielded $p > 0.05$, meaning both models fitted well to the experimental data. Fe^{2+} concentration was the main factor statistically influencing the removal of COD and AOX. Optimal operating conditions to maximise COD removal from the wastewater were modelled to be 286 mM H_2O_2, 17 mM Fe^{2+}, and 83.3 min, yielding removals of 97.6 % COD and 12.3 % AOX. To maximise the removal of AOX, 489 mM H_2O_2, 9.3 mM Fe^{2+}, and 49.2 min should be adopted, yielding removals of 82.7 % AOX and 68.9 % COD. The latter set of operating conditions presents the best combined performance, reaching overall removal of 82.6 % COD and 89.5 % AOX. Abedinzadeh et al. (2018) used a sequential batch bioreactor followed by Fenton process (6.0 mM H_2O_2 and 3.0 mM Fe^{2+}) to remove COD from pulp wastewater. Overall COD removal of 98 % was achieved, which is higher than the one obtained in this work, using considerably less chemicals. This may be due to the lower initial COD (1.50 $g_{O2} \cdot L^{-1}$ against 2.14 $g_{O2} \cdot L^{-1}$) and higher biodegradability (0.37 against 0.08).

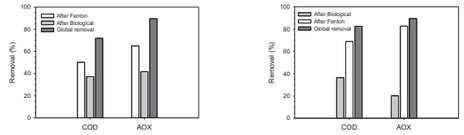

Figure 1. Removal of COD and AOX from the wastewater by the coupled treatments: (a) Fenton followed by biological process; (b) biological process followed by Fenton.

CONCLUSIONS

Fenton and aerobic biological (activated sludge) processes were successfully coupled in the treatment of pulp bleaching wastewater, maximising the removal of COD and recalcitrant AOX. When applied first, Fenton process removed 50.2 % of COD and 65.0 % of AOX from the raw wastewater, with biological treatment increasing the overall removal to 71.9 % of COD and 89.6 % of AOX. Under the inverse sequence, activated sludge removed 36.4 % of COD and 20.2 % of AOX from raw wastewater. Fenton process was optimised under RSM, allowing for global removal of COD and AOX of 82.6 % and 89.5 %, respectively. Therefore, this appeared to be the most suitable treatment setup for combined abatement of COD and AOX. Further research is still needed aiming at the full characterisation of the treated wastewater, to assess possible increase on toxicity.

Abstract
This work proposes a route to valorise the iron sludge from Fenton process, turning it into a heterogeneous Fenton catalyst. The sludge was produced after the treatment of pulp bleaching wastewater by Fenton process catalysed by (i) iron sulphate (homogeneous Fenton), and (ii) residual iron dust from the metallurgic industry (heterogeneous Fenton). The generated sludges were collected and thermochemically treated under nitrogen atmosphere aiming to promote the transition from ferric hydroxide to phases of higher catalytic activity towards Fenton process, mainly magnetite. Suitable temperatures of the thermochemical treatment were defined ($500 \leq T \leq 700$ ºC) by thermodynamic calculations based on the change of standard-state Gibbs energy of the iron reduction reactions. Chemical and structural characterisation of the thermochemically treated sludges will support the study of their performance as Fenton catalyst.

Keywords
AOX; catalyst; iron; magnetite; residual iron dust; wastewater.

INTRODUCTION

It is widely accepted that biological treatment is sometimes insufficient to remove toxic, recalcitrant compounds. Fenton processes are well-studied options to degrade recalcitrant compounds, based on the Fe-catalysed dissociation of hydrogen peroxide (H_2O_2) into hydroxyl radical, a strong non-selective oxidant (M'Arimi, Mecha, et al., 2020; Ribeiro, Marques, et al., 2020). Despite their numerous advantages, Fenton processes are usually linked to two main drawbacks: high exploitation of iron and production of iron sludge requiring management (e.g. Ribeiro and Nunes (2021)).

This work aimed to valorise the Fenton sludge as a catalyst of Fenton process applied to industrial wastewater treatment. To that end, industrial wastewater was treated by homogeneous and heterogeneous Fenton processes, and the resulting sludges were recovered and thermochemically treated. This way, a circular solution was sought to reduce the demand for iron and the amount of iron sludge to manage, by converting it into a waste-derived heterogeneous Fenton catalyst.

MATERIALS AND METHODS

Materials

Pulp bleaching wastewater was collected from a Portuguese pulp industry, after the first bleaching stage with ClO_2, since that stream is usually associated with considerable concentration of recalcitrant adsorbable organic halides (AOX) (Toczyłowska-Mamińska, 2017). H_2O_2 was used as received (30 % m/v solution); Fe^{3+} was supplied from a 184 mM aqueous solution of $Fe_2(SO_4)_3.5H_2O$; sodium hydroxide (NaOH) was used as a 2 M aqueous solution.

Iron sludge production

Wastewater was treated by Fenton processes catalysed by: (i) iron sulphate (homogeneous Fenton), and (ii) residual iron dust (RID) from the metallurgic industry (heterogeneous Fenton). Homogeneous Fenton process was performed with 170 mM H_2O_2, 5.5 mM Fe^{3+}, and reaction time of 10 min. These conditions were found in preliminary trials to maximise the removal of AOX (≈ 80 %) from the wastewater. In the heterogeneous Fenton process, RID was first added to the wastewater at 1:200 (g:mL) ratio and contacted for 30 min. At that point, 100 mM H_2O_2 was added, and further 10 min were allowed (Ribeiro, Sarinho, et al., 2022). For both Fenton processes, wastewater temperature (T) and pH were set at 60 ºC and 2.6, respectively, which are the values at which this wastewater stream is usually generated. After treatment, wastewater was always aerated with compressed air to eliminate residual H_2O_2, and alkalised to pH > 9 with NaOH to precipitate the iron sludges (Zhu, Xia, et al., 2021). The sludges were separated from the treated wastewater by decantation and dried at ≈ 60 ºC.

Thermochemical treatment of iron sludge

For both types of Fenton process, the resulting iron sludges were thermochemically treated in a fixed-bed tubular quartz reactor with 20 mm internal diameter and 350 mm length, under N_2-atmosphere. A type K thermocouple located at the central region of the tubular reactor allowed the monitoring of T, which was regulated by a control and data acquisition electronic system. In this work, 10 ºC·min^{-1} heating rate was adopted in all experiments. Treatment time (t) of 15, 30, and 60 min was tested. Most suitable T were defined by thermodynamic calculations, based on the change of standard-state Gibbs energy of the iron reduction reactions, described in Eq. (2)-(5).

RESULTS AND DISCUSSION

Fenton iron sludge production

Homogeneous Fenton process allowed for 83.4 ± 3.0 % removal of AOX from the wastewater, validating the choice of operating conditions. Heterogeneous RID-catalysed Fenton process yielded AOX removal from the wastewater of 66.2 ± 2.2 % under the chosen operating conditions.

The yield of iron sludge was higher in the homogeneous Fenton process, since the concentration of iron supplied to the wastewater was also higher: 5.5 mM in the homogeneous process, against 1.41 ± 0.11 mM after 30-min contact at 1:200 ratio (g:mL) in the heterogeneous process (Ribeiro, Sarinho, et al., 2022). In the latter, some RID particles were also inevitably collected with the sludge. In both processes, solids and fibres originally present in the wastewater were also collected with the sludge, due to the simple precipitation and decantation recovery procedure. Overall, the recovery of sludge was 2.55 g·L^{-1} and 1.75 g·L^{-1} for the homogeneous and heterogeneous Fenton processes, respectively.

Thermochemical treatment of iron sludge

Iron in the raw Fenton sludge consists mainly on ferric hydroxide $Fe(OH)_3$ or goethite (α-FeOOH) at high pH (Zhu, Xia, et al., 2021). Above 300 ºC, dehydration is expected to drive the conversion of goethite to hematite (α-Fe_2O_3) (Eq. (1)) (Gialanella, Girardi, et al., 2010). Depending on T and organic matter content, CO and/or H_2 may convert hematite to magnetite (Fe_3O_4) (Eq. (2)-(3)), which in turn may be reduced to Fe^0 (Eq. (4)-(5)) (Ye, Zhou, et al., 2022). To find adequate T to drive the reactions in these directions, thermodynamic calculations were made aiming to determine the change of standard-state Gibbs energy of the reactions (ΔG_R^0) described in Eq. (2)-(5). ΔG_R^0 is a state-function incorporating entropy and enthalpy to describe equilibrium and spontaneity of a reaction (Chang and Thoman Jr., 2014). It can be calculated from Eq. (6), where ΔH_R^0 and ΔS_R^0 are the changes of the standard-state enthalpy and entropy of the reaction, respectively.

$$2FeOOH_{(s)} \rightleftharpoons Fe_2O_{3(s)} + H_2O_{(g)} \quad (1)$$

$$3Fe_2O_{3(s)} + CO_{(g)} \rightleftharpoons 2Fe_3O_{4(s)} + CO_{2(g)} \quad (2)$$

$$3Fe_2O_{3(s)} + H_{2(g)} \rightleftharpoons 2Fe_3O_{4(s)} + H_2O_{(g)} \quad (3)$$

$$Fe_3O_{4(s)} + 4CO_{(g)} \rightleftharpoons 3Fe^0_{(s)} + 4CO_{2(g)} \quad (4)$$

$$Fe_3O_{4(s)} + 4H_{2(g)} \rightleftharpoons 3Fe^0_{(s)} + 4H_2O_{(g)} \quad (5)$$

$$\Delta G_R^0 = \Delta H_R^0 - T\Delta S_R^0 \quad (6)$$

The values of ΔG_R^0 for the formation of magnetite and Fe^0 (Eq. (2)-(5)) are compiled in Table 1 for T ranging 500 – 985 ºC. For all temperatures, reactions (2) and (3) present $\Delta G_R^0 < 0$, meaning that both reactions are favoured towards the formation of magnetite from hematite at those conditions. Regarding the reduction of magnetite to Fe^0, reactions (4) and (5) presented $\Delta G_R^0 > 0$ up to, at least, 800 ºC, favouring the occurrence of reaction in the reverse direction. Therefore, relatively low temperatures may be sufficient to drive the system towards the formation of magnetite, with high catalytic performance towards Fenton process (Adityosulindro, Rahdhani, et al., 2021). To drive reactions (4)-(5) towards the production of Fe^0, T ≥ 985 ºC could be required, implying higher energy consumption. Moreover, magnetite presents an advantage compared with Fe^0: the easier magnetic separation of spent catalyst from the wastewater. Considering these data, $500 \leq T \leq 700$ ºC was chosen as suitable range to treat the Fenton sludges, aiming to maximise magnetite formation.

Table 1. ΔG_R^0 of the reactions yielding magnetite and metallic iron.

Reaction	ΔG_R^0 (kJ·mol^{-1})				
	500 ºC	600 ºC	700 ºC	800 ºC	985 ºC
(2)	-81.7	-85.1	-88.7	-92.6	-100.3
(3)	-71.3	-78.2	-85.1	-92.2	-105.6
(4)	3.46	6.7	10.1	13.8	20.9
(5)	44.9	34.4	24.6	15.5	-0.02

The yields of char from the treatment of sludges are compiled in Table 2. Regardless of Fenton process, lower T (≤ 600 ºC) allowed for a higher recovery of solid, reaching 73.6 % in homogeneous Fenton, and 69.2 % in heterogeneous Fenton. These values express mainly the recoverability of solid, rather than an actual difference in its production compared with gas or oil fractions. Increasing T led to increasing encrustation of the sludge on the quartz reactor. This behaviour may have been driven by slagging/fouling phenomena, which are usually favoured by high concentrations of low melting point elements, like Na, K, S, Cl (alkali or chloride sulphates), and unfavoured by high melting point ones like Ca, Mg, Si (calcium or magnesium silicates) (García, Pizarro, et al., 2015). The chemical and structural characterisation of the obtained solids is currently being performed. This will allow the verification of the distribution of the expected iron phases in the solids and the evaluation of their real catalytic performance in (heterogeneous) Fenton process.

Table 2. Solid yield (%) of thermochemically treated Fenton sludges at the different operating conditions studied.

T (ºC)	Homogeneous Fenton			Heterogeneous Fenton		
	t (min)			t (min)		
	15	30	60	15	30	60
500	71.5	71.7	73.6	69.2	68.7	69.2
600	70.8	70.5	70.3	66.3	65.1	66.2
700	26.6	32.3	29.2	60.5	55.2	54.4
800	6.3	~0	~0	45.5	40.3	34.9

CONCLUSIONS

This work proposed a circular solution to valorise the main by-product – iron sludge – of Fenton processes applied to remove AOX from pulp bleaching wastewater. The spent iron catalyst was recovered by precipitation after homogeneous and heterogeneous Fenton processes. The recovery of iron sludges reached 2.55 g·L^{-1} and 1.75 g·L^{-1} for the homogeneous and heterogeneous Fenton processes, respectively. Thermodynamic calculations were made and indicated $500 \leq T \leq 700$ ºC as suitable conditions to treat the Fenton sludges aiming at the formation of magnetite, due to its known catalytic activity and magnetic properties. Thermochemical treatment in N_2 atmosphere was used at those conditions to produce a waste-derived Fenton catalyst, yielding 73.6 % in homogeneous Fenton, and 69.2 % in heterogeneous Fenton.

Abstract:

Efficient resource recovery from domestic wastewater by low-cost technologies, achieving a reduced-carbon footprint and affordable wastewater reuse in small populations, remains a key challenge to ensure sustainable and cost-effective resource management. In this study, a novel and disruptive technology for low-cost domestic wastewater reuse in anaerobic photobioreactors using purple phototrophic bacteria is proposed. This process is aimed at small population areas, due to reduced energy consumption and simple operation, as well as a biomass rich in polyhydroxyalkanoates (PHAs) available for beneficial use in bioplastics or fertilisers.

After thorough investigation and development, the technology has been scaled to two demonstrative photobioreactors of 150 m^3 each at the wastewater treatment plant (WWTP) Linares in Jaén, Spain. With a maximum treatment capacity of 350 m^3/d, the treated water complies with limits for agricultural reuse, reaching average concentrations of 55 mgCOD/L, 12 mgBOD5/L and 10 mgTSS/L. To allow maintaining nutrients as fertilizer in the effluent during irrigation season, the removal of nitrogen and phosphorus can be optimized due to the alternance of aerobic and anaerobic conditions in the raceway reactors, varying hydraulic retention times and operational conditions. This article describes the control parameters to obtain optimised process benefits.

Keywords: PPB, small populations, photobioreactors, nutrient recovery, water reuse.

Introduction

The traditional and centralized concept of wastewater treatment (WWT) has been successfully applied during the last decades in highly populated and industrialized areas. Conventional WWT is characterized by high energy consumption related to aeration and coupled to limited nutrient recovery. Since the approval of the Directive Urban WWT 91/271/CEE more than 30 years ago, WWT has been applied to municipalities of more than 2000 population equivalent (p.e.). However, a recent revision of this Directive now lowers its applicability to small populations areas (> 1000 p.e.), and proposes energy neutrality of the WWT process, making it extremely challenging to an economically viable implementation using conventional technologies. Considering that 25% of the EU population lived in rural areas in 2021 (The World bank, 2021), this leads to the need to develop low-cost decentralized wastewater reuse that provides high quality treated water without significant carbon footprints.

The present study focuses on the development of a novel and disruptive single-step wastewater reuse concept based on Purple Phototrophic Bacteria (PPB) in anaerobic raceways or photobioreactors (PBR). The versatile metabolism of PBBs by assimilation of carbon and nutrients opens new possibilities for domestic WWT and the recovery of resources such as polyhydroxyalkanoates (PHAs), single-cell-proteins (SCP) and hydrogen, among others – as published by Puyol et al. 2020 showing the initial process evolution.

After this detailed development with King Juan Carlos University (URJC) since 2015, full scale anaerobic photobioreactors using PPB photobioreactors with solar radiation have been commissioned at the WWTP Linares (Jaén, Spain), under the name ANPHORA® (ANaerobic PHOtotrophic RAceways), scaling it to Technology Readiness Level (TRL) 7.

Material and Methods

The demonstrative PBRs have a treatment capacity of 350 m^3/d (approximately 1500 p.e.) (Figure 1), made up of two anaerobic raceways with a surface area of 465 m^2 each, and a volume of 149.5 m^3 each, coupled to two secondary clarifiers with a volume of 80 m^3 each. The PBRs are equipped with paddle wheels to keep the phototrophic biomass in suspension and in contact with solar radiation. To enhance the growth of PPBs, the photobioreactors are covered by filters that allow only the passage of infrared radiation.

Figure 1 (A) ANPHORA® demonstrative photobioreactors; (B) Secondary clarifiers at WWTP Linares.

Start-up of the PBRs was carried out in August 2022 and since then they have been operated in batch mode to enhance the growth of the PPB biomass, feeding the different batches with primary settled wastewater from Linares WWTP with the average composition (SD in brackets): BOD_5: 134 (31), TCOD: 241 (34), TSS: 85 (10), TN: 45 (9), TP: 4 (1), BOD/COD: 0.6 (0.1), pH: 7.7 (0.1) and conductivity: 659 (61) μScm^{-1}.

NH_4^+, PO_3^{4-}, total and soluble COD, TN and TP concentrations were determined by commercial colorimetric kits (Hach Lange, Spain). TSS, VSS and BDO5 were measured according to standard methods (Standard Methods, 2005). The phototrophic activity ratio was calculated according to the relationship between the absorbance measurement of the biomass at 850 nm and at 660 nm.

Results and Conclusions

During the start-up the PBRs were operated in batch mode for more than three months, achieving the removal efficiencies of the soluble components (sCOD, NH^{4+} and PO_4^{3-}) as shown in Table 1. Soluble COD removal was maintained at a range from 30 to 50% to keep PPB in a constant exponential growth phase. Within the batch periods, NH^{4+} and PO_4^{3-} removal efficiencies have steadily increased up to almost 100% and 25%, respectively.

This increasing removal efficiency is a clear indication of the growth of PPB biomass within the PBRs. Figure 2 shows the evolution in the concentration of MLSS, as well as the evolution of the ABS850/ABS660 ratio. The concentration of the MLSS followed a positive evolution but stagnated at the end due to intense rains lowering the organic load of the feed. Regarding the ABS850/ABS660 ratio, a positive evolution over time can be clearly seen, reaching values above 1.1, indicating that the biomass is enriched in PPB.

Table 1 Average removal efficiencies in demonstrative PPB photobioreactors.

Batch number	Duration	sCOD (%)	NH^{4+} (%)	PO_4^{3-} (%)
1	8	29.8	35.9	2.2
2	5	30.3	71.7	3.5
3	6	36.9	47.4	3.7
4	7	77.6	72.0	4.1
5	6	43.6	99.8	5.6
6	6	34.6	54.9	6.0
7	9	55.4	76.0	25.8
8	11	37.4	99.6	14.9
9	8	38.5	98.6	10.9
10	5	27.9	42.8	23.7
11	5	26.8	99.9	21.0

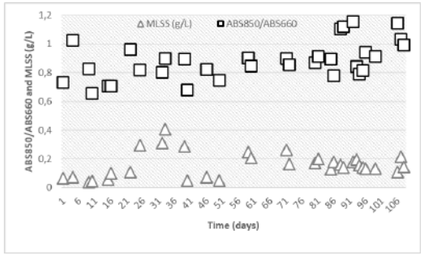

Figure 2 Time course of MLSS and ABS850/ABS660 ratio in demostrative PPB photobioreactors.

At the end of each batch, the photobioreactors are emptied and the biomass is conducted by gravity to the secondary clarifiers. There, the separation of the liquid and solid phases is carried out, the biomass being recirculated back to the PBRs and the treated effluent sent by gravity to the discharge of Linares WWTP. The treated water was compared to the Spanish discharge limits for areas without nutrient removal (COD, BOD5 and TSS). Figure 3 depicts the evolution of water quality treated by demonstrative PBRs using PPB, which consistently complied with discharge limits, with average concentrations of 55 mg COD/L, 12 mg BOD5/L and 10 mg TSS/L, respectively.

As shown in Table 1, the elimination of N and P is depending on operational parameters, and can be adapted to various requirements. For water reuse during irrigation periods, the nutrients can be maintained to bring fertilizers for crop watering, while for sensitive receiving waters low nutrient limits can be achieved.

Once the PPB biomass has been established (Abs 850/Abs 660 > 0.9) and the optimal MLSS (0.5-0.6 g/L) concentration has been reached, the operation mode will be switched to continuous mode with the aim to increase overall treatment capacity. Biomass characteristics also depend on operational parameters, and enrichment of PHA are observed at higher COD influent loadings. The fertilizer value of the biomass and the options of bioplastics extraction were evaluated, to complete a cost/benefit analysis and Life Cycle Assessment, and achieve an energy positive balance and a favourable carbon footprint for water reuse applications.

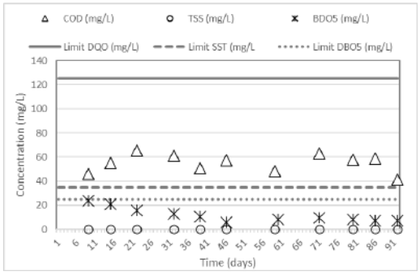

Figure 3 Time course of COD, TSS and BDO5 concentrations in treated water against discharge limits by Spanish regulation (EU Urban WWTD).

Abstract

The mechanisms involved in the removal of a mixture of four veterinary antibiotics (VA) – tetracycline (TTC), ciprofloxacin (CPF), sulfadiazine (SDZ) and sulfamethoxazole (SMX) – in synthetic wastewater using microalgae-bacteria consortia (MBC) dominated by Scenedesmus almeriensis was studied at different initial concentrations of 1000, 500, 100 and 20 µg/L per antibiotic. Ultra-high performance liquid chromatography and tandem mass spectrometry (UHPLC-MS/MS) were used to determine the removal of the VA for each mechanism. For a hydraulic retention time of 4 days, the overall removal of antibiotics by the MBC was 99.9% for TTC, 78.0% for CPF, 52.6% for SDZ and 5.0% for SMX. A pseudo-first order irreversible model was applied to best fit the experimental data. The degradation constant rates were 0.136 h^{-1} for TTC, 0.012 h^{-1} for CPF, 0.010 h^{-1} for SDZ and 0.0007 h^{-1} for SMX. Under all the evaluated conditions, CPF and TTC exhibited the highest removal efficiency. Biosorption was the main mechanism for all four antibiotics, followed by biodegradation in the cases of TTC and SDZ. CPF did not show removal via biodegradation. SMX did not show removal via hydrolysis or photolysis. This study i) integrates and evaluates individually the mechanisms involved in VA removal using an MBC; ii) determines an overall removal rate constant for a wide array of TTC, CPF, SDZ and SMX concentrations; and iii) demonstrates the high removal capacity and potential use of microalgae as an ecofriendly wastewater treatment process.

Keywords
Biodegradation; Biosorption; Hydrolysis; Microalgae; Photolysis

INTRODUCTION

The fate of antibiotics in microalgae-based systems is largely unknown. In order to broadly use microalgae in wastewater treatment applications for the removal of antibiotics it is critical to assess the mechanisms involved in this process. With this objective, the aim of this study was to determine the mechanisms of TET, CIP, SDZ and SMX removal using a microalgae-bacteria consortium from a high-rate algae pond (HRAP) used for piggery wastewater treatment. The four antibiotics were chosen as representative compounds of three families of antibiotics most found in water samples (fluoroquinolones, sulfonamides and tetracyclines). Different initial concentrations were analyzed, similar to those found in real water samples.

MATERIALS AND METHODS

Tests were performed in 1 L glass beakers containing 1 L Milli-Q water spiked with a mixture of 4 antibiotics to a final concentration of 1000, 500, 100 or 20 µg/L per antibiotic. After taking a first sample to determine the initial antibiotic concentration in each reactor, the microalgae-bacteria consortium were added (on selected reactors for biosorption and biodegradation) under continuous mixing to obtain a concentration of 1 g/L. Samples were taken at different time intervals until 4 days of operation. Experiments were conducted in triplicate.

RESULTS AND DISCUSSIONS

Removal of VA by the MBC

The whole process for VA removal using a MBC was studied in batch experiments for 96 h. For a mixture of the four aforementioned VA, the initial concentration decreased over time. The removal efficiency of VA by the MBC is highly dependent on the antibiotic classes, as was indicated by other authors (Leng et al., 2020). In all the conditions studied, only TTC was completely removed. In order to understand the mechanisms of VA removal, hydrolysis, photolysis and biodegradation were studied. As biosorption was expected to be the most important removal process, biosorption data was reported separately in a previous study (Zambrano et al., 2021). Data showed biosorption as the main removal process for CPF and TTC; however, it was not significant for SDZ and SMX removal. Batch experiments without algae under dark conditions indicated that antibiotic hydrolysis took place. The initial concentration decreased over time for three antibiotics, except for SMX which was not removed by hydrolysis in any of the studied conditions. Antibiotic photolysis was studied in batch experiments without algae under illuminated conditions. SMX was not removed by photolysis in any of the studied conditions. For the other three antibiotics, a decrease in the initial concentration over time was more prominent for 20 µg/L. VA biodegradation was also studied in batch experiments for 96 h. CPF did not biodegrade under any of the studied conditions. From the four antibiotics, SMX had the highest biodegradation capacity, possible due to a good adaptation of S. almeriensis to this antibiotic because other algae of the genus Scenedesmus, such as Scenedesmus obliquus, have been shown to have an efficient adaptation mechanism for SMX (Leng et al., 2020). In the following sections, the kinetics of the removal of VA using a MBC and each of the removal modes involved in this process will be determined.

Kinetics for the removal of VA using MBC

The removal of TTC, CPF, SDZ and SMX was investigated with zero-order and pseudo-first order kinetic models (the latter being both an irreversible and a reversible reaction). R^2 values closer to unity were presented by the pseudo-first order irreversible kinetic model (Fig.1). This model fit the best to the experimental data for the whole process of VA removal via the MBC as well as for hydrolysis, photolysis and biodegradation. In the whole process of VA removal it was observed that TTC, CPF and SDZ were removed faster than SMX. The highest rate constant was presented by TTC. The pseudo-first order irreversible rate constant for the removal of VA by the MBC were 0.1362 h^{-1} for TTC, 0.0119 h^{-1} for CPF, 0.0098 h^{-1} for SDZ and 0.0007 h^{-1} for SMX. The pseudo first-order irreversible rate constant k for the removal of VA by hydrolysis were 0.0001 h^{-1} for TTC, 0.0002 h^{-1} for CPF and 0.0004 h^{-1} for SDZ. The pseudo first-order irreversible rate constant k for the removal of VA by photolysis were 0.0011 h^{-1} for TTC, 0.0012 h^{-1} for CPF and 0.0005 h^{-1} for SDZ. On the other hand, k values found for biodegradation were 0.0018 h^{-1} for TTC, 0.0026 h^{-1} for SDZ and 0.0006 h^{-1} for SMX. In our previous work, biosorption kinetics were evaluated and a pseudo second-order kinetic model best fit the biosorption experimental data. The results suggested that the rate constant increased with a decrease in the initial VA concentration and that CPF presented the highest k value (Zambrano et al., 2021).

Removal of VA using MBC

The removal of the four VA MBC is shown in Fig. 5B. The VA results are consistent with the ones previously reported in the literature. In the present study, TTC removal was complete after 5.7 days. Current results showed that CPF removal was complete after 15 days. In the case of SDZ, removal was 88.3 and 92.5% after 9 and 12 days, respectively. Finally, SMX removal was 10.9, 16.6 and 20.6% after 7, 11 and 14 days, respectively. The comparison of the results obtained in the present study with those previously reported in the literature showed that the VA removal efficiency is highly dependent on the algae strain used for the water treatment process and that the S. almeriensis algae-bacteria consortium presented good removal efficiencies. For comparison purposes, removal efficiencies are reported in Table 1. Biosorption data was reported in our previous study (Zambrano et al., 2021), where CPF and TTC exhibited the highest removal efficiencies. Removal efficiencies of biosorption ranged between 74.6 – 81.5% for TTC, 43.5 – 100% for CPF, 11.6 – 30.4% for SDZ, and 0 – 31.5% for SMX. The removal of the four VA by hydrolysis is shown in Fig. 6B. SMX was not removed by hydrolysis. Using the kinetic parameters obtained in the previous section, it can be estimated that the complete removal of TTC, CPF and SDZ using only hydrolysis could be achieved after 1204, 956 and 400 days, respectively. In view of these results, and due to the hydrophobic characteristics of the four antibiotics analyzed in this study, hydrolysis is not representative in VA removal. The removal of the four VA using a MBC by photolysis is shown in Fig. 7B. The complete removal of TTC, CPF and SDZ can be achieved after 162, 125, and 311 days, respectively, while SMX was not removed by photolysis. The removal of the four veterinary antibiotics using a microalgae-bacteria consortium by biodegradation is shown in Fig. 8B. The complete removal of TTC, SDZ and SMX can be achieved after 125, 31 and 292 days, respectively. CPF was not removed by biodegradation.

CONCLUSIONS

To our knowledge, the mechanisms involved in the removal of TTC, CPF, SDZ and SMX in synthetic wastewater using a Scenedesmus almeriensis microalgae-bacteria consortia, as well as the determination of their rate constants by fitting experimental data over a wide range of concentrations to a single general equation, were analyzed for the first time. Working with a pH of 8 and a mixture of low concentrations of four VA that resemble the characteristics of real water samples, the MBC proved to be highly efficient in the removal of a mixture of VA. The overall removal of the four VA followed a pseudo-first order irreversible kinetic. Biosorption turned out to be the most important removal process for the four antibiotics while hydrolysis was insignificant. Hydrolysis and photolysis took place in the removal of the VA except for SMX. Biodegradation was an important mechanism for TTC, SDZ and SMX but was not present in CPF removal. Further investigations must focus on the optimization of operational parameters to improve photolysis and biodegradation in order to increase VA degradation. Additionally, studies should be done on byproduct formation in pursuit of a widely used industrial scale implementation of microalgae-based technology for the removal of VA.

Table 1. Efficiency for the different removal mechanisms of veterinary antibiotics in synthetic wastewater using microalgae-bacteria consortia (4 day hydraulic retention time)

Compound	Removal (%)				
	Global process	Hydrolysis	Photolysis	Biodegradation	Biosorption*
Tetracycline	99.93	1.03	6.83	14.29	74.61 - 81.53
Ciprofloxacin	78.01	1.39	7.29	0	43.45 - 100
Sulfadiazine	52.58	2.94	3.94	9.94	11.62 - 30.35

Abstract
Aerobic granular sludge is an advantageous technology for wastewater treatment, however its actual operating mode by cycles is inefficient if used at full scale. The design of continuous-flow reactors could improve the application of this technology. We designed and evaluated a single-chamber continuous-flow reactor at lab-scale with the aim to know if it could maintain a good granulation while achieve a successful organic matter removal rate. After the operation, it could be concluded that the new reactor was able to adapt the microbial community to the new conditions, leading to compact and well-structured biomass able to reach a 90% of organic matter remotion. The presented design could be an optimal alternative to implement at full scale.

INTRODUCTION

Aerobic granular sludge technology (AGS) is an advantageous biological system for wastewater treatment. It is based in the formation of dense spherical biofilms, which are responsible of the technology's advantages over other systems (Nancharaiah and Kiran Kumar Reddy, 2018). The high density of granules promotes high concentrations of biomass. Moreover, granules are able to withstand toxic substances and influent changes. Furthermore, there is a redox gradient along the granule, that promotes the selection of different microorganisms, which makes possible the simultaneous removal of diverse pollutants. Additionally, the excellent settleability properties avoid the implantation of a secondary settling tank. All these advantages improve the water quality and lead to energy and cost savings. Traditionally, AGS has been operated in sequential batch reactors. However, this mode of operation has difficulties when it is implemented in wastewater treatment plants (WWTPs) at full-scale, due to the continuous character of the wastewater's arrival to the WWTPs. For that reason, the use of continuous-flow reactors (CFRs) improve the application of AGS at full-scale, because it allows easier operation, technology compaction and the treatment of larger volumes of wastewater (Kent, 2018). But CFRs have traditionally two disadvantages, on one hand, the low retention capacity and, on the other side, the accumulation of fluffy aggregates that destabilize the system. Recent investigations are being made to avoid these drawbacks, but, until this moment, an efficient single-chamber reactor had not been implemented.

Our research group designed and evaluated a single-chamber CFR for treating wastewater with AGS, with the aim to create an alternative to implement at full scale and improve de biological treatment.

MATERIALS AND METHODS

The bioreactor consisted on a cylinder of 10 cm of diameter and 72 cm of height with an eccentric cone where the air diffuser was placed. The operative volume was 6 L. The influent was introduced incessantly at mid-height of bioreactor, while effluent overflowed continuously by the output which was located at the top. To avoid the loss of granules, a decanter of 6.3 cm of diameter was placed in the water discharge zone. With this element, granular biomass could not reach the outlet zone while floc biomass could. The influent was a synthetic medium that simulated urban wastewater. The bioreactor was inoculated with 600 mL of granular sludge from a sequential batch reactor, and it was operated for 55 days with a hydraulic retention time of 6 h.

During the experimentation, chemical oxygen demand (COD) and biological oxygen demand (BOD_5) were quantified to evaluate the removal rate of organic matter. Moreover, to control the biomass, mix liquor suspended solids (MLSS), mean size and settling velocity of granules were determined. On the other hand, next generation sequencing was made for Prokarya and Eukarya. The raw data were analysed and sequences were classified against SiLVA nr v132 database and clustered into operational taxonomic units (OTUs).

RESULTS AND DISCUSSION

Granular characteristics

Granules increased their mean size and achieved a value around 12 mm. In terms of MLSS, reactor stabilized at 2.5 $g \cdot L^{-1}$, but at the end of experimentation, biomass concentration reached 3.5 $g \cdot L^{-1}$. Regarding the settling velocity of granules, they reached more than 100 $m \cdot h^{-1}$, which meant that granules had high density, a key parameter to reach the optimum purpose of AGS. In terms of organic matter removal performance, the system achieved around a 90%. These values do not differ from those obtained from sequential batch reactors, so the CFR could be implemented in WWTPs.

Microbial community dynamic

Microbial community dynamic showed that the dominant OTUs of the inoculum were displaced and other OTUs dominated the system, due to the change in operational conditions and reactor configuration. In this way, the most dominant phylotype of prokaryotic community in the inoculum was OTU02, which belonged to the *Chitinophagaceae* family, with a 8.8% of total relative abundance, followed by OTU04 (8.3%), OTU01 (7.1%) and OTU06 (5.9%), affiliated to the *Allorhizobium-Neorhizobium-Pararhizobium-Rhizobium* genus, the *Brevundimonas* genus and the *Xanthobacteraceae* family, respectively. After the operation in the novel CFR, OTU01, and OTU06 suffered a sharp reduction until 0.6% and 1.4% of total relative abundance respectively at day 55. On the contrary, OTU03 increased its total relative abundance until 11.1%. It belonged to the *Xanthomonadaceae* family, a group of microorganisms with extracellular polymeric substances excretion activity. On the other hand, for eukaryotic community, OTU01 was the dominant phylotype in the inoculum with a 63.3% of total relative abundance, followed by OTU02 (13.1%) and OTU04 (12.5) belonging to the *Ascomycota* phylum, the *Hypocreales* order and the *Trichosporonaceae* family respectively. While at the end of the experiment with the new bioreactor, the dominant phylotypes were OTU01, with 62.1% of total relative abundance, OTU03 affiliated to the *Peronosporomycetes* class with a 15.8% and OTU07, an unclassified *Eukaryota* with 8.1%.

Abstract
Surfactants are among the most widely disseminated xenobiotic that contribute significantly to the pollution profile of sewage and wastewaters of all kinds. Among the currently employed chemical unit processes in the treatment of wastewaters, coagulation-flocculation has received considerable attention for yielding high pollutant removal efficiency. Dissolved Air Flotation-DAF, is a well-established separation process that employs micro-bubbles as a carrier phase.DAF can be divided into three group. pressure atmospheric & vacuum . In this work effect of aeration rate & retention time were investigated on COD removal of detergent industries wastewater.
Keywords: surfactant; wastewater; air flotation

Introduction

For many applications of flotation in the wastewater treatment field, it is more efficient to use micro-bubbles generated by nucleation of dissolved air, rather than the dispersed air method used for minerals. Flotation offers process advantages over sedimentation, including better treated-water quality, rapid startup, high rate operation, and thicker sludges. DAF is considered not only an alternative to sedimentation plants, but also a clarification method to improve filtration. In this work we tried to remove surfactant with air flotation. DAF tests were carried out using pilot units (Figure 1). The operational specification of system is according to table 2 and physicochemical characteristic of effluents is shown in table 1. Process efficiency was evaluated by measuring COD removal. We find that increase in aeration rate up to 200 ml/min will remove surfactant but after more increase in rate COD removal will reduce. It is because of reduce in bubbles retention time, increase in wet bubbles & reduce solution height which cause solution of more foam. According to the results, in short retention time, aeration rate of 250 ml/min has the best recovery for COD removal. But with increasing in retention time ,aeration rate of 200 ml/min has the best recovery.(figure2)

Abstract
Many challenges are decelerating solving the global sanitation problem , such as the financial limitations and lack of technical capacities. Parallel to this, many countries are facing a growing demand on their limited water resources. There is a growing interest in finding low-cost, easy-to-operate and sustainable sanitation solutions. Constructed wetlands (CWs) in recent years have proved their capability in the sanitation sector as an appropriate sanitation system in different contexts, CWs have proved their ability to treat several types of wastewaters for several decades. Several benefits and facts, such as the low construction and operational costs of CWs, low-energy, and less operational requirements, have raised the interests in CWs as a treatment technology. Several studies have investigated CWs suitability based on different sustainability indices (technical,social, environmental, etc.). In this paper we tried to investigate the experiments about the use of wetlands for wastewater treatment in iran.

The utilization of environmentally friendly and eco-safe wastewater treatment plan is nowadays widespread. There are the different conventional methods for wastewaters treatment such as active sludge process (ASP), rotating biological contactor (RBC), stabilization ponds, oxidation ditch, trickling filter (TF), sequence batch reactors (SBR), lagoons and up flow anaerobic sludge blanket (UASB), Micro-algae techniques etc.. These methods having the limitations like energy, economic, complex construction and operation, sensitive to temperature and excessive sludge. Currently, the global interest for simple, safe, cost-effective and green technology has been developed. Constructed wetland as a natural process, environmentally friendly, eco-friendly with simple construction and low maintenance is one of the interested technique. Constructed wetlands (CWs) as human made basin according to engineering design that create ecological condition same to natural wetlands for treating wastewater in different physical, chemical and biological conditions. Figure1.

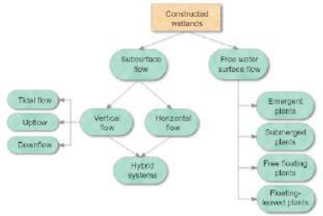

Figure 1. Classification of constructed wetlands for wastewater treatment

The effect of artificial wetland treatment of Qasr-e-shirin in Kermanshah province on water quality, growth performance and biochemical composition of fish body for optimal use in the aquaculture industry was investigated. In this study, water quality parameters including turbidity, DO, COD,MPN total coliform, nitrate, phosphate, and experiments in sections of bioassay, monitoring of aquatic tissue due to the presence of pathogens were satisfactory.The results show that the COD, turbidity and MPN values of the total effluent from the treatment plant are 33 mg/L, 13.4 NTU and 230,000, respectively. Effluent analysis took place after passing through the UV pool. and complete dewatering of the pool with treated and disinfected effluent; COD, turbidity and MPN values of total coliform were 25 mg/L, 13 NTU and 8000, respectively. The microbial load of the effluent is dramatically reduced by passing through the UV pool.figure2.

Figure 2. pool dewatered by wastewater treated by wetland method

The applications of constructed horizontal surface flow (HF-CW) wetland with two different local plants (Louis latifoila and Phragmites -australis (Cav.) Trin) at the wastewater treatment plant in Babol city Iran was investigated. This system was designed as an advanced treatment unit in field scale after the treatment plant. Parameters such as Total Dissolved Solid (TDS), Total Suspended Solid (TSS), Turbidity, Biological Oxygen Demand (BOD) and Chemical Oxygen Demand (COD), were investigated. The result shows that treatment efficiency increases with the passage of time. The efficiency of Phragmites planted setups in open environment was fairly good for all studied parameters (28.6% of TDS, 94.4% for TSS, 79.8% for turbidity, 93.7% for BOD and 82.6% for COD). The efficiency of the latifoila set up was also good, but lower than that of Phragmites (26.5% of TDS, 76.9% for TSS, 71.5% for turbidity, 79.1 for BOD and 68.8% for COD).figure 3.

Figure3. Set up of constructed wetland built in an open field environment.

As alternative to the conventional treatment systems, the constructed wetlands are man-made systems implemented for the control of environmental pollution control by natural treatment of a variety of wastewaters including industrial effluents, domestic, municipal, agricultural, livestock wastewaters, sludge, and landfill leachate.
Wastewater treatment is achieved in constructed wetlands through a combination of biological, physical and chemical interactions between plants, substrate and microorganisms. Vegetation plays a vital role in the treatment, because it provides surfaces and a suitable environment for microbial growth and filtration. A wide variety of contaminants, such as suspended solids, organic compounds, nutrients, pathogens, metals, and emerging contaminants are effectively removed in constructed wetlands.

Abstract

This study focuses on evaluating the fate of microplastics retained in the sludge during mesophilic anaerobic digestion. For this purpose, two laboratory-scale digesters were operated in parallel; the first one is a conventional anaerobic digester and was operated at 20 days hydraulic and sludge retention time (HRT and SRT, respectively). The second reactor was an anaerobic membrane bioreactor (AnMBR) equipped with an ultrafiltration membrane which allowed the decoupling of the HRT and SRT values, thus increasing the retention of biomass to 40 days. Both digesters were continuously fed with a combination of primary and secondary sludge from a wastewater treatment plant. The results obtained show that the AnMBR is more efficient than the conventional digester in terms of biomethanization (58 % vs. 39 %), methane production (0.20 L CH_4·g COD^{-1} vs. 0.16 L CH_4·g COD^{-1}) and microplastics removal (89 % vs. 62 %).

INTRODUCTION

The inefficient end-of-life management of diverse plastic materials represents a global environmental challenge that affects the quality of human life, wildlife, and ecosystems (Cazaudehore et al., 2022). One of the greatest concerns regarding plastic pollution comes from the so-called "microplastics" (MPs), i.e. plastic particles with sizes smaller than 5 mm that account for up to 90% of total microlitter (ML) present found in waters (OSPAR Commission, 2014). MPs may be vectors for toxic micropollutants (originally present in their production processes or subsequently adsorbed on their surface), for priority pollutants (i.e., organochlorine pesticides, polycyclic aromatic hydrocarbons, polychlorinated biphenyls, and polybrominated diphenyl ethers) and pathogens (Gatidou et al., 2019). Some of these MPs are directly released into the environment (primary MPs) but most result from the deterioration and fragmentation of coarser plastic pieces subjected to physical, chemical, and biological processes (secondary MPs). Many MPs are found in urban and industrial wastewater and thus wastewater treatment plants (WWTPs) act as the final barriers to reduce MPs emissions into the aquatic environments, with efficiencies of over 90 % (Edo et al., 2020). As a result, MPs are mainly transferred from wastewater to the sludge. Therefore, sludge management is of great importance to reduce or even avoid the spread of the retained MPs, especially when digested sludge is used for agricultural soil amendment (Cesaro et al., 2022). Anaerobic digestion (AD) is the most common process applied in medium-large WWTPs to stabilize waste sludge, but only a few studies have investigated the fate of MPs in anaerobic digesters (Chand et al., 2021; Mahon et al., 2016). This work aims to assess the MPs removal in two laboratory-scale mesophilic anaerobic digesters (one conventional anaerobic digester (AnR) and the other one equipped with an ultrafiltration membrane) fed with mixed sludge from a conventional WWTP. Moreover, COD removal, methane production and microbial population are also evaluated to compare the effect of the ultrafiltration membrane on the AD process.

MATERIALS AND METHODS

Inoculum and mixed sludge characterization

The reactors were inoculated with sludge from the anaerobic digester of an urban WWTP and were fed with mixed sludge from the same WWTP. The characteristics of the substrate and inoculum used are shown in Table 1.

Experimental set-up and operating conditions of continuous anaerobic digesters at lab-scale

The experimental set-up consisted of two cylindrical methacrylate tanks with a total volume of 14 L and a working volume of 8 L (Figure 1). Both systems were equipped with a data acquisition program used to monitor pH, redox, and temperature through electrodes, headspace pressure using a pressure transducer and volumetric biogas production using a milligas counter. In addition, the anaerobic membrane bioreactor (AnMBR) was equipped with an external hollow-fiber ultrafiltration membrane module (PURON Koch membrane systems, 0.03µm pore size) with a surface area of 0.42 m^2, installed in a membrane tank with a total volume of 1 L and a working volume of 0.9 L. The permeate pump was programmed to operate the membrane in three different modes: filtration, backwash, and relaxation. Regarding the operating conditions, both reactors were maintained for 130 days in mesophilic conditions and they were operated at an organic loading rate (OLR) of 1.69 g $COD{\cdot}L^{-1}{\cdot}d^{-1}$. The SRT and HRT were set at 20 days in the AnR reactor. The AnMBR reactor was operated at an SRT of 40 days and an HRT of 20 days.

AD performance analyses

Samples from both reactors, the AnMBR permeate and the feed sludge were analyzed weekly to evaluate the biological process performance. The following parameters were analyzed in duplicate and using standard methods (APHA, 2017): total and soluble COD (T-COD and S-COD, respectively), total solids (TS), volatile solids (VS), total suspended solids (TSS), volatile suspended solids (VSS), volatile fatty acids (VFA), alkalinity (ALK), total nitrogen (T-N), ammonium (NH_4-N), total phosphorus (T-P), phosphate (PO_4-P), and sulfate (SO_4-S). Biogas samples from the reactor headspace were collected three times a week, and the methane content was analyzed by a gas chromatograph fitted with a flame ionization detector.

Microbial population analyses

Three samples were collected from the AnMBR and the AnR in the pseudo-steady period when COD, TS and biogas production showed variations lower than 10% and were therefore considered biological replicates. Following the E.Z.N.A. ® Soil DNA Kit-Protocol the nucleic acid material was extracted from all the samples and sequencing was performed during the Illumina sequencing platform.

Microplastic analyses

MPs were extracted from sludge during a three-step process, including sludge purification by adding 30% hydrogen peroxide (H_2O_2) to oxidize the organic material, density separation using sodium chloride (NaCl) (1.2 g/mL), and filtration through stainless steel grids of different mesh sizes (500, 104 and 41 µm). The quantification of microplastics was carried out by gravimetric analysis and samples of the particles retained by the larger mesh were collected for analysis by FTIR-Attenuated Total Reflectance (FTIR-ATR) to identify genuine MPs particles from other microlitter (i.e. other inorganic and organic materials such as metals, wood, rubber, glass and paper) that can be extracted with the MPs during the experimental procedure.

RESULTS AND DISCUSSION

Table 2 shows the sludge characterization of both digesters at the end of the experimental period when a pseudo-steady state was reached. The higher SRT in the AnMBR resulted in higher biomethanization (58% vs. 39%) (Figure 2) and higher methane production (0.20 L CH_4·g COD^{-1} vs. 0.16 L CH_4·g COD^{-1}) (Table 3) than in the AnR. Regarding MPs biodegradation, the results obtained again suggest a higher removal efficiency in the AnMBR (89 %) than in the AnR (62 %) (Table 4). It is yet to be determined whether the higher removal rates observed in the AnMBR are due to the degradation obtained from the longer SRT, or due to the adsorption of MPs on the biomass cake layer of the membrane. Also, as other authors have stated (Chand et al., 2021), MPs reduction in the digesters could have been caused by plastic degradation, depolymerization or fragmentation of the particles to sizes below 41 µm (i.e. the detection limit for the applied analytical method). Differences between microbial populations in both digesters are being assessed.

Abstract
LIFE BIODAPH$_2$O is a demonstration project that has the main objective of scaling-up and implementing an eco-efficient nature-based tertiary wastewater treatment (BIODAPH) at two demo sites located in two water-stressed regions of the Mediterranean area, Quart WWTP (Spain) and Antissa WWTP (Greece). During the execution of the project, the impact of the implementation of this technology on the ecological and chemical status of the receptor aquatic media in Spain and the irrigated agroforestry media in Greece will be assessed. The BIODAPH system is based on the depuration capacity of biological organisms: water fleas (*Daphnia*), microalgae and biofilms for removing pollutants (nutrients, organic carbon, suspended solids, pathogens, heavy metals, emerging and priority pollutants, and micro plastics). This compact and low-energy consumption system does not produce sludge nor uses chemicals.

Keywords: Daphnia; nature-based tertiary system, water reclamation, micropollutant removal.

INTRODUCTION

The project aims to demonstrate the effectiveness of BIODAPH technology, an eco-efficient and nature-based wastewater tertiary treatment, in producing reclaimed water while at the same time reducing dependence on conventional energy sources, in accordance with circular and green economy criteria. This will be applied in wastewater treatment plants to diminish discharges of pollutants and pathogens in freshwater ecosystems and promote agricultural reuse of the reclaimed water. The BIODAPH technology combines the filtration capacity of zooplankton (*Daphnia*) with the capacity of bacterial and algal biofilm to remove nutrients. In previous studies, we have demonstrated that *Daphnia* can remove particles <35 µm that do not settle in secondary clarifiers or do so slowly. The removal of solids is associated with a decrease in organic matter and pathogens such as coliforms and *E. coli* from secondary wastewater. However, *Daphnia* is sensitive to common contaminants when they are at raw wastewater levels (e.g. organic matter, ammonium and nitrite, and metals) and, thus, the integration of zooplankton in wastewater treatment lines is limited to a tertiary treatment (Pous et al., 2020). With regard to organic micropollutants, *Daphnia* filtration had shown high efficiencies (80% average) in the removal of pharmaceuticals and personal care products (Matamoros et al., 2012). As for microplastics, given that *Daphnia* are efficient filters for suspended solids, it can be expected that they are also efficient filters for microplastics; a hypothesis that has received support in as laboratory experiments (Colomer et al., 2019). Up to now, no results have been published regarding the capacity of *Daphnia* to remove perfluoroalkyl substances (PFAs) and antibiotic resistant genes (ARGs).

METHODOLOGY

The project aims to design a 100 m^3 reactor, scaling up from the 1.5 m^3-cylindric reactor previously developed within the framework of the INNOQUA project (https://innoqua-project.eu/). Two of these large-scale reactors will be connected to an activated sludge secondary treatment at Quart (Spain) to treat 200 m^3/d, whereas in the case of Antissa (Greece), a reactor that is able to treat a maximum of 50 m^3/d will be connected to a treatment system that combines an upflow anaerobic sludge blanket reactor (UASB) with constructed wetlands (https://www.hydrousa.org/).

The optimisation of the key design factors of the BIODAPH reactor will be carried out by monitoring its efficiency in terms of the biological, microbiological and chemical quality of the effluent to meet the standards set out in the Water Framework Directive (Directive 2000/60/EC) and the requirements for agricultural irrigation (EU Directive 2020/741) as well as to reduce the discharge of emerging contaminants such as pharmaceuticals and microplastics into the aquatic media. The sustainability assessment impacts of the technology will be assessed (environmental LCA, techno-economic LCC, and socio-economic S-LCA). The feasibility of the process will be evaluated using environmental technology verification (ETV). An economic validation, including the exploitation and the business plan and the assessment of the transferability and replicability of the BIODAPH technology, will also be performed.

EXPECTED RESULTS

- Demonstration of the capacity of the BIODAPH technology to remove emerging pollutants: ~70%, for pharmaceuticals, ~90% for antibiotic resistant genes (ARGs), ~80% for microplastics, and ~60% for perfluoroalkyl substances (PFAs).
- Demonstration of the capacity of the BIODAPH system to reach the standards set in national wastewater reuse guidelines and recent EU regulations (2020/741 of the European Parliament) on minimum requirements for water reuse (PE/12/2020/INIT). To recover and recycle resources by discharging reclaimed water with low nutrient content (~50%) and reduce the regulated microbiological parameters by between 90 and 99%.
- Production of reclaimed water with improved quality to reduce the impact generated by the discharge of treated sewage waters in the River Onyar at the Spanish site. At the Greek site, a reduction in the use of freshwater and potable water for agricultural irrigation, which will also reduce the environmental impacts associated with wastewater release into the aquatic media.
- Energy consumption reduction of more than 90% and a carbon footprint and greenhouse gas production reduction of more than 80% in comparison with conventional tertiary wastewater treatments.
- Significant reduction in operating costs (OPEX) as the treatment is free from chemicals and is less energy intensive.

AGNOWLEDGEMENTS

This research is co-funded by the European Union Life Programme under Grant Agreement nº 101074191 - LIFE21-ENV-ES-BIODAPH2O and the Spanish Ministry of Science and Innovation (Project TED2021-132721B-100).

Abstract
This work is focused on the study of Specific Hydrogenotrophic Methanogenic Activity (SHMA) tests, as a practical tool for the monitoring and optimization of biological biogas upgrading process. In view of the development of a standardized protocol, the influence of three main test operating conditions (mixing speed, liquid working volume, and initial H_2 partial pressure) was investigated by analysing data from a total of 42 SHMA tests. Operating conditions were varied to assess their role on the estimation of the SHMA value. Preliminary analyses on data show that SHMA is strongly influenced by mixing speed (in relation to gas-liquid mass transfer process) and by the liquid working volume adopted (affecting hydrodynamics of the test).

Keywords
Anaerobic activity test, anaerobic processes, bioenergy production, biological biogas upgrading, hydrogenotrophic methanogens

INTRODUCTION

Chemoautotrophic biological biogas upgrading is attracting significant attention in order to yield high quality biomethane to be used as an alternative energy source to natural gas. Carbon dioxide and hydrogen can be converted into methane by Archaea hydrogenotrophic methanogens (HM) and the relation describing the metabolic reaction is reported in literature as in eq.1 (Speece, 1983):

$$H_2 + 0.256CO_2 + 0.004HCO_3^- + 0.004NH_4^+ \rightarrow 0.239CH_4 + 0.004C_5H_7O_2N + 0.517H_2O \quad \text{eq.1}$$

This process is naturally carried out during anaerobic digestion at low yield and rate, depending on digester environmental conditions and on the abundance of HM over other microbial species. The opportunity to exploit and boost hydrogenotrophic methanogenesis in order to engineer and optimize CO_2 conversion into CH_4 makes biological biogas upgrading an interesting solution to recycle and reduce carbon emissions to the environment (Zabranska & Pokorna, 2018). Hence, the need for a measuring method of the hydrogenotrophic methanogenesis activity is becoming essential for process monitoring, optimization, and control.

The Specific Hydrogenotrophic Methanogenic Activity test (SHMA) indirectly measures H_2 consumption and thus, methane-specific production rate mediated by HM microorganisms. It is a key tool to evaluate possible inhibition effects or supporting the monitoring of an operating plant. Scientific literature reports about SHMA test results, but, due to the lack of a standardized protocol (Ripoll et al., 2020) the use of SHMA remains a prerogative of the research world. In order to exploit and export this tool for process monitoring at the full-scale, a standardized method needs to be developed. A first step towards this objective is provided by this study, which aims at investigating the role of test operating conditions on SHMA results.

MATERIALS AND METHODS

Guidelines proposed by Coates et al. (1996) and Ripoll et al. (2020) were taken as reference to carry out SHMA tests. MethanTUBE® (Biological Care, IT) instrumentation was used: each 3.76 L reactor is equipped with a digital pressure manometer, temperature regulation system, screws, and gaskets to ensure sealed anaerobic conditions. A total number of 42 trials was performed. Each set of trials included duplicate blank bottles (tests performed with inoculum only) and duplicate activity test bottles. As inoculum, an enriched hydrogenotrophic methanogens culture previously collected from a biological biogas upgrading ex-situ pilot plant, after 300 days of operation, was used. Bottles were fed with inoculum and nutrients. The concentration of inoculum in the reactor on a volatile solids basis (C_{vs}) was kept at 1.52 ± 0.26 g VS·L^{-1}. As soon as the bottle reached the operating temperature, the headspace (V_{gas}) was flushed with a mixture of H_2:CO_2 (80:20 v/v) for 10 minutes (total gas replacement is verified) and, finally, the desired overpressure was set. During the test pressure was continuously measured over time, thus allowing the estimation of H_2 consumption rate and, in turn, of CH_4 production. SHMA is expressed as mL_N CH_4·g VS^{-1}·d^{-1} and is calculated as follows (eq.2), by selecting the maximum slope of the linear part of the curve, before elbow occurred:

$$SHMA = max\left(\frac{\Delta p}{\Delta t} \cdot \frac{V_{gas} \cdot VM}{VS \cdot R \cdot T_{op}} \cdot s\right) \quad \text{eq.2}$$

Where:

- Δp is the pressure increase/decrease at a generic time interval Δt;
- VM is the molar volume at standard conditions (22.414 L_N·mole^{-1});
- VS is the total mass of volatile solids, expressed as g_{VS};
- R is the ideal gas constant (0.0083145 L_N·bar·mole^{-1}·K^{-1});
- T_{op} is the operating temperature of the test (310 ± 0.5 K);
- *s* is the stoichiometric methane production, *s* = 0.239 (eq.1).

Three parameters (values reported in **Table 1**) were selected to elucidate the role of operating conditions on test results: the initial overpressure in the headspace ($p_{gas,0}$, absolute bar), the mixing speed (rpm), and the working volume (V_{liq}). Those parameters have been selected according to their role in gas-liquid mass transfer theory (Jensen et al., 2021; Whitman, 1962).

Table 1. Operating conditions of the tests.

Parameter		Values
$p_{gas,0}$	(absolute bar)	1.2 – 1.6 – 2.0
Mixing speed	(rpm)	0 – 400 – 800
V_{liq}	(mL)	200 – 400 – 600

The combination of tested operating conditions is selected according to a Box-Behnken design of experiments (**Figure 1**), plus an extreme of interest ($p_{gas,0}$ = 2.0 bar, V_{liq} = 200 mL and mixing speed = 800 rpm).

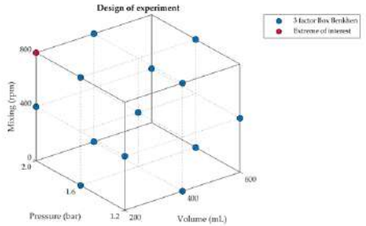

Figure 1. Box-Benkhen DOE graphical representation.

RESULTS

The minimum value of SHMA obtained is 118 mL_N CH_4·g_{SV}^{-1}·d^{-1} and the maximum is 5'709 mL_N CH_4·g_{SV}^{-1}·d^{-1}, showing an order of magnitude variation in the SHMA value. The mean value is 1'622 mL_N CH_4·g_{SV}^{-1}·d^{-1}, the median 1'115 mL_N CH_4·g_{SV}^{-1}·d^{-1}, and a standard deviation of 1'627 mL_N CH_4·g_{SV}^{-1}·d^{-1} which highlights the high variation between SHMA values.

Figure 2 shows the results in form of boxplots. A liquid volume increase results in an average decrease of SHMA values, contrarily to what observed for an increase of mixing speed and initial overpressure (except for $p_{gas,0}$ = 1.6 bar). Possible explanations for these trends are summarized as follows:

1. An increase of mixing speed and, hence, of system turbulence, improves gas-liquid mass transfer rates, allowing for increased concentrations of dissolved H_2 that can be up taken by microorganisms. This means that at high stirring speed, the process rate is limited by gas-liquid mass transfer efficiency to a lower extent, hence resulting in more reliable SHMA values, actually describing the kinetic behavior of biomass;
2. An increase of starting overpressure positively affects substrate availability (Henry's law), hence increasing the amount of hydrogen that can be dissolved in the liquid phase;
3. A liquid volume decrease leads to an increase in both substrate availability (V_{gas} increase) and the turbulence hydrodynamics and, as for the first two points the whole mass transfer of hydrogen.

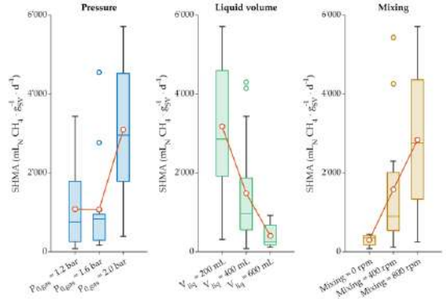

Figure 2. SHMA boxplots at varying of operative parameters. Line connected dots represent mean values for each category.

CONCLUSIONS AND FUTURE DEVELOPMENTS

This work confirms that SHMA values obtained are highly influenced by the operating conditions, varying by more than one order of magnitude. The general conclusion is that SHMA results are influenced by operating conditions which influence the transfer rate (k_La) of the test. As future development, it is necessary to measure also the k_La of the test. Knowing this parameter is fundamental to understanding the SHMA test according to user interests. Moreover, support of data interpretation by means of batch test modelling will be implemented to get more insights.

Abstract

Nitrogen biogeochemical cycling have been one of the most important nutrient cycles in terrestrial environments. By their agriculture and economical importance, there are an excessive nitrogen use in soils that infiltrate to water bodies. Recently, a new biological pathway involved the anaerobic ammonium oxidation coupled with iron reduction and has been called Feammox, has been described. We study the effect of several abiotic and biotic conditions to determine their impact on the Feammox process enriched from wastewater sludges. In this way, parameters such as iron source, temperature, carbon source, pH, and sludge inoculum are tested to determine which conditions allow the best reduction of ferric iron along with the oxidation of NH_4^+.

Keywords
Feammox, iron, ammonium removal, NGS, nitrogen, wastewater.

INTRODUCTION

Recently, a new biological pathway of nitrogen cycle called Feammox, has received significant research attention (Clément et al., 2005). This process occurs in anoxic, iron-rich, and water-saturated systems such as riparian, forested, coastal wetlands, and and wastewater sludge (Kappler et al., 2021). Feammox is a process that can be described as the oxidation of NH_4^+ under iron-reducing conditions, with iron oxides [Ferric iron, Fe(III)] as the electron acceptor (Huang et al., 2016). Fe(III) is reduced to ferric iron Fe(II), while NH_4^+ is transformed to N_2, NO_2^- or NO_3^- (Huang and Jaffé, 2015). As Feammox is related to a particular group of microorganisms, it is evident that the conditions in which they are found will affect their development. Thus, essential factors such as iron source, pH, temperature, and carbon source will affect the microbial composition (Yao et al., 2019; Zhu et al., 2021).

MATERIALS AND METHODS

The Feammox enrichment process was carried out using the two sludge sources collected from two wastewater treatment plants, both located in Santiago, Chile as from anaerobic reactors (EGSB and IC). The cultures were enriched with variable iron sources, initial pH, temperature, and different organic and inorganic carbon sources to determine the optimal conditions for Feammox activity by 42 days. A sequential enrichment process (56 days) was carried out using the best enrichments resulting from the previous stage as inoculum for the next one, discarding the less favorable environmental conditions. For molecular analysis DNA extraction from the sludge and enrichments was performed using the DNeasy® PowerSoil® Pro kit (QIAGEN)). Phylogenetic analysis of the sludge samples and enrichments at the end of incubations were performed by 16S rRNA gene sequencing (V3/V4 region) at Genoma Mayor, Universidad Mayor, Chile. The amplicons were purified, quantified, pooled, and then sequenced on the NovaSeq 6000 platform (Illumina, USA), in 250 pair-end (PE) mode. The DADA2 bioinformatics protocol on the R platform was used for sample analyses (Callahan et al., 2016).

RESULTS AND DISCUSSION

The first enrichments carried out by 42 days with $FeCl_3$ presented better results associated with Feammox activity than Ferrihidrite and Goethite (data non shown). These enrichments were used as inoculum to study the effect of environmental conditions on crop performance in a second step of enrichment by 56 days. Figure 1 summarizes the best conditions related to the Feammox process in a second enrichment. The variable conditions that allowed the optimal Feammox response are constituted by a common culture medium, having $FeCl_3$ as Fe source, sodium acetate as carbon source, at initial pH 7.0 and purged with CO_2 (Figure 1).

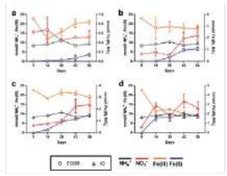

Figure 1. Study of environmental conditions using FeCl3 as iron source: (a) EGSB enrichment as inoculum at room temperature (EGSB 2.1); (b) EGSB enrichment as inoculum at 35°C (EGSB 2.2); (c) IC enrichment as inoculum at room temperature (IC 2.1); and (d) IC enrichment as inoculum at 35°C (IC 2.2). The left and right Y-axes show the concentrations in millimols per liter (mmol/l) of the different chemical species.

The results obtained from the enrichment steps show the importance of incubation temperature and inoculum type. Although the candidates did not show a tendency to decrease the ammonium level, they behaved in the same way in terms of the other parameters NO_3^-, Fe (II) and Fe (III) according to the Feammox process (320% increase in NO_3^- and 1.67 mmoles/l of Fe (II)). On the other hand, it was possible to enrich cultures that can carry out the Feammox process in a period of 56 days. behavioural that are supported by other similar results presented in the literature (Feng et al., 2020; Le et al., 2021).

Given that there is evidence of the occurrence of the Feammox process in our enrichments and sludge, a massive sequencing analysis was carried out to determine the composition of the microbial community. From the sequencing, a total of 1,198,557 reads were obtained from the total of the 8 samples, which indicates an average of 149,820 reads per sample. A total of 1844 ASVs were identified from the data analysis for the 8 samples. The graphs below present the results of the microbial community diversity analysis (relative abundance). Sludge, enrichments, and environmental conditions study samples are reported by Phylum and Class.

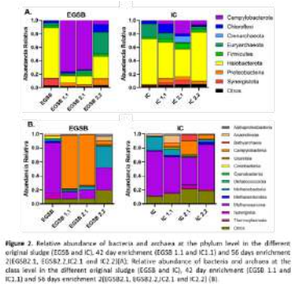

Figure 2. Relative abundance of bacteria and archaea at the phylum level in the different original sludge (EGSB and IC), 42 day enrichment (EGSB 1.1 and IC1.1) and 56 days enrichment 2(EGSB2.1, EGSB2.2,IC2.1 and IC2.2)(A). Relative abundance of bacteria and archaea at the class level in the different original sludge (EGSB and IC), 42 day enrichment (EGSB 1.1 and IC1.1) and 56 days enrichment 2(EGSB2.1, EGSB2.2,IC2.1 and IC2.2) (B).

Abstract
Metal removal from acidic solution is an important issue to deal with both industrial wastewater and environmental pollution. Conventionally, chemical neutralization and precipitation process is applied widely. However, it requires considerable amount of neutralizer and generates waste sludge. Considering this, we proposed a novel concept of bacterial sequential biosorption process under acidic condition. Here, we established a model process using 5 bacterial strains and evaluated metal adsorption abilities from metal solution (pH 1.5, containing 100 mg L^{-1} each of Co, Cu, Li, Mn, and Ni). Among 5 strains, *Priestia* sp. Mn7 was regarded as the most efficient adsorbent. Using the strain, same process was performed, and dynamics of various metals were evaluated. These results suggest metal biosorption of the strain was related to K and Mg release. Although further experiments are expected, this study potentially contributes to develop a sustainable metal removal process by reducing the required additives and generated waste.

Keywords (maximum 6 in alphabetical order)
Acid tolerant bacteria, Acidic hydrosphere, Biosorption, Heavy metal

INTRODUCTION

Rapid spread of information technologies and electric vehicles causes increased metal consumption. Due to this, treatment of wastewater containing various heavy metals is becoming an important issue from both industrial and environmental aspects. To prevent waste metal pollution of hydrosphere and human health problems, various metal removal processes have been proposed. However, there are serious drawbacks in conventional neutralization and precipitation process since they consume large amount of neutralizer and generate a large amount of waste sludge. To improve sustainability and reduce effort and waste generation, biosorption process has been studied, and bacteria, plants, and other biomass have been applied as metal adsorbent (Wang and Chen 2009, Rizvi *et al.* 2020). Although it is an environmentally friendly process, most of the studies on biosorption are performed under neutral pH conditions. On the other hand, metal containing wastewater is mainly acidic pH due to the solubility. Considering this situation, we focused on acid tolerant bacteria as an expected adsorbent that can work under strongly acidic conditions and developed a novel screening method (Takano and Aoyagi 2022). Using this method, acid tolerant metal adsorbing bacteria were isolated. In this study, those strains were applied for a sequential metal biosorption process under acidic condition.

MATERIAL AND METHOD

Material

Four previously isolated bacterial strains and a model bacterial strain *Micrococcus luteus* JCM1464 were used in this study. These strains have exhibited acid tolerance and metal adsorbing abilities under acidic conditions. Considering the wastewater containing metals from waste lithium-ion battery and printed circuit board, simulated metal solution was prepared by dissolving Co, Cu, Li, Mn, and Ni ions in distilled water (pH was modified by using 10× H_2SO_4). Inductively coupled plasma atomic emission spectroscopy (ICPE-9820, Shimazu, Kyoto, Japan, ICP-AES) was applied to metal ions quantification. Standard curves were prepared using ICP multi-element standard solution IV (Merck, Germany).

Sequential metal biosorption process

Adsorbents were prepared by cultivating the 5 bacterial strains overnight (30°C, 160 rpm). According to their metal adsorption ability and selectivity, reaction conditions of sequential metal biosorption process was designed (**Table 1**). The first strain was centrifuged and suspended into simulated metal solution containing 1 g L^{-1} each metal ion. Metal biosorption reaction was performed and bacterial cells were removed. Then, the second strain was suspended to adsorb metals. This process was repeated for 5 strains sequentially. Metal adsorption ability and selectivity of each strain was quantified based on the metal concentrations after each step using ICP-AES. To improve the metal removal efficiency, the same sequential process was performed using the single strain *Priestia* sp. Mn7, the most effective adsorbent.

Evaluation of metal ions dynamics

To clarify the bacterial response to simulated metal solution, dynamics of 23 metal species during the sequential metal adsorption process using the strain *Priestia* sp. Mn7 was quantified using ICP-AES. Same sequential process was performed using acidic solution without metal ions (pH 1.5) to evaluate effect of acidic environmental stress. Bacterial response against the metal solution was estimated based on adsorbed and released metal ions. All experiments were performed in triplicate.

RESULT AND DISCUSSION

Sequential metal biosorption process

The sequential metal biosorption process with 5 bacterial strains adsorbed 6.99% total metal ions from the simulated metal solution (**Table 2**). Although the metal adsorption under strongly acidic conditions was achieved, the efficiency of the process was impractical, and it has a long reaction period. In this study, *Priestia* sp. Mn7 was regarded as the most effective adsorbent considering its high adsorbing efficiency and the highest cell productivity. Using this strain, reaction period was shortened from 6 h to 2.5 h, and metal adsorption efficiency was not affected significantly (7.04%). Although the efficiency of the process is still lower than conventional chemical process (>40%, Provazi *et al.* 2011), metal biosorption process without neutralization was established.

Evaluation of metal ions dynamics

Metal concentration dynamics was evaluated for 23 metal species during the biosorption process. In the acidic solution not containing metal ions, Ca, K, Mg, and Na were released from bacterial cell (Ca: 0.36, K: 13.40, Mg: 2.18, and Na: 1.36 mg g^{-1}-dry cell) compared to the initial acidic solution. Under metal containing conditions, K and Mg concentrations were significantly increased (24.43 and 2.70 mg g^{-1}-dry cell, respectively) after the sequential biosorption process (**Figure 1**). These results indicate that *Priestia* sp. Mn7 releases K and Mg ions to deal with high metal concentrations. Similar response was observed during bacterial enhanced expression of metal efflux pump (Huang *et al.* 2018). Further experiments are required to understand bacterial metal adsorbing mechanisms and to improve the metal biosorption efficiency.

In this study, metal biosorption process under strongly acidic conditions was established using the acid tolerant metal adsorbing bacteria *Priestia* sp. Mn7. The strain can adsorb 5 metals and release K and Mg ions in response to metal existing acidic environment. Although further studies are required, this is the first step to establish a treatment process for metal containing wastewater without neutralization.

Table 1. Reaction order and period of bacterial strains applied to the sequential metal biosorption process and their growth abilities under neutral pH condition.

Order	Strain	Reaction period [h]	Growth ability [g-dry cell L^{-1}]

Abstract
The first pilot scale test of Membrane Aerated Biofilm Reactor (MABR) in Japan was conducted. The MABR total working volume of 14 m^3 was installed at a municipal wastewater treatment plant (WWTP). The operation started with hydraulic retention time (HRT) of 8.4 hours, and the loading rate was stepwise increased, finally the highest load of HRT 1.6 hours was kept for more than 218 days. The MABR showed remarkable performance of COD, S-COD and NH_4^+-N removal, the mean removal rates were 77 %, 63 % and 90 %, respectively. T-N removal rate by simultaneous nitrification- denitrification was 44 %, with a maximum of 73%.

Keywords
MABR; municipal sewage treatment

INTRODUCTION

Membrane Aerated Biofilm Reactor (MABR) is a promising wastewater treatment technology because of its advantages such as energy saving based on high oxygen-supplying ability, a small footprint of reactor, and simultaneous nitrification-denitrification, therefore, applications of MABR to sewage are increasing around the globe (He *et al*. 2021; Lu *et al*. 2021). However, there are only some lab-scale studies reported in Japan so far. This report describes the first result of pilot scale MABR applied to sewage in a major Japanese city.

MATERIALS AND METHODS

Pilot plant setup and operational conditions

A reactor, total working volume of 14 m^3 with a couple of membrane module was installed at a municipal wastewater treatment plant (WWTP) in Yokohama city, Japan. The reactor was divided into two stages for each module. The system was a pure biofilm reactor, without suspended activated sludge. The effluent of primary settlement of the WWTP was pumped through 1 mm mesh screen to the reactor. **Table 1** shows the specifications and operational conditions of the membrane module.

Water quality and sludge analysis

Influent and effluent of the MABR were grab sampled at least once a week to determine COD, S-COD, NH_4^+-N, T-N. From 118 days, the excess sludge generated in the scouring process of the membrane was also sampled to determine its amount, and sludge yield was estimated with COD removal rate once a month. COD and S-COD was determined by spectrometry (DR400, Hach, USA). Others were analyzed according to *Standard Methods for the Examination of Water and Wastewater* (2017).

Table 1. Specifications and operational conditions of the membrane module.

Membrane			Process/Mixing Air		Scour air			
Type	Material	Diameter	Surface area	Flowrate	Pressure	Flowrate	Duration	Frequency
-	-	mm	m^2/module	Nm^3/(hr・module)	kPa (G)	Nm^3/(reactor・hr)	min./module	times/ (day・module)
Hollow fiber	PDMS	OD 0.5	2200	10	20-25	180	1-2	1-4

Energy requirement

The required energy of blowers for the operation was calculated based on the actual air flow rate and pressure with assuming overall efficiency of the blower as 68%.

RESULTS AND DISCUSSION

Sewage load and water wuality

The operation of the MABR was started with hydraulic retention time (HRT) of 8.4 hours, without seeding activated sludge etc. The loading rate was stepwise increased and finally 1.6 hours of HRT, the highest load, was kept for more than 218 days.

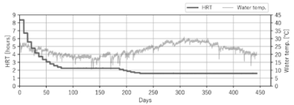

Figure 1. Time course of HRT and temp. of the reactor.

The MABR showed remarkable performance of COD, S-COD and NH_4^+-N removal through whole period of the operation. The mean removal rates of them were 77 %, 63 % and 90 %, respectively. Regarding T-N removal by simultaneous nitrification- denitrification, the removal rate was 44 % as mean values, with a maximum of 73%.

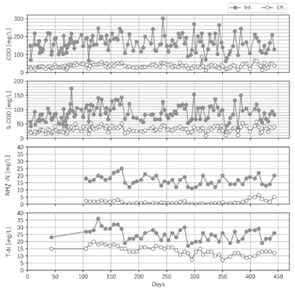

Figure 2. Time course of water quality.

Excess sludge production

The sludge yield was estimated as 0.2-0.5 kg $_{SS}$ per kg $_{COD\ removal}$. It tended to be lower in the period of high water temperature and higher in the period of low temperature.

Energy requirement

The required energy for air supply (including process air, mixing air and souring air) during the period of the highest load was calculated as 0.04 kWh per m^3 of sewage loading.

CONCLUSION

The advantages of MABR, such as small footprint based on high performance of sewage treatment, simultaneous nitrification-denitrification and low energy were demonstrated.

ACKNOWLEDGEMENT

We are grateful to Yokohama city for providing the site and sewage for this study.

Evapotranspiration toilet: a safe and sustainable treatment for black water

Tonetti, A. L.*, Figueiredo, I. C. S., Almeida, M. E. P., Leonel, L. P., Portela, D. G., Miyazaki, C. K., Barbosa, A. C.

School of Civil Engineering, Architecture and Urban Design – FECFAU, Sanitation and Environment Department, University of Campinas – UNICAMP, PO box 6021, 13083-830, Campinas (SP), Brazil. (E-mail: tonetti@unicamp.br).

Abstract
In this work, we evaluated the evapotranspiration toilet (EVT), which is one of the possible solutions for sewage treatment in rural communities or isolated areas. Although, the system is still poorly widespread, it stands out for not generating final effluent or large amounts of sludge. Thus, it is possible for plants to use most of the nutrients contained in domestic wastewater, without the need of post treatments or human contact with the effluent. We found that the systems' removal efficiency is over 90% for COD and BOD, above 98% for turbidity and Total Suspended Solids and 58% for phosphorus.
Keywords
Decentralized strategies; Decentralized treatment; Ecological sanitation; Reuse.

INTRODUCTION

Nutrient removal in the effluent of isolated communities is a challenge since most of decentralized wastewater treatment systems has low efficiency to remove it. The evapotranspiration toilet (EVT) is one of the existing alternatives for this purpose. The EVT is a waterproof tank filled with different layers of filter material and covered with several plant species (Figure 1).

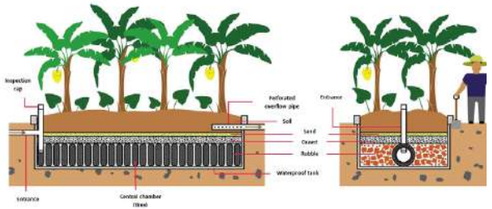

Figure 1 Evapotranspiration toilet system. Source: Translated from Tonetti et. al. (2018).

Natural processes occur within the tank, among them degradation of organic matter, absorption of nutrients and the evapotranspiration through the soil and plants into the atmosphere. An important advantage of the system is that it provides water and nutrient recycling through biomass and food production. Moreover, the system avoids human contact with the effluent, lowering the risk of contamination by pathogens.

MATERIALS AND METHODS

In this work, we monitored for eight months an EVT installed in a rural site in Campinas (Brazil). Banana trees and taioba growth was visually monitored and the effluents were collected in two points of the system, before and after the treatment, for which the parameters were measured: turbidity, pH, COD, BOD, total phosphorous (P_{total}), E-coli, and Total Suspended Solids (TSS).

RESULTS AND DISCUSSION

The plants above the tank shown a regular growth. Three banana trees fructified during the period of the project and taioba leafs were harvested and consumed. The results of the parameters monitored are in Table 1 and removals over 90% efficiency for TSS, turbidity, BOD and COD were registered, while the removal of P_{total} was of 58%.

Table 1 Physiochemical characterization on EVT

Parameter	Sample size	Influent	Effluent	Efficiency (%)
BOD (mg O_2 L^{-1})	8	1009 ± 813*a*	64 ± 48*b*	93.6
COD (mg O_2 L^{-1})	17	2375 ± 1652*a*	220 ± 116*b*	90,7
P_{total} (mg P L^{-1})	7	23.1 ± 13.7*a*	9.7 ± 4.8*b*	58.0
TSS (mg L^{-1})	16	2817 ± 2710*a*	42.9 ± 21.6*b*	98.5
Turbidity (UT)	17	1511 ± 1268*a*	26 ± 20*b*	98.3
pH	17	7.60 ± 0,13*a*	7.76 ± 0.5*a*	-
E. *coli* (MPN 100 mL^{-1})	7	4.0 x 10^7*a*	7.6 x 10^5*b*	-

MPN – most probable number *Different lowercase letters on the same line may differentiate between media (Mann-Whitney, p<0.05).

This result indicates a high removal rate and a high efficiency of physical filtration process inside the tank. An analogous trend was found for BOD removal, with an efficiency of 93,6%. This value far exceeds the minimum of 60% required by the Brazilian law of discharge pattern of treated effluent into water bodies. The efficiency removal of 58% total phosphorus was 20% higher than that found by Galbiati (2009) in a similar setting. The removal of this nutrient can be explained by the plant's high absorption during their grow phase. Regarding E. coli, the removal rates we found are compatible removal with the rates of typical anaerobic reactors, which usually vary from 70 to 90% (Von Sperling, 2014). However, as the effluent is trapped within the tank, there is no risk of contact with the residents or even with the underground aquifer. This feature can demonstrate that EVT would be a great alternative to the cesspool pit, a system traditionally used in rural areas in Brazil (Tonetti et al., 2018).

Abstract

Microorganisms live in Nature in complex communities, the microbiomes. This allows them to cooperate with each other by intra and interspecies interactions, performing tasks not possible for a single organism to do on its own and conferring them robustness and metabolic diversity. Thanks to that, mixed microbial consortia derived from different ecosystems are powerful tools for harnessing Nature's potential for producing metabolites with commercial interest, like biopolymers. Whitin biopolymers, are the polyhydroxyalkanoate (PHAs) that are biodegradable and biocompatible biopolyesters, whose physical-chemical properties makes them sustainable alternatives to petroleum-based plastics. This work aims to study the evolution of a natural microbiomes collected from distinct habitats towards polyhydroxyalkanoates (PHAs) enriched consortia. Therefore, sediments from different habitats (forest soil, sediments from marine environments (sand and mud) and, plant roots) were collected and subjected to feast and famine alternate cycles for the selection of PHA-storing microorganisms. The different microbiomes evolved into consortia containing PHA-storing bacteria. The microbiomes from forest soils and river marshland yielded the higher PHA content. The different abilities to accumulate PHA presented by the different microbiomes are a result of the initial microbial population of each community, since the same metabolic pressure was imposed to the all the original microbiomes. This work is being performed within the European project PROMICON – Harnessing the power of nature (GA 101000733).

Biopolymers, microbiome, natural habitats, polyhydroxyalkanoates

MATERIALS AND METHODS

Samples collection and processing

Seven sites from two main areas (Setúbal and Aveiro) were chosen to collect the environmental samples (Figure 1). These areas are exposed to different environmental and climate conditions.
Plant, forest soil and aquatic sediments were collected. The soil (~500 g) and root (~250 g) samples were collected into clean bags, while the sediments (~1 L) were collected into clean flasks. All the samples were stored at 4 ºC and processed within 24 h after collection. The different sites were chosen to provide natural microbiomes samples of higher microbial diversity given the different geographical origin and diverse ecosystems' characteristics. The seven collected samples were characterized for their physical-chemical characteristics, including pH, conductivity, total suspended solids (TSS), volatile suspended solids (VSS), and nutrients. Prior to the analyses, samples were pre-treated to remove large fragments (solid microbiomes), root samples were milled. All samples were mixed with milli-Q water to obtain suspensions of similar solids content (30 wt.%).

Selection assays

Aiming to select for PHA-producing bacteria, a strategy of alternate feast-and-famine periods was imposed to each of the environmental microbiomes' samples. During the feast phase, the culture was fed with a suitable carbon source to promote cell growth, while during the subsequent famine phase the bacteria able to synthesize PHA will thrive, using the accumulated biopolymer as a source of carbon and energy. By imposing consecutive feast-and-famine cycles, a culture enriched in PHA-accumulating organisms is selected from the initial microbiome (Albuquerque et al. 2010).
The experiments were performed in 500 mL baffled shake flasks with a working volume of 200 mL. The pH value was adjusted to 7.0 before autoclaving. To each collected microbiome sample (160 mL), 40 mL of cultivation medium were added to give an initial acetate concentration of 20 g/L. Samples (40 mL) were periodically collected from each flask over the experiments, and replaced by the same volume of fresh medium, thus creating periods of alternate feast and famine conditions. At each sampling time, the pH was measured and adjusted to 7.0 ± 0.2 by the addition of 5 M NaOH or 5 M HCl. The culture broth samples were used for determination of the total suspended solids (TSS) and the volatile suspended solids (VSS), according to the Standard Methods (APHA, 1995). The supernatant obtained by centrifuging the broth samples (8000×g, 15 min, 4 ºC) was used for the quantification of acetate (by HPLC). The resulting pellet was washed twice with deionized water, lyophilized and used for PHA quantification by gas chromatography (GC).

Optimizing Culture Conditions

From the microbiome screening tests, the marshland sediments consortium was selected. To enrich the microbiome in PHA producer's microorganisms, the strategy of feast and famine was used, and shake flask studies at different pH, temperature and initial acetate concentration were performed to optimize the cultivation conditions. For these experiments fresh sediments of the selected microbiome were collected, in order to evaluate the impact of different cultivation parameter on sample from nature effectively. Assays were done at 2 different pH values, namely 7, and 8 and at 20 ºC and 30ºC, with an initial acetate concentration of 20 g/L for each cycle.

Samples' microbiological characterization

The general microbial composition of the Marshland microbiome (fresh samlple) and after cultivation at certain condition was assessed by Fluorescence in Situ Hybridization (FISH). Aiming to characterize the bacteria present in each condition, several oligonucleotide probes were applied Fluorescein isothiocyanate (FITC)-labelled EUBmix probe for all Bacteria (mixture of EUB338, EUB338-II and EUB338-III and Cyanine 3 (Cy3)-labelled ALF969 for *Alphaproteobacteria*, BET42a for *Betaproteobacteria* and GAM42a for *Gammaproteobacteria*, Delta495a for *Deltaproteobacteria,* BAC303 for *Bacteroidaceae* and *Prevotellaceae* families; LGC0354 and LGC355 for *Firmicutes*. The oligonucleotide probes are specifically detailed in probeBase. The slides were observed using an epifluorescence microscope, and the images were analyzed by Zeiss Imager D2 at 1000x.

RESULTS AND DISCUSSION

Seven environmental samples originating from two different geographical areas, and encompassing distinct habitats, namely, marshland, forest soil, river sediments and plant roots, were collected and characterized. Each environmental sample was subjected to a selective pressure, aiming to select for PHA-accumulating microorganisms. The microbiomes, both the environmental collected samples and those obtained during the selection assays, were characterized for their potential for the production of PHA (Table 1).
For all the microbiomes tested the microbial content increased, however the population diversity decreased (data not shown), as a result of the selective pressure imposed. Further all the microbiome showed the ability to accumulate PHA (Table 1). However, during the duration of the assays the marshland microbiome was the one that achieved faster the feast and famine conditions, achieving also higher PHA contents, which demonstrated a higher capacity to adapt to the conditions imposed to the system.

Table 1. Results obtained in the shake flask microbiome selection assays: VSS (g/L), PHA_{max} (mg_{PHA}/g_{VSS}).

Microbiome	Max VSS (g/L)	mg PHA/g VSS
River Sediments	9.54 ± 0.35	17.83 ± 0.48
Marshland Sediments	17.31 ± 6.69	46.70 ± 3.78
Dunes plant roots	17.45 ± 3.28	7.69 ± 2.44
Forest soil (Caparica)	25.89 ± 0.28	18.56 ± 1.43
Forest soil (Bussaco)	26.39 ± 4.65	9.14 ± 0.66
Fenal roots	21.55 ± 3.43	11.14 ± 0.77
Lima bean roots	14.14 ± 0.31	14.55 ± 0.51

Therefore, marshland sediments microbiome was chosen to study the effect of different environmental condition (pH and temperature) on the population evolution and PHA accumulation capacity. Assays were done at 2 different pH values, namely 7, and 8, at 20 ºC and 30ºC, with an initial acetate concentration of 20 g/L for each cycle.

After microbiome characterization, the 30 days' experiments started. At pH 7 and 20 ºC (Figure 1) the acetate uptake was almost complete on the first cycle (between day 1-5) and on the 6th cycle (day 15-17). On the rest of the cycles the acetate uptake was never complete, this may indicate that the time of feast and famine cycles needs to be higher or the changes that were observed on the initial microbiome influence its performance. The overall acetate uptake was 177.55 g/L. Regarding, nitrogen consumption it varied between 0.30±0.01 g/L and 0.71±0.05 g/L with the exception of the fifth cycle (between day 13 and 15) where no nitrogen uptake was observed.

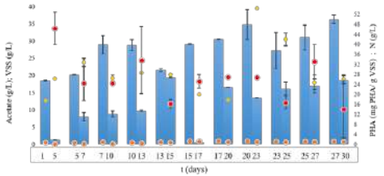

Figure 1 Microbiome cultivation at pH 7 and 20ºC for 30 days. Blue columns: acetate; Red dots: PHA (mg PHA/mg VSS); Orange dots: N (g/L); Yellow dots: VSS (g/L).

Across the 30 days the ratio between VSS/TSS increase across the assay (from 8.58 wt.% and 82.61wt.%), meaning that the inorganic content of microbiome is being substituted by organic content (biomass). PHA was always present in the samples, indicating that there was no famine phase that lead to PHA consumption and therefore enrichment of biomass on PHA producers.
The microbiome was also cultivated at pH 8 and 20 ºC. The acetate uptake was complete between day 1 and 5(first cycle). Thereafter, the consumption varied across the cycles however there was a continuous availability of acetate across the experiment that led to no need of PHA accumulation by the selected bacteria. For the assays at 30ºC pH 7 and pH 8 the behaviour for acetate uptake is similar to the prior assays with the acetate not being consumed for all the cycles and therefore impacting the ability of microbiome to accumulate PHA.
From the condition tested seemed that the time cycle (2 or 3 days) were not enough to exhaust the media in acetate and therefore select the bacteria with PHA producing ability. However, taking in consideration the performance of microbiome at the different conditions tested, the 20ºC seems better than the 30ºC, since the increase in VSS was higher. Further, at 20ºC and pH 8 there was PHA consumption at the end of the experiments while that behaviour was not observed at pH 7. Thus, it was decided to perform the next cultivations at 20 ºC and pH 8.

FISH of fresh microbiome and selected populations

FISH results of initial marshland sediments microbiome shown the presence of major bacterial groups of *Alphaproteobacteria, Bacteroidaceae, Betaproteobacteria, Gammaproteobacteria, Deltaproteobacteria and Firmicutes* identified by the positive fluorescent signal of the oligonucleotide probes. No dominant bacteria group was observed in microbiome, but some abundant populations were identified, which is the case, for instance, of the *Alphaproteobacteria, Deltaproteobacteria and Firmicutes* population, targeted by the Cy3 and FITC labelled (Figure 2).

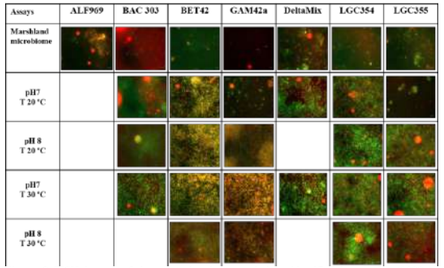

Figure 2 FISH images of the most abundant populations identified in samples (1000x): fresh marshland microbiome; population selected after 30 days at pH 7/ pH8 and 20 ºC; population selected after 30 days at pH 7/ pH 8 and 30 ºC. The images show bacteria hybridized with Cy3-labelled ALFA969, BAC303, BET42, CF319a; DELTA495; GAM42a; HGC69a and LGC0355.

After the 30 days of selection it is observed that population of the assay at pH 7 and 20ºC is enriched in *Betaproteobacteria*, identified by the abundant positive signal of the BET42a probe, *Deltaproteobacteria* (DeltaMix) *and Firmicutes* (LGC354 andLGC35). At the same pH but 30 ºC the population is enriched in the same bacteria but also *Bacteroidaceae* (BAC 303) and *Gammaproteobacteria* (GAM42a). At pH 8 and different temperatures the *Deltaproteobacteria* disappeared and at 30 ºC the *Bacteroidaceae* also disappeared. At pH 8 and 20 ºC the culture is enriched in *Betaproteobacteria*, identified by the abundant positive signal of the BET42a and *Firmicutes* (abundant positive signal LGC354) (Figure 2).
Results of FISH showed that the different conditions of temperature and pH enriched the bacterial population in different families.

Abstract
Carbamazepine is removed by most oxidative processes, however, they generate various transformation products, which might be even more hazardous for aquatic environment than carbamazepine itself. The prediction of such molecule formation by computer-based modelling thus appears as a relevant solution for risk evaluation and processes design assessment. In this context, this work aims to improve the knowledge on the nature, fate and dynamics of carbamazepine and its transformation products by an extensive literature analysis and computer modelling. Preliminary literature review and model calibration show promising results concerning transformation products prediction.

INTRODUCTION

Carbamazepine (CBZ) is an anticonvulsant drug, derived from dibenzazepine, mainly used for the treatment of epilepsy, bipolar disorder and trigeminal neuralgia (Hai *et al*., 2018). This drug is released in domestic and hospital wastewater and then reaches wastewater treatment plants (WWTP). CBZ is one of the most detected drugs in surface water (Luo *et al*., 2014), even in areas with low anthropogenic pressure (Wilkinson *et al*., 2022). Indeed, CBZ global consumption is estimated at 1000 tons per year (Zhang *et al*., 2008) and is poorly removed (< 25%) by conventional secondary processes (Joss *et al*., 2006). Moreover, CBZ is also known for its toxicity on aquatic organisms such as green algae, daphnia or fishes (ECOSAR, 2022).

In order to achieve CBZ removal, polishing treatment processes, such as ozone or advanced oxidation processes (AOP) and water disinfection processes (drinking water), have been studied for several years (Mathon *et al*., 2017; Bourgin *et al*., 2017). However, many unknowns remain about the fate of this molecule. Indeed, the diversity of degradation mechanisms involved in these processes implies a multitude of reaction pathways leading to many transformation products (TPs). TPs display different physicochemical properties and their structures are still poorly identified (Bonnot *et al*., 2022). Therefore, the behavior of TPs is not fully understood and the anticipation of their removal seems even more complex than MPs. Recently, computer-based modelling emerges as a promising tool to predict the fate of MPs and their TPs. Indeed, considering the technological advances made in MPs monitoring and quantification, model predictions can be used for both risk evaluation and processes design improvement (Delli Compagni *et al*., 2020; Plósz *et al*., 2013)).

This work aims to improve the knowledge on the nature, fate and dynamics of CBZ and its TPs. In this context, the objectives of this study are: 1) to identify and model the transformation pathways of CBZ in various oxidation processes and 2) to suggest classification criteria for these processes.

MATERIALS AND METHODS

The project is based on an extensive literature review of more than 80 scientific papers published between 2000 and 2022. The abatement of CBZ in various processes as well as the measured TPs resulting from its degradation have been determined. The data collected were processed using RStudio interface [v2022.07.2] and Gephi software [v0.9.5]. CBZ and TPs modelling was performed using a Python encoded program through the Spyder interface [v5.1.5]. This program uses the Symfit library for the resolution of ordinary differential equations (ODE) based on formation and degradation kinetic equations. Indeed, equations were written from mass balance performed thanks to CBZ degradation reactions.

RESULTS AND DISCUSSION

Literature review

More than 100 different TPs have been identified after the degradation of CBZ (Figure 1). They have very different chemical properties (molecular weight, pKa, LogD) leading to resistance mechanisms towards degradation specific to each molecule. Thus, a review of the degradation pathways for each identified TPs has been performed as shown in Figure 1. We have shown a very complex network of possible reactions. Some degradation reactions of CBZ were common to all studied processes, and therefore, resulting primary TPs appear to be very important. Furthermore, results highlight the relevance to study intermediary TPs such as acridine and acridone, which appears to be responsible for a high number of final products. Indeed, the great diversity of these TPs as well as the multiplicity of the reactions involved make it difficult to follow them in the water cycle and molecules of interest need to be targeted. Moreover, most of the TPs from CBZ show a significant toxicity on aquatic organisms (United Nations GHS report, 2011) pointing out the importance of improving our knowledge on the fate of this micropollutant, its degradation or its accumulation potential.

Modelling

From the transformation pathways of CBZ found in literature, we have set-up a numerical model (Figure 2). Calibration was performed using different data sets (i.e quantified concentration versus time in batch test conditions) published in literature. Various CBZ degradation processes were studied such as TiO_2 photocatalysis (Franz *et al.,* 2020; Jelic *et al*., 2013), UV-Cl (Pan *et al.,* 2017; Suara & Bezares-Cruz., 2022), UV-H_2O_2 (Lu & Hu, 2019) or UV-NH_2Cl (Wang *et al*., 2022). Overall, we obtained a good fit of the CBZ degradation model with experimental data ($R^2 > 85\%$). Concerning TPs modelling, quality of the model is highly variable ($14 < R^2 < 98\%$), most likely because of the diversity of reaction mechanisms involved in TPs formation and the differences in experimental conditions between studies. However, due to the very low concentration (ng.L^{-1}) of some TPs, the R^2 might not be the most adapted quality descriptor. The assessment method of our model might therefore be improved by calculation of other criteria. For model validation, there is a lack of experimental data on TPs quantification. Indeed, there is a need for further TPs studies in various water treatment processes, which is still a challenge due to poor reference standards availability.

CONLUSIONS AND PERSPECTIVES

Our knowledge of the fate and dynamics of CBZ in wastewater is still incomplete, particularly concerning its various transformation products. This is why comprehensive studies through modelling are needed, but the lack of TPs quantification remains an important challenge.

Therefore, the perspectives of this work consist of carrying a series of batch tests for biological and oxidative processes for micropollutant degradation. The chemical analysis is under process. The results might be presented during the conference.

ACKNOWLEDGMENT

The authors thank the French National Research Agency (ANR) for funding this project "TRANSPRO".

The impact of high and low temperatures on *Candidatus* Competibacter fed with industrial wastewater

E. Tsertou*, K. Goossens*, K. Seguel Suazo* and J. Dries*

* Research group BioWaVE, Biochemical Wastewater Valorization & Engineering, Faculty of Applied Engineering, University of Antwerp, Groenenborgerlaan 171, 2020 Antwerp, Belgium

Abstract
The goal of this study was the investigation of the impact of high and low temperatures on biomass anaerobic metabolism, when the biomass is exposed to them both in long-term and short-term. Furthermore, the settleability and the structure of the sludge as well as the carbon removal efficiency is evaluated. All in all, the high temperatures (above 38°C) had irreversible negative impact on *Ca.*Competibacter. The low temperatures (11°C) was the reason that *Ca.*Competibacter decreased in number and the uptake capacity deteriorated but not at an alarming level.

Keywords
Aerobic granular sludge; feast/famine feeding strategy; sequencing batch reactor; slow growing microorganisms; substrate consumption rate, tank truck cleaning

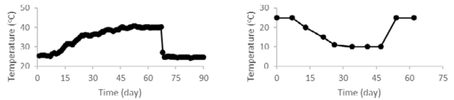
INTRODUCTION /

Aerobic granular sludge is considered a novel biological treatment technology because it improves the settleability of the biomass without carrier materials (de Kreuk, 2005). De Kreuk et al. (2004) showed that the selection of slow growing microorganisms such as the phosphate accumulating organisms (PAO) and glycogen accumulating microorganisms (GAO) improves the stability of the aerobic granular sludge. GAO will proliferate under certain circumstances. Both the wastewater composition and the feeding strategy play crucial role on GAO selection. Feast (anaerobic)/ famine (aerobic) regime as feeding strategy and wastewater poor in nutrients have been proved perfect conditions for GAO enrichment both in lab and full scale (Caluwé, 2022) (Tsertou, 2022) (Tsertou, 2023 submitted). Temperature is another factor that has strong impact on the growth rate of the microorganisms. Low temperatures slow down the growth rate and high temperatures accelerate it. However, it is believed that there is an upper limit-temperature above which the rate is decreasing, probably because of the destruction of enzymes at higher temperatures (Lopez-Vazquez, 2009). The temperature effect on GAOs has been studied before but with synthetic wastewater. This research focus on the impact of temperatures on enriched *Candidatus* Competibacter biomass which is fed with industrial wastewater, which is derived from the cleaning of trucks transporting chocolate and beer.

MATERIALS AND METHODS

The investigation of temperature impact was done with two different set ups. First experiment was about the investigation of high temperatures (range from 25 to 40°C) and the second one about the low temperatures (range from 25 to 10°C). Each set up was consisted of two Sequencing Batch Reactors (SBR); the reference and the experimental. The temperature was held at 25°C for the reference reactor and was changed for the experimental reactor (Figure 1).The anaerobic feast/aerobic famine regime was applied in both experiments. The 24 h SBR cycle consisted of a prolonged anaerobic feeding (4h slow feeding) followed by 0.5h mixing, aeration (approx.18h), settling (1h) and discharge.
MLSS, MLVSS and SVI were performed in accordance with Standard Methods (APHA, 1998). Sludge morphology was observed using an Olympus B310 light microscope with phase contrast illumination (Ph1) and a total magnification of 2 times.

16S RNA gene amplicon sequencing is the molecular technique that was used for identification of the microbial community. A detailed description can be found in the study by Tsertou et al. (2022). The long term anaerobic uptake (in-situ measurement) was determined during an ordinary SBR cycle as described by Tsertou et al. (2022). The short term anaerobic uptake (ex-situ measurement) was determined by collecting endogenous sludge in the end of the experimental and reference SBR cycle as described by Tsertou et al. (2023). For the ex-situ measurements only two extreme temperatures were selected (10°C and 40°C). The test started only when the endogenous sludges reached the temperature setting and after increasing the pH of the wastewater up to 7 with NaOH.



a. b.

Figure 1. Temperature profile for the experimental reactor. Experimental design of high (a) and low (b) temperatures.

RESULTS AND DISCUSSION

Part A. Impact of High Temperatures on settleability, morphology, bacteria abundancies, anaerobic metabolism, carbon removal efficiency.
% COD removal was 97.4 ±1.5 for the EXP and 98.2±0.3 for the REF reactor. Despite the high efficiency of both reactors in COD removal, only the REF reactor complied always with the Flemish discharge limits (COD <125 mg.L^{-1}). Regarding the settling performance, SVI 30 remained always below 70 mL.g^{-1} for the REF reactor. On the other hand, the SVI 30 deteriorated after DAY 41 (approx. 38°C) in the EXP reactor. SVI 30 peaked at 94 mg.L^{-1}. The evolution of the structure of the sludge is similar in both reactors (Figure 3). The size of the granules increased in function of time. During the long term operation of the reactors, the anaerobic metabolism of *Ca.* Competibacter was very sensitive to temperatures changes above 37°C. Consequently, % anaerobic uptake and % abundance of *Ca*. Competibacter dropped to zero (Figure 2). On the contrary, the REF reactor had av. 89.4 ± 6.4 % anaerobic uptake and 18.1 ± 5.6 % abundance of *Ca.* Competibacter. The abundance of *Ca.* Competibacter in the EXP reactor was not restored even when the temperature was set back at 25°C. The results from ex-situ anaerobic test showed that the REF reactor had higher uptake capacity than the EXP reactor either at 25°C or 40°C. Furthermore, both reactors had slightly higher uptake rate at 40°C (Figure 4).

Part B. Impact of Low Temperatures on settleability, morphology, bacteria abundancies, anaerobic metabolism, carbon removal efficiency.
% COD removal was 96 ± 1.7 for the EXP and 98± 0.6 for the REF reactor. REF reactor complied most of the time with the discharge limits (102.4±33.5 mg.L^{-1} av.COD) but EXP reactor did not (179.8±90.5 mg.L^{-1} av.COD). SVI 30 was below 35 mg.L^{-1} for both reactors. The microscopic examination showed similar structures for the two reactors (Figure 6). The long term operation under low temperatures affected negatively the % anaerobic uptake (Figure 5.a) and the % abundancies (Figure 5.b). The average uptake was 82.7±15.6% and 94.7±1.8% for the EXP and REF reactor respectively. The average read abundance of *Ca.*Competibacter was 18.7±6.6% and 20.8±2.9% for the EXP and REF reactor respectively. The high deviations in the EXP reactor is because of measured values during the operational period at low T. The short term experiments showed clearly that the low Temperature decreased the uptake rate in both reactors (Figure 7).

Figure 2. a. In situ measurement of % DOC uptake during the anaerobic phase. b. % Relative read abundancy of *Candidatus* Competibacter.

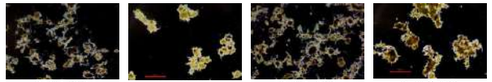

Figure 3. Microscopic examination of the biomass structure. Bar indicates 500µm.

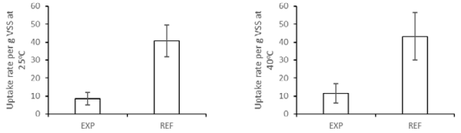
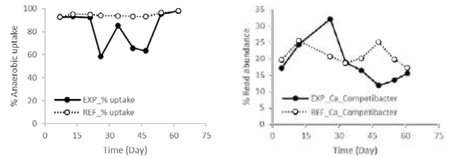


a. b.

Figure 4. Substrate Anaerobic uptake rate (mg DOC.g^{-1}VSS.h^{-1}) at 25°C (a) and 40°C (b).



a. b.

Figure 5. a. In situ measurement of % DOC uptake during the anaerobic phase. b. % Relative read abundancy of *Candidatus* Competibacter.

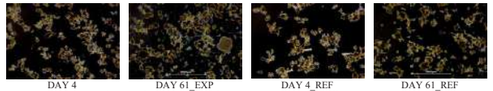


Figure 6. Microscopic examination of the biomass structure. Bar indicates 1000 µm.

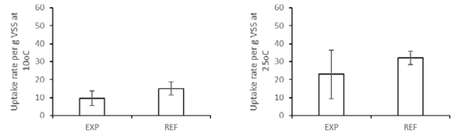

a. b.

Figure 7. Substrate Anaerobic uptake rate (mg DOC.g^{-1}VSS.h^{-1}) at 10°C (a) and 25°C (b).

To sum up, the results indicate a strong sensitivity of Ca.Competibacter at high T (above 37°C). The decrease of temperature had also a negative impact. However, Ca.Competibacter was not hindered completely as it happened with the high temperatures' experiment. In addition, it seems that the recovery from the exposure to low temperatures is fast enough.

Phosphorus extraction from sewage sludge ashes and subsequent co-precipitation with other nutrients: insight into factors favouring a beneficial recovery

G. Boniardi*, T. Seljak**, R. Canziani*, A. Turolla*

* Department of Civil and Environmental Engineering, Politecnico di Milano, Piazza Leonardo da Vinci, 32, Milano, IT (E-mail: gaia.boniardi@polimi.it; roberto.canziani@polimi.it; andrea.turolla@polimi.it)

Abstract
The present works, representing the first outcome of the ERA-MIN 3 "PHOSTER" project, investigates the most relevant factors affecting nutrient recovery from ashes in the view of providing preliminary guidelines for process development. In detail, the work is focused on the assessment of two process steps, poorly investigated so far, namely incineration and co-precipitation of phosphorus with other nutrients (i.e., K and Mg). Experimental results demonstrated that incineration phase is fundamental, with the addition of calcium-based additives in the combustion chamber strongly affecting the pH of ashes and hindering the subsequent phosphorus extraction. Furthermore, precipitation tests indicated best conditions for phosphorus precipitation, with 100% recovery at pH 9.5 with a molar ratio of K:Mg:P=1:2:2. Cattiite was the main crystalline compound in the solid product, while K was mostly present in amorphous form.

INTRODUCTION

Phosphorus (P) is considered a primary resource for life on earth. It is an irreplaceable element in agricultural activities, especially in the production of fertilizers, because it is essential for crops growth (Meng et al., 2019). Phosphate rocks are the most important source of P, being non-renewable resources concentrated in limited countries (e.g., Morocco, Western Sahara, China). Because of excessive exploitation of natural reserves and excessive use of P in agriculture, the world is heading towards P scarcity. Thus, the recovery of P from alternative sources such as sewage sludge and derived ashes is emerging as a key element for the development of circular and sustainable systems. Even if lot of research has been conducted during the past years to recover P via wet chemical extraction (Liang et al., 2019; Fang et al., 2020; Baldi et al., 2021; Liu et al., 2021), high operational costs and quality of the recovered material are the main issues to tackle. This works, which is part of the ERA-MIN 3 "PHOSTER" project, primarily investigates the impact of incineration process on ashes composition and thus on P extraction, providing guidelines for optimizing the extraction process. In addition, the influence of operating conditions on the co-precipitation of P in multi-nutrient high-value products is assessed for enhancing the overall quality of recovered material.

MATERIALS AND METHODS

Sewage sludge ashes (SSA) samples (S1-S7) were collected from bag filters of a pilot-scale fluidized bed (FB) incinerator at the wastewater treatment plant (WWTP) of Milano San Rocco (IT). To assess the influence of incineration process conditions on SSA composition, 3 different feed type were tested: (1) dewatered sewage sludge (DSS), (2) DSS with a Ca-based additive, and (3) a mixture of DSS and dried sewage sludge. A reference sample S0 was taken from electro-filters of a full-scale incineration plant (Werdhölzli, CH). Characterization was conducted for total solid (TS) content, volatile solid (VS) content and pH as in Bontempi et al. (2010). Grain size distribution was determined as in ASTM 2020 and ISO 3310–1:2016. Al, Ca, Fe, K, Mg and As, Cd, Cr, Cu, Ni, Pb, Zn were measured with ICP-MS after aqua regia digestion (UNI EN ISO 17294-1:2007), while P was determined after mineralization (EN 15959:2011) with UV-Vis method (Hach LCK 348). After preliminary experiments, P extraction for S1-S7 was performed with the following operating conditions: 1 M H_2SO_4, liquid-to-solid ratio of 20:1, 2-h contact time, room temperature. For S0, instead, 0.2 M H_2SO_4 was used. Extraction procedure details are in Boniardi et al. (2021).

Precipitation tests were conducted with synthetic P solution (H_3PO_4 or KH_2PO_4), leachate with high PEE from S1-S7 and leachate from S0. K (from leaching of carbonized biomass) was added to P leachate, while Mg was added as $MgCl_2$. Nutrients were added to have molar ratio K:Mg:P=1:1:1 and 1:2:2. pH was then increased till 3.5, 5, 8, 9, 9.5, 10 and 11 with 0.1 M NaOH. P precipitation efficiency (PPE) and K precipitation efficiency (KPE) were determined, XRD was used to detect crystalline structures.

RESULTS AND DISCUSSION

pH of S1-S7 varied between 12.6 and 12.8, pH of S0 was 7.1. This can be explained by the different incineration process conditions and treatment layouts. At San Rocco WWTP, $CaCO_3$ was dosed in the incineration chamber so that S1-S7 have a higher Ca content (16.4-23.5%) compared to S0 and literature (Krüger et al., 2014). The higher buffer capacity may hinder the subsequent acid extraction suggesting that SSA collection point and type of flue gas treatment are of paramount importance. S1-S7 showed lower P content (5.6-6.6%) compared to S0 (8.6%) but a similar K and Mg content (**Table 1**). Instead, Al and Fe were higher in S0 (5.2-17.5%) due to chemical P removal. To optimize the P recovery, guidelines are provided on (i) WWTP layout and treatment capacity, (ii) type of incinerator and process conditions (e.g., temperature, contact time, additives), (iii) flue gas treatment layout, (iv) SSA collection point, (v) pH of SSA and grain size. In summary, most suitable SSA for P recovery were obtained in case of enhanced biological P removal, FB technology without direct Ca-based addition, multi-step flue gas treatment to reduce the metal content in P-rich SSA, SSA collection point located along the flue gas treatment train allowing for minimization of metals presence, SSA characterized by neutral SSA and fine size (D50 < 100-200 µm).

PEE ranged between 57.4% and 91.5%, achieving its maximum for sample S2 (91.1%) and S6 (91.5%) as shown in **Figure 1**, suggesting that the type of incinerator feed may not affect the subsequent extraction. Similar extraction efficiency was obtained from S0 (91.1%) with much lower acid consumption, therefore suggesting the high importance of SSA pH.

Results from synthetic solutions showed that the addition of K increased the PPE (except at pH 9) (**Figure 2**). Maximum PPE (85%) and KPE (68%) were achieved at pH 10, suggesting the occurrence of P and K co-precipitation resulting in P and K content in the solid of 15.2% and 15.3%, respectively. Results from leachate confirmed high PPE (97%) and KPE (28%) at pH 9 with K:Mg:P=1:2:2 (**Figure 3**). XRD identified cattiite ($Mg_3(PO_4)_2(H_2O)_{22}$) as the main crystalline phase, while K was mainly present as amorphous phase. These results suggest that the addition of other nutrient besides the available P may be beneficial for the quality of the final solid product.

In conclusion, to optimize the P recovery several parameters besides P extraction must be considered. Experimental results showed that nearly 100% of P can precipitate at pH 9 from leachate with K:Mg:P=1:2:2, resulting in a P and K content in the final solid of 14% and 3% respectively. Cattiite was the main crystalline compound present, while K was mostly present in amorphous form. Additional experimental activities are planned to understand the effect of incineration process conditions and the role of heavy metals in the co-precipitation process within the ERA-MIN 3 "PHOSTER" project framework.

ACKNOWLEDGMENTS
The present work was partly funded by the ERA-MIN 3 "PHOSTER" project (https://phoster-project.eu/). The authors would like to thank Rea Dalmine (Greenthesis group) for granting the PhD of Ms Gaia Boniardi, and Prof. Elza Bontempi and Dr. Laura Fiameni for the analytical support.

Abstract
There is an urgent need for new wastewater treatment techniques that reduce the amount of sludge produced, and lower effluent nutrient concentrations, while greenhouse gas emissions are limited. In an Aquafarm-system, macroinvertebrates degrade sludge, while aquatic plants take up and assimilate nutrients, thereby minimizing effluent nutrient concentrations and maximizing CO_2 uptake. Biomass produced in this way may have applications in the circular economy. To test the efficiency of the Aquafarm principle, we performed several experiments on sludge degradation by macroinvertebrates, and nutrient removal by macrophytes, while also measuring GHG fluxes. The results revealed that macroinvertebrates increased sludge degradation, and floating plants effectively removed nutrients, while taking up CO_2, without emitting GHGs. Sludge degradation, nutrient removal, as well as GHG reduction depended on the macroinvertebrate taxa or plant species. Thus, it is concluded that the treatment of municipal wastewater sludge and effluent by macroinvertebrates and macrophytes is a promising treatment technique.

Keywords
Floating plants; macroinvertebrates; municipal wastewater; self-purification; nature-based solution

INTRODUCTION

Wastewater treatment plants (WWTPs) are often a point-source of nutrients, and contaminants, and produce excess sludge and greenhouse gasses (GHGs). Meanwhile 48% of global wastewater is not treated at all, leading to poor surface water quality and associated human and environmental health risks (Jones et al., 2021). Therefore, there is an urgent need for affordable WWTP and (post-)treatment techniques that further reduce the nutrient concentrations in wastewater effluent, as well as the amount of produced sludge, while having a minimal GHG footprint (European Commission, 2022). We here argue that utilizing the self-purifying capacity of surface waters may pave the way to such a futureproof wastewater treatment system, since aquatic organisms have the potential to aid in the degradation of sludge and nutrient removal, as they also degrade organic matter and take up nutrients in their natural environment. Indeed, multiple species of macroinvertebrate collector-gatherers can feed on WWTP sludge (van der Meer et al., 2022) and macrophytes and especially floating plants can effectively remove nutrients from WWTP effluent (Hendriks et al., under review). During these processes, the organisms grow and reproduce, and thus produce biomass. Nutrients can be permanently extracted from the system by removing the produced biomass, preventing nutrient discharge into the environment. Utilizing the removed biomass for products, would also aid in the ambition to achieve 100% circularity in terms of resource use which has been agreed upon in the Paris Agreement. Furthermore, the interactions between these organisms in their natural environment may enhance these functions. Therefore, a cascade of monocultures of aquatic invertebrates and plants may serve as a WWTP (post-) treatment step to combat eutrophication, excess sludge production and GHG emissions from WWTPs. An Aquafarm cascade would aim to provide the optimal conditions for each monoculture in the cascade, thus achieving optimal functioning of the organisms, therewith fuelling the processes. In contrast to some other nature-based treatment techniques, the harvesting of biomass allows permanent removal of nutrients from the system and benefits the circular use of resources.

MATERIALS AND METHODS

In the first part of this project, several experiments have been performed assessing the capability of sludge degradation by (combinations of) multiple species of macroinvertebrates. Furthermore, multiple species of submerged, emerged, and floating plants have been cultured on WWTP effluent to assess their nutrient uptake, growth and effects on GHG emissions. Here, we have highlighted two of these experiments. In the first experiment, all possible combinations of 3 taxa of detritivorous macroinvertebrates; worms, chironomids and snails have been grown on sludge from three WWTPs differing in contaminant loads. After 7 days, the amount of degraded sludge was determined. In the second experiment, eight species of floating plants (*Eichhornia crassipes*, *Pistia stratiotes*, *Stratiotes aloides*, *Salvinia molesta*, *Azolla filiculoides*, *Azolla pinnata*, *Lemna minuta*, *Trapa natans*) were grown on effluent for two weeks, and nutrient uptake, biomass production and GHG fluxes were measured.

RESULTS

Macroinvertebrates can stimulate sludge degradation (Fig. 1)

The results of the macroinvertebrate experiment showed that these could stimulate the degradation of sludge from all three WWTPs, regardless of contaminant level. The least contaminated WWTP was Rhenen, followed by Mijdrecht and then Alkmaar. Sludge degradation did differ between taxa and WWTP site, with % of degraded sludge being highest in Rhenen (18.5%), and lowest in Alkmaar and Mijdrecht (7.4%). Degradation by invertebrates could be as high as 39.2% of initial sludge in 7 days. However, the sludge degradation of the multispecies treatments was only higher than expected based on the single-species treatments in Alkmaar, indicating that positive species interactions may only occur in higher stressed/contaminated environments.

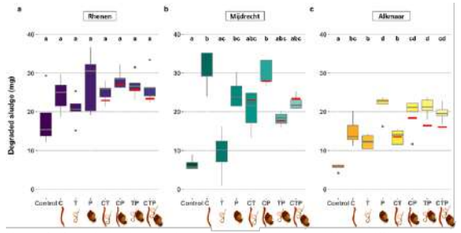

Figure 1. Degradation (mg) by (combinations of) chironomid larvae (C), worms (T), and snails (P) of sludge from the WWTPs of Rhenen (a), Mijdrecht (b), and Alkmaar (c). Boxes show interquartile range, bold lines represent the median, whiskers indicate the lowest and highest values within a 1.5x interquartile range from the box, dots represent outliers. Letters indicate significant ($p < 0.05$) differences between species (combinations). Two outliers at Mijdrecht (C-treatment: 50.1 mg; CP-treatment: 66.0 mg) are not shown to increase figure readability. Red lines indicate the median of the predicted degradation by multi-taxa assemblages based on single-taxa degradations.

Floating macrophytes stimulate nutrient removal while taking up GHGs (Fig. 2)

All of the tested plants were able to completely remove ammonium, most likely by stimulating nitrification. Only *E. crassipes*, *P. stratiotes* and *S. molesta* were able to lower nitrate concentrations to the limits set for natural waterbodies. *A. filiculoides* and *A. pinnata* were the only plants lowering phosphate concentrations. CH_4 and N_2O emission were lowest in treatments with *A. filiculoides*, *A. pinnata*, *L. minuta* and *T. natans*. CO_2 was sequestered in all treatments, but *A. filiculoides* showed the highest uptake. Both *Azolla* species had the highest biomass gain.

DISCUSSION

The present experiments have shown that aquatic macroinvertebrates are able to enhance sludge degradation, and that the efficiency of these processes are taxa and WWTP specific. We also showed that floating macrophytes increase the nutrient removal from the effluent, and can limit GHG emissions during wastewater treatment. The efficiency of these processes depends on different plant traits, like growth rate.

The present results indicate that the use of a cascade of aquatic organisms may offer promising future-proof solutions to the challenges of the creation of circular and zero emissions systems. The Aquafarm cascades degraded excess sludge and reduced nutrient concentrations in the effluent to be within the limits set for natural waterbodies, while also resulting in a net uptake of GHGs. During these processes, the organisms converted sludge and nutrients into biomass, which may be harvested, and possibly applied for other uses such as fish feed and fertilizer. This will aid the goal of a circular treatment process. The next step in the development of such a well-functioning treatment-process is the scaling of these processes and making them robust for different climates is. However, as different organisms have different traits in terms of sludge degradation and nutrient transformations, selection and combining the right species depending on the type of WWTP, and providing the appropriate conditions for the organisms to grow, is needed to optimize further wastewater treatment and effluent polishing. In this way, wastewater treatment using macroinvertebrates and macrophytes contributes to a circular economy and energy-neutrality of wastewater treatment, but mostly to the urgently needed decrease in eutrophication.

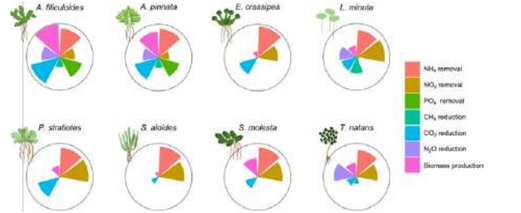

Figure 2. Efficiency of the eight measured floating plant species in nutrient removal, biomass production and greenhouse gas reduction when grown on municipal wastewater effluent. Data are normalized to the highest removal, reduction or biomass production, i.e. they were expressed as a fraction of the highest removal rate, reduction potential and biomass production, where the black line depicts 1.

Abstract
The use of engineered Nanoparticles (NPs) is increasing across all domains – from personal care products to medical purposes and currently, treatment plants are not equipped to remove these. Microbial Fuel Cell (MFC) uses microorganisms to degrade wastewater and generate electricity, with lower cost, lesser space requirement and minimal chemical usage. NPs exist as a mixture of ions and particles in water – of which ions have been removed in MFCs. To use this technology for NP removal, it is imperative to understand the possible interactions in the system. NPs have been reported to adversely affect biofilm, but there is a lack of studies in the context of anode biofilm. This study thus summarises the knowns of NPs with biofilm and MFC to draw out the course of future research in this direction.

Keywords – Biofilm; Microbial Fuel cell; Nanoparticle; Toxicity

INTRODUCTION

With advent of technology and development, newer contaminants, aka emerging contaminants, are becoming concerning. Within this category, contaminants in particulate form, especially in nano size range are rapidly increasing. Broadly classified as "nanoparticle (NP)", it refers to any particle whose size is within 100 nm. Several types of NPs are in existence – carbon-based (carbon nano tubes, fullerene, etc.), metal-based (nano Ag, metal oxides etc.), nano plastics, etc. Personal care products, health sector, electronics, paints, petrochemical industry are major contributors to these NP wastes. The nano size facilitates easy penetration into cells of living organisms, causing many harmful effects.

Recent years have seen increased exploration in the usage of Microbial Fuel Cell (MFC) for treating wastewater due to possibility of simultaneous clean energy generation and wastewater treatment – catering to 2 of the Sustainable Development Goals by the UN. A keyword search of "Nanoparticle; MFC" on Scopus yielded 427 research publications over the last decade, with over half of studies emerging in the last 4 years. Majority of the 427 studies have employed nanomaterials for enhancement of electrode surface or as mediators. On the other hand, only 5 studies were obtained on keyword search of "Nanoparticle; toxicity; MFC", indicating that very few studies have focused on NP as a contaminant in MFC. This study forms a preliminary assessment for understanding (i) removal of NPs in MFC and (ii) NP effect on anode biofilm and then presents a hypothesis of NP induced toxicity to biofilm.

RESULTS

NP removal in MFC

As the occurrence of NPs in wastewater will inevitably rise exponentially in the coming years, the need to understand their impact on bio-electrochemical treatment technologies becomes important. Due to limited prior knowledge in this domain, the effect of NPs on different components of the MFC was explored. The anode biofilm is the main reaction site of the MFC where the electrogenic microbes colonise, degrade organic matter and release electrons. Biofilm directly influences the MFC performance, thus studying the impact of NPs on biofilm can be a reliable estimate. In solution, NPs occur in both particle and ion form – of which the latter has been extensively investigated in the context of MFC. MFC has achieved high removal efficiencies for several heavy metal ions. The phenomena such as biosorption, electrochemical reduction, etc. which have been attributed to their removal can also be extrapolated for the NP derived ion. A brief literature review covering these aspects is shown in Table 1. The major shortcoming that emerged from the literature study is that no study has targeted the removal of NPs using MFC. Further, most bioreactor experiments focus on a single type of NP with substrate. Along with that, other contaminants and constituents will also influence the impact NPs will have on the overall treatment process. More research is required to understand the realistic wastewaters where a mixture of NPs will occur.

Impact of NP on anode biofilm

The biofilm over an anode consists of numerous microbial colonies interlinked in a matrix of extracellular polymeric substances (EPS). With time, the biofilm thickens, which gives rise to a concentration gradient of substrate across the depth. The presence of NPs in the wastewater can disrupt this process in different ways – inhibition of initial surface attachment and growth, cell penetration and destruction, deterioration of biofilm structure etc. The studies covering these aspects are described in Table 2 and the same is illustrated in Fig 1. Most of the NP biofilm toxicity studies have scrutinized pure culture biofilms, which is not the case for real wastewaters that contain mixed culture of microbes. Although, entrapment of NPs in biofilm is desired for its removal, its further implications on the performance of MFC has to be delved into.

Table 2. Literature review on effect of NPs on biofilm

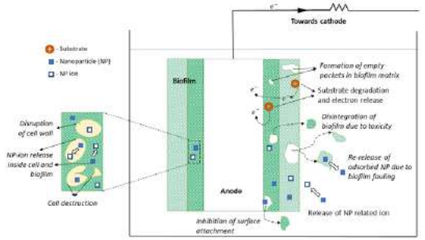

Figure 1. Hypothesized possible impacts of nanoparticles (NP) to anode biofilm. The effects written in italics indicate the NP-induced effects

CONCLUSIONS

MFC has the potential to become an in-situ treatment facility for industries with high concentration of NPs in effluent or even central treatment facilities with mixed, NP-containing wastewaters. There are very few studies in the context of NP and anode biofilm – which plays a pivotal role both for treatment and electricity generation. In ion form, similar to heavy metal ions, NP ions can be removed by biosorption, reduction. Once entrained in the biofilm, adverse impacts such as reduction in growth and viability, destruction of microbial cell and fouling can occur. For future studies, the incorporation of the following points can lend an enhanced perspective in this ambit:

- To study the effect of NP-inducted impacts on biofilm on the performance of MFC
- Use of realistic wastewaters considering co-existence of NPs with other contaminants in MFC studies for facilitating field adoption of this technology.
- To study MFC performance using mixed culture biofilms and NPs.

Microbial-Mediated Biological Treatment of Wastewater Containing Arsenic (III) and Arsenic (V)

Manoj Kumar Verma [1] and Vishal Mishra [1]
[1] School of Biochemical Engineering, Indian Institute of Technology (BHU), Varanasi, Uttar Pradesh, India 221005
E-mail: manojkverma.rs.bce18@itbhu.ac.in

Abstract

Biological treatments for arsenic and other pollutant removal from wastewater involve using microorganisms, such as bacteria, to convert the contaminant into a less toxic form. Microbe-mediated bioaccumulation provides cost-effective and eco-friendly technology for removing heavy metals and other pollutants from water. *Kurthia gibsonii* strain MKVVM3 IITBHU was shown to be capable of adsorbing and accumulating, including both As (III) and As (V) from the contaminated water. Arsenic resistance gene expression from MKVVM3 IITBHU was regulated by various mechanisms, including gene regulation and metabolic adaptation conferring bacterial resistance against arsenic. These include arsenate reductase and arsenite oxidase, which play a role in arsenic detoxification. In the SEM study, the bacteria appeared to be long and rod-shaped cells. AFM analysis revealed that MKVVM3 IITBHU accumulated arsenic in its cell walls, increasing its surface area in aqueous solutions. XRD confirmed the isolates' size and shape conformation and indicated amorphous nature. EDS and Elemental mapping were conducted to infer the presence and distribution of elements in the sample. The combined study of these techniques provides the bioremediation potential of MKVVM3 IITBHU in removing arsenic. The process of using bacteria to bind the arsenic to their cell surface, thus preventing it from entering the environment. It further provides researchers with a deeper understanding of the pathways of how these bacteria utilize their energy for wastewater treatments.

Keywords: *Kurthia gibsonii* strain MKVVM3 IITBHU, Bioremediation, As (III) and As (V), Wastewater treatment

INTRODUCTION

Arsenic (As) groundwater contamination is caused by the weathering of rocks, water pH, competing ions' presence, biological alteration of minerals, and other anthropogenic sources. As poisoning in people can lead to illnesses such as skin rashes, neurological and respiratory issues, and various cancers. (Chung et al., 2014). Several countries, including Argentina, Bangladesh, China, Chile, Canada, Japan, Vietnam, Taiwan, India, Mongolia, Nepal, and the United States, have reported elevated As levels in their drinking water. (Smith et al., 2009). This research aims to characterize arsenic-resistant bacteria and establish their role in arsenic bioremediation.

MATERIALS AND METHODS

Bacterial coevolved genes were investigated to identify gene expressions that support resistance. To evaluate the isolate's effectiveness in the bioremediation of As (III) and As (V), biochemical and morphological analysis was also carried out using SEM and AFM.

RESULTS AND DISCUSSION

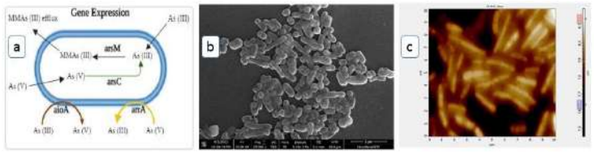

Figure 1. *Kurthia gibsonii* strain MKVVM3 IITBHU (a) Gene expression, (b) SEM and (c) AFM

In the present work, *the Kurthia gibsonii strain MKVVM3 IITBHU (NCBI accession no. - ON248393.1) w*as Gram-positive. Oxidizing, reducing, methyltransferase, and respiring gene expressions suggested that it can play an essential role in the biogeochemical cycle of As. These include genes involved in producing the arsenate-reducing enzyme, ArsC and aioA gene responsible for As (III) transformation by oxidation Fig.1(a). Rod-shaped species of bacteria Fig. 1(b) that SEM has identified. Surface morphology investigations using AFM Fig. 1(c) provided insight into how adhesion forces supported As adsorption on bacterial surfaces to remove metalloid contaminants.

Abstract
An innovative water solution, to improve and minimise brine discharges in the mining and metallurgy industry, is demonstrated in a mineral processing industry with the aim of reduce brine discharges applying innovative technologies getting salts as valuable by-products and a clean water ready to reuse it. A prototype (10 m^3/h) based on a softening step, followed by nanofiltration, reverse osmosis, electrodialysis and evaporation will be operated for 18 months in a real environment in order to gather the operational data to assess from a technical, economic and environmental point of view the feasibility of scaling up this system.

Keywords
AMD, brine discharges, membranes, mining wastewater, water reuse

Introduction

The application of dense membrane-based technologies such as nanofiltration (NF) or reverse osmosis (RO) to remove sulphates in acid mine drainage (AMD) from the mining industry has grown in the last few years to bring water quality in line with these new regulations (Masisdi et al, 2017). Membrane processes allow a lower consumption of chemicals than physico-chemical systems, a fixed removal rate of the target parameters and the possibility to produce purified water, suitable for reuse or to improve discharge water quality. Nevertheless, the rejection of dissolved salts and the consequent generation of brines needs to be managed, especially in inland areas where marine discharge is not a possibility.

LIFE REMINE WATER project aims to demonstrate an alternative treatment train for sulphates removal and deploy innovative solutions for brine concentration in the mining sector, in which water can be recovered to enhance water quality discharged and boost the recovery of valuable by-products. Additionally, the use of renewable energies such as solar-thermal systems to reduce the carbon footprint and OPEX associated to evaporation will be assessed.

Material and Methods

The project is carried out in an ore treatment plant (copper, zinc and lead) located in the south-west of Spain. Industrial wastewater is currently derived to an iWWTP based on a physico-chemical system. Table 1 shows the intake water characterization for the pilot plant. An innovative integrated solution has been designed to remove effectively sulphates in AMD and minimize the generated brines volume in a cost-efficient way.

Table 1. Intake water characteristics

Parameters	Units	Raw water
pH	-	2.27 ± 0.10
conductivity	mS/cm	7.94 ± 0.99
Sulphates	mg/l	3763 ± 173
Ca	mg/l	660 ± 79
Mg	mg/l	223 ± 27

Firstly, a NF unit treats 7 m^3/h with the goal of eliminate the sulphates and the remaining divalent elements that are present in the raw water. Before the NF, a softening stage (based on CO_2 and NaOH) is applied to ensure the maximum removal of calcium and magnesium to minimize the risk of membranes scaling due to an uncontrolled precipitation of $CaSO_4$, pH is neutralized with HCl addition and a sand filter is used as pretreatment to avoid that suspended matter can provoke membrane clogging.

The NF (DK-400, Veolia Water Technology) has been designed to operate at a maximum recovery of 80%. The unit was composed by a single pressure vessel containing 7 membrane elements. The obtained permeate can be directly used to improve the water discharge; nevertheless, in this research a further step of RO will be applied to reduce TDS concentration and produce process water for it reuse. The rejection will be recirculated to one of the buffer ponds of the mine.

The RO stage (AG8050F-100, Veolia Water Technology) will treat 5,6 m^3/h and the goal of this stage is to remove the monovalent elements to reduce the conductivity and obtain a permeate ready to reuse it or discharge. The permeate will be reused in industrial uses, and the brine (0.7 m^3/h), which contains 36 g/L of TDS, will feed an Electrodialysis (ED) unit.

ED-BC (electrodialysis brine concentration) allows without applying pressure as a driving force, to concentrate the brine up to 150 g/L TDS. The brine feeds the stack composed by anionic and cationic membranes. The concentrated brine (0.05 m^3/h) is accumulated and will feed a low temperature evaporator coupled with solar thermal collectors.

The low temperature evaporator is based on Multi Effect Distillation to concentrate the brine up to 250 g/L TDS. Once water has been recovered, the remaining concentrate stream is derived to a crystallizer to obtain a solid waste. In this research, a four stages distillation has been designed. One of the main advantages of low temperature evaporation is that can be coupled with renewable energies. Solar thermal collectors will be used to provide this heat and thus reduce the OPEX and carbon footprint of the process.

Results and Conclusions

The pilot plant has been operating for almost 4-5 months, in these months the different stages have been started up in cascade. Once we obtain the expected results, we move on to the next one and so on with all the stages. Currently the pretreatment, NF and RO are under operation, and it is expected that in the following months the ED-BC and the evaporator will be fully demonstrated.

The pretreatment has been carried out with a Ca/CO_2 mass ratio of 2 and a pH on the settler between 10-10,5. The average calcium removal obtained is 70%, even reaching removals of 96%. Regarding magnesium, the average removal obtained is 60% reaching removals of 90% in a few days. The next step in this stage is to optimize the process by using less CO_2 and consequently reducing the consumption of NaOH.

The NF has been operated with a pressure of 7 bar and an antiscaling concentration (MDC776, Veolia Water Technology) of 4 ppm, obtaining sulphate removals over 95%, an average removal conductivity of 60% and calcium concentration at the outlet for below 25ppm. The quality of the permeate obtained is sufficient (even with better quality than what is needed) for most of the production stages of a mine, and it also has the quality that will allow it to be discharged in compliance with the current limits (and in the coming years) of discharge.

The RO has been operated like the NF with a pressure of 7 bar and an antiscaling concentration (MDC776, Veolia Water Technology) of 5 ppm. The average conductivity removal obtained is over 96% with an outlet calcium concentration of less than 10 ppm. This permeate can be used in all the industrial processes of a mine (reducing the consumption of fresh water). In the event of a discharge, this current will comply with the current limits and with the most stringent discharge limits that may arise. The next step at the membrane stages is to optimize the operation by reducing antiscaling consumption and improving recovery through the use of recirculation in the membranes.

If the abstract is accepted detailed results (including the ED-BC and the evaporator) of the prototypes performance will be shared in the conference.

Abstract

Water shortages occur in semi-arid countries, mainly due to their geographical location, climate change, droughts, urbanisation, and pollution of existing water resources. Alternative technologies, not depending on surface water sources, should be investigated in these regions, with atmospheric water harvesting (AWH) a possible approach. The successful application of this technology mainly depends on the weather parameters, such as temperature (T) and relative humidity (RH). In this study, the performance of atmospheric water generators (AWGs) to produce water, was assessed during the four seasons in a remote town in the Gauteng Province of South Africa. The results show that the highest production of water was during summer and autumn seasons, whilst limited or no water production was recorded on some days in the winter and spring months. AWGs could be considered as an alternative source of water, during specific seasons of the years.

Keywords
Atmospheric water generators, Climate change, Water harvesting

INTRODUCTION

Essential to life is to have a sustainable fresh water supply to satisfy the needs of society. Atmospheric water harvesting (AWH) should be seen as an alternative technology for drinking water supply. The water formation within the air is dependent on the temperature (T) and relative humidity (RH) of the air with the suitability of AWH dependent on the thermodynamic principles of an active cooling, condensation, vapour compression cycle, technique. At the AWH location, the 1st annual rains occur during spring, at a minimal rate, with most of the rain falling during the summer season and no rain falls in autumn and winter, hence it is classified as a "semi-arid" region. Careful assessment of the performance of the technology at high altitude, semi-arid regions, is thus needed. In this paper the case study outcomes of the use and performance of atmospheric water generators (AWGs) was investigated to address the challenges of drinking water security [1].

MATERIALS AND METHODS

Atmospheric water generators

Two atmospheric water generators (AWGs), each with a maximum production capacity of 10 000 L per day, were used. The generators are installed at the Ga-Rankuwa site with geographical location coordinates 25°33'24.43'' S, 28°0'5.75'' E in the Gauteng Province, South Africa. The AWGs draw air from the atmosphere, filter it, and condenses it below its dew point temperature for water generation, typically when T≥ 15°C and RH≥ 30%.

Operating Data Recording and Capturing

The control of the AWGs consisted of a human interface screen, that displays the operating conditions, such as the T and RH, and when AWH commences. From 1/1/2020 until 31/1/2021, T and RH were recorded daily to ensure seasonal coverage and behavioural performance of the generators through the different seasons. Concurrently to the recording, weekly average weather forecast from the South African Weather Services (SAWS) [2] were added to the manual collected data on an Excel spread sheet to conduct an analysis of deviation from the climate to predict and optimise water productivity by the AWGs. A 3rd party forecast tool, Meteoblue [3], was later introduced and provided more accurate, hourly forecasts for up to 2 weeks at a time.
All data were recorded manually, including the water production from the AWGs, which was measured from the internal flowmeters near the final water collection tank within the AWGs.

RESULTS AND DISCUSSION

The performance of the AWGs was assessed by plotting water harvested (Litres), T (°C) and RH(%) over a period of one year. For the cold season (winter) and the warm seasons (summer, spring, autumn) a considerable influence on the water production was observed (Figure 1). The average weather forecasts from the SAWS used, showed significant deviations, and thus the hourly weather forecast tool, Meteoblue, was subsequently used to close the water production gap between the SAWS forecasts and site expectation outcomes from the AWGs.

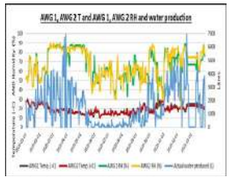

Figure 1: AWGs temperatures and relative humidities with water production for the study year.

The highest water production was observed during the autumn season; March - May 2020. Water production picked up again in the middle of spring (starting in September) towards the summer season (December - February 2021), in a range of about 5000 L to 7000 L water production per day, with less water harvested from the atmosphere during the winter season, where the lowest average T was 9°C with RH being around 17%, as was observed between June and August 2020. A total of almost 60 000L of water production was recorded within the year studied.

CONCLUSION

The results showed that atmospheric water harvesting in a semi-arid, high altitude region using AWGs may be sustainable during autumn and summer seasons as these generators can only perform at their maximum under favourable ambient conditions; implying that T and RH are continually within a specified range. This study provides information that will be useful during the implementation of AWH in remote areas lacking a conventional water supply in South Africa.

Abstract
Polycyclic Aromatic Hydrocarbons (PAHs), derived from coal-tar pollution in water, remain in the water for very long, creating hazards to the environment. A need arose to develop and implement an effective technique that will remove these pollutants in polluted water sources.
A self-made flatbed photoreactor was built to degrade, under visible light, the PAHs in acidic-alkaline mine drainage, and sewage wastewater. Zinc oxide (ZnO) and silver (Ag) solutions, functionalised with the agrowastes moringa oleifera seed (MO), groundnut shells (GS) and apatite (A), to obtain a novel heterogeneous photocatalysts, were used in the photo degradation process.
Less than 65% removal of PAHs in 60 min for the different wastewaters when using only the flatbed photoreactor, but the photocatalyst combination of MO/GS/A/ZnO/Ag in a 1:1:1 ratio, removed almost 100% of PAHs from the different water sources for a 60 min period.

INTRODUCTION

Water is a valuable resource for humans; therefore, it is essential to have a sustainable fresh water supply to satisfies the society. The water crises, in particular occurring in South Africa, has exacerbated and major concerns are raised regarding the pollution of the environment from various industries [1,2], with coal conversion, petroleum refining, processing of organic chemicals, among others, responsible for the degradation of water qualities through releasing organic pollutants such as polycyclic aromatic hydrocarbons (PAHs) into the receiving waters [3].
The PAHs remain in the water for very long, creating various hazards, resulting in a need to develop and implement an effective technique that will remove these pollutants in the water sources. In the present investigation a flatbed photoreactor was designed and built to degrade, under visible light, the PAHs in acidic-, alkaline mine drainage, and sewage wastewater.

MATERIALS AND METHODS

The coal-tar used in this study was obtained from a coal coking plant and the interaction of the coal tar with acid mine drainage (pH 2.77), alkaline mine drainage (pH 7.95) and sewage wastewater (pH 6.70) was used to simulate the release of PAHs from the coal tar into the environment. A mass of 116.3 mg coal tar with 2 mL of hexane added, was used to extract, and analyse the PAHs using GC-MS.
For leaching, 5 grams of coal tar was added to a glass column, containing 300mL of either one of the solutions mentioned, with the leaching process conducted over a period of 8 weeks.
The three water sources containing the PAHs were left in solar radiation to determine the degradation efficiency and subsequently a flatbed photoreactor, made of Perspex glass (dimensions: length 40 cm, width 35 cm and height 15 cm) was designed and built to degrade, under visible light, the PAHs in the acidic-, alkaline mine drainage, as well as sewage wastewater. Zinc oxide (ZnO) and silver (Ag) solutions, functionalised with three agrowastes, moringa oleifera seed (MO), groundnut shells (GS) and apatite (A) were used in the final photodegradation process to obtain a higher removal efficiency of PAHs.
Analytical techniques used, included photoluminescence (PL), scanning electroscopic microscopy (SEM), X-ray diffraction (XRD), energy-dispersive X-ray spectroscopy analysis (EDS), gas chromatography-mass spectrometry (GC-MS) and Fourier transform infrared analyses (FTIR).

RESULTS AND DISCUSSION

Leaching of PAHs

The coal tar contained 2917 mg/L of PAHs, with the most abundant PAHs being naphthalene (788 mg/L), phenanthrene (632 mg/L), fluoranthene (395 mg/L), acenaphthylene (356 mg/L), fluorene (327 mg/L), pyrene (266 mg/L), and anthracene (245 mg/L).
After 8 weeks of leaching, 19.3 mg/L, 1.62 mg/L and 1.81 mg/L PAHs were released from the acidic mine drainage, alkaline mine drainage, and sewage wastewater respectively. The release of PAHs from the coal tar was observed to increase over time. The PAHs with lower weight, between 2 to 4 rings, were observed to be highly dissolved in the samples.

Photodegradation of PAHs

The photodegradation of the PAHs in the three water sources (acidic-, alkaline mine drainage, and sewage wastewater) was significantly influenced by time, irradiation method used, i.e., without the flatbed reactor, with the flatbed reactor and with the addition of a heterogeneous photobiocatalyst.
The degradation of PAHs via solar energy only, was proven to be spontaneous in the acidic mine drainage, followed by alkaline mine drainage and lastly the sewage wastewater, with a reduction of PAHs obtained for the three water sources investigated, to be 53%, 33% and 39% respectively over time [1].
It was observed that the use of only a flatbed photoreactor was effective in achieving the photodegradation efficiency of 64%, 58% and 55% under solar irradiation for 60 min for the acidic, alkaline and sewage wastewater [1].
The added agrowastes (groundnut shells (GS), *moringa oleifera* seed (MO) and apatite (A)), including silver to enhance the properties of the ZnO semiconductor, were used to make a heterogeneous photobiocatalyst, with the MO/GS/A/ZnO/Ag photobiocatalyst, mixed in a ratio of 1:1:1, resulted in the best properties and lowest bandgap of 1.96 eV compared to the parental ZnO bandgap, which was found to be 3.35 eV and 2.96eV for ZnO/Ag respectively.
The ZnO/Ag photocatalyst showed a decrease in photodegradation over time in the acid mine drainage, although the removal efficiency increased over time, in contrast to the MO/GS/A/ZnO/Ag in the acidic water, that showed an increase in photodegradation with an almost constant removal efficiency occurring over time, removing 100%, 97% and 98% of PAHs in the acidic, alkaline and sewage wastewater for a 60 min period, respectively [1].

CONCLUSION

The application of green synthesis, using plant materials, functionalised on the semiconductors, could add value to the green synthesis of the metal oxides ZnO or TiO_2 on the photodegradation of PAHs in wastewater with an almost 100% removal in the photodegradation process.

Abstract
Per- and polyfluoroalkyl substances (PFAS) are one of the most persistent pollutants in the environment and recent research points to human health risks at low concentrations in environmental media. Hydrated electrons (e^-_{aq}) generated from H_2O under vacuum UV (VUV) irradiation can cleave C-F, leading to the PFAS transformation. Six types of PFASs with two different head groups and various chain lengths were investigated in a specialized VUV reactor to assess removal efficiency. Without additional chemicals, four perfluoroalkyl carboxylic acids (PFCA, CF_3-$(CF_2)_n$-COOH) were transformed at both neutral and alkaline conditions, while one perfluoroalkyl sulfonate (PFSA, CF_3-$(CF_2)_n$-SO_3) was abated at a high pH condition. Elimination of dissolved oxygen improved PFAS transformation using VUV irradiation.

Keywords
Vacuum UV, PFAS, hydrated electron

INTRODUCTION

Per- and polyfluoroalkyl substances (PFAS) have been widely used for industrial applications and consumer products due to their properties. Because of their widespread use, PFAS are frequently detected in surface water and drinking water. PFAS are bioaccumulative and toxic, which poses risks to human health and the environment. Due to the stability of the C-F bonds, PFAS is highly persistent in the environment. Physical treatments, e.g., membrane filtration and ion exchange, separate PFAS from contaminated water into a more concentrated waste stream, and do not destroy the target PFAS compounds (Bentel et al., 2019). Hydrated electrons (e^-_{aq}), with a reduction potential (E^0) of -2.9 V, can cleave the C-F bond (Buxton et al., 2009). UV-based methods, e.g., UV/sulfite, have been used to generate e^-_{aq} for halogenated compound degradation. The obvious disadvantages of applying chemicals are undesired by-products and additional post-treatment. Vacuum UV (VUV) at 185 nm photolyzes water molecules into various radicals, including e^-_{aq}, requiring no additional chemical addition. Apart from e^-_{aq}, hydroxyl radicals ($HO\cdot$) are generated during water ionization and further assist oxidation of defluorinated PFAS products. Simultaneous reduction and oxidation reactions provide a promising alternative for PFAS degradation. Existing studies on PFAS degradation have primarily focused on PFOA and PFOS. Few studies have investigated multiple PFAS at the same time. In this study, we used four perfluoroalkyl carboxylic acids (PFCA, carbon number = 4, 7, 8, 10) and two perfluoroalkyl sulfonates (PFSA, carbon number = 4, 8) to examine their removal performance with VUV irradiation.

MATERIALS AND METHOD

PFBA ($CF_3(CF_2)_2COOH$, 99.5%), PFHpA ($CF_3(CF_2)_5COOH$, 97%), PFOA ($CF_3(CF_2)_6COOH$, 95%), PFDA ($CF_3(CF_2)_8COOH$, 98%), PFBS ($CF_3(CF_2)_3SO_3H$, 97%), PFOS ($CF_3(CF_2)_7SO_3H$, 40% in water), NaOH (1 mol/L), and H_2O_2 (30%) were purchased from Sigma Aldrich. All experimental solutions were made by spiking Milli-Q water with PFAS. NaOH was used for pH adjustment. The experiment was conducted in a collimated beam with a low-pressure mercury UV/VUV lamp. Light intensity at 254 nm on the reactor surface was measured at 6.5×10^{-4} (W cm^{-2}), using a NIST Traceable Light Measurement System from International Light Technologies. The intensity of 185 nm was calculated at 1.3×10^{-4} (W cm^{-2}). The depth of the reactor cell was 10 mm. Control experiments under UV, UV/H_2O_2, and dark conditions were conducted to assess the role of HO-, only, on PFAS removal. To eliminate dissolved oxygen (DO), nitrogen gas (N_2) was used to purge the solution and reactor. LC-MS was used to analyze PFAS concentrations.

RESULTS

- Four PFCAs were transformed at all three pH conditions after 5 min VUV treatment (Figure 1). After 810 min treatment, PFCAs abatement exceeded 90%. PFDA (carbon number = 10) evaluated, which is the longest PFCA, had the highest decay rate at three pH conditions.
- The degradation rates of PFCAs improved with increasing pH (Figure 1). At pH 11, the decay rates of PFCAs improved by approximately 60% compared to pH 7.
- Short-chain PFBS (carbon number = 4) did not degrade in any of the three pH conditions. Long-chain PFOS (carbon number = 8) showed moderate removal (~60%) at pH 11 after 810 min treatment.
- Eliminating DO improved the removal of PFBA, PFHpA, and PFOA by approximately 20%, while the abatement of PFDA was only slightly improved (~3%, Figure 2).
- Oxidation via $HO\cdot$ (Figure 2) or direct photolysis at 254 nm (not shown in the figures) did not initiate PFAS abatement.

DISCUSSION

- The degradation of PFAS depends on the functional group and chain length. PFAS with sulfonate groups were more refractory to VUV irradiation than carboxylic acids groups. In general, long-chain PFAS compounds were less persistent than short-chain compounds and showed higher transformation in the VUV system.
- PFAS had better abatement at high pH because alkaline conditions favored the generation and accumulation of e^-_{aq}. At 185 nm, the quantum yield of e^-_{aq} from OH^- is 0.11, while from H_2O is 0.045 (Dainton et al., 1965; Gonzalez et al., 2004). Moreover, alkaline conditions suppress e^-_{aq} scavenging by H^+ and promote the transformation of $H\cdot$ to the stronger reductive radical - e^-_{aq} (Gonzalez et al., 2004).
- DO in solution is a scavenger for e^-_{aq}, thus eliminating DO enhanced PFAS degradation. But the difference in PFAS transformation with and without purging N_2 gas was not drastic, which may result from the long experimental time and/or direct photolysis at 185 nm. DO could be transformed into different forms (e.g., $O_2^{\cdot-}$) under 185 nm irradiation, leading to decreased DO concentration at a later reaction time (Heit et al., 1998). Besides, the direct photolysis of PFAS at 185 nm could reduce the impact of DO on PFAS removal.

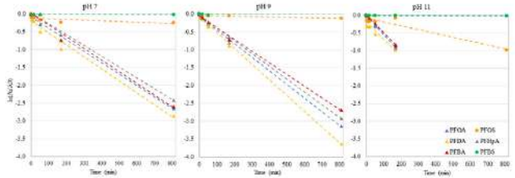

Figure 1. Degradation of six PFAS in VUV processes vs. time. N_2 gas was prior purged into the solution. Reaction time = 5, 17, 52, 170, 810 (min). The initial concentration was 0.1 umol/L for each PFAS. The concentration of PFCAs at pH 11 and 810 mins were lower than detection limits (0.05 ng/L).

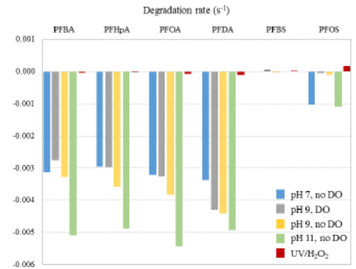

Figure 2. Comparison of the PFAS degradation rates in VUV processes. The initial concentration was 0.1 umol/L for each PFAS. [H_2O_2] = 0.15 mmol/L.

Fenton self-cleaning MOF and MOF-derived porous carbons modified ceramic membrane towards highly efficient for oil/water emulsion separation

Pei Wang and Xiao-yan Li

Department of Civil Engineering, the University of Hong Kong, Pokfulam, Hong Kong, China (E-mail: *u3007979@connect.hku.hk)**

Abstract
A novel catalytic flat sheet ceramic membrane (CFSCM) is fabricated that is integrated with the advanced oxidation process (AOPs) to achieve a synergistic effect on the mitigation of membrane fouling and removal of organic pollutants from wastewater. With the increased hydrophilicity, higher electronegativity, and narrowed pore size, NPC-MIL-53(Fe)-functionalized catalytic ceramic membrane (NPC53@CM) exhibited a more effective antifouling capability during its application in oil removal from an oily wastewater. The CFSCM performed particularly well in the cleaning and regeneration of fouled membranes, which might be attributed to its increased hydrophilicity and Fenton reaction activity of the coated catalysts.

Keywords
Antifouling, Flat sheet ceramic membrane, Fenton self-cleaning, MOF-derived porous carbon, Oil-in-water emulsion separation

RESULTS AND DISCUSSION

Antifouling performance of the ceramic membrane

Membrane fouling is still one of the greatest challenges for membrane applications, especially in the oil/water separation process. In this work, a MIL(Fe)-type metal-organic framework (MOF) and its calcination yielded MOF-derived N-doped porous carbon were grown in situ on the CFSCM surface to obtain the NH_2-MIL-53(Fe)-functionalized catalytic ceramic membrane (NM53@CM) and NPC-MIL-53(Fe)-functionalized catalytic ceramic membrane (NPC53@CM). The antifouling performance and self-cleaning function of the membranes in the oil emulsion removal from water were investigated.

Under the similar permeability coefficient and separation efficiency conditions (NM53@CM and NPC53@CM had oil removals of 96.4% and 96.9%, respectively), NPC53@CM had a more effective antifouling capability during its application in oil/water emulsion treatment, as shown in Fig. 1. This is likely due to the enhanced hydrophilicity and higher electronegativity of the CFSCM. According to the membrane fouling model analysis, the fouling behavior, including adsorption, deposition, pore blockage, and cake layer formation were alleviated with NPC53@CM owing to the increased hydrophilicity and oleophobicity of the membrane surface. Assessed by extended Derjaguin-Landau-Verwey-Overbeek (XDLVO) theory, NPC53@CM exhibited a higher energy barrier and a powerful repulsive force for foulants to overcome to attach onto membrane surface.

Self-cleaning function of the ceramic membrane

During a long operating period, membrane fouling remains inevitable for CFSCM. The catalytic cleaning performance by Fenton reagent was investigated to evaluate the self-cleaning function of the membrane. As shown in Fig. 2b, the NPC53@CM showed a good catalytic performance in the cleaning and regeneration of the fouled membranes with a flux recovery ratio of 98.8%, which is likely attributed to its increased membrane hydrophilicity and Fenton reaction activity of the coated catalysts. In addition, NPC53@CM maintained a good stability and recyclability after multiple cleaning cycles, indicating its excellent application potential. The research work provides a new technical strategy for modification of ceramic membranes with Fe-based MOFs to achieve antifouling and Fenton self-cleaning function of the membranes for water purification and wastewater treatment.

Abstract
Phosphorus (P) in the effluent of wastewater treatment plants (WWTPs) and agricultural run-off is a major cause for eutrophication of freshwater bodies and should be sufficiently removed. Removal of phosphorus to ultra-low levels is also becoming more important to prevent/minimize biofouling when wastewater effluent is treated with membrane technologies. BioPhree is a technology which uses iron (hydr)oxide-based adsorbents to remove P to ultra-low levels. This presentation shows past and present demonstrations of the technology on freshwater and urban wastewater, including an overview of different pilot tests, performance data and lessons learnt. Finally, it will provide an overview of future demonstrations and perspectives for this adsorption technology.

Adsorption; Biofouling; Demonstration; Eutrophication; Mossbauer; Phosphorus

INTRODUCTION

Eutrophication and algal blooms are an increasing threat for water bodies and can cause huge environmental and economic damages. Phosphorus (P) in the effluent of wastewater treatment plants (WWTPs) and agricultural run-off is a major cause for eutrophication in freshwater bodies and should be sufficiently removed. P concentrations greater than 100 µg/L are commonly considered high enough to cause eutrophication (Vollenweider R.A., 1980; Dodds et al., 1998; Richardson et al., 2007; Lurling and Oosterhout, 2013). However, the strictest regulations target 10 µg/L as a good ecological level for fresh waterbodies (Carvalho et al., 2013.)
Removal of phosphorus to ultra-low levels is also becoming more important to combat biofouling when wastewater effluent is treated with membrane technology (Vrouwenvelder et al., 2010). With a trend of complete re-use of wastewater (zero-liquid discharge), Nano Filtration (NF) and Reverse Osmosis (RO) membranes are applied more often to remove pollutants and recover nutrients and salts.
Adsorption is a suitable method for P removal in terms of performances and economics, with a low footprint (Kumar et al, 2019). Some of the most promising adsorption media are iron (hydr)oxide granules and hybrid ion exchange resins (HAIX) with ferric oxide nanoparticles embedded in the structure (Huang et al., 2020). These adsorbents can be regenerated many times with an alkaline solution from which the phosphorus can be subsequently recovered. BioPhree is a technology which uses iron (hydr)oxide-based adsorbents to remove P to ultra-low levels. This presentation shows past and present demonstrations of the technology on freshwater and urban wastewater, including an overview of different pilot tests, performance data and lessons learnt. Finally, it will provide an overview of future demonstrations and perspectives for this adsorption technology.

GEORGE BARLEY PRIZE

The BioPhree technology was demonstrated for 3 months in eutrophicated marsh water in Canada in the George Barley Water Prize contest in 2018. The BioPhree technology treated up to 32 m3/day of water with ortho-P (oP) and particulate-P (pP) concentrations of 0.177 mg/L and 0.220 mg/L respectively. The installation consisted of an advanced filtration stage for particulate P-removal, followed by an iron oxide-based resin adsorbent system for ortho-P adsorption. The total oP and pP removal was 97% and 78% respectively. The adsorbent could be regenerated and re-used and P could be recovered from the regenerant solution as raw material for fertilizer application. The regeneration is a key factor which considerably decreases operational cost of adsorption systems.

H2020 WATER-MINING

In the H2020 Water-Mining project, Wetsus is demonstrating reversible P-adsorption on pilot-scale at two case study sites in Cyprus and Catalonia. At these sites, effluent wastewater from the WWTPs is reused for irrigation purposes. Due to salinity concerns of the water in Cyprus, a desalination pilot plant is demonstrated at the wastewater treatment plant of Larnaca. Biofouling of membranes is a common occurrence when treating wastewater and can seriously limit the efficiency of such processes. BioPhree is implemented before the desalination process system to remove P down to ultra-low levels, thus limiting biofouling. Moreover, the irrigation water in Larnaca is stored in a lagoon before use. This lagoon is heavily eutrophied and can lead to clogging of the irrigation system with algae. Especially for drip irrigation this can be problematic. By removing phosphorus down to ultra-low levels BioPhree has the benefit of preventing eutrophication in storage lagoons. The BioPhree system in Larnaca is currently operational for over a year with effluent quality <50 ug/L demonstrated and repeated regenerations performed. In the spring of 2023, the pilot system will be moved and demonstrated in La Llagosta, Catalonia, for another year. In La Llagosta, Wetsus will also demonstrate a vivianite crystallization technology named ViviCryst to remove the bulk of phosphorus as a post-precipitation method, before polishing the effluent with BioPhree.

ADSORBENT SPECIATION WITH MOSSBAUER SPECTROSCOPY

One of Wetsus' greatest tools in studying and developing P adsorbents is Mossbauer Spectroscopy (MB). It was observed that many adsorbents lack in terms of speciation characterization (Kumar et al., 2019) and that especially during regeneration, the iron oxide species in the adsorbent can transform or sinter, thus impacting the performances (Kumar et al., 2018). MB is a non-destructive nuclear technique, which works with few elements, among which Fe is the most widely investigated. It provides information on the oxidation state, structural properties, magnetic properties, particle size, and can provide a quantitative speciation of the iron species in the sample. MB allows us to fully characterize iron oxide-based adsorbents, identifying and quantifying the different Fe species, both crystalline and amorphous, monitoring their transformations throughout the process.
MB provides the chance to investigate and monitor the properties of our adsorbents and the regeneration thereof on a fundamental level, understanding their behavior throughout the process, to further improve adsorbent stability for P-recovery. For example, MB has been applied in our group to develop innovative doped iron-based nanoparticles with improved stability.

PERSPECTIVES

Adsorption is a promising technology to recover P. Precipitations becomes too expensive when aiming at ultra-low P removal (Kumar et al., 2019). Current P-removal technologies to prevent eutrophication consist of (coated) sand filtration, which does not efficiently remove oP or makes it impossible to recover it, and constructed wetlands, which have a considerable footprint and eventually turns in P hotspots for downstream waterbodies (Bishop & Szafraniec, 2019). An adsorption plant requires tens to hundreds of times less area than wetlands, allows recovery of P and regeneration of the adsorbent, decreasing the OpEx. Too little attention on adsorption to target P sources (as WWTP effluent or agricultural runoff) to prevent eutrophication of freshwater bodies and for lake remediation has been spent. In fact, in-lake treatments like P precipitation with Al or La based chemicals are still widely preferred (Mucci et al., 2019), despite the former revealed to be ineffective for long-term P-blocking and to affect the waterbody pH, while the latter effectively blocks P without allowing its recovery and regeneration of the adsorbent.

Biophree has proven its efficacy to fill the gap between current regulations limits (which are not always met) and actual good ecological quality of water, meeting the circularity targets as environmental impact (eutrophication prevention), nutrients and resources recovery (P), and reusability of materials (adsorbent) with a low footprint.

Abstract
Among advanced oxidation processes (AOPs) – key technologies for the degradation of persistent trace substances in wastewater (WW) treatment – photocatalysis shows great promise, but needs improvement in efficiency. In this study, we investigated the influence of improved catalyst material and adapted reactor geometry on the photocatalytic degradation of organic trace substances. In particular, we studied the extent to which mixing reduced mass transport limitations and thus increased the efficiency of the process. Kinetic rate constants were determined and compared well to data from other studies These comprehensive investigations and promising results are the prerequisites for up-scaling the process and hence contribute to narrowing the gap between fundamental research and industrial application of photocatalysis in WW treatment.

Keywords
Advanced oxidation process; micropollutants; pilot plant; rapid prototyping; wastewater treatment

INTRODUCTION

A good ecological and chemical status of water bodies - set as a target by the Water Framework Directive - has not been achieved in many rivers (Land.Nrw, 2023). One reason are substance inputs from point sources like municipal WW treatment plants, which can be reduced by advanced treatment (Rizzo et al. 2020). Photochemical AOP derive energy from light radiation and photocatalysts can be used to promote the formation of the reactive OH radicals. Due to this high reactivity, critically persistent substance groups such as PFAS can also be eliminated (Leonello et al., 2021). The efficiency of this process depends on the reactor setup, the catalyst material and the light transmission and chemical composition of the water matrix (Venieri et al., 2020). In this study, we holistically investigated these influencing factors at lab-scale, with a view to operating a pilot plant at a WW treatment plant.

MATERIALS AND METHODS

The methodology of the preliminary study is based on DIN 52980 to determine the photocatalytic activity of surfaces (10^{-5} mol L^{-1} methylene blue as test substance). A collimated beam device was uses with λ = 365 nm and E = 15.000 µW cm^2. Pseudo-first-order rate constant was used for evaluation.
Different reactor variants were produced with 3D printing.

Figure 1. Lab set-up: (a) pump; (b) control box of irradiation unit (c) PearlLab Beam™ and (d) reactor.

RESULTS AND DISCUSSION

The effectiveness of the catalyst under UV radiation could be increased by various structural modifications. In addition, a shift in the absorption spectrum from the UV range to the visible light range could be achieved. (Daskalova et al. 2022 preprint) Figure 2 shows how our preliminary results outperform the rate constants of many other laboratory studies.

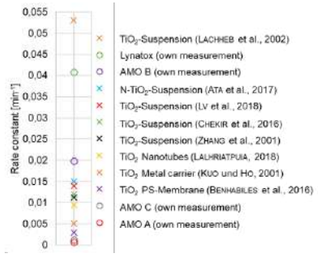

Figure 2. Efficiency of different UV catalyst systems for water purification. AMO B is currently the best self-made catalyst (immobilized: plasmonic structure of gold and ammonil with TiO2 coating on quartz glass carrier).

In addition to these nanoscopic but far-reaching material changes, the meaningful use of these advantages requires changes in the reactor design. In the reactor, the catalyst is irradiated with light while the WW to be cleaned moves over the reactive surface. Consequently, mixers have to be introduced into the used flat-bed and tubular reactors in order to maximize the contacts of reactants by minimizing the laminar boundary layer. (Chong et al. 2010) The first attempts at mixing by means of overflow and the resulting reduction in mass transport limitations are presented in Figure 3.

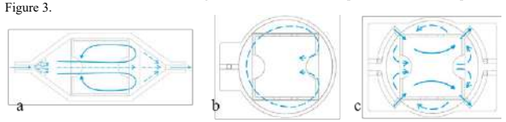

Figure 3. Reactor designs: (a) loop reactor; (b) aereation reactor and (c) flow through reactor - The flow through reactor achieved the best degradation performance with 91.8%, followed by the aeration reactor with 74.7% and the circulation reactor with 59.9%. The degradation performance could be improved by additional ventilation.

Abstract
In this study, novel walnut shell biochar-nano zero-valent iron nanocomposites (WSBC-nZVI) were synthesized using a combined pyrolysis/reduction process. The WSBC-nZVI displayed a high removal efficiency (85%) for carbamazepine (CBZ) compared with WSBC (70%) and nZVI (77%) in the presence of persulfate. Subsequently, WSBC-nZVI was applied for the fabrication of the membrane using a phase inversion method. The membrane demonstrated an excellent degradation efficiency (91%) for CBZ in a dead-end system. In addition, the effect of different operating parameters on the degradation efficiency in the membrane/persulfate system was investigated. The optimum pH was achieved under near-neutral conditions and by increasing the concentration of CBZ a drop in the efficiency of the system was observed. The degradation mechanisms and degradation products were also investigated, and the possible degradation pathways and the predicted toxicity of intermediates were proposed. Furthermore, the feasibility of this membrane technology was examined by the treatment of real wastewater.
Keywords
catalytic membrane; mechanisms; nano zero-valent iron; persulfate; walnut shell biochar

MATERIALS AND METHODS

The walnut shell was obtained from Matthys Bvba (Belgium) with a particle size ranging from 450 µm to 800 µm. A controlled pyrolysis process was implemented for the preparation of the walnut shell biochar. In detail, 20 g of the walnut shell was impregnated with 100 mL H_3PO_4 (0.6 M) at 90 °C for 3 h, then dried at 80 °C overnight. Subsequently, the obtained precursor was pyrolyzed at 520 °C for 2 h with a heating rate of 10 °C/min. The entire pyrolysis process was carried out under the nitrogen atmosphere. The prepared black powder was collected and labelled as WSBC for further characterization and use. The WSBC-nZVI was synthesized using a liquid phase reduction process. Typically, 0.4 g WSBC and 6 g $FeSO_4{\cdot}7H_2O$ were dispersed in 400 mL distilled water under the stirring and nitrogen atmosphere for 30 min. Then, 200 mL $NaBH_4$ solution with a concentration of 20g/L was added into the mixture drop by drop with the flowing nitrogen. After 1 h of reaction, the final black powder was collected and washed with distilled water three times. Finally, the nanomaterial was dried at 60 °C overnight under the nitrogen atmosphere. The nZVI was also synthesized through the same method without the WSBC.

The WSBC-nZVI membrane was fabricated by a phase inversion method. In a typical process, the WSBC-nZVI nanomaterial (2%) was dispersed into a DMF solution (70%), then it was distributed uniformly under ultrasound conditions for 30 min. Subsequently, the PES (16%) and PEG (12%) were added to the above solution. The mixture was heated at 60 °C for 6 h under continuous stirring conditions. The obtained homogenous solution was degassed under ultrasound conditions for 30 min to remove bubbles in the solution. Then, the solution was evenly spread onto a glass plate using a casting knife (Elcometer 3580, Netherlands) to set a wet membrane thickness of 200 µm. Thereafter, the glass plate was immediately immersed in a distilled water bath at room temperature until the membrane spontaneously detached from the glass plate. The membrane was stored in the distilled water under an N_2 atmosphere to remove the residual organic solvent.

RESULTS AND DISCUSSION

Characterization of the nanomaterials and membrane

Fig. 1a demonstrates the vesicle-type morphology of WSBC with a porous structure. The nZVI presents as agglomerated spherical particles. The aggregation of the nanosized particles is due to the Van der Waals effects between the nano-size magnetic particles. In Fig. 1d-e, the morphology of WSBC-nZVI clearly confirms that the nZVI particles are well dispersed on the surfaces and pores of WSBC. In addition, the mapping of WSBC-nZVI proves the presence of C, O, and Fe in the composition of the materials, as indicated in Fig. 1e-i. Furthermore, the presence of WSBC-nZVI particles on the flat surface of the membrane is evident from Fig. 1j. The cross-sectional images of the membrane (Fig. 1 k-m) also reveal its porous and spongy morphology. Formation of the porous structures is due to the use of PEG as a pore-forming agent in the membrane fabrication process. In addition, the presence of hydrophilic oxygen-containing groups (such as -COOH, C-O) on the surface of WSBC-nZVI nanoparticles can improve the diffusion rate of water into the membrane during the fabrication process of the membrane, which results in the formation and development of pores.

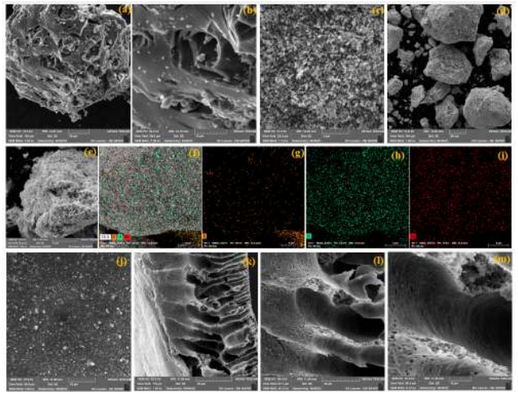

Figure 1. SEM images of WSBC (a-b), nZVI (c), WSBC-nZVI nanocomposite (d-e), mapping (f-i) of WSBC-nZVI nanocomposite, surface (j), and cross-section (k, l, m) of the WSBC-nZVI membrane.

Degradation of CBZ

Fig. 2a indicates that WSBC exhibits the highest adsorption capacity for CBZ (75%) among the studied materials This can be attributed to the presence of surface functional groups such as -COOH, -N-H on the surface of WSBC which can provide more active sites for the adsorption of pollutants, and may also promote the formation of hydrogen bonds between adsorbent and the contaminant. In addition, the adsorption capacity of WSBC-nZVI for CBZ was slightly increased (9%) compared to nZVI (4%), which can be related to the surface functional groups still remained at the surface of BC after loading of nZVI. Furthermore, the addition of PS had no significant effect on the removal of CBZ with WSBC (Fig. 2 b). In this situation, the competitive adsorption occurs between CBZ and PS, and a part of the adsorption sites of WSBC is occupied by PS. On the other hand, the WSBC can't efficiently activate PS to degrade CBZ. As indicated in Fig. 2b, both nZVI and WSBC-nZVI demonstrated high CBZ degradation efficiencies of 86% and 76%, respectively, indicating that these nanomaterials can efficiently activate PS for the degradation of CBZ. In addition, the WSBC-nZVI exhibits a higher degradation efficiency than nZVI, which can be attributed to the high surface area high porosity, and abundant functional groups of WSBC-nZVI.

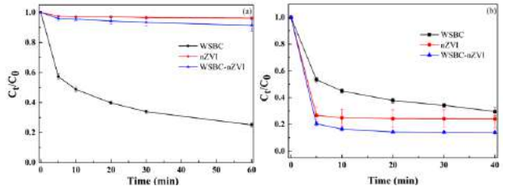

Figure 2. Adsorption (a) and degradation (b) kinetics of CBZ by different nanomaterials (conditions: 0.5 g/L catalyst, 10 mg/L CBZ, 1mM PS).

Degradation mechanisms

Fig. 3 illustrates the reaction mechanism for the WSBC-nZVI membrane/PS system proposed according to the results achieved by the scavenging experiments. The Fe species (Fe^{2+}) is quickly generated from WSBC-nZVI via different routes, such as the direct reaction of Fe^0 with PS, indirect reaction of Fe^0 with oxygen, the indirect reaction of Fe^0 with water molecular. Subsequently, Fe^{2+} can react with PS to produce Fe^{3+} and $SO_4^{\cdot-}$. A part of $SO_4^{\cdot-}$ is converted into SO_4^{2-} and ·OH by the reaction of H_2O or OH^-. In addition, $O_2^{\cdot-}$ can be produced from two routes including the reaction between Fe^{2+} and O_2 and the reaction between O_2 and electrons. The $^1O_2$ can also be generated from the reaction between $O_2^{\cdot-}$ and water (or H^+). Meanwhile, Fe^{3+} can be reduced into Fe^{2+} through the reaction of Fe^0 and Fe^{3+}, which is a key reaction for the degradation of CBZ. Moreover, WSBC as a supporter can not only prevents the agglomeration of nZVI but also promotes the conversion of Fe^{3+} to Fe^{2+} by supplying electrons. The abundant functional groups (such as -COOH, C-O) of WSBC can improve the adsorption capacity for CBZ and boost the activation efficiency of PS for the degradation of organic pollutants. In a conclusion, the CBZ can be firstly adsorbed on the surface of the membrane, then it's decomposed in the presence of active species (e.g. ·OH, $SO4^{\cdot-}$, $O_2^{\cdot-}$, $^1O_2$). Finally, the CBZ can be further oxidized into small molecular intermediates, CO_2, and H_2O (Fig. 4).

Abstract
A previous study has developed a new bioreduction process for the continuous treatment of chromium wastewater by predicting the effluent concentration of Cr(VI). In this study, we introduce the ICT-Brduction process that measures the influent characteristics in real-time by applying information and communication technology (ICT) and calculates the Cr(VI) concentration of the influent through machine learning. In addition, the bioreductant used in this process can be recovered as Cr_2O_3, which has a high recycling value. Therefore, the ICT-Bioreduction process applying biosorption technology has a high value in the ESG industry because it can purify the chromium wastewater using biowaste and recover chromium resources therefrom.

Keywords
Biosorption; Chromium; ESG; ICT; Machin learning; Sensor

INTRODUCTION

In previous studies, we developed a new bioreductant and bioreduction process that simultaneously remove Cr(VI) and Cr(III). In addition, for practical process development, a new model suitable for the bioreduction process was developed to predict the effluent concentration of Cr(VI). In this model, the values of influent Cr(VI) concentration and the pH determine the effluent concentration of Cr(VI). Therefore, to put the bioreduction process to practical use, it is necessary to measure the Cr(VI) concentration and pH value of the influent in real-time. The influent concentration of Cr(VI) was calculated in real-time through OPR, EC, and RGB sensors, and the pH value was measured in real-time through the pH sensor. In addition, this study aims to suggest the possibility of using biosorption technology in the field of environmental society and governance (ESG) by researching on the disposal or recycling of bioreductants treated with Cr(VI) wastewater.

MATERIALS AND METHODS

Information and communication technology (ICT)

Arduino (Arduino Uno SMD R3, arduino. cc), which is a single-board microcontroller for building a digital device, was used as ICT to predict the influent concentration of Cr(VI) in real-time. An automatic measurement system that consisted of five sensor devices: pH (SEN0161-V2, DFRobot, China), oxidation-reduction potential (ORP) (SEN0165, DFRobot), electrical conductivity (EC) (DFR0300, DFRobot, China), temperature (KIT0021, DFRobot, China), and color (RGB) (SEN0212, DFRobot, China) sensor connected to one Arduino was developed to measure the properties of Cr(VI) wastewater influent in real-time. The sensors were installed in two cylindrical reactors with a volume of 500 mL. The reactor equipped with the RGB sensor was wrapped with black insulating tape to block ambient light. The data measured through the sensors were programmed to be monitored in real-time using Tkinter, which is a module used for graphical user interface programming.

Bioreduction process

Bioreduction process incorporates an up-flowed fixed-bed column with inlet and outlet ports. Acrylic columns with an internal diameter of 2 cm and a length of 17 cm were connected in series to facilitate their replacement. The column was moderately densely packed with a bioreductant (500 g/L) composed of pine bark and alginate. Thin cotton was placed in the bottom of the column to ensure uniform distribution of influent across the entire cross-section of the column. A top layer of thin cotton was used to minimize washing out of the bioreductant. The process was operated in an up-flow mode at a constant temperature.

RESULTS AND DISCUSSION

To predict the influent concentration of Cr(VI), chromium synthesis wastewater was prepared under 46 conditions and the characteristics of the chromium synthesis wastewater were measured using the automatic measurement system. As a result of convolution neural networks (CNN) of about 7,000 measurement data collected from the automatic measurement system, RGB values showed a very high correlation with Cr(VI) concentration. Therefore, an empirical model for calculating the Cr(VI) concentration was derived using the RGB values (Fig. 1). Thus, the Cr(VI) concentration of influent can be calculated in real-time using machine learning, and the Cr(VI) concentration of effluent can be predicted from the concentration and pH of influent measured through the automatic measurement system. The ICT-Bioreduction process is a process that can be put to practical use in actual processes by continuously treating Cr(VI) wastewater through ICT convergence.
Table 1 shows the XRF results of components after incinerating the bioreductant treated with Cr(VI)wastewater at 1100 °C. The incinerated bioreductant was mainly composed of Cr and O, which was composed of Cr_2O_3 molecular structure as a result of XRD analysis. Cr_2O_3 is used in various industrial fields such as links, glasses, paints, and ceramics. Therefore, chromium can be recovered by incineration of the bioreductant, and can be recycled in other industries.

Abstract
A bioreduction process was composed by filling the column with a new bioreductant capable of simultaneously removing Cr(VI) and Cr(III) using natural biomass. The bioreduction process is in the form of connecting several columns in series, that continuously treat Cr(VI) wastewater by the column rotation system. A new mathematical model was applied to this process to predict the concentration of Cr(VI) in the effluent. As a result of simulating the process using the mathematical model, the predicted value and the experimental value of the effluent concentration showed similar tendencies. In addition, this process is very economical when compared to chemical treatment. This study shows the possibility of applying biosorption technology to the actual process for Cr(VI) wastewater treatment.

Keywords
Biomass; Bioreductant; Bioreduction process; Biosorption; Chromium

INTRODUCTION

Biosorption, one of the Cr(VI) removal methods, is dominated by oxidation-reduction reaction, which has been recognized as 'adsorption-coupled reduction' (Park et al., 2005a). Over the past decades, many researchers have tested various biomass for the removal of toxic Cr(VI) from aqueous solutions. However, research on the practical use of Cr(VI) wastewater treatment using biosorption technology is still insignificant. This study introduces a bioreductant developed using abiotic biomass and shows a new bioreduction process developed for practical use and the results of the process simulation.

MATERIALS AND METHODS

Bioreductant

The abiotic biomass, pine bark (*Pinus sp.*), is a biowaste from a sawmill. The pine bark was sun-dried, then cut into pieces approximately 2–3 cm in size. The small pieces were dried at 100 °C for 24 h, after which they were ground into smaller particles and then sieved to select finer particles between 38–106 μm in diameter. The fine particles were immobilized by entrapment in alginate polymeric matrices. The immobilization content ratio is 4.8 g of fine particles to 2 g of sodium alginate in 100 mL of DI water. The alginate-bark slurry was extruded into 0.1 M $CaCl_2$ to form of unbreakable fiber using a 1 mm diameter of syringe for polymerization. The polymerized resultant formed a skein shape. The skein-bioreductant was washed several times, and the water was wiped off the surface. This bioreductant contained approximately 80% water.

Bioreduction process

Bioreduction process incorporates an up-flowed fixed-bed column with inlet and outlet ports. Acrylic columns with an internal diameter of 2 cm and a length of 17 cm were connected in series to facilitate their replacement. The columns were packed moderately densely with the bioreductant (500 g/L). Thin cotton was placed in the bottom of the column to ensure uniform distribution of influent across the entire cross-section of the column. A top layer of thin cotton was used to minimize washing out of the bioreductant. The process was operated in an up-flow mode at a constant temperature.

RESULTS AND DISCUSSION

Bioreduction process was configured to continuously treat Cr(VI) wastewater by recovering the first column before the Cr(VI) concentration in the effluent was detected above the standard value and installing a new column behind the last column (Figure 1). The Cr(VI) concentration of effluent was predicted through a mathematical model when determining the value of Cr(VI) concentration and pH in influent. The mathematical model was developed by expanding of 'modified dose-response' model. The mathematical model simulated the Cr(VI) concentration in the effluent of each column in the process and obtained the replacement period of the column.
Table 1 shows the required amount of $FeSO_4 \cdot 7H_2O$ and $Ca(OH)_2$ to remove 1 ton of 1 mM Cr(VI), which was calculated from the batch experiment result. The bioreduction process was simulated through the expanded modified dose-response model to calculate the required amount of the bioreductant to treat 1 ton of 1 mM Cr(VI). The bioreduction process reduced costs by 86% compared to the chemical treatment.

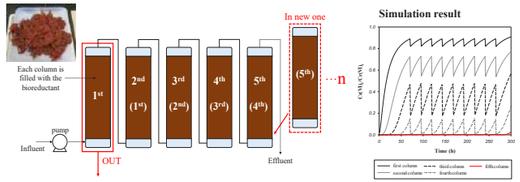

Figure 1. Schematic of bioreduction process.

Table 1. Comparison of the economic value of chemical treatment and bioreduction process for treatment of the 1 ton of 1 mM Cr(VI) wastewater at pH 2.

		Price (won/g)	Required amount (g)	Required cost (won)	Total cost (won)
Chemical treatment	$FeSO_4 \cdot 7H_2O$	4.16	845	3,515	3,996
	$Ca(OH)_2$	0.69	697	481	
Bioreduction process	Bark	-	235	-	565
	Alginate	5.5	98	539	
	$CaCl_2$	0.48	55	26

Abstract
A novel freestanding ceramic SnO_2-Sb electrocatalytic membrane is developed, which functions as both an anode and a membrane for advanced wastewater treatment, including emerging organic pollutant removal and high-rate virus disinfection. Nearly 100% removal of the pollutants can be achieved by the charged SnO_2-Sb anode membrane in a single-pass treatment.

Keywords (maximum 6 in alphabetical order)
Disinfection; electrochemical oxidation; electroactive membrane; emerging organic pollutants, water treatment

INTRODUCTION

Emerging organic pollutants in wastewater, which are commonly resistant to conventional biological wastewater treatment, have not only posed considerable risks to the eco-system but also worsened the water scarcity problem. Meanwhile, viruses in wastewater are also causing more concerns on human health. Thus, there is an urgent demand of effective technologies for advanced wastewater treatment and water reuse. Electrochemical technology is a promising method for the removal of emerging contaminants from wastewater, due to its strong oxidation capability and environmental compatibility (Radjenovic & Sedlak, 2015). However, the practical application of electrochemical oxidation processes has been hindered by the mass-transfer-limited kinetics and high energy consumption. Reactive electrochemical membrane, also named electrocatalytic membrane, is an innovative strategy to overcome the challenges in electrochemical water treatment (Guo et al., 2016). The porous electrodes simultaneously serve as an electrocatalytic electrode and a membrane filter, which can substantially increase the electroactive surface area of the electrode and improve the mass transport of the process for efficient wastewater treatment (Yang et al., 2021). Herein, a novel freestanding and permeable SnO_2-Sb electrocatalytic membrane was fabricated for electrochemical oxidation and wastewater treatment. The anode was operated in the single-pass flow-through pattern for the removal of emerging organic pollutants and the inactivation of viruses in wastewater. The robustness, feasibility, and stability of the SnO_2-Sb electrocatalytic membrane system was also evaluated in this experimental study.

RESULTS AND DISCUSSION

The schematics of the electrochemical wastewater treatment system equipped with the SnO_2-Sb membrane are shown in Figure 1. The porous and permeable 3D reactive membrane allows wastewater to flow depth-wise through the anode, thus providing a multitude of active sites for direct organic oxidation and reactive radical generation. The treated effluent can be collected for reuse.

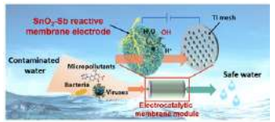

Figure 1. Schematic illustration of the novel electrochemical treatment system equipped with a SnO_2-Sb electrocatalytic membrane for wastewater treatment and reuse.

Performance of the electrocatalytic membrane for antibiotics degradation and virus disinfection

Ciprofloxacin (CIP) was used as a model emerging organic pollutant to evaluate the effectiveness of the ceramic SnO_2-Sb electrocatalytic membrane-based treatment system (Figure 2). In the conventional flow-by configuration, the electrochemical treatment removed approximately 48.0% of the CIP. In the flow-through mode with the electrocatalytic membrane, the CIP removal efficiency increased significantly to 92.1% under the same experimental conditions. The rate constant k_{obs} of CIP degradation for the flow-through anode (0.077 min^{-1}) was more than five times that of the flow-by anode (0.014 min^{-1}). The power consumption of CIP degradation for the flow-through mode was 0.31 kWh g^{-1} CIP, significantly lower than that for the flow-by mode (2.43 kWh g^{-1} CIP).

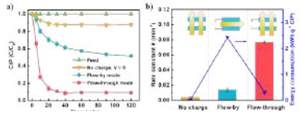

Figure 2. ECO experiments in the flow-by and flow-through configurations: (a) CIP degradation, (b) pseudo-first-order degradation rate constants and energy consumption (conditions: [CIP] = 10 μM, cell potential = 4.0 V, pH = 6.0).

Bacteriophage MS2 was selected as a model virus in this study because its similarity to human pathogenic viruses. Figure 3 shows the virus removal efficiencies of the electrochemical treatment. Nearly no MS2 removal was observed under the non-charged conditions (0 V), as the size of MS2 (20–30 nm) was too small to be removed by membrane filtration. In the conventional flow-by mode with an applied voltage of 3.5 V, a 2.6-log inactivation of MS2 was obtained, with a large amount of MS2 virus remaining in the effluent (10^5–10^6 PFU mL^{-1}). Using the reactive membrane in the flow-through mode, the MS2 virus removal efficiency significantly increased to 100% (> 8.3-log inactivation), and no live MS2 virus was detected in the treated effluent.

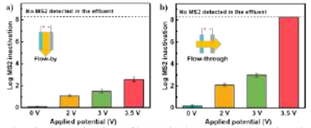

Figure 3. The electrochemical inactivation of bacteriophage MS2: (a) using the conventional flow-by operation and (b) the SnO_2-Sb catalytic membrane flow-through operation with a feed of ~1.5 × 10^8 PFU mL^{-1} of MS2 in 0.05-M Na_2SO_4 at a flux of 54 LMH.

These results prove the superiority of the electrocatalytic SnO_2-Sb membrane in the electrochemical treatment of emerging organic contaminants and viruses within a short period of only about 1.7 min through the membrane anode. The improved mass transport and enlarged electroactive surface area facilitated the direct oxidation and reactive radical generation for organic degradation, resulting in the excellent treatment performance. Overall, this research provides a new strategy for the design and operation of ceramic electrocatalytic membrane systems to achieve effective and reliable purification and disinfection of water and wastewater in decentralized applications.

Abstract
This research investigates the process performance of down-flow hanging sponge reactor (DHS) for the post-treatment of effluent from activated sludge process. The reactor was operated under high flow rate condition and low hydraulic retention time (HRT) at 0.5-1 hour for one year. At the shortest HRT of 0.5 hour, the BOD and ammonium loading was 0.96±0.26 kg BOD/m^3/day and 0.30±0.08 kg N/m^3/day, respectively. The reactor illustrated effective performance with respect to high removal efficiency of organic matter (86±7% of BOD removed) without excess sludge treatment. Inorganic nitrogens (ammonium, nitrite, and nitrate) were effectively eliminated (46±19% removal efficiency). The *E. coli* log reduction was 2.2±0.7. So, it is possible to use this reactor as an energy efficiency technology for the post-treatment of domestic wastewater from residential building with HRT of 0.5-1 hour.

Keywords
DHS, Energy efficient; Inorganic nitrogen; Post-treatment; Sponge; Trickling filter

INTRODUCTION

Insufficient aeration process of decentralized wastewater treatment plant is one of the reasons that Bangkok water resources were deteriorated. Installation of post-treatment system is required to improve the organic matter and nitrogen reduction from the discharge. However, huge area (due to the longer retention time) is required which is unfavorable for the space limit area like Bangkok. The down-flow hanging sponge (DHS) technology is one of alternative wastewater treatment technology with the compact size and energy efficient (Tandukar *et al.*, 2005). Because of the self-aeration, the electricity consumption is about 68% reduction from conventional activated sludge process (Yoochatchaval *et al.*, 2014). So, it is an attractive technology for developing countries where are facing with the limitation on budget and space. The DHS system was developed as an aerobic trickling filter using polyurethane sponge media where the oxic and anoxic zone are available. As a result, there are nitrification and denitrification reaction occur. Moreover, the snails (macrofauna) were present on the surface of the sponge resulted to the small excess sludge generated from this system (Onodera *et al.*,2015). From previous research, DHS reactor explicated the significant organic matter removal efficiency under HRT of 1-5 hours (Danshita *et al.*, 2020; Takemura *et al.*, 2022). In this study, the investigated HRT was 0.5- 1 hour. The treatment efficiency of DHS as a post-treatment was observed about 370 days.

MATERIALS AND METHODS

A pilot-scale DHS reactor has been setup at Bongai national housing, in Bangkok area. This cylinder shape reactor has a diameter at 40 cm. The reactor has 4 segments inoculated with sponge media followed by clarifier unit. The total height is 4.12 m. The total volume of sponge media was 175 L with 8,000 pieces of the sponge media. To simulate insufficient water quality of decentralized wastewater treatment plants' effluent, the effluent from Bongai's activated sludge process has been collected and mixed with raw sewage from the national housing at mixing ratio of 2:1. Then, it flowed through the reactor under ambient temperature condition. The operating HRT was set at 1 hour for 170 days. As a result, the BOD and ammonium loading rate were 0.83±0.34 kg BOD/m^3/day and 0.36±0.11 kg N/m^3/day, respectively. At HRT of 0.5 hour (from day 171), the mixing ratio of AS effluent and fresh sewage was changed to 5:1. Then, the BOD and ammonium loading rate were 0.96±0.26 kg BOD/m^3/day and 0.30±0.08 kg N/m^3/day, respectively. The DHS reactor's process performance was investigated routinely by the composite sampling technique. The water quality parameters such as temperature, oxidation reduction potential (ORP), DO and pH were measured onsite. The following parameters were analyzed at laboratory; total suspended solids (TSS), volatile suspended solids (VSS), biochemical oxygen demand (BOD), chemical oxygen demand (COD), total nitrogen (TN), ammonium, nitrite, nitrate (inorganic nitrogen, sum of ammonium, nitrite, and nitrate) and *Escherichia coli* (*E. coli*). The tracer experiment was conducted to confirm the actual HRT. In this experiment, saturated NaCl concentration has been used as the tracer mineral. The NaCl was loaded from the top of the reactor. Then the conductivity of the effluent from DHS reactor was determined.

RESULTS AND DISCUSSION

According to the water quality data, the DHS reactor showed effective process performance. For physical treatment capacity, sponge media was able to trap the suspended solid on the surface area of sponge. As a result, the TSS removal efficiency was more than 85% throughout the experiment. The excess sludge generation was low as compare with other aerobic process. The retained sludge concentration was about 4.7-13.0 kg VSS/m^3-sponge. Because of the long sludge retention time and sufficient oxygen supply, the DHS reactor can successfully treat the organic matter (BOD). The BOD removal efficiency was 86±7% at HRT of 0.5 hour. The DO concentration of the effluent was about twice as compare with the influent (Table 1). The water samples were collected from onsite wastewater treatment plant which located nearby the dense population community. So, fresh sewage was predominated with the pathogens which impacted to human health. *E. coli* could be classified as a sanitation indicator. Interestingly, the DHS reactor can supply enough oxygen and the *E. coli* reduction achieved at 2.2 $\log_{10}$.

Table 1. The water quality data of post-treatment DHS reactor

	HRT 1 hour (day 0-170) AS Effluent: fresh sewage = 2:1			HRT 0.5 hour (day 171-370) AS Effluent: fresh sewage = 5:1		
BOD loading (kg BOD/m^3/day)	0.83±0.34			0.96±0.26		
Ammonium loading (kg N/m^3/day)	0.36±0.11			0.30±0.08		
	Influent	Effluent	Removal	Influent	Effluent	Removal
DO (mg/L)	2.5±0.8	5.2±0.8		3.2±1.0	5.4±0.4	
TSS (mg/L)	20±5	3±3	85±12%	11±4	1±1	91±4%
Total COD (mg/L)	88±23	22±18	76±10%	52±18	13±10	76±13%
Total BOD (mg/L)*	34±14	4±2	87±5%	20±5	3±1	86±7%
Ammonium (mgN/L)	14.9±4.1	2.5±2.4	84±14%	6.4±1.7	0.5±0.4	93±4%
Inorganic N. (mgN/L)	15.8±4.0	3.84±1.80	46±18%	6.46±2.78	3.63±1.93	46±19%
E. coli (CFU/mL)	4.5 E+04	3.1 E+02	2.16 $\log_{10}$	1.7 E+04	1.2 E+02	2.17 $\log_{10}$

*The BOD measurement with additional of allylthiourea (ATU)

The DHS reactor has high potential for nitrification process. As a result, ammonium concentration of the effluent is very low (0.5-2.5 mgN/L). From previous research the removal efficiency of ammonia was 79% at 0.046 kg N/m^3 day loading and HRT of 1.5 hour (Onodera *et al.*, 2016). Interestingly, this experiment confirmed the super high rate of ammonia removal at 93±4% with the loading of 0.30±0.08 kg N/m^3/day under HRT of 0.5 hour. So, short HRT condition did not significantly impact to the nitrification process. Also, the inorganic nitrogen removal efficiency was about 45% of both HRT. This evidence confirmed that the DHS reactor is possible for application as the post-treatment system.

The information of retained sludge concentration is shown in figure 1. When the HRT reduced to 1 hour, the sludge was washed out from the first segment due to effect of wastewater volume and hydraulic impact. As a result, the concentration of retain sludge reduced in segment 1-4. However, the reduction of sludge concentration was not obvious in segment 2-4 due to the lower hydraulic impact and higher growth of biomass. Finally, the retained sludge in segment 4 remained at 13.0 kg VSS/m^3/sponge. The retained sludge concentration of segment 2-4 is similar to previous research.

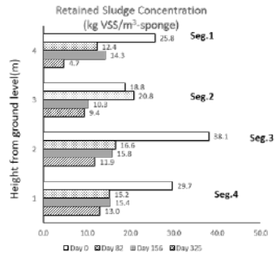

Figure 1. Retained sludge concentration

CONCLUSIONS

A pilot-scale DHS reactor was installed at a small-scale wastewater treatment plant. This reactor has been used as the post-treatment system of sewage from residential area (Bangai community, Bangkok). The DHS reactor illustrated the effective process performance at HRT of 0.5 hour. The organic matter and inorganic nitrogen could be treated sufficiently by this reactor. BOD removal efficiency reached 86±7%. The inorganic nitrogen removal efficiency was 46%. The energy consumption for this system is for the purpose of water lift up (self-aeration). Sponge media can retain the sludge in sufficient concentration. Sludge deterioration and washed out slightly occurred resulting to long sludge retention time. So, the DHS reactor is possible to apply for post-treatment of onsite wastewater treatment plant.

ACKNOWLEDGMENT

We wish to thank the Bangkok Metropolitan Administration for providing space for the installation of the DHS reactor. This research project was supported by the NIES Research Funding (Type A) of the National Institute for Environmental Studies; Japan

Abstract

The interest on membrane recycling has been growing in the last 20 years. Environmental Directives (such as waste management and circular economies), public grants (e.g. in Europe LIFE and Horizon H2020 programs) and private funding (mainly from water management utilities) promote the investigation of alternatives regarding end-of-life membrane management. Recently published literature indicates that the design of reusable and recyclable membranes is being investigated. Research carried out over the last decade has been focused on restoring reverse osmosis (RO) membrane performance or their recycling through transformation as other membrane types. The study of how an RO membrane is affected by oxidizing agents and/or by drying conditions is one of the topics that is still not fully understood. This lack of knowledge, along with the need to push membrane recycling concept towards the implementation of a cascade recycling cycle with RO membrane end-of-life to give them more than one recycled lives, is being studied in this project called Osmo4Lives.

Keywords (maximum 6 in alphabetical order)
Desalination; membrane drying; membrane oxidation; recycling; regeneration; reverse osmosis

INTRODUCTION

Membrane processes are key elements for water reuse and desalination. They can be classified by membrane type (dense/porous), removal mechanisms, driving force used and/or industrial application. In terms of seawater desalination, reverse osmosis (RO) is the fastest growing technique and has taken the leading position thanks to its lower water production costs compared to thermal desalination processes. Globally, in 2025 to combat water scarcity, 75 Mm^3/day of water will be treated with RO membranes[1]. This number represents the 77% of the total desalinated water, showing the consolidation of the RO technology. Nanofiltration (NF) membranes were recognized in the late 80's as a process intermediate between RO and ultrafiltration (UF) which was developed in the late 1960s[2]. Those technologies have been continuously developed being applied in different fields such as chemical compounds recovery, water treatment, WW reclamation, juice concentration, dairy industry or medical usage. Other processes such as forward osmosis (FO) gained interests for the two decades following the commercialization of the first dedicated FO membrane by Hydration Technologies. Both for RO and FO, thin-film composite (TFC) most available commercial membranes are thin-film composite (TFC). Both TFC FO and RO membranes, feature a selective polyamide (PA) layer formed by interfacial polymerization on top of a porous substrate (polysulfone (PSF) typically).

At the end of their life (typically 5-10 years for seawater and brackish water desalination processes), membranes are discharged, leading the production of waste. The interest on membrane recycling has been growing in the last 20 years. Environmental Directives, public grants and private funding promoted the investigation of alternatives regarding end-of-life membrane management. Recently published literature indicates that the design of reusable and recyclable membranes is possible. Research carried out over the last decade has been focused on restoring reverse osmosis (RO) membrane performance or their recycling through transformation as other membrane types (UF, NF…). Still, how an RO membrane is affected by oxidizing agents and/or by drying conditions is one of the topics that is still not fully understood. This lack of knowledge, along with the need to push membrane recycling concept towards the implementation of a cascade recycling cycle with RO membrane end-of-life to give them more than one recycled lives, is being studied in this project called Osmo4Lives. Apart from new alternatives for RO membrane recycling, Osmo4Lives propose to better understand how dense membrane (FO, RO) and especially their PA layer are affected by oxidising agents and drying that can occur during their usage or storage so to extend their life and favour their recycling.

MATERIALS AND METHODS

The study of the impact on membrane properties at laboratory scale is organized in three principal tasks (T): evaluate various oxidizing agents and tests their impact on PA active layer (T1), evaluate the impact of drying on membrane characteristics (T2) and cascade recycling of membrane coupons (T3).

During T1, the exposure time and dose and the impact on permeability and selectivity as a result of this exposition for several oxidation agents such as chlorine will be studied. T2 evaluates the impact of drying conditions (temperature, time…) on membrane characteristics (permeability, pore size) and the impact of various solvents (as water, seawater, ethanol…) on rehydration/recovery of membranes. T3 will consists of standardizing oxidizing protocols for membrane surface modifications and optimize it based on results from T1 using innovative protocols. RO membrane coupons will be tested and characterized before and after applying any treatment using a standard saline solution[3]. A flat-sheet membrane cell testing equipment will be used to assess the permeability and the rejection of the membranes, to identify properly the impact of each treatment. Advanced characterization will be performed in collaboration with Khalifa University (EAU) and The University of New South Wales (Australia) to better evaluation of treatment impacts on membrane surface and structure. Finally, the cascade recycling process will consist on gradually degrading SWRO performance as shown in Figure 1. At each step, membranes will be characterized and the cascade recycling process will be compared with one step process.

Figure 1. Cascade recycling process

RESULTS AND DISCUSSION

Initial results of the Osmo4Lives project including the impact of drying conditions, solvents and contact time on membrane properties, as well as their potential recovery will be presented. First results showed that full recovery of permeability and selectivity is observed in some membrane brands when using Ethanol as a soaking solution.

Abstract
In many nations, particularly those experiencing water scarcity, novel approaches are being applied to clean wastewater. Heterogeneous photocatalysis is the most widely used of these approaches because it entails the decomposition of organic molecules into water and carbon dioxide, which is a more ecologically benign process. In our study, we studied the photocatalytic degradation process of organic pollutant in wastewater.
Keywords
Organic pollutant; Photocatalyst; wastewater

Introduction

With increasing worldwide interest in environmental issues such as global warming, water/air pollution and waste management, many efforts are being made to find cost effective and sustainable processes for energy production, pollution elimination or recycling. The most abundant energy source available on earth is sunlight. Consequently, engineering efficient solar technologies is a critical step towards carbon-free energy production. photocatalytic materials are materials that are able to convert an incident photon into a consumable or storable energy source, through the creation of an electron/hole pair at the photocatalyst level. Various types of pollutants have contaminated water resources in recent decades. Emerging organic pollutants and resistant organic and inorganic compounds are among the pollutants that conventional water and wastewater treatment processes have a hard time removing with suitable efficiency. New, and sometimes costly methods, are being explored to remove these pollutants, highlighting the need for economical and effective solutions. Thus far, the application of photocatalytic methods to remove pigments, phenols, nitrogen compounds, sulfur compounds, pharmaceutical compounds, pesticides and many other compounds has been investigated.

$ZnTiO_3$ has high thermal and chemical stability, a wide energy gap, high electron mobility, high reduction potential, and low oxidation potential, plus it is cost-effective and environmentally friendly. In recent years, $ZnTiO_3$ has been investigated for application in many fields, such as regenerable sorbent for desulfurization of hot coal gases,gas sensor, humidity sensor, paint pigment, microwave dielectric material, antibacterial agent, and as photocatalyst . It is well known that the photocatalytic activity of semiconductors is closely related to physical properties such as crystalline phase, particle size, crystallinity, and morphology.

Therefore, at present, several methods have been used to obtain $ZnTiO_3$ of controlled shape and size with high purity and low cost. To synthesize $ZnTiO_3$ particles, various techniques have been reported, including conventional solid-state reaction, spin coating, chemical vapor deposition, spray pyrolysis, sputtering, laser sintering, sonochemistry, co-precipitation, hydrothermal/ion exchange process, sol-gel process, chemical bath deposition and Pechini method. Among these methods, the sol-gel process was chosen as a well-established green chemistry technique. The photocatalytic activity of the compounds was evaluated by the photocatalytic degradation of methylene blue under solar light radiation.Figure1 shows the Schematic diagram of the principle of photocatalysis.

Result and disscution

Characterizations of photocatalysts

X-ray diffraction (XRD) patterns of the synthesized perovskites were collected to by D8 Advance, Bruker (Germany), diffractometer with monochromatic high-intensity Cu Kα radiation (l = 1.5406˚A), an accelerating voltage of 40 kV and current of 30 mA. Field emission scanning electron microscopy (FESEM) images, Energy-dispersive X-ray spectroscopy (EDX) patterns and elemental mapping analysis were achieved by Mira 3, Tescan (Czech Republic) microscope. Transmission electron microscopy (TEM) was carried out using CM30, Philips (Netherlands) microscope.figure2

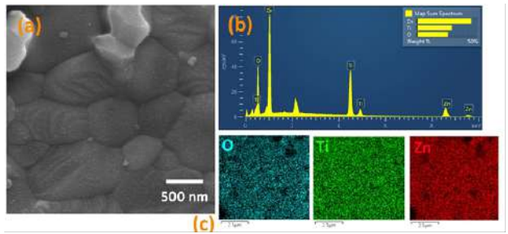

Figure 2. . FESEM images and EDX spectrum accompanied by EDX mapping for $ZnTiO_3$

photocatalytic activity

The photocatalytic activity of the ZnTiO3 was determined by decomposition under visible light irradiation of Methylene Blue (MB) in wastewater. The results obtained in the present study clearly indicate that ZnTiO3 possesses excellent photocatalytic performance. Figure 3. Shows the photocatalytic activity of $ZnTiO_3$ in dark and in presence of visible light. The degradation efficiency was defined as $X=(A_0-A)/A_0$, where X is the degradation efficiency, A_0 is the initial absorbance and A_t is the absorbance of the solution at t min. During the photocatalysis, samples (3 mL) were taken from the reactor every 15 min.

Abstract
In this study, CuO was synthesized using a facile precipitation method and was characterized using various techniques for the efficient activation of periodate (PI). Compared to systems consisting of PI alone (0.5 mM) and CuO alone (0.5 g/L), the CuO (0.5 g/L)/PI (0.5 mM) process exhibited improved degradation performance for ciprofloxacin (CIP), a widely used refractory antibacterial drug, with 98% of this pollutant (20 mg/L) removed in a reaction time of 30 min. Both radical and nonradical degradation pathways were identified to play a significant role in the developed CuO/PI system, where the nonradical pathway (holes and electrons) played the most important role in the degradation of CIP. Under both acidic (pH = 3) and near-neutral (pH = 6) conditions, the system showed an improved efficiency for the degradation of CIP in comparison with alkaline conditions (pH = 10). This was attributed to a more facile adsorption of the PI ions onto the surface of the CuO nanoparticles, induced by the electrostatic attraction between the PI ions and the CuO nanomaterial. Analysis of the degraded samples with ultrahigh-performance liquid chromatography quadropole time-of-flight mass spectrometry (UHPLC Q-TOF MS) demonstrated that cleavage of the piperazine ring and defluorination were the primary degradation pathways of CIP under this oxidation process. The CuO/PI system also showed an excellent removal efficiency for other refractory organic contaminants, such as sulfamethoxazole (SMX) and methylene blue (MB), in various water matrices, including real wastewater. Moreover, respiration tests revealed that the toxicity of the effluents was reduced after the treatment process. In conclusion, this research presents a novel, promising periodate activation technique for the removal of refractory organic contaminants in wastewater treatment.

CuO nanomaterials; degradation mechanism; periodate activation; pharmaceutical micropollutants; toxicity analysis

MAJOR HEADINGS FOR INTRODUCTION

The discharge of antibiotic drugs into natural waters due to their widespread use in medical therapy has sparked serious global concerns. Among them, ciprofloxacin (CIP), a fluoroquinolone antibiotic, is widely used to cure a wide range of microbial diseases in both animals and humans. It has also been discussed in the literature that the migration and transformation of these antibiotic compounds in water bodies can result in the formation of toxic intermediates with the potential to pose a serious threat to both ecosystem safety and public health [1]. Moreover, antibiotic compounds can exert selective pressure on microbes, resulting in antibiotic-resistant bacteria in water bodies [2].
Hence, it is critical to develop wastewater treatment techniques that can deal with a wide range of environmental pollutants, such as antibiotics and dyes, before being discharged into natural waters. To address this need, various advanced oxidation processes (AOPs) have been developed in recent years [3]. The basis of these methods is the generation of oxidative agents (such as $^{\bullet}OH$, $O_2^{\bullet-}$, and $SO_4^{\bullet-}$), which can strongly attack and decompose a wide range of complex organic compounds. Among AOPs, the activation of oxidation agents (such as persulfate, peroxymonosulfate, periodate, and chlorine) using various physical or chemical techniques has received much interest in recent years [4,5].
Periodate (PI, IO_4^-) is a relatively novel oxidation agent that has recently been used for the degradation of various types of recalcitrant organic contaminants. It has some advantages over other oxidation agents, such as being stable and easy to ship and store [6]. PI with a reduction potential of +1.60 V is able to produce a plethora of different radicals and highly reactive substances, such as $IO_3^{\bullet}$, $IO_4^{\bullet}$, $O(^3P)$, $^{\bullet}OH$, and $^1O_2$ [7], when activated with different techniques, such as UV light [8], ultrasound [9], microwaves [10] and freezing [11]. However, the need for an external source of energy for most of these techniques has restricted their wider application [12]. PI can also be activated by chemicals, such as hydrogen peroxide [13] and hydroxylamine [14]. Additionally, there is an interest in the application of carbonaceous materials (such as activated carbon [14]) or transition metals and metal oxides as catalysts for the generation of powerful oxidation agents from PI, with advantages such as low cost, energy savings and ease of use [15,16].
Copper oxide (CuO) is one of the most popular transition metal oxides, widely used in AOPs, such as the photocatalytic degradation of organic compounds [17], and very recently used for the activation of oxidation agents (OAs), such as persulfate (PS) and peroxymonosulfate (PMS) [18] to generate oxidative radicals. However, to the best of our knowledge, it has not been used for the activation of novel OAs, such as PI. Copper is a cheap, eco-friendly, and abundant element in nature that is present in the Earth's crust at concentrations ranging from 146 g/t to 60 g/t [19]. Furthermore, copper oxide nanomaterials normally have a large specific surface area and porous structure, which makes them ideal candidates for surface oxidative reactions [20,21].
In this study, a facile precipitation method was employed to prepare CuO nanomaterials for the activation of PI. The prepared materials were used in a novel CuO/PI activation system for the degradation of pharmaceuticals, including CIP and sulfamethoxazole (SMX).

MATERIALS AND MATHODS

Experimental procedures

The removal of CIP was investigated in a 500 mL glass Erlenmeyer flask containing a 200 mL reaction solution. The initial pH of the solution was adjusted to the required pH (3–10) with diluted H_2SO_4 and NaOH solutions. Because only a small volume was required for the pH adjustment, the volume increase of the reaction volume was negligible. During the reaction, a magnetic stir bar was used to constantly stir the reaction medium. The preferred concentration of PI and the dosage of CuO were mixed in a conical flask to start the reaction. Liquid (1.5 mL) was collected with a syringe at specific time intervals and instantly filtered by a 0.45 µm membrane filter into a clear tube. To halt the oxidation reactions, 1.5 mL of the collected sample was mixed with 50 µL of $Na_2S_2O_3$ (0.1 M). After that, the solution was analysed with HPLC to determine the concentration of the remaining CIP.
For the respirometry experiments, 250 mg/L sodium acetate (NaAc) was chosen as the reference control substrate [22,23]. The activated sludge was received from a sewage treatment plant (Aquafin, Mechelen-Noord, Belgium) and was mixed with water to ensure a biomass concentration of 2.5 g/L MLVSS (mixed liquid volatile suspended solids) for respirometry experiments.

RESULTS AND DISCUSSION

Degradation of CIP and identification of active species in the CuO/PI system

CuO nanoparticles were tested for their catalytic activity as a PI activator for the removal of CIP from aqueous solutions. Fig. 3(a) shows the removal efficiency of 20 mg/L CIP under control conditions (i.e., CuO alone or PI alone) and using the CuO/PI system within 30 min of reaction. CuO alone removed only 37% of CIP in the absence of PI. Here, it is suggested that adsorption is the main mechanism for the removal of CIP, which is supported by the relatively large BET surface area (36 m^2 g^{-1}) of the material [24]. A very low degradation efficiency was also observed for PI alone (28%, within 30 min), which can be attributed to the low oxidation potential of PI. The combination of CuO and PI, on the other hand, exhibited a significant enhancement in CIP removal. The degradation rate reached 53% after 2 min and 92% after 30 min, with a mineralization rate of 44%. The CIP removal kinetics were subsequently fitted to a pseudo-first-order model to further investigate the catalytic performance of the system [8]. The rate constant (k) of the CuO/PI system was calculated to be 0.11 min^{-1}, which is much higher than that of CuO alone (0.011 min^{-1}) and PI alone (0.021 min^{-1}). As shown in Fig. 3(b), the leaching rate of copper in CuO/PI system is less than 0.65 mg/L, which is lower than the discharge limit of copper ion in industrial wastewaters set by the United States Environmental Protection Agency (US-EPA, 1.3 mg/L) [25]. The contribution of leached Cu^{2+} to PI activation was also tested. As we can see from Fig. 3(c), Cu^{2+} can activate PI and 49% of CIP was removed in 2 min. After that, the degradation rate remains almost unchanged. The PI activation efficiency of Cu^{2+} is lower than that of CuO with the same molar mass (6.29 mM). We also used 0.65 mg/L (0.01 mM) Cu^{2+} to simulate the released Cu^{2+} to activate PI. After 30min, the degradation efficiency of CIP reached only 8.86%, which was similar to that of PI alone system. It shows that in CuO/PI system, the activation effect on PI can be ignored because the concentration of leached Cu^{2+} is too low.
Quenching tests were subsequently conducted to determine the main active species involved in the degradation of CIP using the CuO/PI system. For this purpose, hydroxyl radicals (·OH) and $O(^3P)$ were quenched with 2-propanol, and iodate (IO_3^-), periodate radicals ($IO_4^{\bullet}$) and ·OH were quenched with phenol [26]. The contribution of these different active species to the degradation of CIP using the CuO/PI system is indicated in Fig. 3(d) and 3(e). The addition of 2-propanol had almost no effect on the CIP removal efficiency (Fig. 3(d)), implying that ·OH and $O(^3P)$ do not play a role in CIP removal in the CuO/PI system. Because the interference of ·OH has been eliminated by 2-propanol, phenol was added to the system to explore the effect of $IO_3^{\bullet}$ and $IO_4^{\bullet}$. The quenching studies indicated that the kinetics of CIP removal decreased by 54% when phenol was added, revealing that $IO_3^{\bullet}$ and $IO_4^{\bullet}$ effectively contribute to the removal of CIP in the CuO/PI system. Extra analysis was also performed to exclude the effects of the addition of the scavenger on the adsorption of CIP and the consumption of PI, as shown in Fig. 3(f). The results indicated that the addition of phenol can inhibit a bit the adsorption of CIP by CuO probably because of occupying the available active area on the surface of CuO. There are also reports in the literature to support such a statement, for instance by Liao et al. [27].
The possible mechanisms involved in the degradation of CIP using the PI/CuO system were explored using the results obtained from the scavenging experiments and XPS results. The peaks for the used CuO nanomaterial undergo a slight negative shift of 4eV, revealing that CuO acts as an electron acceptor and Cu(II) valence state decreases. It is speculated that the periodate molecules are first adsorbed onto the CuO surface. Then, the interaction between CuO and PI leads to the formation of surface-bonding active complexes, which facilitate electron transfer from PI to Cu(II). In this process, PI and Cu(II) act as the electron donor and the electron acceptor, respectively. As a result, $^{\equiv}Cu^{+}$ and $IO_4^{\bullet}$ are formed according to Eq. 1. In the presence of H^+ and e^-, IO_3^- and $IO_4^{\bullet}$ can be formed for the efficient degradation of CIP (Eq. 2, 3 and 4).

$$\equiv Cu^{2+} + IO_4^- \rightarrow \equiv Cu^{2+} + IO_4^{\bullet} \quad \text{(Eq. 1)}$$

$$IO_4^{\bullet} + 2H^+ + e^- \rightarrow IO_3^- + H_2O \quad \text{(Eq. 2) [12,28]}$$

$$IO_4^{\bullet} + IO_3^- \rightarrow IO_4^- + IO_3^{\bullet} \quad \text{(Eq. 3) [12]}$$

$$IO_4^{\bullet} + \text{pollutants} \rightarrow IO_3^- + \text{products} \quad \text{(Eq. 4) [28]}$$

Abstract
Titanium suboxides (TSO) are identified as a series of compounds showing excellent electro- and photochemical properties. TSO composites with carbon-based materials such as graphene have further improved water splitting and pollutant removal performance. However, their expensive and multistep synthesis limits their wide-scale use. Furthermore, recently discovered laser-induced graphene (LIG) is a facile and less expensive fabrication method for graphene-based composites having various environmental application such as anti-microbial, anti-biofouling, and pollutant sensing. Moreover, various heteroatoms doping in LIG are done to enhance their catalytical performance in pollutant decontamination. Here, we demonstrate the single-step in-situ fabrication of TSO-doped LIG composites as electrodes and porous conductive filters on polymer sheets using a CO_2 infrared laser. The various spectroscopic and electron microscopic techniques confirmed the successful fabrication of TSO doped LIG on the polymer surface. Moreover, the TSO-LIG composite has enhance electrochemical activity as demonstrated using cyclic voltammetry and electrochemical impedance spectroscopy. Furthermore, the TSO-LIG composite surfaces were tested for electrochemical application as electrodes and filters. The composite electrodes exhibit enhanced degradation performance for removing emerging pollutant due to the in-situ hydroxyl radical generation. Additionally, the TSO-LIG conductive filters showed the complete 6-log microbial killing in flow-through filtration mode and showed ~ 2.5-log more killing compared to undoped LIG filers. Nevertheless, the performance of these LIG composites was examined on various doping concentrations and applied potentials.

Keywords
Antimicrobial, Conductive filters, Laser-induced graphene, Electrochemical decontamination, Titanium suboxide

MATERIALS AND METHODS

All chemicals for electrochemical testing was purchased from Sigma-Aldrich and Merck life science Pvt Ltd., India. Nutrient broth and Luria Bertani agar were purchased from HiMedia Laboratories, India. Unless specified, all chemicals were dissolved in distilled water from the distillation unit.
The LIG composites with different concentration of heteroatom were fabricated by irradiating the titanium oxide doped polymer precursor using a 10.6 µm CO_2 pulse laser. All characterisation was done in the central facility of Indian Institute of Technology Bombay, India.

RESULTS

The laser-induced formation of TSO, along with graphene was achieved in a chemical-free, facile, and cost-efficient method using CO_2 infrared laser. The graphene formation was confirmed is using various characterisation techniques such as Raman in Figure 1a. Moreover, the insertion of TSO in the surface was confirmed with the presence of characteristic Ti2p peak in XPS spectrum as shown in Figure 1b.
Moreover, the TSO-LIG composite had enhanced electrochemical activity as demonstrated by electrochemical characterisation with increase cyclic voltammetry curve area of TSO-LIG as compared to the non-doped LIG electrodes (Figure 2a). Furthermore, the in-situ generation of •OH enhanced the pollutants removal efficiency of the TSO-LIG electrodes against MB, giving the best results in the case of 10% doping of TSO at 2.5 V (Figure 2b). Nonetheless, the degradation efficiency of the TSO-LIG electrodes is proportional to the applied voltage and doping concentration.

Abstract:
The potential use of hot combustion gas to produce hot bubbles in a bubble column reactor, as a new water sterilization and desalination process on farms offers a new attractive energy-efficient alternative to disinfecting wastewater from the agricultural industry while producing pure condensed water. Many industries, such as pig farms, landfills, biogas power plants, and coal power plants, emit large amounts of hot combustion gases. This work investigates the potential use of these hot combustion gases (waste) to create hot bubbles in a bubble column reactor, as a new water sterilization and desalination process on farms. This new technology fits within the circular economy principles by using waste gases as an input for the system at 0 running cost.
The use of hot combustion gases as the main input makes this new process highly energy efficient, with potentially no energy requirements (0 kWh/m3).

Keywords:
Combustion gas; Pilot plant; sterilisation; water reuse

INTRODUCTION

The new HBPP transfers heat from the hot gas bubbles of 1-3 mm diameter to the surrounding solution (effluent or sea water). The heat transfer rate between liquid and gas is 100 times more efficient in a gas-liquid bubble column than in a single-phase flow according to Deckwer [1].

This is because the hot bubble surface acts as a natural semi-permeable membrane to purify ions, pollutants, and microorganisms while allowing the heat transfer and mass transfer of the evaporated water vapor [2]. The improved evaporation efficiency of the bubble column, compared with the other thermal process, can sterilise and produce pure condensed water from wastewater. In addition, the use of combustion gas and low-quality waste heat can further reduce the energy consumption of the BCE process [4].

MATERIAL AND METHODS

The exhaust pipe of a gas generator was attached to the inlet of the HBPP. Then hot gases traveled through the sinter into the effluent in the form of hot gas bubbles, inactivating different types of pathogens and producing two potentially valuable water products (Stream 1 and 2). See Figure 1.

- Stream 1, pure condensed water (pure distilled water).
- Stream 2, sterilized water (disinfected water from the HBPP reactor).

RESULTS

Sterilised water

The new HBPP offers a viable water sterilization technology that can sterilize different types of bacteria [3] and protozoa spores in the most heavily infected piggery effluent (see Table 1) using hot combustion gases at 115°C and hot air at 175°C. Inlet gas temperature is the key variable needed to improve the performance of the plant.

Pure condensed Water

The results prove that the new HBPP can evaporate brackish water and piggery effluent at virtually no cost when operated with exhaust gases producing high-quality water condensed water that fits within different international drinking water quality standards such as the European Drinking Water Directive (EU 2020), the Guidelines for Drinking-water Quality from the World Health Organisation (WHO 2011), and the Australian and New Zealand Guidelines for Fresh and Marine Water Quality (ANZECC 2000). Values of conductivity, chloride, sulfate, total nitrogen, calcium, magnesium, and sodium are much lower than the acceptable level for drinking water proving that the HBPP can provide high-quality condensed water (see Table 2).

CONCLUSION

Many industries, such as pig farms, landfills, biogas plants, and coal power plants, emit large amounts of hot combustion gas bubbles in the new HBPP for water-desalination and water-sterilisation processes offers an attractive new energy-efficient technology that produces high quality condensed and desalinated water which complies with international standards.

Abstract
As part of ongoing efforts to effectively remove ammonia from industrial wastewater, electrochemical oxidation has become an alternative to conventional biological treatment due to its easier operation and better tolerance of toxic pollutants. This study aims to prepare CuCo/nickel foam (CuCo/NF) electrodes by depositing different ratios of Cu and Co as catalysts and investigate their performance for ammonia electrooxidation (AEO). Under optimum conditions (pH 11 and applied voltage of 1.1 V vs Ag/AgCl), excellent ammonia removal was obtained using the $Cu_{0.5}Co_{0.5}$/NF electrode system, with 93% removal after 5 h for a low level of ammonia loading (50 mg-N/L), which was superior to the performance of the bare NF electrode (only 54%). The $Cu_{0.5}Co_{0.5}$/NF electrode also had a higher current efficiency of 34% and lower energy consumption of 0.11 kWh g^{-1} compared to the bare NF and single metal Cu (Cu/NF) or Co (Co/NF) electrodes. The high catalytic performance of the $Cu_{0.5}Co_{0.5}$/NF electrode towards ammonia indicates that a CuCo bimetallic catalyst on a NF substrate is a promising solution for effective removal of ammonia from industrial wastewater.

Keywords
Ammonia; CuCo catalyst; Electrooxidation; Nickel foam

INTRODUCTION

Ammonia discharged in wastewater is a major cause of eutrophication, which is a concern in aquatic ecosystems. Electrochemical method, as one of potential eco-technologies, applied in the ammonia removal from wastewater has several advantages over conventional biological treatment, such as easier operation, greater environmental friendliness, and a higher tolerance to pollutants. Pt-based electrodes have been the most widely studied due to their low overpotential and high activity towards ammonia electrooxidation. However, Pt is quite expensive to commercialize and is susceptible to poisoning by N_{ads} during ammonia electrooxidation (AEO). Therefore, the development of a low-cost electrode material with high electrocatalytic performance and low overpotential is highly desirable.

Nickel foam (NF) electrodes have been promoted as an alternative to Pt-based materials for AEO because of their three-dimensional porous structure and relatively high specific area. It has been reported that the addition of a catalyst (e.g. Co, Cu) on the NF substrate can enhance the current density and activity of the electrode (Yan et al., 2012). Copper in particular is one of the most active catalysts for AEO due to its highly conductive nature and abundant active sites. However, the binding of Cu to N atoms is weak, somewhat limiting its performance for AEO. To solve this problem, it is proposed to add cobalt because Co combines a low onset potential with high stability for the electrochemical process. Co is also a low-cost and highly active catalyst. Bimetallic catalysts involving transition metals Ni-Cu and Ni-Co on a NF substrate have shown potential for urea electrooxidation and hydrogen evolution (Wu et al., 2019). It is therefore expected that the combination of conductive Cu and active Co deposited on NF could produce a synergistic catalytic effect to enhance AEO. To further test this hypothesis, bimetallic catalysts with different ratios of Cu and Co (Cu_xCo_y) were prepared on a NF substrate (Cu_xCo_y/NF) as novel anodes for AEO. The electrochemical properties and surface characteristics of these catalytic Cu_xCo_y/NF electrodes were investigated. In addition, the effects of the different atomic ratios of Cu and Co in the Cu_xCo_y/NF electrodes on both removal efficiency and product selectivity were studied.

MATERIALS AND METHODS

The Cu_xCo_y/NF electrodes were prepared by electrodeposition of Cu and Co using different concentration ratios in the plating solution. The variables x and y in Cu_xCo_y (i.e. Cu_1Co_0, $Cu_{0.75}Co_{0.25}$, $Cu_{0.5}Co_{0.5}$, $Cu_{0.25}Co_{0.75}$ and Cu_0Co_1) represent the concentration ratio of $Cu(NO_3)_2$ and $Co(NO_3)_2$ in the plating solutions. The electrodeposition was conducted by adding $Cu(NO_3)_2$ and $Co(NO_3)_2$ with 0.5 M Na_2NO_3 as an electrolyte using a current of 3 mA and 3 C. As a result, Cu_xCo_y film was deposited on the NF substrate (thickness: 1.7 mm, area density: 320 g/m^2, effective area: 6 × 6 cm^2) to form different Cu_xCo_y/NF electrodes.

The synthetic ammonia-containing wastewater was prepared by adding NH_4Cl at low and high concentrations (50 mg/L and 450 mg/L). Na_2SO_4 was used as the electrolyte, and the initial pH was adjusted to 11 using NaOH (0.5 M). CuCo/NF, Pt, and Ag/AgCl were used as the working, counter, and reference electrodes, respectively. The performance of the Cu_xCo_y/NF electrodes for ammonia electrooxidation was investigated over a period of 5 h. The electrochemical characterization and batch AEO experiment were conducted using an Autolab Potentiostat/Galvanostat 302N. The surface properties, and chemical composition of the electrode were analyzed by scanning electron microscopy (SEM), energy-dispersive X-ray analysis (EDX), and X-ray photoelectron spectroscopy (XPS). The electrooxidation performance was assessed by evaluating the ammonia removal efficiency, product selectivity, current efficiency (CE) and energy consumption (EC).

RESULTS AND DISCUSSION

Fig. 1 shows the SEM images of CuCo deposited NF electrodes. Bare NF (**Fig. 1a**) had a porous and/or a mesh structure with a smooth surface. For Cu/NF, Cu was homogeneously distributed on the NF substrate (**Fig. 1b**). Cu tended to agglomerate, which resulted in large particle sizes ranging from 6 to 21 μm, leading to the formation of a thicker surface. Compared to Cu, the Co particles were smaller and more widely dispersed on NF (**Fig. 1c**). For $Cu_{0.5}Co_{0.5}$/NF, the surface of the NF was thicker and rougher (compared to bare NF) due to the electrodeposition of the CuCo bimetallic material, typically by the agglomeration of Cu (**Fig. 1d**). Furthermore, EDS mapping confirmed that Cu and Co had been successfully deposited on the NF substrate.

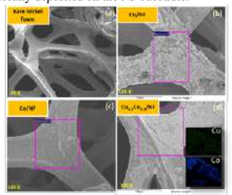

Figure 1. SEM images of (a) bare NF, (b) Cu/NF, (c) Co/NF, (d) $Cu_{0.5}Co_{0.5}$/NF.

The cyclic voltammograms of the NF, Cu/NF, Co/NF, and $Cu_{0.5}Co_{0.5}$/NF electrodes in the absence and presence of NH_3 are illustrated in **Fig. 2**. For NF, Cu/NF, and Co/NF electrode, the current density increased slightly in the presence of NH_3 (**Figs. 2a-2c**). These observations demonstrated the low catalytic activity of monometallic catalyst towards NH_3 (Xu et al., 2017). For $Cu_{0.5}Co_{0.5}$/NF in the absence of NH_3 (**Fig. 2d**), an oxidation peak occurred at 0.42 V vs Ag/AgCl, indicating the oxidation of β-$Ni(OH)_2$ to NiOOH. Astonishingly, the $Cu_{0.5}Co_{0.5}$/NF electrode exhibited a significant increase in current density (from 2 to 9 mA cm^{-2}) in the presence of NH_3 at 0.47 V. The faradaic reaction at this potential was similar to that without NH_3 addition where β-$Ni(OH)_2$ was oxidized to NiOOH. To conclude, the catalytic effect of the $Cu_{0.5}Co_{0.5}$/NF electrode is activated when interacting with NH_3.

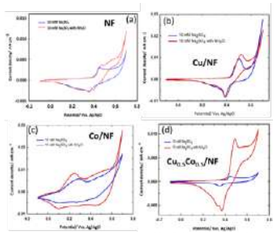

Figure 2. Cyclic voltammograms of (a) NF, (b) Cu/NF, (c) Co/NF, (d) $Cu_{0.5}Co_{0.5}$/NF in the absence and presence of ammonia (NH_3: 0–0.01 M, electrolyte: 10 mM of Na_2SO_4, scan rate: 10 mV/s).

The chemical composition of the $Cu_{0.5}Co_{0.5}$/NF electrode before and after the electrochemical treatment (ECT) was analysed using XPS (**Fig. 3**). Before the ECT, Ni existed in the form of Ni^0, NiO and β-$Ni(OH)_2$ (**Fig. 3a**). After the ECT, Ni^0 and Ni^{2+}oxidized to Ni^{3+} in the form of β-$Ni(OH)_2$ and NiOOH (**Fig. 3d**). The presence of active NiOOH could mediate the electron transfer of the NF-based electrode during AEO (Shih et al., 2018). For Cu, the peak of Cu_2O was transformed to $Cu(OH)_2$ after the ECT (**Figs. 3b and 3e**). Like Cu, CoO was transformed to $Co(OH)_2$ after the ECT (**Figs. 3c and 3f**). In addition, the formation of oxyhydroxide CoOOH was observed. To sum up, the metal oxides, whether Cu, Co, or Ni, were oxidized to metal hydroxides after ECT. The formation of active metal hydroxides and oxyhydroxide on the $Cu_{0.5}Co_{0.5}$/NF electrode is responsible for its superior performance toward AEO.

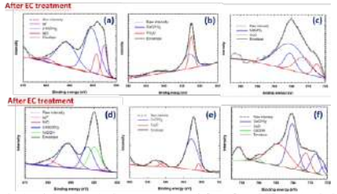

Figure 3. XPS analysis of the chemical composition of $Cu_{0.5}Co_{0.5}$/NF electrode before and after the electrochemical treatment: (a, d) Ni, (b, e) Cu, (c, f) Co.

NF and CuCo/NF electrodes with different CuCo ratios were tested for AEO at pH 11 using 1.1 V vs Ag/AgCl of applied potential. **Fig. 4a** shows that the highest NH_3 removal was obtained with $Cu_{0.5}Co_{0.5}$/NF (93%) followed by $Cu_{0.75}Co_{0.25}$/NF (84%), $Cu_{0.25}Co_{0.75}$/NF (78%), Cu_1Co_0/NF (64%), bare NF (58%), and Cu_0Co_1/NF (44%). Although $Cu_{0.5}Co_{0.5}$/NF provided the highest NH_3 removal, the N_2 selectivity was only 15.3%. By contrast, the highest N_2 selectivity (48.2%) was obtained by Cu_0Co_1/NF, which however showed less capability towards the removal of NH_3 (**Fig. 4b**). **Fig. 4c** shows the EC and CE for different electrodes at pH 11 and 1.1 V vs Ag/AgCl of applied potential. It can be seen that $Cu_{0.5}Co_{0.5}$/NF with a low NH_3 concentration had the highest CE (34%) and lowest energy consumption (0.11 kWh g^{-1}) compared with the bare NF, Cu/NF and Co/NF systems. At a high NH_3 concentration of 450 mg-N/L, although the NH_3 removal efficiency of the $Cu_{0.5}Co_{0.5}$/NF electrode decreased to 72%, its CE substantially increased (77%) with an energy consumption of only 0.03 kWh g^{-1}. This corresponds to better N_2 selectivity with 57% of N_2 being selected (i.e. 3.8 times higher than in the low NH_3 concentration case).

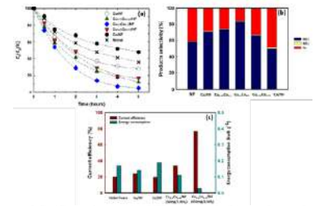

Figure 4. The effects of Cu/Co ratios on (a) NH_3 removal, (b) product selectivity after 5 h (50 mg/L NH_3, 10 mM Na_2SO_4, pH 11, 1.1 V vs Ag/AgCl), (c) comparison of different electrode systems on CE and EC.

CONCLUSION

This study demonstrates that the $Cu_{0.5}Co_{0.5}$/NF electrode is effective for AEO in terms of ammonia removal efficiency, current efficiency and energy consumption compared to the bare NF, Cu/NF, and Co/NF electrodes. The increase in catalytic activity towards ammonia is attributed to the formation of active CuCo oxyhydroxide. However, the main product is NO_3^- instead of the more desirable N_2 gas. Further investigations into the effect of pH and applied voltage should be conducted to achieve higher N_2 selectivity.

Abstract
Onsite domestic reuse of light greywater (LWG) for non-potable uses is an alternative to fulfill water demand worldwide. However, the main challenge for its reuse is the selection of appropriate treatment technologies, given the high variability in its quality. This study analyzed the physicochemical characteristics of LGW in a household from Colombia to propose potential treatment processes. We found high variability of LWG quality compared with data reported in the literature. Biological processes are not recommended for treating LWG, due to their low nutrient content, while filtration in granular media or membranes is highly recommended.

Keywords
Light greywater quality; light greywater treatment; reuse.

INTRODUCTION

Onsite domestic greywater (GW) reuse, specifically light greywater (LWG), is currently one of the most studied alternatives to mitigate water scarcity scenarios worldwide. According to Noutsopoulos et al. (2018), the main advantage of LWG reuse is its relatively low pollutant load compared with other domestic wastewater. Therefore, its treatment could be achieved with lower costs and level of complexity. Previous studies in Colombia show social acceptance of LWG reuse from potential end-users (Domínguez et al., 2017; Oviedo-Ocaña et al., 2018). However, the lack of knowledge about LWG quality in that context makes it a challenge to select appropriate treatment technologies to apply such reuse. While many studies have assessed the quality characteristics of LGW, most of them have been conducted in high-income countries (Eriksson et al., 2009; Ziemba et al., 2018), and have shown the high variability in LWG quality. Given the knowledge gap about LWG in low- and middle-income countries like Colombia, and the high variability their characteristics may have, in this study, we analyze physicochemical quality from a Colombian household to determine its consistency and explore potential treatments for countries from a similar context.

MATERIALS AND METHODS

Study area

The study was conducted in a household located in a residential area of Bucaramanga (Colombia) with 100% coverage of potable water supply, sewage, and solid waste management services. The residence is a family house of four people whose ages are 52, 32, 27, and 12 years old. The household has a total built area of 133.5 m^2 and has a living room, a kitchen, four bedrooms, three bathrooms, and a patio.

Sample collection

We collected 16 LGW samples produced in the household during September and December of 2022. We adopted a protocol based on those implemented in other studies (Shaikh & Ahammed, 2022; Teh et al., 2015) for sample collection. Due to the impossibility of accessing the shower's outflow pipes, each family member was asked to collect the greywater generated while showering using a 59-L plastic tub. Greywater from hand basins was collected directly from the outflow pipe with a 1-L plastic graduated cylinder. From previous studies in the house, we concluded that 94% of the daily production of LGW occurs from 5:00 to 14:00 h. Therefore, on each sampling day, LWG collected from both sources during that period was emptied and thoroughly mixed in a 55-gal plastic barrel.

Laboratory analysis

LGW samples for analysis were collected from the barrel and transported to the laboratory for immediate analysis of physicochemical parameters. Based on the literature review, the main physic-chemical parameters of the GW were identified and used in this study, i.e., pH, electrical conductivity (EC), turbidity, total phosphorous (TP), total nitrogen (TN), total suspended solids (TSS), total chemical oxygen demand (COD) and biochemical oxygen demand (BOD_5). TN was measured according to the persulfate digestion method proposed by Hach®, whereas other quality parameters were analyzed following the standard methods (APHA-AWWA-WEF, 2017). The results of the physicochemical characterization were analyzed with descriptive statistics and contrasted with values found in the literature for LGW in other geographical contexts.

RESULTS AND DISCUSSION

Table 1 presents descriptive statistics for each quality parameter analyzed for LGW samples and data reported in the literature. We found that LGW analyzed in this study gives pH values close to neutrality (7.46 ± 0.15), which is similar to data reported in the literature. Turbidity values were relatively high (242.90 ± 45.12) compared to those found by other authors (Jamrah et al., 2006), which could be related to the use of solid soaps. TSS values (214.57 ± 54.38) were close to values reported in the literature (Friedler, 2004; Teh et al., 2015) and may be associated with hair strands and skin cells. EC values (191.69 ± 9.35) were similar to those found in other contexts (Morandi et al., 2021; Santos et al., 2014) and could be related to the use of personal care products with high salt concentration.

LGW from our study household has a high organic pollutant load in terms of COD and BOD_5 with values of 874.54 ± 161.75 mgO_2/L and 397.88 ± 78.04 mgO_2/L, respectively, which is contrasting to most of the values found in the literature (Jamrah et al., 2006; Morandi et al., 2021; Noutsopoulos et al., 2018), but similar to results found for LWG in Turkey (Oktor & Çelik, 2019). Kadewa et al. (2020) explain that high organic matter concentration in LWG is related to the presence of fatty alcohols used as emollients in personal care products. In addition, the high COD and BOD_5 concentrations in LGW from our study could be attributed to the tendency of less water consumption in low- and middle-income countries compared to high-income countries (Khanam & Patidar, 2022). As our studied LWG showed a BOD_5:COD ratio of 0.45 and neutral pH, it would be acceptable to consider the biological process for its treatment. However, the LWG low nutrient content could compromise biological treatment efficiency, with TN and TP concentrations of 6.17 ± 1.73 and 0.88 ± 0.38, respectively. Furthermore, as the recommended COD:TN:TP ratio for biological treatment is 100:5:1 (Jefferson et al., 2004; Ziemba et al., 2018), the nutrients deficiency is also evident for our studied LWG whit a ratio of 381.90:2.85:1.

With the measured turbidity, TSS, COD, and BOD_5 values, and for LGW decentralized reuse for non-potable uses, we suggest considering granular media filtration, which in previous studies have reported remotion efficiencies of 88%, 76%, 52%, and 20% for COD, BOD_5, turbidity, and TSS, respectively (Ghaitidak & Yadav, 2016; Shaikh & Ahammed, 2021). In addition, the use of ultrafiltration membranes and inverse osmosis is also recommended based on organic matter remotion efficiency above 50%, achieved in other studies (Kant et al., 2018). This study shows the need to deepen the aspects that affect the variability of LWG quality, and to continue monitoring the quality of LWG (i.e., in one and several households) to establish typical characteristics in the context of low- and middle-income countries such as Colombia.

Abstract
Touristic facilities located in water scarce areas of the Euro-Mediterranean are simultaneously facing growing incoming numbers of tourists and decreasing availability of water resources. Decentralised water reuse has become one of the most promising practices for insuring dramatic reduction of water consumption in the touristic sector. Different targets in terms of water quality requirements are established by national and international regulations. However, emerging micropollutants have not yet been included in such policies, partially because of the lack of information on their occurrence. This article investigates the occurrence of a set of OMP in the water cycle of a large resort located in Lloret de Mar, Spain. It hereby considers tap and pool water, as well as the separate wastewater streams: black water and kitchen, laundry, and bathroom greywater, where part of the greywater is reused for toilet flushing.

Keywords
Endocrine disrupting compounds; greywater; hotel; micropollutants; pharmaceuticals; tourism

INTRODUCTION

Global water use has tripled in the last 50 years due to population increase, economic growth, changes in lifestyle, technologies, and international trade. Fresh water availability is unevenly distributed between countries and within countries and water scarcity may exist at the regional and local scale. High and concentrated tourism may exceed the levels of consumption of water resources in arid and water-stressed regions, some of which have already needed water transfers to prevent salinization (Cazcarro et al., 2014). Increasing water consumption and intensity as well as tourist numbers and tourism activities standards are expected. Tourism water consumption is typically below 5 % of domestic water use, but can be as high as 40 % (e.g., Mauritius; Gössling et al., 2012). Additionally, touristic nuclei can have a strong impact on water quality and have been considered as probable sources of micropollutants in seawater especially during the high season (Moreno-Gonzalez et al., 2015). At present, there is a general lack of studies addressing the occurrence of organic micropollutants (OMP) such as personal care products, pharmaceuticals (PhACs), and endocrine-disrupting compounds (EDCs) in closed water cycles.
This study aims at filling a knowledge gap on OMP in tourist facilities in a water-scarce area. A large resort located in Lloret de Mar (NE Spain) that implements a partially closed water cycle was chosen as study site to assess the occurrence of OMP in the water cycle, comprising different water streams, including greywater, in the high and low tourist season. The data gathered may prove useful to evaluate future reuse opportunities and for policy makers and public health authorities.

MATERIALS AND METHODS

Hotel Samba is in an extremely touristic area of the North-Eastern Mediterranean coast of Spain, where dramatic water demand increase coincides with water scarcity events during the summer months. Hotel Samba is a large 3-star resort with 441 air-conditioned rooms, green areas and exterior pools, conference rooms, bar, and restaurant. Water use reported by the hotel ranges from 25,000 to 34,000 m^3/year (100-135 L/person/day). Two sampling campaigns have been performed in the high season (June, with 76-99% of rooms occupied) and in the low season (November, with 35-67% of rooms occupied). The sampling points are presented in Figure 1. Different chemical, physical and microbiological parameters were analyzed as well as 39 OMP: 10 endocrine disruptors and related compounds (EDCs) and 29 pharmaceuticals (PhACs).

RESULTS AND DISCUSSION

It emerged an important seasonal variation in water consumption per use (Figure 1) with a 48% total tap water reduction during low season (128 vs 67 m^3/day in high and low season, respectively).

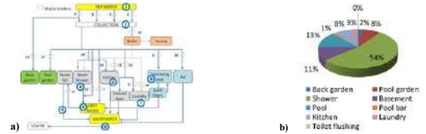

Figure 1. a) Sampling points. b) Tap water consumption by use during the high season.

Overall, the present study evidences a knowledge gap regarding the occurrence of micropollutants in closed water cycles, especially laundry and kitchen greywater, and in relation to tourism. Further studies are needed to be able to choose adequate reuse trains without disregarding important sources of contamination. The load of micropollutants is as variable in different GW sources as it is in different blackwater sources. The provided differentiation of loads by GW streams helps to deepen the understanding of the reuse and treatment potential of the different wastewater streams, besides the commonly reported standard parameters, as well as shining a light on the impact of seasonality on compound distribution in the different water streams, in the context of tourism.

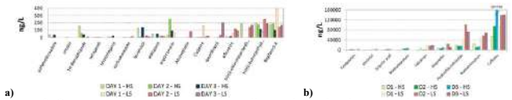

Figure 2. Occurrence of a selection of micropollutants in the hotel water cycle (HS: high season; LS: low season; a) greywater, b) wastewater).

Abstract
Constructed wetlands (CW) are one of the nature-based solutions for wastewater treatment. The main drawback of CW is their large footprint, which is due to both clogging problems and purification efficiency that requires long retention times. In order to improve the process, we are studying the potential of introducing earthworms into CW such as bioaugmented filters. These invertebrates are known for their ability to lower the clogging process, facilitate oxygen penetration into the substrate, increase the bioavailability of organic matter through molecular simplification and influencing microbial biodiversity. Our working hypothesis is to reduce the space requirement of the CW by introducing earthworms in the system. In continuity with the O'BIOM project (French ANR) carried out during 2022, two Ph-D projects have just started with the objective to describe and to perform the earthworms' influence on the porosity of the filtering substrate and on the biofilm microbial communities' structure at larger spatial and temporal scales through a CW living lab. The galleries network of different functional groups of earthworms (anecic, epigeic, endogeic) will be assessed via X-ray tomography image analysis to estimate the macroporosity dynamics. And the OTUs richness of the interstitial biofilm will be compared in order to seek the temporal evolution of the microbial composition under earthworm feeding pressure.

Keywords
Biodiversity ; biofilm ; constructed wetland ; earthworms ; macroporosity ; water flow

INTRODUCTION

This work is based on a biomimetic approach of the natural service of water-quality regulation. The constructed wetlands (CWs) require more space than conventional wastewater treatment systems, and the main lock of this system is their large footprint, which is due to both clogging problems[1] and purification efficiency that requires long retention times[2]. In order to improve the process efficiency, from a microbial and hydrological point of view, we are studying the potential of introducing earthworms into CW. Earthworms are known for their ability to stem the clogging process[3], facilitate oxygen penetration into the substrate[4], increase the bioavailability of organic matter through molecular simplification[5] and increase microbial biodiversity in the biofilm[6]. On the one hand, the biophysical relationship between the 3D galleries network and the water infiltration in the macroporous soil system is investigated for a better description of the water flow in these unsteady conditions. On the other hand, the challenge is to identify the dynamics of microbial communities in relation to the biodiversity involved in the filters (invertebrates and plants) and the substrate.

EXPERIMENTAL PROTOCOL

The preliminary results presented here have been provided by experiments at microcosm scale for 2 months with synthetic water. They are 40 cm high and 12.5 cm diameter cylindrical cores, made of a combination of filter sand and white peat, and inoculated with 3 earthworms species (the control microcosm excepted). The biofilm was sampled for eDNA metabarcoding sequencing with the Nanopore MinIon technology, and the microcosms were scanned by X-ray tomography. Image processing is carried out with Matlab and Avizo to make 3D volume renderings and extract salient features of the spatial arrangement of the network.

RESULTS

Influence of earthworms on the macroporosity of constructed wetlands

At a microscopic scale, we study the impact of the earthworms' galleries network on the residence time of wastewater in CW, thus optimising the use of the volume of the filtering substrate. To visualise both the substrate natural macroporosity and the network of earthworms' galleries, high spatial resolution X-ray tomography will be used extensively.

Influence of earthworms on biofilm of constructed wetlands

The partially recovered results allowed us to see slight differences in biofilm microbial community structure in presence of earthworm. A new sequencing run is scheduled to go further into the interpretation of these results. The comparison of the microbial species richness in the interstitial biofilm with and without earthworms provides evidence of these invertebrate influences on the biofilm composition. It is suggested that this biofilm biocontrol by the invertebrate increases the adaptation to pollutants occurrence.

PERSPECTIVES AND ON-GOING RESEARCH WORK

Together, these experimental works will demonstrate the existence of a combination of earthworms/substrates and plants that optimises the retention time of the wastewater and the level of wastewater purification in the filter. It should be noted that the preliminary study was carried out at a short time scale (2 months), which does not allow to obtain a mature state of the ecosystem. It is therefore necessary to extend the study duration, in order to reach a steady state. Two PhD thesis projects have just started, with the objective of continuing the assessment of the impact of earthworms on the porosity of the filtering substrate and on the biofilm microbial communities' structure at larger spatial and temporal scales. The experiments will be carried out at mesocosm and pilot scales through a CW living lab collecting domestic wastewaters from UT3 University (2,5 to 10 EqInhab). The water treatment efficiency will be controlled by analysing physico-chemical parameters (BOD_5, COD, NO_3^-, PO_4^{3-}, TSS). And the permeability will be monitored.

Abstract
The main goal of SYMSITES is to implement the regional industrial-urban symbiosis in four European regions different in socio-economic and environmental aspects, from the north of Denmark, through the centre, Austria to the south, Spain, and Greece. The Spanish Ecosite consists of an urban organic waste management plant coupled to anaerobic treatment of urban wastewater by an Anaerobic Membrane Bioreactor (AnMBR). Biogas production will be upgraded into hydrogen using protonic membranes. Also, new anti-fouling membrane technologies are developed such as magnetic vibration systems and corrugated membranes. The microbial risk associated with the effluent of the plant will be analysed using viral infectivity and bacterial activation assays. The contribution of this project for Alcoy region sustainable development and industrial-urban symbiosis is here presented highlighting the innovative technologies that are being developed and implemented to maximize resource recovery using AnMBR systems.

Keywords (maximum 6 in alphabetical order)
AnMBR; hydrogen; industrial-urban symbiosis; regional development; wastewater; water reuse.

INTRODUCTION

Transition into a circular economy requires the development of multidisciplinary approaches and can be a strategy for sustainable regional development. Hydrogen production should be implemented in WWTP to guarantee their positive carbon footprint. Also, water reclamation and reuse for industrial purposes should be facilitated. The aim of this project is to develop and prove the concept of Industrial-Urban Symbiosis (IU-S) in Alcoy region (textile, and cosmetic industries). The technologies will include: (i) AnMBR with magnetically induced membrane vibration (MMV) for advanced antifouling control without biogas sparging, (ii) adsorption column-based of antibacterial and antiviral lignin nanoparticles (LigNP) for antibacterial and antiviral treatment (Morena et al., 2022), (iii) pyrolysis of textile and cosmetic non-recyclable wastes (NRW) and (iv) hydrogen from protonic membrane reformer (PMR) for biogas upgrading (Clark et al., 2022).

MATERIALS AND METHODS

Urban and industrial biowastes

Urban wastes are collected through two strategies: organic wastes container and on-source household separation. After separation of non-organic wastes, the biowaste is grinded and shrived up to 0.1 mm in wet conditions. The resulting bio-pulp is fed into the AnMBR based pilot plant as a co-substrate. Industrial wastes from textile and cosmetic facilities are treated in a pyrolysis system operated at 650-850°C, to produce char and pyrolysis oils. Analytical measurements of pH, COD, solids, nutrients and VFA have been carried out to characterize the resulting slurries and pyrolysis inputs. Biomethane Potential (BMP) tests have been carried out following standard UNI/TS 11703.

AnMBR with MMV pilot plant and hydrogen production

The plant is designed for treating 4m^3/day when operating at 70d Solids Retention Time (SRT), 12h Hydraulic Retention Time (HRT) at ambient temperature (15-25°C). The external membrane modules are equipped with submerged membranes: (i) 0.03µm ultrafiltration hollow fibre membrane (Pulsion, KOCH) with biogas sparging and (ii) 0.1µm microfiltration flat corrugated membranes of micro-patterned PVDF with MMV anti-fouling control (Ilyas et al., 2022). PMR technology is being applied to the resulting biogas from the AnMBR to produce, separate and compress hydrogen in a single-step reaction. In this process, CO_2 is captured through a steam methane reforming reaction. Before PMR the H_2S fraction is removed from the biogas using water scrubbing methods at different efficiency ratios to optimise the process and reduce purification efforts towards the minimum energy requirements.

Water reuse

AnMBR effluent is being used for liquid fertilizer in ammonia sulphate form using a membrane contactor (Accurel PP 300/1200, Germany). The microbial risk assessment analysis of this effluent is being analysed using the standards: EN ISO 19458, EN ISO/IEC-17025, UNE-EN ISO 8199:2019, UNE-EN ISO 15216-1:2017 and ISO 9308-1:2014 according to European Regulation (EU) 2020/741. Analysis of the AnMBR effluent for circular reuse in textile and cosmetic water demands is being carried out analysing parameters like pH, conductivity, turbidity, chemical oxygen demand, total nitrogen, phosphates, chloride, total solids, Fe, and microbial parameters such as Escherichia coli.

RESULTS AND DISCUSSION

The pilot-plant is expected for 2023 but on-going work is being carried out for biowastes characterization. Future work would be presented including the results of BMP tests over the different mixtures of biowastes retrieved from the municipality, textile, and cosmetics industrial wastewater effluents. Ratio adjustment for the conversion of these wastes into energy is necessary before pilot plant operation. The expected outcome of the project is achieving a 90% COD removal with a pathogen elimination over 4.0 log10 levels. Also, the sludge reduction capacity will be analysed and adjusted to achieve values over 80% which is feasible through the application of anaerobic processes in membrane bioreactors. The biomethane obtained and biogas composition will be used to simulate its conversion into hydrogen also in CSIC pilot plant facilities. Theoretical energy recovery values will be obtained in the batch and laboratory stage that is being carried out and will be used as a baseline before pilot plant start-up.

ACKNOWLEDGEMENTS

Identifying substrates for greywater treatment in a novel green wall system based on trickling filters

M.G.P. Grau*, N. Krähenbühl*, N. Antenen*

* Institute of Natural Resource Sciences, Zurich University of Applied Sciences, Grüentalstrasse 14, 8820 Wädenswil, Switzerland (E-mail: *maximiliangerdphilipp.grau@zhaw.ch)*

Abstract
Green walls with greywater treatment capabilities can play a key role to close water cycles in growing cities worldwide. Most green wall systems for greywater treatment apply a similar process as in constructed wetlands, where the substrate acts as plant substrate and to treat the polluted water. A novel green wall system is in development that separates the plant layer from the greywater treatment, by introducing a setup similar to a trickling filter. In a first step, various commercial substrates were tested for their suitability in terms of treatment performance at two different hydraulic loading rates over a 10-week period, using synthetic greywater. Measured parameters for determining pollutant removal were turbidity, chemical oxygen demand (COD), and others over a treatment time of seven days, measuring concentrations at the beginning, after three days and at seven days. The first substrate, expanded shale, performed best, achieving removal rates up to 60% for COD, closely followed by the other two substrates, plastic Hel-x and foam carriers. Generally, most pollutants were removed within the first three days of treatment. Even though plastic Hel-x carriers were not as efficient in pollutant removal as expanded clay, the carrier will be used for planned pilot trials of the novel green wall system due to their lower weight.

Keywords
Green walls; greywater treatment; substrate tests; trickling filter; water re-use

INTRODUCTION

The urbanization of the world's population is steadily increasing. 68% of people are projected to live in urban areas by 2050 (United Nations 2019), which will increase the pressure on water supply and sanitation. It is essential that water resources are managed sustainably, and also the use of alternative water sources must be considered (Bahri 2012). Greywater has shown great potential for re-use, however treatment technologies on household level need to be developed (Ghaitidak and Yadav 2013). In recent years, nature-based solutions have emerged as potential treatment options for greywater treatment in urban settings, especially green roofs and green walls, demonstrating high removal efficiencies of up to 80% for organic matter (Boano et al. 2020). Additionally, green walls have the potential to address other pressing issues of growing cities, such as the heat island effect (Pucher et al. 2022). Most green wall systems with integrated greywater treatment are designed similarly to constructed wetlands, where the substrate in pot-based, vertical systems acts as the substrate for the plants and also for greywater treatment, optimized for pollutant removal (Masi et al. 2016; Prodanovic et al. 2017). Also other processes such as trickling filters have been demonstrated to be suitable for greywater treatment (Ghaitidak and Yadav 2013; Gross, Kaplan, and Baker 2007). However, trickling filters have hardly been developed in the form of a green wall. In this study, a novel, layered green wall system, that separates the greywater treatment from the plant section is being developed. A filter system operates like a trickling filter on the back of the module, with a separate plant part in the front layer. The focus of this study was to test various commercially available substrates for their application as filter media for the green wall system in development.

MATERIALS AND METHODS

In order to find the most suitable substrate for the back layer of the green wall, the pollutant removal efficiency of three commercially available substrates (i.e., expanded shale, plastic Hel-x carriers, and foam carriers) were investigated in a column experiment over a period of 10 weeks under controlled climate conditions (25 °C and 60 % rH). Each column contained 2 L of a single substrate and was operated as a trickling filter under either a fast (34 l m-2 h-1) or slow (8 l m-2 h-1) hydraulic loading rate (HLR). Each column had a separate bucket for the greywater that was continuously recirculated through the columns with an aquarium pump. Each substrate and hydraulic loading regime was performed in triplicate, resulting in a combined setup of 18 columns. Prior to the experiment, each substrate was inoculated by being submerged in real greywater for 1 month. Every week each replicate was dosed with 15 ml of synthetic greywater and tap water was added to maintain a starting volume of 20 litres. The greywater addition was approximated to contain 300 mg/l chemical oxygen demand (COD), 14 mg/l total nitrogen (TN) and 3.5 mg/l total phosphorus (TP). This addition was maintained throughout the trial regardless of the concentrations remaining from the previous week. To determine the pollutant removal efficiency of the substrate and general conditions several parameters relevant to water quality were measured 2 hours (Day 0), 3 and 7 days after synthetic greywater addition. Removal rates were calculated compared to day 0 measurements. Measured parameters were pH, dissolved oxygen, temperature and conductivity, turbidity, COD, TP, total organic carbon (TOC) and TN.

RESULTS AND DISCUSSION

Expanded shale consistently exhibited the highest removal across all examined parameters, followed by Hel-x carriers, reaching removal efficiencies for COD up to 60% (Figure 1). Foam carriers generally performed either similar or worse than the Hel-x counterparts. A slower HLR showed partially better treatment performance compared to the faster HLR, while still preventing excessive biofilm formation that could clog the trickling filter. Particularly changes in TP highlighted the benefit of utilising complex materials containing natural adsorption sites, such as expanded shale for phosphorus removal. Apart from TOC most of the removal for various pollutants occurred within the first 3 days after greywater addition (up to: 80% for turbidity, 60% for TN, 40% for TP). This highlights the importance of biofilm establishment and adaptation to the pollutants present in greywater when in operation. Even though expanded shale demonstrated the best treatment performance, plastic Hel-x will be considered for the use in a pilot installation of the novel green wall system, mainly due to its lower weight of the material, thus achieving a lighter weight per m^2 green wall installed.

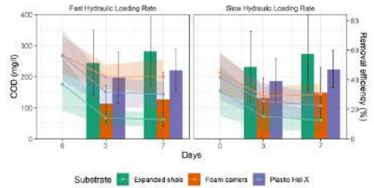

Figure 1. Treatment efficiency for COD of the three substrates; Average COD concentrations plotted as lines at the beginning and after 3 and 7 days over a 10-week period on the left axis. Average COD removal efficiency % plotted as bar graphs on the right axis.

Abstract
Continuous monitoring of treatment plants can be costly and is essential to guarantee the proper functioning of these systems. For the case of UASB reactors hydraulic retention time, up flow velocity and volumetric organic loading can be controlled via triangular fuzzy numbers. In this sense it is possible to compute risk of failure. This paper shows the potential of a fuzzy approach to improve operational control of full-scale plants.

Keywords: Fuzzy risk; UASB reactors; Hydraulic Retention Time.

INTRODUCTION

The UASB reactors are applied for different types of effluents, from domestic to industrial and are especially suitable for regions with warm climate. However, many treatment plants may show performance below the design considerations due to the fact that they are poorly operated and monitored. Operational problems alert to the fact that although UASB reactors are considered robust they require adequate monitoring, control and optimization strategies. The risk of failure must be interpreted over an interval or under measurable conditions. A marginal risk of failure can undergo a better scrutinization via triangular fuzzy numbers (TFN) and represent operating conditions. For such cases TFN numbers provide a process mapping based (Kaufmann and Gupta, 1991) on typical flow variation profiles throughout the day, as well documented in the technical and scientific literature (*e.g.* CAMPOS; VON SPERLING, 1996; METCALF; EDDY, 2016; QASIM; ZHU, 2018). The present paper approaches the monitoring and operational diagnosis based on the fuzzy risk assessment for hydraulic retention time in UASB reactors.

MATERIAL AND METHODS

Operational Fuzzy Risk

The study was based on regular monitoring data from 19 full-scale UASB operating in the Ceará State, Brazil. Treatment plants were located in the polygon formed by 3º26' to 4º13' South and 38º28' to 39º02' West, 45 m asl. Local air temperature ranged from 23.8 to 31.5º C. Flow rate (Q) was measured at the Parshall flume including flow charts at the preliminar treatment unit of the plants. Chemical oxygen demand (COD) was analised in grab samples collected at 10 am. Triangular fuzzy numbers (TFN) were considered according to the minimum, most probable (represented by average) and maximum values of Q and COD. These numbers were used to compute fuzzy functions to estimate hydraulic retention time (HRT), up flow velocity (V_{UF}) and applied organic load (L_V). Classification of operational fuzzy risk followed rules for mapping marginal fuzzy intervals as showed in Table 1.

Table 1 – Intervals for mapping Fuzzy Risk (F_R) regarding to HRT, V_{UF} and L_V.

Marginal *Fuzzy* Risk	HRT (h)	V_{UF} (m/h)	L_V (kg DQO/m³.dia)
Very Low to Low	HRT ≥ 10	$V_{UF} \leq 0,7$	$L_V \leq 3,5$
Low to Medium	$10 \geq HRT \geq 6$	$0,7 \leq V_{UF} \leq 1,1$	$3,5 \leq L_V \leq 7,0$
Medium to High	$6 \geq HRT \geq 4$	$1,1 \leq V_{UF} \leq 1,5$	$7,0 \leq L_V \leq 9,0$
High to Very High	HRT ≤ 4	$V_{UF} \geq 1,5$	$L_V \geq 9,0$

Fonte: adapted from Mara (2003) and von Sperling and Chernicharo (2005).

RESULTS AND DISCUSSION

The complement of the marginal fuzzy risk (F_R) is the marginal fuzzy guarantee (F_G), and the summation is equal to 1. From this logical reasoning Table 2 shows F_G according to the fuzzy number resulted from dilation of the crisp average value of Q. The results point out that higher peaks over average flow rate may reduce significantly the F_G.

Table 2 – Fuzzy state guarantee, based on NFT, regarding the mapping of hydraulic detention time in UASB reactors treating domestic wastewater.

HRT (h)	Ranges of flow rate (m³/h)			
	0.25 to 2Q	0.25 to 3Q	0.25 to 3.5Q	0.25 to 4Q
≥ 10	0.720	0.688	0.679	0.672
10 to 6	0.244	0.241	0.240	0.239
6 to 4	0.036	0.060	0.064	0.067
≤ 4	0.000	0.011	0.017	0.022

Same reasoning was confirmed in relation of V_{UF} and L_V. Although organic overloading appeared to show more sensitivity in respect to reactor stability, the limits of V_{UF} can be considered more relevant in terms of sludge washout. In this sense F_G for V_{UF} control is more relevant in terms of performance.

CONCLUSIONS

The described behavior referring to the increase of the flow of 2 times the average flow, is repeated for the other flows of 3; 3.5 and 4 times, disregarding the times where the flows have a 4-fold increase and consequently a reduction in HRT, the fuzzy guarantee is reduced and the fuzzy risk increased. The HRT variation combined with COD (*i.e.* organic loading) followed the same pattern. However, fluctuation of V_{UF} is an excellent indicator for the stability control because it is a simple physical variable.

Evaluation of a low-tech, passively solar-driven pilot plant for nutrients recovery from source-separated urine on household level

L. Luethi*, D. Buehler*

Abstract
This study presents a pilot-scale technology for solar-driven evaporation of human urine, and investigates its feasibility for nutrient recovery and use as fertilizer. A field experiment was conducted at Zurich University of Applied Sciences in Switzerland, in which source-separated urine was stabilized with acetic acid to suppress hydrolysis by the enzyme urease and associated ammonia outgassing, while also promoting pathogen inactivation by bringing the pH below 4.
The stabilized urine was then passed through a six-piece tube system that was oriented towards the sun, with a black-lined housing and Plexiglas windows to create a greenhouse effect, and air holes to allow air flow and therefore increased evaporation rate. The powder obtained from evaporation was analyzed for nutrient content and compared with conventional fertilizers in a hydroponic growth experiment with basil.
The stabilization process was successful, with evaporation rates of up to 1.7 L/m²/d and an average recovery of 24 g/L nitrogen, 17.7 g/L phosphorus, and 55 g/L potassium oxide. The use of evaporated urine as a fertilizer at a dilution rate of 2 g/L resulted in plant growth comparable to that of conventional fertilizers. This demonstrates the feasibility of utilizing urine as a resource while also positively contributing to sustainable agriculture without the need for additional energy inputs (for the production of mineral fertilizer) or incurring high costs.

Keywords
Acid stabilization, hydroponic planting trials, nutrient recovery, passive evaporation, solar energy, source-separated urine

INTRODUCTION

The natural availability of nutrients, such as nitrogen, phosphorus, and potassium, needed for conventional fertilizer in agriculture, is limited (Mehta et al., 2015). Since human urine contains most of the excreted nutrients, fertilizer from urine has the potential to replace conventional fertilizers (Bischel et al., 2015; Martin et al., 2022). The use of urine as a fertilizer can not only conserve scarce resources, but also reduce the need for synthetic fertilizers, help to conserve water, decrease disruption of planetary biogeochemical cycles, and reduce the amount of waste sent to landfills (Escher et al., 2006; Larsen & Gujer, 2001; Reynaert et al., 2020). Previous laboratory studies (Bethune, 2015; Mayer, 2002) and field trials (Antonini et al., 2012; Simha et al., 2020) indicate that urine evaporation is a viable option for nutrient recovery. However, research on urine evaporation has been limited and most solutions are either technologically demanding, require high use of energy, or the use of chemicals (Ek et al., 2006; Maurer et al., 2003 & 2006). The aim of this study was to develop and test a low-tech urine evaporation system that can be implemented on household level in order to locally close the nutrient cycle. The study examined the functionality of the evaporation module, dosage and amount of acid with varying urine volumes, and long-term stabilization success to prevent nitrogen loss in order to produce a fertilizer that is comparable to conventional fertilizers.

MATERIALS AND METHODS

In the experimental setup (Figure 1), the urine was separately collected from feces using a dry toilet system based on a conveyor belt (Figure 1, no 1). Driven by gravity, the urine was led to and collected in a tank under the toilet (Figure 1, no 1, 2). A light sensor above the toilet was used to detect use of the toilet in order to trigger a pump to feed acetic acid into the urine tank for its stabilization (Figure 1, no 3). The stabilized urine was manually fed onto the evaporation module where weekly evaporation rates were measured and compared to temperature, solar radiation, and humidity (Figure 1, no 4). Samples of the urine residue were collected weekly and analyzed for nutrient content (ammonium, calcium, chloride, magnesium, nitrate, nitrite, phosphate, potassium, sodium, sulfate), pH, and electrical conductivity (Figure 1, no 5). The urine residue was diluted in water to be used as fertilizer (2g/l and 0.2g/l). Plant growth in a hydroponic culture of the two urine fertilizer dilutions was compared to a conventional fertilizer and a commercially available urine fertilizer (Figure 1, no 6).

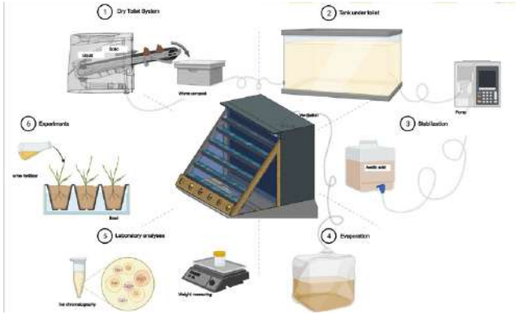

Figure 1: Experimental setup for the production and analysis of urine fertilizer from a urine evaporation module

RESULTS AND DISCUSSION

The stabilization in the urine tank functioned effectively with automatic dosing, however, the pH level in the evaporation module increased. Other experiments have confirmed a slight increase in pH level in vinegar-stabilized urine (Boncz et al., 2003). Our results indicate that the increase in pH could potentially rise exponentially rather than linearly. With a surface area of 0.47 m², it took approximately 21 days to achieve complete evaporation of the liquid fraction of approximately 18L undiluted urine. This corresponds to an average evaporation rate of 1.7 l/m²/d. The end product of the urine had an average of 24 g/l TN (ammonium and nitrate only), 18 g/l P_2O_5, and 55 g/l K_2O. The plant growth experiments confirmed the suitability of urine as a fertilizer when diluted at a ratio of 2g/l. The results of this study indicate that urine evaporation on household level holds great potential as a viable option for nutrient recovery. However, for further experiments, more stable constructions materials should be used to build the evaporation module, and its design should be simplified to improve operation and monitoring. Since accurate data for evaporation over time could not be collected, the exact dependence of evaporation rate on temperature, solar radiation, and humidity could not be determined. However, it was observed that the evaporation rate increased with rising temperatures and decreasing humidity. Previous studies (Joyce et al.,1996; Ren et al., 2021) have shown that solar radiation can kill pathogens in urine. Therefore, solar disinfection should also be further investigated in this type of technology.

Multidimensional assessment of a Nature-based Solution for decentralized small-scale greywater treatment in Costa Rica (max. 250 characters)

M. Perez Rubi and J. Hack

Institute for Environmental Planning, Leibniz University Hannover, Herrenhäuser Str. 2, Hannover, Germany
(Email: *perez@umwelt.uni-hannover.de*)

Abstract

In Costa Rica, water supply networks cover more than 94% of the country; however, it is estimated that only 10% of wastewater receive proper treatment. The lack of centralized sanitation infrastructures has led to the implementation of domestic septic tanks for blackwater disposal and the discharge of greywater into rivers without any treatment, hence, causing environmental degradation of surface waters. Retrofitting conventional centralized sewerage networks and treatment plants into the existing urban grid implies extensive social, economic and technical challenges. Since greywater has potentially less pollutants than mixed wastewaters, there is an intrinsic opportunity in the current situation for a leapfrogging toward onsite treatment and resource recovery. In this sense, proposing decentralized technologies for greywater treatment contributes to reducing pollutant loads being discharged, therefore, improving the environmental status of water resources. In this study, we assess the performance of a small-scale horizontal flow constructed wetland, called "Biojardinera" in Costa Rica, as a Nature-based Solution prototype for decentralized domestic greywater treatment. Organic matter, nutrients and microbiological water quality standards are being analysed and compared with reported removal efficiencies from other case studies in the country. Furthermore, economic, social and legal aspects for the implementation of this low-cost ecotechnology are evaluated for the context of Costa Rica. The results contribute to the understanding of performance and application potential which is needed to adopting this type of Nature-based Solution for water quality improvement, not only in Costa Rica, but also other areas in the region where a comparable sanitation situation prevails.

Abstract
Anaerobic digestion effluents can be a reservoir of pollutants and need effective treatment strategies to avoid dissemination to the environment and associated risks to public health. This study aims to determine the potential of constructed wetlands (CWs) to eliminate metals, antibiotics and ARG, from the liquid fraction of the digestate for agricultural reuse.

Twelve laboratory scale vertical subsurface flow CWs systems were assembled with gravel, light expanded clay aggregate and sand planted with *Sparganium erectum* testing four different treating conditions (liquid digestate dosed with oxytetracycline or with sulfadiazine or with ofloxacin or without dosing).

Removal of Fe, Zn, Cu, Pb and Cr were always > 92 % and Mn removal was between 82 and 94 %. In addition, high organic matter and nutrients removal were reported (69-99.8 %). No significant differences between presence or absence of antibiotics were observed.

Acknowledgments - This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 861088.

Keywords (maximum 6 in alphabetical order)
Antibiotics, antimicrobial resistant genes, constructed wetlands, liquid digestate, metals.

INTRODUCTION

Constructed wetlands (CWs) are nature-based solutions that can be used to treat liquid effluents from different industries. These biotechnological tools can eliminate a wide range of pollutants from nitrogen nutrients or trace metals to contaminants of emerging concern from water through different physical, chemical and biological reactions (Gorito et al., 2017).

Anaerobic digestion is a well-known process to valorise organic waste into bioenergy products. A byproduct is the digestate, a complex matrix of biosolids rich in organic matter and nutrients that has conventionally been disposed by landspreading as a fertilizer (Wang et al., 2023). However, the digestate can be a reservoir of metals, antibiotics, and antimicrobial resistant genes (ARG) and it is necessary to implement efficient treating methods to prevent their diffusion to the environment (Venegas et al., 2021).

There are several studies investigating the capacity of CWs to remove the high nutrient content of liquid digestates, but studies focusing on the removal of other contaminants from this complex matrix are scarce (Maucieri et al., 2016; Zhou et al., 2020; Wu et al., 2016).

The objective of this study is to evaluate the potential of CWs, at a microcosm scale, to remove metals, antibiotics and ARG, from the liquid fraction of the digestate to valorise the effluent in fertigation.

MATERIALS AND METHODS

Twelve laboratory scale vertical subsurface flow CWs systems were assembled with gravel, light expanded clay aggregate and sand planted with *Sparganium erectum* testing four different treating conditions (liquid digestate dosed with oxytetracycline, or dosed with sulfadiazine, or dosed with ofloxacin or without dosing) in a four-month period. The digestate was recirculated over 14 days, then removed from the systems and replaced with a new influent with the same conditions. Samples of all effluents were collected for analysis of nutrients and metals and for quantification of *intI1*, *tetA, tetW, sul1* and *qnrS* genes. The removal efficiencies of the pollutants were calculated according to the following equation:

$$Removal\ efficiency\ (\%) = \frac{C_{in} - C_{out}}{C_{in}} \times 100$$

RESULTS AND DISCUSSION

The initial concentration of Fe, Mn, Zn, Cu and Cr in the liquid digestate before the treatment in the CWs was much higher than levels reported in guidelines for irrigation water. Removals of organic matter, and ammonium, nitrate, nitrite and phosphate ions ranged between 69 and 99.8 % with no significant differences between the presence or absence of antibiotics. Removal efficiencies of Fe, Mn, Zn, Cu, Pb and Cr reached over 82 %. An increase in relative abundance of the *intI1*, *tetA* and *sul1* genes was observed in the effluent after the CWs treatment, while a decrease in *tetW* was noticed.

CONCLUSION

Overall, CWs are a suitable alternative to valorise the liquid effluent of anaerobic digestors using it in fertigation, closing the loop of circular bioeconomy. However, ARGs dissemination in the environment remains a grand challenge that needs further understanding and management for their proper removal and wastewater treatment solutions must take that into consideration.

Comparison of engineered, natural and hybrid wastewater treatment schemes for the removal of nanoparticles from wastewater

R. Sharma* and A. Kumar*

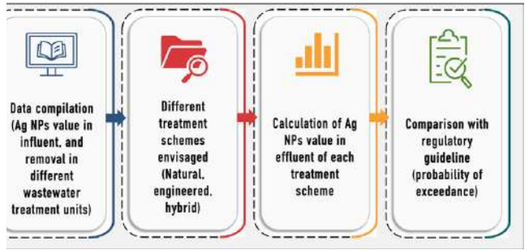
* Department of Civil Engineering, Indian Institute of Technology Delhi, Hauz Khas, New Delhi, India (E-mail: *r.bwn24@gmail.com*; *arunku@civil.iitd.ac.in)*

Abstract
The advancement in the field of nanotechnology has led to their wide usage in commercial products, leading to their disposal in environmental waters. The use of both engineered treatment technologies and nature-based treatment technologies, such as constructed wetlands, soil aquifer treatment have been explored for the removal of nanoparticles from raw wastewater. In this work, various wastewater treatment schemes including engineered and/or nature-based treatment technologies were envisaged. Published literature data was then utilized to find the removal of Ag nanoparticles through each of these treatment schemes. Monte Carlo simulation approach was utilized to generate a large dataset for probabilistic computations & avoid point calculation. The nanoparticles' concentration in the effluent were calculated and compared with regulatory guidelines. Probability of exceedance was used to compare and rank the treatment schemes for removal of Ag nanoparticles. The treatment scheme involving both engineered and nature-based treatment technologies was ranked one. Treatment schemes involving only the engineered treatment technologies were ranked last. Hence, the use of nature-based solutions along with the existing treatment infrastructure is required for the effective removal of nanoparticles. The decision-making framework presented here, can be utilized to identify suitable treatment schemes for treatment of wastewater laden with metal nanoparticles.

Keywords
Decision making; nanoparticles; constructed wetlands

INTRODUCTION

Nanotechnology has enabled the integration of metal & metal-based nanoparticles (NPs) into our daily-usage products (cosmetics, antibacterial paints & fabrics, paints, electronics etc.). Their frequent usage implies their frequent detection in environmental waters, as has been now detected frequently by researchers around the world (Gagnon, Turcotte, et al., 2021). Both engineered wastewater treatment units and nature- based treatment technologies [such as vertical scale subsurface flow Constructed Wetlands (VSSF CW) and Soil Aquifer Treatment (SAT)] have been explored for removal of nanoparticles, with latter showing immense scope despite their low operating costs (Huang, Xiao, et al., 2019). Nature-based solutions can be used in combination with the existing wastewater treatment infrastructure, for removal of nanoparticles. The objective for this work is to compare different treatment schemes (engineered, natural or hybrid) for efficient removal of Ag nanoparticles from wastewater. Literature data already published was searched and utilized in this work to calculate the concentration of Ag NPs in effluent of the derived treatment schemes. The decision-making framework developed here for finding the top 3 treatment schemes for Ag NPs removal can be further utilized for other metal or metal-based nanoparticles as well.



ıre 1. Illustrative schematic of the framework developed in this work.

TERIALS AND METHODS

erature review was carried out to compile the following data:
'oncentration of Ag NPs in influent wastewater
Removal of Ag NPs in different treatment units of a WWTP [Primary treatment unit (1°), ndary treatment unit (2°) and Tertiary treatment unit (3°)]
Removal of Ag NPs in natural treatment technologies- VSSF CW (Vertical Sub-Surface structed Wetlands) and SAT (Soil Aquifer Treatment).

normal distributions were derived for each of the variable. As part of uncertainty analysis, Monte-o simulation was used to generate 20,000 numbers of each variable. Various treatment schemes : then envisaged involving either the engineered treatment units of a WWTP or the natural ment technologies or a hybrid of both. Then, effluent concentration of Ag NPs was computed for chemes using the distributions developed. The effluent was then compared with regulatory elines. For Ag NPs, only recommended value of 21 mg/L was found (Parsai and Kumar, 2021), no other regulatory authority guideline. Regulation for Ag ions were then searched for, with the mption that Ag NPs disassociate as silver ions completely. Australian guidelines recommend a µg/L value for silver ion in freshwater systems. Corresponding to this, discharged effluent elines was computed as 10 µg/L, back-calculating using a dilution ratio (D) of 99:1 (Tyagi et al.,).

a conservative approach, 10 µg/L was selected to compare the different treatment schemes. ulative probability for remaining Ag NPs conc in effluent was computed for each scheme using bull formulae. Probability of exceedance from the guideline value was calculated and used to pare the treatment schemes with each other. The overall methodology is pictorially depicted in l. Table 1 depicts the different treatment schemes that were envisaged in this work.

ULTS AND DISCUSSION

rage value for all treatment schemes were found to be less than guideline value 10 µg/L (Table Hybrid treatment schemes (i.e., involving both engineered and natural treatment technologies) : the top 2 ranked, T7 and T8, and natural treatment scheme T2 was ranked 3. The treatment mes T7 and T8 showed little difference with respect to average Ag NPs in effluent & probability ceedance.

Table 1. Different engineered, natural and hybrid treatment schemes envisaged

	Treatment Scheme	Type (Engineered, natural or hybrid)
T1		Natural
T2		Natural
T3		Engineered
T4		Hybrid
T5		Hybrid
T6		Engineered
T7		Hybrid
T8		Hybrid
T9		Engineered

Table 2. Statistical summary for the Ag NPs concentration in effluent (Ce) of various treatment schemes, associated probability of exceedance in percentage and ranking

	Treatment Scheme	Average value of Ag NP conc in effluent, µg/L	% Prob of exceedance from guideline value	Ranking
T1	Influent WW→VSSF CW	0.51	0.767	6
T2	Influent WW→VSSF CW→SAT	0.13	0.140	3
T3	Influent WW→WWTP (1°)	8.67	10.997	9
T4	Influent WW→WWTP (1°) →VSSF CW	0.47	0.708	5
T5	Influent WW→WWTP (1°) →VSSF CW→SAT	0.12	0.141	4
T6	Influent WW→WWTP (1°+ 2°)	0.77	1.254	7
T7	Influent WW→WWTP (1°+ 2°) → VSSF CW	0.06	0.071	2
T8	Influent WW→WWTP (1°+ 2°) → VSSF CW→SAT	0.02	0.000	1
T9	Influent WW→WWTP (1°+ 2°+ 3°)	1.41	1.652	8

As many of the existing wastewater treatment plants have only up to secondary treatment (Jamwal, Mittal, et al., 2008), hence retrofitting such plants with low-cost nature-based treatment technologies like VSSF CW and SAT will help in effective removal of nanoparticles. The treatment scheme T3 was ranked the last, due to high probability of exceedance compared to the guideline value, implying that disposal of only primary treated NPs laded WW may invite regulatory actions.

CONCLUSIONS

Only primary treatment of NPs laded wastewater was found to have the highest probability to exceed the regulatory guideline. Hybrid treatment scheme (Secondary treatment in WWTP followed by treatment using CW and SAT) was ranked first for removal of silver nanoparticles from raw WW, based its least probability of exceedance with respect to the guideline value. For effective removal of nanoparticles from wastewater, the idea of retrofitting the existing wastewater treatment plants with nature-based technologies like constructed wetlands and soil aquifer treatment will also offer additional benefits of overall low cost. For wastewater treatment plants receiving wastewater from industries manufacturing or fabricating nanoparticle-enabled products, the presented methodology can be adapted for design or selection of a treatment scheme (natural, engineered or hybrid) for removal of metal/metal-based nanoparticles by utilizing published literature

Abstract
In this study, an innovative onsite wastewater treatment system (OWTS) using a multi-module biochar filter was tested. The system comprised six modules with different biochar and bark sizes constructed vertically. It was composed of saturated/anaerobic modules and unsaturated/aerobic modules. Water samples of the influent and the filter effluent were analyzed to investigate the treatment efficiency of organic matter (COD), nitrogen, phosphate, and *Escherichia coli* (*E. coli*). The results showed a relatively high average removal of organic matter (COD: 82.7%) and moderate nitrogen removal (Tot-N: 40.1 %). The phosphate removal was varied and had an analytical uncertainty. The removal of *E. coli* (2.44 Log_{10} CFU mL^{-1}) was higher than the levels reported in conventional OWTS. Further investigation of the filter design is planned to enhance denitrification and phosphorus removal.

Keywords
Biochar; *E. coli*; Multi-module systems; nitrogen; onsite wastewater treatment

INTRODUCTION

Approximately 1,000,000 onsite wastewater treatment systems (OWTS) have been implemented in Sweden, but some OWTSs are insufficient to meet environmental standards. The issues vary in each system/region, including groundwater ingress, inadequate soil conditions of the site, and insufficient maintenance regulation. The effluent remains a significant source of eutrophication even after the treatment (Roth et al., 2016). Swedish EPA reported that only 66 % of OWTSs comply with Environmental Code Standards (Naturvårdsverket, 2014). In this study, an alternative treatment system using biochar has been tested. Biochar is a carbon-rich product made by the anoxic thermal conversion of biomass. It is advantageous as a filtration medium because of its lighter weight for transportation and high adsorption capacity due to the porous structure with a large surface area (Xiang et al., 2020). In addition, biochar is produced from biowaste and can be used as a fertilizer after its use as a wastewater adsorbent (Li et al., 2020; Werner et al., 2018). Biochar contributes to a sustainable future as a wastewater treatment and soil amendment. Although the potential of biochar-based systems has been studied, few studies have used pilot-scale biochar filtration systems. Hence this study aimed to investigate the performance of a multi-module biochar filter to be operated after the sedimentation unit for OWTS.

MATERIALS AND METHODS

Three identical multi-module filters composed of six modules were constructed, and each module was constructed from plastic boxes (Figure 1). Modules 1-5 were filled with biochar, while module 6 was filled with a pine bark layer topped with biochar. The bark enhances bacterial die-off due to tannins released from the bark (Kaczmarek, 2020). The three filters were placed at the Uppsala wastewater treatment plant (WWTP) to be operated with municipal wastewater. Raw wastewater which passed the rough screen at the wastewater treatment plant was used to feed the filters by the wastewater distribution system operated by peristaltic pumps and timers. Particle density, bulk density, and porosity of solids were determined, and SEM analyzed the morphology of the biochar with X-ray microanalysis.

The removal efficiency of pollutants in the system was investigated during the period between 1st February (day 1) to 7th April 2021 (day 66). The water samples were collected for the influent from the sedimentation tank (Figure 2) and the effluent from the bottom module 6. The following parameters were analyzed for each sample: chemical oxygen demand (COD), ammonium (NH_4-N), Nitrate (NO_3-N), total nitrogen (Tot-N), phosphate (PO_4-P), and *Escherichia coli (E. coli).*

RESULTS AND DISCUSSION

Figure 3 shows the influent and effluent concentration of COD (mg L^{-1}), Nitrogen (mg L^{-1}), phosphate (mg L^{-1}), and *E. coli* (log_{10}CFU mL^{-1}) of each filter 1 to 3. Organic matter was well removed in terms of COD reduction by 82.7%. However, the reported influent COD concentration coming to the WWTP from 2018 to 2020 was 760 - 890 mg L^{-1} (Uppsala Vatten, 2019), so the present influent concentration data (239.0 ± 70.6 mg L^{-1}) is uncertain. This uncertainty might happen due to the test kit's low detection ranges, which were 10-150 mg L^{-1} for both influent and effluent. Though each influent sample was diluted twice, it was not sufficient, and the removal efficiency could even be better regarding the possibility of higher influent concentration. Ammonium was consistently transformed to nitrate at nearly 100 %, while total nitrogen removal was 40 %. Incoming wastewater had a phosphate concentration of 1.3 ± 1.6 mg L^{-1}, but the reported Tot-P influent concentration from WWTP from 2018 to 2020 was 5.9 – 6.3 mg L^{-1} (Uppsala Vatten, 2019), so the influent concentration is uncertain due to the analytical error which could also affect to the effluent concentration. Nevertheless, the metal ion composition of the biochar used in this filter was only 0.24% of Potassium and 0.42% of calcium, which could influence the low removal ratio of PO_4-P.

The process of bacteria treatment was planned to be performed in the last module with biochar and bark. The bark is the primary source of antibacterial phenolic compounds called tannin, so it was expected to inactivate the bacteria coming to the last module (Das et al., 2020; Kaczmarek, 2020). Biochar could also retain the bacteria by physical removal through filtration since it could provide micropores in the module. There were few visible colony units in the effluent sample plates for *E. coli,* which resulted in a reduction rate of 2.44 log_{10}CFU mL^{-1}. It is higher performance than the conventional onsite treatment system. Harrison et al. (2000) reported the reduction rate of fecal coliform treated by OWTS designed with a septic tank and soil drainage field as 0.75-1.86 log_{10} CFU mL^{-1}. Suppose it is only a septic tank; the reduction rate of *E. coli* was reported as 0.14 - 1.05 log_{10} CFU mL^{-1} (Wang et al., 2021)

In summary, the multi-module biochar filter system performed well for organic matter removal, nitrification and *E. coli* removal, and the further filter-design update will enhance the denitrification and phosphorus removal.

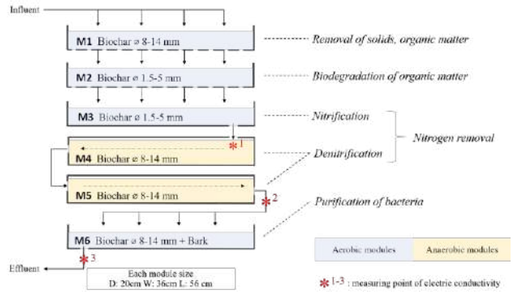

Figure 1. Multi-module filter (side view) with the contents and aim of each module, *1-3 shows the measuring points of electric conductivity during the tracer test. The aerobic modules (M1-3, 6) have a downflow (unsaturated), and the anaerobic modules (M4, 5) have a horizontal flow (saturated).

Abstract
Greywater reclamation has increasingly been recognized as an alternative water resource for non-potable or potable use. Laboratory-scale experiments were conducted to evaluate the removal performances of membranes and TiO_2-based advanced oxidation processes (AOP). The membrane processes include a flat sheet ceramic microfiltration (MF), a nanocomposite nanofiltration (NF) and a polyamide reverse osmosis (RO) membrane. The AOP system consisted of a flat sheet ceramic MF with TiO_2 cake layer on its surface, and low-pressure mercury lamps with 254 nm wavelength as a radiation source. Although the RO process provided high removal rates for salts and organic matters, membrane fouling was formed quickly. On the other hand, the NF process exhibited high removal rates for salts and moderate removal rates for organic matters. The residual organic matters in NF permeate were further decomposed by the following TiO_2-based AOP. Since membrane fouling was less significant in the NF process than the RO process, the integrated NF and TiO_2-based AOP processes can be a viable option for sustainable system operation and greywater reclamation.
Keywords
Greywater reclamation; membrane technology; photocatalyst

INTRODUCTION

Greywater reclamation has increasingly been recognized as an alternative water resource for non-potable or potable use. While membrane processes have become key components of greywater reclamation, studies on their combination with advanced oxidation processes (AOP) for greywater reclamation are still limited. This study aimed to evaluate removal performance of membrane technologies and TiO_2-based AOP for greywater reclamation. Laboratory-scale experiments were conducted using three greywater samples for assessing the qualities of reclaimed water from the membrane and AOP treatments.

MATERIALS AND METHODS

Domestic greywater samples were collected from a tub shower and a washing machine (denoted as GW1 and GW2) by a resident. Another greywater sample was collected at a complex commercial building (denoted as GW3), in which greywater consists of wastewater from tub showers and washbasins in a hotel, offices and commercial facilities. Tap water was also collected to compare the water qualities with greywater samples.

Laboratory-scale experiments were conducted to investigate the performances of microbubble floatation, membrane processes and a TiO_2-based AOP for greywater reclamation. Greywater samples were first treated by microbubble floatation (MBF) to remove suspended solids which can cause severe membrane fouling in the following membrane processes. The membrane processes include a flat sheet ceramic microfiltration (MF) with membrane pore size of 0.1 μm, a nanocomposite nanofiltration (NF) and a polyamide reverse osmosis (RO) membrane with salt rejection of 40% and 99.7%, respectively. The MBF effluents were supplied to either of the membrane processes to compare their removal performances. After the membrane processes, treated water samples were further fed to a TiO_2-based AOP to decompose the residual components. The AOP system consisted of a flat sheet ceramic MF with 2.0 mg/cm^2 of TiO_2 cake layer on its surface, and UV-LED with 310 nm wavelength as a radiation source (irradiation intensity: 10 mW/cm^2). Water qualities of the samples were assessed by measuring their excitation emission matrix (EEM), total organic carbon (TOC), turbidity, salt concentrations, and surfactant concentrations.

RESULTS AND DISCUSSION

By the MBF process, turbidity of the greywater samples was decreased from 33.0 to 18.5 NTU for GW1, from 18.3 to 8.1 NTU for GW2, and from 19.4 to 7.0 NTU for GW3. The removal rate ranged from 44% to 64%, which may reduce membrane fouling and membrane damage in the following membrane treatments.

While the MF process provided limited removal rates for TOC and salts, the NF and RO processes exhibited high removal rates for TOC (>82%) and salts (>70%) for all greywater samples. As a result, salt levels in NF (GW1: 4.7 mg/L, GW2: 3.8 mg/L and GW3: 14.6 mg/L) and RO permeate (GW1: 1.5 mg/L, GW2: 1.2 mg/L and GW3: 2.6 mg/L) were lower than the value in tap water (21.8 mg/L) (Figure 1). TOC level in RO permeates (GW1: 1.9 mg/L, GW2: 2.0 mg/L and GW3: 0.6 mg/L) was also lower than that in tap water (2.2 mg/L). Even though the NF process gave higher TOC level than tap water, the following TiO_2-based AOP further decreased the TOC levels (GW1: 1.4 mg/L, GW2: 2.0 mg/L and GW3: 0.8 mg/L). The same tendency was observed with the EEM analysis (Figure 2). Since membrane fouling progressed faster with the RO process than the NF process, the integrated NF and TiO_2-based AOP processes can be a viable option for greywater reclamation in terms of water quality and continuous system operation.

Nutrients and characterization of greywater from rural households

Tonetti, A. L.; Figueiredo, I. C. S, Almeida, M. E. P.; Portela, D.G., Miyazaki, C. K.

*School of Civil Engineering, Architecture and Urban Design – FECFAU, Sanitation and Environment Department, University of Campinas – UNICAMP, PO box 6021, 13083-830, Campinas (SP), Brazil. (E-mail: tonetti@unicamp.br).

Abstract
It was found that in a rural area of Campinas (SP), over 90% of households segregated greywater. The source of greywater generation had a great influence on its composition, especially due to cleaning products in it. Greywater from showers presented higher NTK concentration, due to the habit of urinating in the shower.

Keywords (maximum 6 in alphabetical order)
Greywater; Nitrate; Phosphorus; Source Separation.

INTRODUCTION

Greywater composition and generation depend on factors such as the finality and quantity of clean water used, which are directly influenced by regional and cultural characteristics (Boyjoo et al., 2013). Greywater can contain organic matter, chemicals, fat, soap, fibers, and hair, with different compositions due to their origin (Paulo et al., 2018).

There are little data available about greywater composition from rural households in Latin America. Thus, the present study evaluated the composition of segregated greywater from Campinas (SP) rural area and characterized samples of this specific wastewater fraction.

MATERIALS AND METHODS

Source-separation of water is very common in the study area. About 91% of households separate the water from laundry tub and washing machine, 83.2% separate kitchen water and 63.2% separate shower water (Madrid et al., 2015). The quality analysis results followed the methods described in APHA et al. (2012).

RESULTS AND DISCUSSION

According to Table 1, COD and total suspended solids (TSS) concentration in kitchen water were higher than the typical value for domestic sewage (Von Sperling, 2014), linking these parameters values with food waste. The higher pH average of effluents from shower and laundry probably occurred due to sodium hydroxide-based soaps and bleach laundry uses, which raised the water pH (Morel and Diener, 2006).

Shower samples presented high concentrations of total phosphorus (Pt), which were near to the 7 mgL^{-1} typical sewage levels (Von Sperling, 2014). A possible explanation for this is the use of shampoos, sunscreen, and liquid soap, which have phosphates in their composition to fulfil the function of foam stabilizers. Regarding nitrogen analysis, shower samples presented the highest concentration in comparison with the other sources. The results are probably associated with to the habit of peeing in the shower. However, this habit is not common for all residents, causing a variation of NTK concentration (126.0 ± 132.0 mgN L^{-1}). Thus, NTK values from the shower became comparable to those values from other sources. The nitrogen concentration of laundry and mixed water were significant due to the large variation of NTK concentration in all samples. Nitrogen presence in laundry and mixed water had contributions from the disinfectants and cleaning products use, which have ammonia-based composition.

Table 1. Quality analysis of the different greywater sources.

Parameter	Kitchen	Mixed	Shower and washbasin	Laundry
COD (mgO2L-1)	2331±308 a	1296±565 b	611±723 c	748±519 c
TSS (mgL-1)	1109±706 a	318±283 ab	178 + 158 bc	93±78 c
NTK (mgN L-1)	9.5±4.9 a	24.5±15.1 ab	126.0±132.0 b	22.5±18.9 ab
Ptot (mgL-1)	3.4±2.1 a	5.3±8.7 a	6.9±11.3 a	3.7±2.1 a
pH	5.5±0.5 a	6.0±0.6 ab	7.1±0.2 b	8.6±1.4 b
Conductivity (mS cm-1)	0.4±0.1 a	0.5±0.1 a	0.6±0.4 a	2.1±1.3 b
Turbidity (uT)	242±106 a	179±95 a	154±185 ab	66±42 b

The statistical study presented indicate the absence of a relationship between the analysed parameters. Thus, it was produced wastewater with different characteristics, despite all wastewaters have been called greywater. Bakare et al. (2016) found similar results after evaluating greywater samples from 75 households in South Africa. Jefferson and Jeffrey (2013) also found that greywater variability depends on people's activities, and is a consequence of geographic, economic, and social factors.

Abstract

In recent times, population growth has implied a higher generation of wastewater and contamination of water resources. The country of Bolivia has not been the exception. Thus, methods and materials for wastewater treatment suitable for Bolivian society should be studied. Bolivian natural zeolite (BZ) was selected as an adsorbent for the removal of cadmium. Likewise, BZ was converted to Na-form (NaBZ) by a treatment in a solution of 2M NaCl. BZ and NaBZ were characterized by XRD, scanning electron microscope SEM, and N_2 adsorption-desorption measurements. Additionally, the techniques of XPS and FT-IR were used to study the adsorption mechanism. Cadmium adsorption on BZ and NaBZ was described by Langmuir model, which provided considerable values of maximum cadmium adsorption capacity of 20.2 and 25.6 mg/g for BZ and NaBZ, respectively. The adsorption data followed the pseudo-second-order model. Additionally, the effect of pH (5-11), temperature (25-60 °C), contact time (5-180 min), and desorption test was studied. Moreover, a study of the adsorption of heavy metals (As, Cd, Cu, Co, Ni, Pb, and Zn) from an actual sample (Brine from Uyuni salt flat) was studied. The obtained results in this study show the efficacy of Bolivian natural zeolites in the adsorption of heavy metals.

Keywords (maximum 6 in alphabetical order)
Adsorption; cadmium; clinoptilolite; heavy metals; natural zeolites

INTRODUCTION

Nowadays, pollution is one of the biggest problems around the world. Remove of toxic heavy metal ions from wastewater has received significant attention due to their harmful impact on the environmental and public health (Anbia & Amirmahmoodi, 2016). Within the group of heavy metals is cadmium which is carcinogen and can produce a damage in the kidney, bones and respiratory system (Godt et al., 2006).According to the literature, many conventional approaches have been used to reduce concentrations of heavy metals from wastewater, such as coagulation, flocculation, chemical precipitation, flotation, reverse osmosis, ion exchange, and ultra-filtration (Da'na, 2017). Among the many methods available, adsorption is considered a very promising technique for metals removal, due to its high efficiency, easy operation, low cost, and the availability of different adsorbents (Fu & Wang, 2011; Prelot et al., 2012). The natural zeolites are one of the adsorbents with high availability, mainly due to zeolites are undoubtedly the most inexpensive alternative adsorbents compared to others. Additionally, natural zeolites have been reported as a good adsorbents for the retention of heavy metal ions due to their open pore structure, accessible adsorption sites, regeneration ability (Babel & Kurniawan, 2003; Da'na, 2017; De Gisi et al., 2016; Zhao, 2011) . Moreover, pretreatment of natural zeolites by NaCl was highly reported due to the increase in the heavy metals removal(Cortés-Martínez, R., Martínez-Miranda, V., Solache-Ríos, M., & García-Sosa, 2004; Gedik & Imamoglu, 2008; Giornoa & Driolia, 1997; Lonin et al., 2018).
Bolivia is a rich country in the mineralogical field (Valle & Holmes, 2013). The availability of nonmetallic minerals is a good alternative to using them and transforming them in specialized products (Zeballos et al., 2017). One of the mineral available are natural zeolites, thus their application in the adsorption of heavy metals will be suitable and useful for the treatment of water sources of communities and wastewater from industries.
Currently, the application of Bolivian natural zeolites and their application in the removal of heavy metals has not been reported. Therefore, the aim of the present study is the application of raw and NaCl-treated Bolivian natural zeolites in the adsorption cadmium. Furthermore, a study of heavy metals adsorption from the brines of Salar de Uyuni, Bolivia has been developed.

MATERIALS AND METHODS

Bolivian natural zeolite (BZ) of Clinoptilolite type was provided from Sucre, Bolivia. Firstly, BZ was crushed and sieved through meshes in the range of 45-500 µm, then washed with abundant distilled water and dried at 105 °C for 24 h. The brine to be treated was obtained from the salt flat of Salar de Uyuni, located in Potosi, Bolivia. The brine was collected in September 2019 (geographical coordinates: 20° 17' 22" S 67°04'35" W).

2.1. Bolivian Natural Zeolite Pretreatment

Na-form was prepared similar to the procedures reported in the literature (Bektaş & Kara, 2004; Semra Çoruh & Osman Nuri Ergun, 2008). 100 g of BZ was added to a solution of 2M NaCl, and the solution was stirred at 120 rpm, 25 °C for 24 h, then was filtered and washed with plenty of distilled water to remove the chloride ions (Cl^-) completely. The resultant pretreated zeolite was labeled as NaBZ. To ensure that the Cl^- has been eliminated, the verification of the presence of Cl^- was performed by the silver nitrate ($AgNO_3$) (0.1 M) test.

2.2. Characterization of zeolites

The mineralogical composition of BZ and NaBZ was determined by X-ray powder diffraction (XRD) by (ADP 2000 Pro X-ray diffractometer, Italy) with Cukα radiation (λ=1.5418Å) in the 2Θ range of 5-50 between with a step of 0.02. The microstructure was characterized by scanning electron microscope (JSM-IT 300 SEM JEOL, Japan). The characterization of BZ and NaBZ before and after the adsorption of cadmium by Fourier transform infrared spectroscopy FT-IR (Vertex 70v vacuum-based, USA), and X-ray photoelectron spectroscopy (Kratos Analytical Ltd., UK) were used to study the mechanism.

2.3. Batch adsorption experiments

The adsorption of cadmium on BZ and NaBZ was carried out using the batch method. 1 g of zeolite was added to 50 mL of 500 ppm of Cd. The solution was stirred at 200 rpm, for 24 h. Once the equilibrium was achieved, the solution was filtered with a syringe filter of 0.45 µm to collect the final solutions. Cadmium adsorption was determined by the difference between initial and final metal concentrations in the solution. The concentration of initial and final of cadmium solutions was measured by inductively coupled plasma sector field mass spectrometry (ICP-SFMS, USA).
Moreover, the adsorption isotherms and kinetics were obtained varying the initial concentration in the range of 10 to 500 mg/L and stopping the time each 5, 10, 15, 30 ,60 ,120, and 180 min), respectively. Additionally, the effect of temperature (25-45 °C), and pH (5.5-11) were studied.

2.4. Desorption test

The desorption test was performed adding a cadmium saturated BZ and NaBZ in a solution of HCl 0.1 M, at RT and 24 h. After the desorption process, samples were washed with distilled to remove the excess of Cl^- ions. The desorption process was conducted three times to verify the regeneration process of BZ and NaBZ.

2.5. Adsorption of heavy metals from Salar de Uyuni

The adsorption of heavy metals from brine of Uyuni salt flat on BZ and NaBZ was carried out similarly to the procedure of section 2.3. 1 g of zeolite was added to 50 mL of brine, solutions were stirred at 200 rpm, pH 6, and 25 °C for 24 h. After, the adsorption process, samples were filtrated with a syringe filter of 0.45 µm to recover BZ and NaBZ and measure the final concentrations by atomic absorption spectrophotometer (AA500, England).

RESULTS AND DISCUSSION

Firstly, BZ and NaBZ were characterize, after characterization the results showed no change in the crystallography structure, however an increase in the textural properties after the treatment by NaCl was detected. The obtained values were to surface area (25.93 to 30.94 m^2/g), pore diameter (13.88 to 15.83 m^2/g) and pore volume (0.0051 to 0.0091 cm^3/g). The increase in the textural properties are consistent with previous literature reports (Bektaş & Kara, 2004; Gedik & Imamoglu, 2008).

Subsequently, an adsorption test was performed to analyse the adsorption capacity of BZ and NaBZ towards cadmium. 1 g of zeolite was added to a solution of 500 mg/L of Cd and stirred until reach the equilibrium. The cadmium adsorption process on BZ and NaBZ has been studied using the adsorption isotherms of Langmuir and Freundlich. Between the two models, the Langmuir model was the best fit to the adsorption data obtained, with values of 20.2 and 25.6 mg/g for BZ and NaBZ, respectively. The obtained results showed a higher cadmium adsorption in comparison to some studies which reported lower cadmium adsorption on different natural zeolites from the world such as Ukrainian clinoptilolite (4.22 mg/g) (Sprynskyy et al., 2006), Iranian clinoptilolite (4.00 mg/g) (Merrikhpour & Jalali, 2013), Australian clinoptilolite (1.32 mg/g) (Taamneh et al., 2012).

Furthermore, the adsorption rate was studied through kinetics of pseudo-first and second order. The kinetic data was obtained by stirring Cd concentrations in a range of concentration of 5 to 180 min. According to the obtained data pseudo-second order fitted well with a correlation factor of 1 and similar data than the obtained experimentally.

Subsequently, a desorption process was carried out to verify the regeneration capacity of BZ and NaBZ. The upload zeolites were stirred in a solution of HCl 0.1 M. After, the desorption process percentage of 52.5 and 45.6 for BZ and NaBZ respectively.

Additionally, BZ and NaBZ were applied in the adsorption of heavy metals from a real water source (Brine from Uyuni salt flat, Bolivia). The application of BZ and NaBZ showed effective removal towards heavy metals. The removal percentage in BZ was for As (46 %), Cd (84.8 %), Cu (73.6 %), Co (67.5 %), Ni (85.7%), Pb (33.5%), Zn (12.4 %), and for NaBZ was for As (51.9 %), Cd (73.3 %), Cu (79 %), Co (69.4 %), Ni (96.6 %), Pb (55.9 %), Zn (81.8 %).

CONCLUSION

According to the obtained results, the adsorption capacity of BZ and NaBZ towards cadmium from synthetic solutions and heavy metals from real brine has been effective. Thus, Bolivian natural zeolites should be considered as a suitable candidate for the adsorption of heavy metals from polluted sources which will be a benefit for the Bolivian communities due to the use of own resources which will imply a low-cost method and improvement in the access to drinking water and quality of life.

Abstract
Surfactants are among the main chemical contaminants in greywater and can pose risks to humans and the environment. This study assessed the surfactant removal capacity of 9 different constructed wetland systems for greywater treatment that differed with respect to design and operation as well as input greywater. Anionic surfactants could be detected in all greywaters studied at much higher concentrations than nonionic or cationic surfactants. It was shown that several investigated VFCW systems were suitable for extensive surfactant removal. This is mainly due to the required complete aerobic biodegradability of surfactants to be placed on the market. The investigated HFCW may only be suitable for extensive surfactant removal by operation at considerably lower hydraulic and organic loading rates and thus higher hydraulic retention times and reactor volumes. Based on the results shown, it is advisable to employ aerobic vertical-flow constructed wetlands for surfactant removal for safe greywater reuse.

Keywords (maximum 6 in alphabetical order)
Biodegradability, greywater reuse, HFCW, VFCW, nature-based solution, treatment wetland.

INTRODUCTION

Greywater is household wastewater that excludes urine and faecal wastewater. Given their widespread applicability, surfactants (emulsifiers or surface-active agents that allow two immiscible liquids to mix) are among the main chemical contaminants in greywater and are generally found not only in wastewater but also in natural waters (Ramprasad and Philip 2016). Surfactants usually enter the wastewater stream due to high solubility, without undergoing any metabolic changes. As a result, these compounds persist in the discharged environment for a long time, resulting in many adverse effects. Surfactants can cause increased environmental pollution, specially negative changes in soil properties, e.g., hydrophobicity in soil (Gross *et al.* 2015). In humans, they mostly cause skin irritation and allergic dermatitis, but in chronic conditions they can lead to more severe disorders, such as cancer (Ramprasad and Philip 2016). Conventional wastewater treatment plants (WWTPs) are ineffective at completely removing surfactants (Ramprasad and Philip 2016). Furthermore, surfactants enter greywater predominantly through the use of detergents and cleaning products; typically, anionic surfactants are used to remove dirt particles, nonionic surfactants are employed to eliminate grease, and cationic surfactants are used as fabric softeners (Gross et al. 2015). In the European Union and elsewhere, legislation usually requires proof for both the primary degradability and the complete aerobic biodegradability of surfactants to be placed on the market (EC Detergents Regulation 2004). Due to their linear carbon chains, easily biodegradable anionic surfactants are predominantly used in cleaning products (Gross *et al.* 2015). Hereof, linear alkyl benzene sulfonate (LAS) is the most commonly used surfactant in laundry and dishwashing agents, accounting for approx. 80 % of all household cleaning agents (Venhuis and Mehrvar 2004). In washing machine wastewater, pollutants in the laundry and the ingredients of the detergents, including surfactants, sometimes lead to very high COD concentrations (Friedler 2004; Weingärtner 2013). Due to the use of personal care products, light greywater from showers usually contains compounds that are difficult to biodegrade, such as synthetic surfactants. The presence of surfactants usually reflects in relatively high COD to BOD_5 ratios [COD/BOD_5 = 2.8 ± 1.0 (Jefferson *et al.* 2004); 2.5 ± 0.5 (Gethke *et al.* 2007)]. According to Keysers *et al.* (2008), a concentration range for anionic surfactants of 0.46-0.83 mg/l and for nonionic surfactants of 1.4-1.7 mg/l was found in shower greywater generated at a German WWTP. Cationic surfactants were below the quantitative limit of detection (< 0.05 mg/l).
Nature-based solutions as biological treatment offer a promising approach that benefits both human and environmental health at little cost. For greywater treatment, specially constructed wetlands (CWs) seem to be an adequate treatment option (Boano *et al.* 2020).
This study assessed the surfactant removal capacity of 9 different constructed wetlands that differed with respect to design (horizontal-flow or vertical-flow) and operation (variation in loading rate) as well as input greywater (washing machine greywater or light greywater from showers and hand wash basins with and without kitchen wastewater shares).

MATERIALS AND METHODS

Experimental setup and design

The investigated horizontal-flow constructed wetland (HFCW) showed the dimensions 1.00 m × 1.00 m × 0.70 m (L × W × D) and treated a mean flow of 150 L/d [HLR = 392 ± 272 L/(m^2·d)] greywater generated by two showers, two lavatories, two laundry basins, and one washing machine within an experimental bathroom at UFMS Campus in Campo Grande, Brazil. The system is described in Filho *et al.* (2018) and was monitored for 497 d.
Two investigated pilot-scale vertical-flow constructed wetlands (VFCW) are described in Morandi *et al.* (2021). They consisted of 2.5 m^2 filter area each and were filled either with common fluviatile sand (0 – 2 mm) or lava sand (0 – 4 mm), acquired from a quarry in Rhineland-Palatinate in Germany. The pilot-scale VFCW treated greywater from showers and hand wash basins at a temporary construction workers' housing in Stuttgart, Germany. The hydraulic loading rate to the lava sand VFCW amounted to 65.3 ± 16.2 L/(m^2·d), whereas it corresponded to 75.4 ± 17.2 L/(m^2·d) for the fluviatile sand compartment. The systems were investigated for 446 d.
Moreover, six small-scale VFCW columns S1 to S6 (Ø = 29 cm) made of acrylic glass with inclined bottom and slotted drainage pipe (8 mm) were investigated for the removal of surfactants (see Figure 1). The systems were operated at the facilities of the RPTU Campus in Kaiserslautern, Germany, and filled either with fluviatile sand (0 – 2 mm) or lava sand (0 – 4 mm) as filter layer. The drainage layer of S3, S4, and S6 was functionalized with anthracite coal for enhanced phosphorus removal, which is beyond the scope of this study. The systems were fed with light greywater from showers and hand wash basins with kitchen wastewater shares from students' dormitories in Birkenfeld, Germany, and investigated for 530 d. The HLR varied, depending on the system, from 69 ± 13 L/(m^2·d) [S4] up to 82 ± 21 L/(m^2·d) [S1].

Figure 1. Small-scale VFCW after start-up with greywater (left) and after approx. one and a half years of operation (right) in Kaiserslautern, Germany.

RESULTS AND DISCUSSION

Table 1 illustrates the removal efficiency in terms of COD and surfactants for the 9 constructed wetlands studied. Anionic surfactants could be detected in all greywaters studied, as these readily biodegradable surfactants are predominantly used over nonionic or cationic surfactants due to legal regulations (EC Detergents Regulation 2004). Cationic surfactants, on the other hand, were hardly detected or only in low concentrations, which is in accordance with Keysers *et al.* (2008). The reason for this was the exclusion of washing machine wastewater in all VFCW systems investigated. For the HFCW, neither cationic nor nonionic surfactants were analyzed. The highest concentrations for anionic surfactants with 28 ± 10 mg/l LAS were found to be upstream of the HFCW in mixed greywater after pretreatment. This can be ascribed especially to the washing machine greywater contribution. Also, greywater from the workers' housing showed 12.8 mg/l anionic surfactants. This can be attributed to the regular cleaning of shower stalls (two to three times per week) with an alkaline high-concentrate cleaning agent. Greywater from the student dormitories exhibited 12.1 mg/l anionic surfactants, which can also be found in shampoo formulations (Trüeb 2007). With regards to nonionic surfactants, it is possible that they were introduced into the kitchen wastewater in Birkenfeld via the use of dishwashing detergents as grease solvents, while at the pilot plant they enter the greywater via the bath cleaning agent in the same way as the anionic surfactants.

Table 1. Mean values ± SD for loading rates, COD, and surfactants concentrations in the influent as well as corresponding removal efficiencies in horizontal and vertical-flow constructed wetlands.

Constructed wetland	Hydraulic loading rate in L/(m^2·d)	Organic loading rate in g COD/(m^2·d)	Influent concentration in mg/l	Removal in % or effluent concentration in mg/l
HFCW	392 ± 272	36 ± 30	282 ± 100 (COD) 28 ± 10 (LAS) 270 ± 137 (COD) 3.9 ± 3.7 (nonionic surfactants) 0.7 ± 0.3 (cationic surfactants) 12.8 ± 3.2 (anionic surfactants)	38 ± 16 % COD 35 ± 23 % LAS 97.0 ± 1.6 % COD ; 95.9 ± 1.8 % anion. surf.; < 0.2 (LoD) – 0.57 mg/l cationic surf.; < 0.2 (LoD) – 0.24 mg/l nonionic surf.
VFCW, pilot-scale, Rhine sand	75.4 ± 17.2	16.4 ± 5.5		
VFCW, pilot-scale, lava sand	65.3 ± 16.2	19.0 ± 6.2		98.2 ± 0.7 % COD 96.4 ± 1.5 % anion. surf. < 0.2 (LoD) – 0.73 mg/l cationic surf.; < 0.2 (LoD) – 0.26 mg/l nonionic surf.
S1	82 ± 21	19 ± 8.8	277 ± 148 (COD) 2.5 ± 1.9 (nonionic surfactants) < 0.2 (LoD) – 5 (cationic surfactants) 12.1 ± 18.5 (anionic surfactants)	97.5 ± 1.2 % COD 0.33 ± 0.36 mg/l (anion. surf.)
S2 (lava)	79 ± 11	18 ± 7.4		97.4 ± 1.2 % COD 0.33 ± 0.30 mg/l (anion. surf.)
S3	76 ± 7.8	17 ± 6.7		97.0 ± 1.3 % COD 0.31 ± 0.30 mg/l (anion. surf.)
S4	69 ± 13	16 ± 7.1		96.9 ± 1.2 % COD 0.33 ± 0.32 mg/l (anion. surf.)
S5	71 ± 9.3	16 ± 7.0		97.5 ± 1.2 % COD 0.30 ± 0.19 mg/l (anion. surf.)
S6 (lava)	76 ± 17	17 ± 7.2		97.8 ± 1.1 % COD 0.25 ± 0.12 mg/l (anion. surf.)

< 0.12 mg/l (LoD; cationic surfactants). Predominantly < 0.2 mg/l (LoD; nonionic surfactants)

In contrast to the HFCW, it can be inferred from Table 1 that both the lava and Rhine sand VFCW removed surfactants extremely well. Previous studies have shown that vertical flow is more efficient than horizontal flow for surfactant removal in treatment wetlands (Tamiazzo *et al.* 2015). For instance, Fountoulakis *et al.* (2009) reported a LAS removal efficiency of 55% (inlet concentration 7.17 mg/l) in a 45 m² full-scale HFCW. The results of this study also suggest that higher COD eliminations significantly contribute to higher surfactant removal. Regarding the removal of anionic surfactants, regardless of the VFCW filter material, the influent value was reduced to very low concentrations (see Table 1). In the effluent, the values for cationic and nonionic surfactants fell mostly under 0.20 mg/l (LoD). This indicates a high treatment efficiency also for more recalcitrant substances, such as cationic and nonionic surfactants. It can be concluded that several VFCW investigated were suitable for surfactant removal. The main reason for that is that aerobic biodegradability is a prerequisite for surfactants to be placed on the market (EC Detergents Regulation 2004). An aerobic biodegradability does not, however, necessarily imply a corresponding anaerobic biodegradability. HFCW, in which anaerobic conditions prevail, may only be suitable for surfactant removal by operation at considerably lower hydraulic and organic loading rates and thus higher hydraulic retention times and reactor volumes. Based on the results shown, it is advisable to employ aerobic vertical-flow constructed wetlands for surfactant removal for safe greywater reuse.

Abstract
In the present study, plots from a horticultural field were irrigated with reclaimed water, and the accumulation of pharmaceuticals in the bulk and rhizosphere soils was studied. Analgesics and non-steroidal anti-inflammatories represented the major fraction of the initial pharmaceutical mass load, while irbesartan, hydrochlorothiazide were the most detected compounds after the irrigation. Rhizosphere soils exhibited a greater number of analytes and higher concentrations than bulk soils. Further studies will include the analysis of antibiotic resistant genes and the evaluation of the whole water-soil-plant system, to assess potential human risks.

Keywords (maximum 6 in alphabetical order)
Antibiotics, Rhizosphere, Soil pollution, Soil-plant system, Water treatment.

INTRODUCTION

Freshwater scarcity in times of climate change is a global concern that needs urgent attention. Island communities, especially those receiving high influxes of tourists, demand the availability of fresh water enough to satisfy not only the domestic usage, but for agricultural purposes. The circular economy processes intend to provide alternative solutions to address this situation, such as the application of wastewater treatment systems to obtain water suitable for irrigation. One of the major challenges involves the effective removal of organic pollutants, especially the so-called emerging ones, such as pharmaceuticals (drugs, antibiotics, among others). After passing through the system, these pollutants can reach the soil, generating potential human and environmental health risks, from the promotion of antimicrobial resistance in soils, toxic effects on the edaphic biota, and even a food safety risk, if crops can uptake them into their edible parts. Within the framework of the H2020 EU HYDROUSA project, we studied the accumulation of pharmaceuticals on agricultural soils after two seasonal periods of irrigation with reclaimed water. The study was performed during the growth period of a regular crop (lettuce), at full-scale under environmental conditions.

MATERIALS AND METHODS

The study was performed in Lesvos, a touristic island from Greece, where a demonstration-scale treatment plant was installed. The system consists of an upflow anaerobic sludge blanket reactor, a constructed-wetland system, and finally a tertiary treatment (UV). The reclaimed water is collected in storage tanks and applied for irrigation on adjacent horticultural fields. The field was divided into 2 plots: one irrigated with the reclaimed water (RW) and another with tap water (TW). Common lettuce (*Lactuva sativa*) was grown in both plots for c.a. 45 days (growing period of the crop) in two different seasons: autumn (2021) and summer (2022). Bulk soil samples were collected at 10 cm depth in the proximity of the crop, near the drippers before planting (initial time), and at harvesting time (final time). Additionally, the soil attached to the roots (rhizosphere soil) was collected at the final time by manual shaking of the roots (Shen et al., 2021).

Solid samples were extracted according to Gros et al., (2019). Briefly, 1 gram of freeze-dried soil was extracted with a buffer McIlvaine/MeOH solution in an ultrasound bath, followed by SPE (Oasis HLB) for clean-up. The analytes were eluted with MeOH, the solvent was evaporated, and the sample was reconstituted in LC mobile phase. Before injecting, samples were spiked with isotopically labelled standards. The quantification of samples was performed with a matrix-matched calibration curve, and recovery tests were performed to assess the extraction efficiency. The samples were analyzed in a quadrupole linear ion trap tandem mass spectrometry (UHPLC-QqLIT, SCIEX), following a total of 64 compounds in target mode.

RESULTS AND DISCUSSION

Pharmaceuticals were detected in the TW and RW soils before and after the growth periods. Overall, a higher number of compounds and a total mass load of pharmaceuticals were found in the RW, when compared to the TW soils. The non-steroidal analgesics and anti-inflammatories comprised more than the 90% of the mass burden at the initial time in autumn for both plots, with acetaminophen (max: 15.8 ug/kg), ketoprofen (max: 18.6 ug/kg), and the ibuprofen metabolite 2-OH ibuprofen (max: 23.9 ug/kg) all three with detection frequencies >80%. The same pattern was found in summer, though for the RW soils the fraction of NSAAI was lower (54%), as other groups such as antihypertensive and psychiatric drugs exhibited higher concentrations.

The number of compounds detected in the bulk soils of the RW plots at the final time (harvest) increased at both campaigns (autumn and summer). More pharmaceuticals were detected after the irrigation period in the summer season (n=27) than in the autumn (n=11). Hydrochlorothiazide and irbesartan were the compounds detected at the highest concentrations, at 59.4 and 62.5 µg/kg, respectively (Fig 1). Psychiatric drugs such as venlafaxine, its metabolite O-desmethyl-venlafaxine, and carbamazepine were also detected in the bulk soil in a range of 3.8-17 µg/kg.

Higher numbers of compounds as well as higher concentrations were found in the rhizosphere soil compared to the bulk soil in both seasons. The drugs found at higher concentration levels presented a similar profile in both soils (Fig 2). It is notable that three extra antibiotics were only found at rhizosphere soils (sulfamethazine, sulfamethoxazole, and trimethoprim). Since the soil organic matter did not differ between both types of soils, it is expected that other inherent physicochemical properties (pH, soil texture, among others) might provide better conditions for the sorption and accumulation of these compounds.

CONCLUSIONS

Pharmaceuticals were detected in soils after irrigation with reclaimed water. Although the control plots irrigated with tap water also showed the presence of several compounds (mainly analgesics and non-steroidal anti-inflammatories), reclaimed water for irrigation lead to detections of up to 33 compounds in the soil surrounding the rhizosphere of the lettuce crops. Several metabolites were found, such as the 2-OH ibuprofen and O-desmethyl-venlafaxine. The detection of compounds such as antibiotics in these soils is also relevant from the microbiological point of view. Further studies will include the analysis of antibiotic resistant genes and the evaluation of the whole water-soil-plant system, to assess potential human risks.

Effective radiation transfer as a major element for the optimized design and operation of purple phototrophic bacteria photobioreactors

A. Amini*, E. Porciatti*, M. Greco*, S. Rossi*, E. Ficara*, A. Turolla*

*Department of Civil and Environmental Engineering (DICA), Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133, Milan, Italy (E-mail: ali.amini@polimi.it; elisa.porciatti@mail.polimi.it, michael.greco@mail.polimi.it; simone.rossi@polimi.it; elena.ficara@polimi.it; andrea.turolla@polimi.it)

Abstract

The cultivation of purple phototrophic bacteria (PPB) in photobioreactors (PBRs) using different waste streams offers a promising opportunity for resource recovery. Effective reactor system design and mathematical modeling are crucial for maximizing PPB growth and optimizing the design and operation of PBRs. Insufficient research has been done on radiation transfer in mixed cultures of PPB, despite the fact that scaled systems require a thorough understanding of this phenomenon. In this work, laboratory-scale batch experiments were conducted to study the effect of light intensity on PPB growth. Based on experimental data, light distribution in PBRs was modeled using the most relevant approaches. Results showed that PPB scattering cannot often be ignored under conventional operating conditions. The Aiba model emerged as the best option for predicting the influence of light intensity on kinetic parameters. Guidelines for the optimized design and operation of PBRs were identified in the view of process scale-up.

Keywords

Photobioreactors; purple phototropic bacteria; radiation transfer; resource recovery

INTRODUCTION

Purple phototrophic bacteria (PPB) are among the species in nature with the widest variety of metabolisms (Fradinho et al., 2021). PPB are considered a promising phototrophic mediator for resource recovery from wastewater to produce value-added products (Capson-Tojo et al., 2021). Under photoheterotrophic growth conditions, PPB can use light as energy source for assimilative pollutant removal and maximizing the resource recovery potential (Capson-Tojo et al., 2022).

One of the key factors to be accounted for PPB growth is the light supplied by irradiation sources (artificial, sunlight) in photobioreactors (PBRs). Low light intensity might hinder microbial growth, while high values of light intensity can lead to photooxidation and photoinhibition phenomena (Carvalho et al., 2011). Furthermore, design, operation, and control of PBRs require accurate determination of light distribution within the PBRs (Wágner et al., 2016; Naderi et al., 2017) in order to provide valuable inputs to mathematical models that are able to predict PPB growth.

This work is primarily aimed at (i) the detailed modeling of radiation transfer in PBRs by the most relevant light propagation approaches, namely the Beer-Lambert law and the two-flux approximation model, and (ii) the assessment of the light intensity effect on PPB growth. Modeling results were applied for identifying guidelines for PBR optimized design and operation.

MATERIALS AND METHODS

Laboratory batch experiments were set up using flat-plate PBRs with a volume of 316 mL to assess the effect of different light intensities (10, 20, 40, and 60 W/m^2) on PPB growth at 30 °C and light distribution within the PBR. During the experiments, the light was supplied from one side as monochromatic radiation at 850 nm, and the pH was kept between 6.8 and 7.2. Light distribution within the PBR was evaluated at different biomass concentrations (ranging from 40 to 350 mgTSS/L) by applying the Beer-Lambert law and the two-flux approximation model, and the average light intensity was calculated based on the integration of the models used over the culture depth. Moreover, the kinetic parameters for PPB growth were obtained by fitting the experimental data with appropriate models for describing photooxidation and photoinhibition phenomena. With the aim of further investigating the scattering effect, optical properties were characterized by a spectrophotometer equipped with an integrating sphere over the spectral range of 300 to 1100 nm.

RESULTS AND DISCUSSION

Figure 1 shows the light intensity profiles inside the PBRs for different PPB concentrations at various incident light intensities by applying the Beer-Lambert law. As light passes through the PBR containing a PPB suspension, there is a strong reduction in the light intensity with increasing depth. For concentrations lower than 80 mgTSS/L every point of the reactor is illuminated, while for concentrations higher than 320 mgTSS/L half of the reactor is in the dark.

By comparing the average light intensities between the Beer-Lambert law and the two-flux approximation model, it can be seen that the scattering effect for PPB concentrations up to 500 mgTSS/L is not negligible (Figure 2). Results showed that neglecting scattering phenomena led to discrepancies of 33% and 24% for PPB concentrations of 160 and 320 mgTSS/L, respectively. Moreover, the optical properties confirmed the fact that scattering is a relevant phenomenon (Figure 3-a). As shown in figure 3-b, regarding the absorption peaks in the near-infrared region, for incident light intensities higher than 40 W/m^2 a downward shift in the light absorption of PPB was observed, indicating an adaptation in the pigment content of PPB for facing high light intensities.

The kinetic parameters of PPB in a batch PBR were obtained with particular emphasis on the effect of different light intensities. Experimental data from batch tests evidenced the occurrence of photoinhibition phenomena. The Aiba model emerged as the best modeling solution. As shown in Figure 4, the model correctly described the experimental data for each light intensity investigated. This resulted in a half saturation coefficient in the range of 3.82-4.63 W/m^2.

Modeling results were finally applied to the optimization of PBR design and operation, especially looking for the best geometrical configuration for flat-plate PBRs (in terms of thickness) as a function of PPB concentration, which in turn usually depends on the operating conditions of continuous flow systems (e.g., irradiation intensity, HRT, influent substrate concentration).

CONCLUSIONS

The results indicated that (i) light distribution is fundamental for PPB growth, (ii) scattering is important under certain operating conditions, (iii) light distribution has to be optimized to maximize energy absorption and minimize detrimental phenomena, (iv) it is necessary to design and operate reactors with an accurate assessment of radiation transfer, and (v) this work is paving the way to the scale-up of the technology as much higher productivity is granted by an effective use of radiation.

Abstract
Livestock farming is a relevant economic sector in many countries, generating large amounts of highly polluting wastes loaded with nutrients, organic pollutants and toxic trace elements which cause serious environmental issues if not properly treated. Piggery wastewater treatment in photobioreactors has shown great potential for nutrients recovery and removal of heavy metals. In this work, the removal capacity and biotransformation of arsenic species by microalgae and bacteria grown in photobioreactors treating piggery wastewater is investigated. The effect of contact time and metal concentration on the biosorption of As(III), As(V) and DMA on green microalgae *Scenedesmus almeriensis* and on bacteria from activated sludge were investigated, using batch photobioreactors fed with synthetic wastewater simulating the composition (C, N, P) of piggery wastewater. The maximum biosorption capacity of both biomasses for each metal at 1 and 72 h contact time were obtained from the adsorption isotherms.

Keywords
Arsenic, biosorption, heavy metals, *Scenedesmus almeriensis,* activated sludge, wastewater

INTRODUCTION

Contamination of soil and groundwater by arsenic has become a severe health and environmental concern worldwide due to the toxicity, mobility and persistence of this element. Prolonged exposure to arsenic species through drinking water and food develops cancer and other serious diseases. In water, the primer source of this toxic element to humans, arsenic occurs mainly as inorganic As(III) and As(V), but also organic dimethylarsinic acid (DMA) or monomethylarsonic acid (MMA) species may be present. Wastewater, specially from livestock farming using feed and/or water containing arsenic, is another important source of arsenic and values up to 690 µg/L as total arsenic have been reported (Gao et al., 2018). Bioremediation using microorganisms arises as a promising methodology to eliminate simultaneously organic and inorganic pollutants from wastewater and extensive research is being carried out on the use of this technique for the treatment of water contaminated with heavy metals and metalloids (Benis et al., 2020). Large amounts of valuable biomass are generated in this process and efforts are being carried out to recover nutrients and other high value biomolecules for new applications (fertilizers, feed, industrial applications…) within the context of the circular economy (Bădescu et al., 2018). This work addresses the capability of green microalgae and aerobic bacteria, usually employed in wastewater treatment plants, to remove inorganic and organic arsenic species (As(III), As(V) and DMA).

MATERIALS AND METHODS

Biosorption experiments were carried out with two biomasses of green microalgae *Scenedesmus almeriensis* and bacteria from an activated sludge, grown in a culture medium simulating the composition of piggery wastewater, spiked with 0.1 and 0.5 mg/L of As(III), As(V) or DMA, concentrations adopted from reference values reported for total arsenic in pig manure (ASAE, 2003). The synthetic wastewater was prepared dissolving per litre of deionised water,: 30 mg urea, 32.5 mg KNO_3, 4 mg $CaCl_2 \cdot 2H_2O$, 7 mg NaCl, 2 mg $MgSO_4 \cdot 7\ H_2O$, 110 mg peptone and 160 mg of meat extract (Sigma Aldrich, Germany) (Alcántara et al., 2015). Initial biomass concentration of 2 and 4 g/L of microalgae and activated sludge, respectively, was treated at 25°C under continuous stirring in orbital shaker at 250 rpm and LED lightening at 1200 $\mu E \cdot m^{-2} \cdot s^{-1}$ in 12:12 h light-darkness periods. Bioelimination percentages of arsenic species were determined at different contact times from 8 h to 15 days. The concentration of As species in the filtered supernatant was determined by HPLC-ICP-MS (Agilent 2200 HPLC system coupled to Agilent 7800 ICP-MS). Maximum biosorption capacities of both biomasses for each As species at 1 and 72 h contact time were obtained from the respective adsorption isotherm constructed at concentrations of As species ranging from 1 to 500 $mg \cdot L^{-1}$, using Langmuir and Freundlich approximations.. The biomass growth was determined gravimetrically, measuring the variation in biomass weight after the biosorption experiments.

RESULTS AND DISCUSSION

The adsorption capacities of both microorganisms are depicted in Table 1.

Table 1. Adsorption capacity of As(III), As(V) and DMA species on *Scenedesmus almeriensis* and activated sludge at 1 and 72 h.

1h		Langmuir-1h		Langmuir-72h	
		q_{sat} mg/g	K_L L/mg	q_{sat} mg/g	K_L L/mg
As(III)	*Scenedesmus Al.*	**0.40**	0.021	**9.52**	0.010
	Activated sludge	**1.90**	0.023	**23.15**	0.002
As(V)	*Scenedesmus Al.*	**0.18**	0.032	**4.9**	0.0029
	Activated sludge	**2.46**	0.117	**34.7**	0.0004
DMA	*Scenedesmus Al.*	**0.39**	0.010	**37.0**	0.0007
	Activated sludge	**0.58**	0.156	**3.16**	0.0038

At 1 h contact time, the best adsorption capacity was achieved for As(V) with *activated sludge* (2.46 mg/g) whereas for 72h of contact time DMA showed the maximum adsorption capacity of 37.0 mg/g on *Scenedesmus almeriensis*. The dimensionless separation coefficient R_L was calculated according to the following expression:

$$R_L = \frac{1}{1 + K_L \cdot c_0}$$

R_L between 0 and 1 where obtained which is indicative of a favourable adsorption process (Liu et al., 2011). On the other hand, n values from Freundlich linear fit were higher than 1, which again demonstrates the adsorption process as favorable.

Figure 1 shows the bioremoval efficiency of both microorganisms as a function of the contact time. At short contact times, between 8 and 72 h, the microalgae shows a higher affinity for the more toxic inorganic species As(III) and As(V), with a moderate bioelimination of 13 and 27%, respectively. However, a progressive increase in the bioelimination of the organic species with time is observed, reaching a maximum up to 80% elimination of DMA after 10 days of contact. On the other hand, for activated sludge, the highest affinity for tri- and pentavalent inorganic species is confirmed, resulting in bioelimination percentages up to 80% at a contact time of 1 day for both 0.1 and 0.5 mg/L initial concentrations of arsenic species.

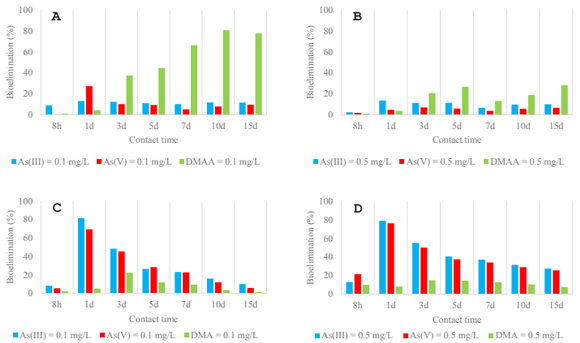

Figure 1. Bioelimination percentages for As(III), As(V) and DMA with the two biomasses tested, *Scendesmus almeriensis* (**A** and **B**) and activated sludge (**C** and **D**) for 0.1 and 0.5 mg/L as initial concentration.

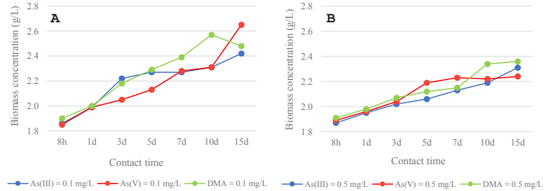
Figure 2 depicts the effect of the arsenic species and concentration on the viability of the biomasses. After 15 days of contact with As species, a progressive growth of microalgae biomass has been observed without causing apparent cell death, while for activated sludge a much faster growth is observed, not needing an acclimatization time as the microalgae exhibits. Maximum biomass concentrations of 2.65 and 4.79 g/L were reached for microalgae and activated sludge, respectively.



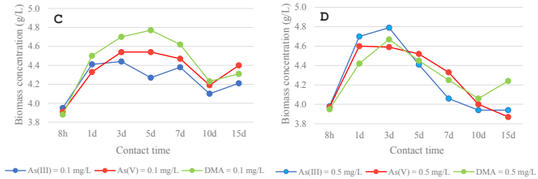


Figure 2. Biomass concentration for the experiments spiked with As(III), As(V) and DMA with the two biomasses tested, *Scendesmus almeriensis* (**A** and **B**) and activated sludge (**C** and **D**) for 0.1 and 0.5 mg/L as initial concentration of each arsenic species.

After 15 days of contact time of both biomasses with arsenic species it was observed the complete oxidation of As(III) to As(V) in the presence of microalgae, while in the solutions spiked with As(V) and DMA arsenic speciation remained unchanged. For the activated sludge biomass, the conversion of added As(III) into As(V) and DMA is observed, although the latter in lower proportion. When the initial species is As(V), no significant transformation is observed. Finally, when the initial species is DMA between 20-45% is transformed into inorganic As(V).

Abstract

Photobioreactors are a sustainable wastewater treatment alternative capable of removing nutrients and pollutants. Microalgae are photosynthetic microorganisms that, if grown in wastewater with high nitrogen loads, contain a high percentage of protein and could be a promising alternative to the increasing demand for this nutrient. New sustainable solvents are needed to extract the proteins from microalgal biomass selectively. Deep eutectic solvents (DES) are a promising green alternative to traditional protein extraction methodologies using classical organic solvents or alkaline/acidic conditions, which are detrimental to protein stability and planet health. In this work, protein extraction from green microalgae *Scenedesmus almeriensis* grown in swine wastewater has been investigated using DES. The response variables measured were the protein yield and the protein/carbohydrate partition ratio. The effects of the solvent used (choline chloride:glycerol [1:2], choline chloride:urea [1:2], and only water) and the amount of water added to the solvent-biomass suspension (0, 3, 6, and 20 g) were investigated through a full factorial design and quantified by ANOVA.

INTRODUCTION

Wastewater pollution is a severe socio-sanitary problem requiring efficient and economically sustainable solutions capable of simultaneously removing water pollutants and converting them into reusable materials while decreasing energy consumption (Zhang et al., 2018). Photosynthetic reactors are emerging as a cost-effective alternative to conventional biological wastewater treatment with promising results. These photobioreactors are based on the cultivation of microalgae, which consume CO_2, produce O_2 and assimilate nutrients from the wastewater (García et al., 2019), converting them into potentially valuable compounds (proteins, sugars, bioactive compounds, or oils). The protein fraction of the grown biomass is a source of peptides, valuable as bio-stimulants in agriculture or as amino acids for animal feed (Gao et al., 2020). However, obtaining proteins from microalgae is a complex process, as they must be separated from the rest of the biomass components. Classical methods employ toxic substances and harsh conditions, which are detrimental to the planet's health and protein stability. Thus, new efficient, selective, and sustainable methodologies for protein recovery from biomass are needed. In this context, deep eutectic solvents (DES) prepared from natural compounds are a promising option as extraction agents since they present a lower environmental impact than conventional solvents (Mehariya et al., 2021).

MATERIALS AND METHODS

Protein recovery from the algal biomass based on *Scenedesmus almeriensis* grown in swine wastewater has been investigated. The effect of water on the extraction of protein has been evaluated, as it is present in fresh microalgal biomass and can reduce solvent viscosity, which might improve the extraction performance. A full factorial experimental design has been carried out studying two factors: the type of solvent (choline chloride:glycerol [1:2], choline chloride:urea [1:2] and only water), and the amount of water added to the solvent-biomass suspension (0, 3, 6, and 20 g). The extraction experiments were performed in duplicate on lyophilized biomass for 1 hour at 25 ºC, with the solvent-to-biomass ratio fixed at 9:1 (in mass). The research aims to maximize the recovery of proteins while reducing carbohydrate extraction, as they may hinder later protein applications. Therefore, two response variables were monitored: the protein recovery yield (PRY) and the protein/carbohydrate partition ratio (PCR). Quantification of proteins and carbohydrates in the extracts was carried out spectrophotometrically using the BCA protein assay and the phenol-sulfuric acid method, respectively. An Analysis of Variance (ANOVA) was performed at a significance level of 0.05 to evaluate the significant factors for each response variable. Subsequently, post hoc pairwise multiple comparisons of means using the Fisher's Least Significant Difference (LSD) test was applied to identify the optimal levels of the factors causing significant differences in the response variables.

RESULTS AND DISCUSSION

The ANOVA of the results showed that the type of solvent and the amount of added water were factors with a significant effect on PRY and PCR (p-values < 0.05). The use of DES increased significantly, and simultaneously, the yield and selectivity of the protein extraction with respect to the values obtained when water was the only extractant. The improvement in PCR was attributed to the increased polarity of the extraction media containing DES. Adding water to the DES-biomass suspension also improved PRY and PCR and facilitated the handling of the samples during the extraction process. The optimum extraction conditions were choline chloride:glycerol (1:2) with 20 g of water, achieving 20.8 of PRY and 1.6 of PCR. Only a few works published to date use DES to extract proteins from microalgae, obtaining similar or lower recoveries even using ultrasonication or ball milling as extraction aids (Cicci et al., 2017). Therefore, despite the low PCR values obtained, our results are promising, and further research is in progress to improve the selectivity and yield of protein extraction using DES.

Abstract
In this work, the efficiency of an industrial magnetite (M1) produced from ferrous wastes to catalyze Fenton reactions in laundry wastewater at pH 6 was investigated. Its reactivity was assessed towards the degradation of two environmental compounds, ciprofloxacin and phenol, under UVC and UVA irradiation, and then compared with that of a synthetic magnetite (SM) and zerovalent iron (ZVI). M1 enhanced ciprofloxacin and phenol degradations under UVC and UVA irradiation respectively. Fe (II)/Fe (III) ratio played a key role while the size and surface area of the particles seemed to be less important. ZVI was found efficient in all cases but its rapid passivation might restrict its application. In addition to being easily magnetically separated, a promoter to photo-Fenton reactions even under circumneutral pH, this "industrial" magnetite made from ferrous wastes can be a promising catalyst in wastewater treatment applications.

Keywords
Ciprofloxacin; industrial magnetite; phenol, photo-Fenton; water treatment

INTRODUCTION

Magnetite is a natural magnetic mineral extensively used as a heterogeneous Fenton catalyst in the Advanced Oxidation Processes (AOPs) [1]. Several studies show that the Fe (II)–Fe (III) mixed valence oxide is a good iron source in the heterogenous Fenton reactions where Fe (II) plays a principal role in their initiation [2]. Its redox properties contribute to its high activity; and its ability to catalyze the oxidative degradation of organic pollutants have attracted the scientific community. Since industrial wastewaters hold a variety of toxic, non-biodegradable organic pollutants, magnetite can be a promising catalyst in Fenton/ photo-Fenton reactions aiming at their removal [3].

Magnetite can be synthesized by many biotic and abiotic pathways in the laboratory; however, to our knowledge, few data exist on the reactivity of magnetites produced from ferrous or steel wastes. Wastes produced from steel industries are abundant in iron oxides; 50 % of the iron is either disposed outside of the companies or accumulated in sedimentation ponds leading to the deterioration of the environment. Hence, recycling and reusing useful parts of the wastes are of pronounced concern [4].

In our experiments, we studied the reactivity of a magnetite produced from steel wastes in the Fenton/ photo-Fenton reactions in laundry wastewater. Laundering processes use large amounts of water; households, hotels, and hospitals pollute water with high COD values [5]. The removal of phenol, a model pollutant, and ciprofloxacin (CIP), a pharmaceutical compound under different conditions (UVC and UVA irradiation) was investigated in the presence of H_2O_2 and magnetite. The reactivity of this magnetite was compared to that of a synthetic magnetite produced in the laboratory via co-precipitation and zerovalent iron (ZVI). Furthermore, TOC of the wastewater was measured before and after the reactions.

MATERIALS AND METHODS

Experiments were conducted on 2 magnetites (M1 and SM) and zerovalent iron (ZVI). M1 was provided by Hymag'in, SM and ZVI were prepared in the lab as explained in detail in previous works [6][7].

Magnetites were characterized by XRD to identify the crystal structures, TEM to obtain information regarding morphology and size of particles, and N_2–BET analysis to determine their specific surface areas. The Fe (II) content in the oxide structure was determined by chemical analysis after acid dissolution with HCl. Ferrous and total iron concentrations were determined using a modified 1,10-phenanthroline method.

In a glass reactor (20 ml), the target compounds (20 µM) and H_2O_2 (25 mM) as well as the magnetites/ ZVI (0.1 g/L) were added to the laundry wastewater (pH ~ 7, TOC= 54 mgC/L, COD= 891 mgO_2/L of the raw wastewater). The pH was adjusted to 6 and irradiation took place under UVA (365 nm, 0.55 mW/cm^2) or UVC (254 nm, 0.87 mW/cm^2) lamps. Samples taken at specific time intervals were analyzed by HPLC-UV to monitor P and CIP degradations. After that, TOC was measured by a TOC analyzer. Solutions of spiked laundry wastewater, magnetite/ ZVI, and H_2O_2 (50 mM) were irradiated under UVA or UVC for 2 days.

Table 1. Some properties of the magnetite samples used in this study.

Magnetites	Specific surface area	Particle size	Fe (II)/Fe(III)
	(m^2/g)	(nm)	-
M1	18,5	100-600	1
SM	89	10-15	0,48

RESULTS AND DISCUSSION

Characterization of magnetites

Magnetite purchased from Hymag'in is called M1 (industrial magnetite) while the lab-synthesized magnetite is called SM (synthesized magnetites). Table 1 shows that they exhibit different specific surface areas and particle sizes. The ratio Fe (II)/Fe (III) was determined and reported in the table as it is a key parameter in heterogeneous Fenton reactions. SM has a high ratio of ~0.5 "stoichiometric magnetite" since it was prepared in a glove box by co-precipitation. However, M1 has a much higher ratio (i.e.1), which is probably due to the presence of elemental metal traces including Fe (0).

Photo-Fenton degradation of ciprofloxacin and phenol

Preliminary experiments showed that the photo-Fenton system with magnetite had an optimal loading of 0.1 g/L, and that 25 mM H_2O_2 was efficient for a complete degradation of 20 µM ciprofloxacin and phenol. Therefore, such conditions were chosen to compare the behavior of different magnetite samples and ZVI.

Photo-Fenton degradation of ciprofloxacin. **Fig.1** reports the time trend of ciprofloxacin degradation in the photo-Fenton system under UVC (left-hand side) and UVA (right-hand side) irradiation at pH ~6 in the presence and absence of magnetites/ZVI.
The left-hand side of the figure shows that almost complete ciprofloxacin degradation was achieved in 2 h in the presence and absence of magnetite. However, ciprofloxacin degradation was faster in the presence of magnetite especially in the first 40 min before the slowing down of the reaction. Although the kinetic behavior was similar, ciprofloxacin degradation after 2 h-irradiation was slightly faster with M1. Experiments with ZVI induced effective degradation.

Experiments under UVA irradiation showed that ~60 % of ciprofloxacin after 4 h was degraded in the presence of M1 and SM while ~80% was observed after 4 h in the presence of ZVI. Unlike experiments under UVC irradiation, the graph shows no difference in CIP degradation in the presence or absence of magnetite. The variation in the degradation profiles may be due to the nature of the laundry wastewater. It contains organic matter (TOC 54 mgC/L), metals, anions, etc.

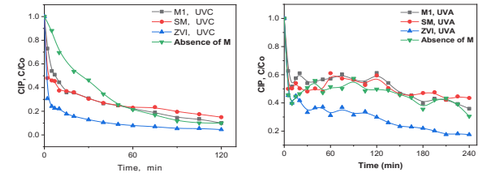

Figure 1 Time trend of ciprofloxacin (initial concentration 20 µM, pH 6 by $HClO_4$) under photo-Fenton conditions (ciprofloxacin + H_2O_2 + magnetite/ ZVI + UVC/UVA) and in the

Photo-Fenton degradation of phenol. **Fig.2** shows that in the presence or absence of magnetites/ ZVI, a high phenol degradation was achieved in less than 2 h. The reaction between phenol and $^{\bullet}OH$ has a high rate constant ≈ 6.6 x 10^9 M/s and the presence of UVC (energetic light) produces a high concentration of radicals that can directly degrade the pollutant. Magnetite had a slight screening effect.

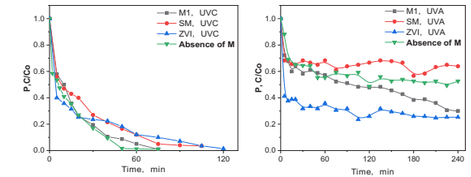

Figure 2 Time trend of phenol (initial concentration 20 µM, pH 6 by HClO4) under photo-Fenton conditions (phenol + H2O2 + magnetite/ ZVI + UVC/UVA) and in the absence of magnetite/ ZVI.

Under UVA, (right-hand side of **Fig.2**), phenol degradation was clearly enhanced in the presence of M1 and ZVI compared to that in the absence of a catalyst. SM, in this case, might have a screening effect. This could be due to the high Fe (II)/ Fe (III) ratio of M1 compared to SM and to the ZVI high reductive capacity. In all cases, a 60-90 % degradation was achieved with a higher removal of phenol under UVC light than under UVA.

TOC measurement. Preliminary experiments with SM (0.1 g/L), ciprofloxacin (20 µM), H_2O_2 (50 mM) under UVC irradiation at pH 6 showed almost complete mineralization in 2 days. The TOC was halved in around 1 day, TOC values decreased from 54 mgC/L to around 20 mgC/L. These experiments can show how the photo-Fenton reaction can progress over time.

The AOPs, specifically photo-Fenton, are effective in removing pollutants from wastewaters. In our experiments, M1 was a good catalyst to the reaction inducing a higher degradation than in the presence of SM or absence of catalyst; especially with ciprofloxacin (under UVC irradiation) and phenol (under UVA irradiation). Although ZVI greatly enhanced the removal of both pollutants, its rapid passivation limits possible applications. Besides being accessible and produced from ferrous/ steel wastes M1showed a promising reactivity to be used for high-scale applications.

Further experiments will focus on the TOC measurement to better understand the evolution of the photo-Fenton reaction with time as well as the metals adsorption before and after the treatment. Fe leaching and H_2O_2 consumption will also be monitored.

Abstract
Elemental white phosphorus is a strategic raw material, while sewage sludge is a P-rich waste material abundantly available in Europe. FlashPhos intends to be the first technology in Europe producing white phosphorus from sewage sludge, with a high energetic efficiency and zero waste production. This paper discusses the process, the planned pilot plant, and the initial lab scale results.

Keywords
Phosphorus recovery; sewage sludge; thermal process; white phosphorus

INTRODUCTION

Elemental white phosphorus is a strategic raw material with high criticality due to its irreplaceability for key industries, for example in the food, pharmaceutical and electronic sector. Currently, the European Union is completely dependent on white phosphorus imports from Kazakhstan, Vietnam and China. Yet, there are enough phosphorus reserves in Europe veiled in sewage sludge to cover the EU's whole demand on white phosphorus plus up to 25% of the phosphate consumed in the EU for other applications.

Sewage sludge, on the other hand, is a waste inevitable in every industrial country. In the EU it is forbidden to landfill sewage sludge due to its high organic content. Thermal treatment is not an alternative for many countries due to high costs, so most of the European sewage sludge is used as fertiliser or soil enhancer. However, regarding soil application, it must not be forgotten that sewage sludge is the sink for all contaminants removed from sewage, including microplastics and pharmaceuticals.

Hence, in several European countries, soil application of sewage sludge is already forbidden or will be stopped in a few years. Also in the EU, there are efforts to reduce this practice, which will require viable solutions in the medium term. The new FlashPhos process can offer a solution to sustainably dispose of sewage sludge and recover phosphorus from it. Accepting mechanically dewatered sludge as it comes from sewage plants, and being attached to industries available all over Europe, FlashPhos will be applicable also in countries still far from fulfilling present or coming EU sludge regulations.

FlashPhos intends to be the first technology in Europe producing white phosphorus for the chemical industry, providing at the same time a solution for the problematic sewage sludge disposal. It is expected that FlashPhos plants will be able to cover 50% of the European P_4-demand by 2040. This will be possible by recycling 15% of the sludge currently generated in Europe.

FlashPhos will significantly contribute to major objectives of the European society:

- **Recover a critical raw material (CRM)**, white phosphorus (P_4). The P_4 produced following FlashPhos' principles will avoid that equivalent P_4 will be produced in other places, consuming natural mined Phosphate Rock, which is a finite world resource. P_4 from FlashPhos will consume less energy and have a higher purity than the P_4 currently available on the market.
- **Reduce the emission of CO_2** by substituting cement clinker – one of the products with the highest CO_2-production worldwide – by alternative cement materials. FlashPhos will be connected to cement plants that will use FlashPhos' fuel gas and waste heat to replace fossil fuels, without disturbing the cement process with phosphorus, which has a negative influence on cement quality. This will increase the cement industry's capability of substituting fossil energy by wastes and still comply with coming phosphorus regulations.
- **Reduction of waste generation** and contributing to reliable long-term-available waste treatment capacities by thermally treating sewage sludge, safely removing the sludge's contaminants from the biosphere.

THE FLASHPHOS PROCESS

The first step of the FlashPhos process is an innovative dryer-grinder, producing fine and dry materials as an input to the Flash reactor.

The second step, the actual "Flash" process, is a high temperature entrained flow (flash) gasification of sewage sludge, and other phosphate-containing waste streams such as meat-and-bone meal. The organic components of the sewage sludge serve as fuel for the gasification, in which they are converted into heat and a combustible gas. This gas and excess heat can be used in cement plants to substitute fossil fuels. The inorganic waste components are melted or evaporated.

The molten inorganic materials are then treated further in a refiner reactor to produce recycled P_4 as the main product. Other output materials of the process are a climate-friendly alternative cement raw material, an iron alloy and a heavy metal concentrate as valuable raw materials for the metal industry. Consequently, practically no solid wastes are produced by the FlashPhos process.

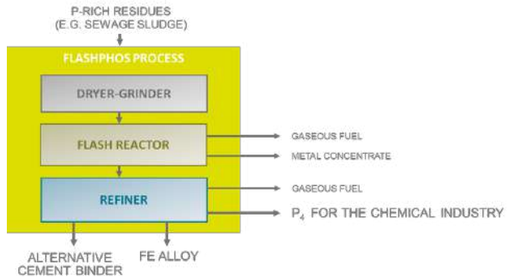

Figure 1. All figures should be embedded correctly positioned within your Word file.

During the four-year innovation action, the industrial FlashPhos process will be demonstrated in a pilot plant with up to 250 kg/h sewage sludge throughput. The first full-scale FlashPhos pilot plant in Europe will be built by 2025 and will provide the basis for industrial scale white phosphorus production. The industrial scale market introduction is expected by 2028.

Currently, the process is in the design and commissioning phase, with extensive support from work packages providing modelling, experimental results, and risk analysis. As part of the experimental work, the thermal behaviour of sewage sludge is investigated on lab scale by InsPyro. These results, discussed in the next paragraph, are important to select process conditions to design the pilot plant and optimize its operations.

EXPERIMENTAL RESULTS

Thermal behaviour

Combustion, melting and reduction of sludge from different sources are studied both theoretically and experimentally in DSC-TGA and lab furnaces. Theoretical values from thermodynamic calculations, such as the expected melting point, gas-metal-slag equilibria and enthalpies corroborate the results. The P-yield is further evaluated in larger scale experiments, in which the behaviour of impurity elements is studied as well. These results are crucial to the quality of the end products: elemental phosphorus, iron alloy and supplementary cementitious material.

In this paper, the focus is on the behaviour of the combusted sludge (ash). The melting behaviour (weight loss and heat of melting) of the ash is shown in Figure 2. Melting is found to occur between 1100 - 1250°C and is accompanied by a small weight loss (possibly loss of oxygen, e.g. Fe_2O_3 to FeO), as well as an endothermic reaction from which the melting enthalpy can be derived.

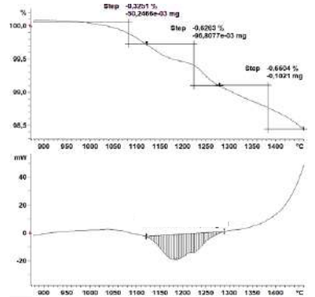

Figure 2: Melting behaviour of ash in an inert atmosphere.

The reduction of the ash is shown in Figure 3. From the curve, it can be observed that the reaction with carbon speeds up around 1300°C. After some 15 min, while reaching 1400°C, limited further reduction is observed. The continued decrease of the sample weight is also due to the minor but continuous loss of carbon to the gas phase. The influence of different temperatures, basicities and carbon particle size is also evaluated but not included in this article.

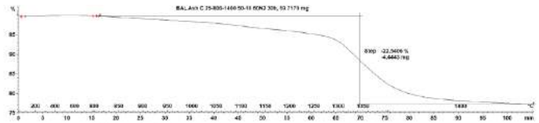

Figure 3: Reduction of ash with carbon in inert N_2 atmosphere.

The results from the DSC-TGA are also compared with thermodynamic calculations conducted in FactSage 8.2. The calculated melting temperature of the combusted slag are in line with those measured in Figure 2. Reduction calculations indicate vapour formation, because of the formation of mainly CO and P_2 gas, of up to 20% of the initial mass, which is in line with the results in Figure 3. These thermal behaviour experiments and calculations determine the optimal operating conditions for the sludge combustion and the refining process. The experiments confirmed recovery of between 50-80% of the phosphorus depending on the sludge origin, which is in line with thermochemical models.

CONCLUSIONS

The FlashPhos process targets the recovery of white phosphorus from sewage sludge, thereby providing a European source of a critical raw material for the chemical industry, and providing a valuable waste-free outlet for sewage sludge. The pilot scale plant will be constructed in the next few years. Initial results at smaller scale define the needed temperatures and confirm the expected recovery yields.

Abstract
Struvite precipitation in wastewater treatment plants could solve the rapid depletion of phosphorus in the world. This process requires a magnesium source and an alkaline reagent, which limit the process economically. This study used a magnesium oxide by-product as the sole reagent to precipitate struvite in a laboratory-scale fluidized-bed reactor. By-product quantity, feed inlet positions and recycle flow rates were studied. The results showed a struvite content higher than 75%. There were two configurations that reached a struvite percentage of 90%, the only different variable being the recirculation flow rate (215.86 and 907.07 mL/min).

Keywords
Fluidized-bed reactor, magnesium oxide by-product, phosphorus, recovery and struvite.

INTRODUCTION

High phosphorus (P) concentrations in Anaerobic Digester (AD) supernatant from wastewater treatment plants (WWTP) (Peng et al., 2018a) could solve the rapid depletion of P rocks and meet 15-20% of global demand (Peng et al., 2018b). P precipitation as struvite has gained interest since it can be used as a slow release fertilizer and simultaneously recovers phosphorus and nitrogen (N). Besides that, controlled precipitation could prevent the auto-precipitation in pipes and elbows of WWTP (Ye et al., 2018). However, this process requires the addition of magnesium (Mg) and alkaline chemicals to increase pH (Ye et al., 2018). The magnesium and other reagents (NaOH) utilized may account for 75% of the overall costs of struvite production (Peng et al., 2018a). For this reason, inexpensive magnesium sources are studied.

This work shows a study of the MAGNYFOS project (RTC2019-007257-5). Where an industrial magnesium oxide by-product (LG-MgO) is used as a Mg source and alkaline reagent for the struvite precipitation in a laboratory-scale fluidized-bed reactor (FBR). LG_MgO has around 56% of MgO and others as $MgCO_3$, $CaMg(CO_3)_2$. Its price is 10 times cheaper than $MgCl_2$ (pure reagent). The use of LG-MgO can reduce reagent costs and revalue an industrial by-product.

MATERIALS AND METHODS

Synthetic supernatant and industrial by-product of magnesium oxides

Synthetic supernatant was prepared using distilled water, dipotassium hydrogen phosphate (K_2HPO_4) and ammonium chloride (NH_4Cl). The concentrations in solution were 80 mg/L of P-PO_4 and 600 mg/L of N-NH_4, respectively. The pH of the solution was not adjusted.
LG-MgO was provided by Magnesitas Navarras, S.A. (Navarra, Spain). This is a by-product from the natural magnesite calcination process. LG-MgO has 56.04% of MgO, 12.04% of $MgCO_3$, 11.59% of $CaCO_3$, 8.55% of $CaMg(CO_3)_2$, 3.75% of $Mg(OH)_2$, 2.24% of $Ca(OH)_2$ and others. The mean diameter was 12 µm.

Experiment set-up

The struvite precipitation was carried out in a laboratory-scale FBR. The glass reactor was designed with two sections of increasing diameter and three sampling points (Figure 1). The working volume was 4,89 L and the hydraulic retention time (HRT) was 2.5 hours. Two peristaltic pumps were used to feed the reactor and control the recycle flow rate.
Twelve experiments were performed to study the most suitable configuration for precipitating struvite. The study variables were molar ratios between P and Mg (magnesium concentration was calculated from LG-MgO composition), feed inlet positions, and recycle flow rates.
The procedure was (i) addition of the LG-MgO into the reactor, (ii) start-up of the feed pump, (iii) start-up of the recycle pump, (iv) stopping both pumps after 5 hours and (v) recovering the solid. The sample interval was 0, 30, 60, 120, 180, 240, and 300 minutes and 4mL of liquid was withdrawn. Initial conditions for each experiment are shown in Table 1.

Analytical methods

The samples were filtered using a 0.45 µm regenerated cellulose syringe filter. Then pH, anions (P-PO_4) and cations (Ca^{2+}, Mg^{2+} and N-NH_4) were measured.
The precipitated solid was dried at 25 ºC. After the solid was characterised by thermogravimetric analysis (TGA), X-ray diffraction (XRD) and particle size distribution (PSD).

RESULTS AND DISCUSSION

Figure 2 shows the P and Mg concentrations in the effluent (reactor outlet stream). The addition of a 1:3.3 molar ratio (P:Mg) succeeded in continuously decreasing the P concentration to values of about 3-4 mg/L. However, high concentrations of Mg were lost to the effluent. The experiments with a 1:1 ratio showed that the P concentration decreased during the first 30 minutes (10.12 mg/L), then remained constant until minute 180, then increased and reached concentrations of 17-19 mg/L. Mg loss decreased over time and concentrations reached of around 31 mg/L. When the molar ratio was 1:0.5, there was a continuous loss of P between 20 and 30 mg/L. Mg was also detected in the effluent, although the amount added was less than the amount necessary for struvite formation.

XRD diffractograms of the 12 experiments showed the presence of struvite, MgO, $MgCO_3$, $CaMg(CO_3)_2$ and $Mg(OH)_2$. Bhuiyan et al. (2008) reported that the decomposition reaction of struvite (Eq. 1) began at around 55 ºC ended around 250 ºC. In this study, the results of the TGA showed that the decomposition temperature range was 60 to 200 ºC. The weight loss percentage of struvite was followed through NH_3 and H_2O (Ray L. et al., 2004). The struvite percentage in each experiment was estimated (Table 2). When the ratio was 1:0.5, a high recycle flow rate favoured the formation of struvite (Ex. 2 and 4), reaching 85%. This may be due to a higher homogeneity of Mg in the reactor. If one wants to work with low recycle flow rates, the feed inlet should be at the bottom of the reactor. The feed comes into direct contact with the LG-MgO particles, since at low recycle flow rates they mostly fluidise in the lower part of the reactor. At a 1:1 molar ratio and bottom feed position, the highest percentage of struvite formation was achieved (91-92%) and the variation of the recycle flow rate had almost no influence. When there was an excess of Mg (1:3.3), the percentage of struvite in the precipitate decreased (ex. 9, 10, 11 and 12), this may be due to the higher amount of undissolved LG-MgO.

$$MgNH_4PO_4 \cdot 6H_2O \rightarrow MgHPO_4 + NH_3 + H_2O \qquad \textbf{Eq. 1}$$

Configurations with low recycle flow rates had larger particle sizes than high flow rate configurations, except for configuration 4 with respect to configuration 3 (Table 2). A higher mixing intensity reduces induction time and particle size (Elduayen-Echave, 2020).

Table 1. Initial conditions of the twelve experiments in the FBR.

Nº	Feed position	P:Mg^{2+}	LG-MgO (g/L)	Recycle flow rate (mL/min)	Feed flow rate (mL/min)
1	Side	1:0.5	0.08	215.86	32.60
2	Side	1:0.5	0.08	907.07	32.60

Abstract
This study evaluated the combined phosphorus, nitrogen, methane, and extracellular polymeric substances (EPS) recovery from aerobic granular sludge wastewater treatment plants. The study showed that 30% of sludge organics are recovered as EPS, and 25-30% can be recovered through integrated alkaline anaerobic digestion (AD) producing ≈260 ml methane/g VS. It also showed that 20% of excess sludge total phosphorus (TP) ends in the EPS, 20-30% in the acidic liquid by-product stream (≈600 mg PO_4-P/L), and 15% in the AD liquid effluent (≈800 mg PO_4-P/L) which can be recovered through an integrated chemical precipitation unit. Ammonium recovery from the alkaline high-temperature liquid stream is attractive but it is not feasible for existing large-scale established technologies because of low concentrations. However, ammonium concentration in AD liquid effluent was calculated to be 2600 mg NH_4-N/L and ≈20% of total nitrogen in sludge, making it feasible for recovery. The methodology used in this study consisted of three main steps. The first step was developing a laboratory protocol mimicking large-scale EPS extraction conditions. The second step was establishing mass balances over EPS extraction on laboratory and demonstration scales within a full-scale AGS WWTP. Finally, the feasibility of resource recovery was evaluated based on concentrations, loads, and integration of existing technologies for resource recovery.

Keywords: Nereda®, mass balances, phosphate, methane, ammonium

INTRODUCTION

A Dutch public-private partnership led to the development of the full-scale aerobic granular sludge technology, also known as "Nereda technology" for wastewater treatment. The study of AGS not only opened a door for a new, more resource-efficient wastewater treatment technology (Pronk et al., 2015) but also created new opportunities for resource recovery, with the recovery of extracellular polymeric substances (EPS) as a successful example. EPS is a polymeric gel material produced by bacteria during cell metabolism that consists of proteins, polysaccharides, DNA, lipids, glycoproteins, and humic substances that form the matrix in which the cells are immobilized as granular particles (Seviour et al., 2019). Recovered EPS from aerobic granular sludge are flexible, practical, versatile, and valuable in agriculture, building, textile, and paper industries (Feng et al., 2019). The Netherlands has the world's first two demonstration-scale installations to extract EPS polymers from Nereda® granules under the product name "Kaumera".

The fate of nutrients through the EPS extraction process is unknown. A careful analysis of the EPS production process is vital to identify the best synergies to combine these elements' recovery within the EPS extraction process. Mass balances can provide insight into how and what to expect from integrated recovery technologies to evaluate these synergies. Mass balances are a robust decision tool to estimate quantities of elements of interest in all relevant streams and recovery potential, make value chains, and evaluate market potential. Concentrations are also crucial in technology selection and its efficiency. This study used mass balances over the EPS extraction in the lab and demonstration scale plant in municipal sewage Epe WWTP to evaluate combined recovery. We aim to set the foundation for future AGS-based resource factories by answering two main research questions. The recovery% potential of combined phosphorus, nitrogen, EPS, and methane from AGS is the first question. To answer that, a modified laboratory protocol for EPS extraction was developed to mimic demonstration-scale conditions, and mass balances were established both on laboratory and demonstration scales in Epe and extrapolated to a full-scale Nereda AGS WWTP. The second question is about the possible existing technologies that can be applied to have a fully integrated AGS WWTP to recover these elements. To address this, concentrations, stream composition, speciation of nutrients, and loads were used to evaluate the feasibility of existing technologies.

MATERIALS AND METHODS

Laboratory EPS extractions were performed using AGS surplus sludge samples collected from Epe AGS WWTP. Extractions were performed based on a newly developed modified protocol adapted from demonstration-scale practices in Epe and Zutphen, The Netherlands.

The resemblance/differences between laboratory extractions and Epe demonstration extraction installations were assessed. Epe WWTP was the first full-scale domestic wastewater treatment plant in the Netherlands to install the innovative Nereda (AGS) sewage treatment technology, and its EPS extraction process installation is the second installation in the Netherlands. Sampling for this mass balance study was performed on a continuous process with a capacity equal to 0.5 m^3 thickened AGS/hour. Mass balances of carbon, phosphorus, and nitrogen were established based on samples analysis and flows, and Epe demonstration-scale mass balances were extrapolated within the context of Epe AGS WWTP. Mass flows were depicted by Sankey diagrams, where flow sizes are proportional to the waste sludge (lab) and wastewater influent (Epe) mass flow expressed in %.

RESULTS AND DISCUSSION

The resemblance between modified lab protocol and demonstration extractions

The total solids, TCOD, total nitrogen, total phosphorus, and dissolved species relevant for nutrient recovery as phosphate, ammonium, calcium, and magnesium ions in the alkaline and acidic liquid streams were compared between the original, modified lab protocol developed in this study and Epe demonstration. Unlike the original laboratory protocol, the new modified laboratory protocol concentrations are comparable and have the same order of magnitude as the demonstration-scale concentrations.

Carbon Recovery

COD balances showed a 30% EPS yield in the lab and Epe demonstration scales. 50-60% of organics end in the alkaline sludge residue by-product stream, and 25-30% of sludge TCOD can be recovered as methane by AD technology. The AD process is proposed to be mesophilic (35°C) and alkaline (pH=9-11), similar to the characteristics of the alkaline sludge residue after solid-liquid separation. Alkaline conditions are used as an effective pretreatment step for better degradability, higher biogas production, and methane-rich biogas. The potential of methane production using the alkaline sludge residue is calculated to be ≈260 ml/g VS. The first proof of principle batch experiments on digestion of this residue under mesophilic alkaline conditions showed that the methane yield was equal to 200-240 ml/g VS, and the substrate recovered as methane was about 40-50% (unpublished results), which is in line with the calculations in this study. The same experiments also showed that methane content was around 98%, with 2% CO_2.

Phosphorus Recovery

According to the established mass balances, phosphorus recovery is realized in two ways during the EPS chemical extraction process.

Phosphorus Recovery in the EPS

EPS-Kaumera from AGS is a potential example of upcycling P-recovery products as it can substitute some P_4 derivatives, i.e., as flame retardant. Kim et al., 2020 reported that EPS-Kaumera acts as a high-performance bio-based flame retardant as it shows self-extinguishing properties attributed to phosphorus present in the EPS.

Ortho-phosphorus recovery from alkaline, acidic, and digestate liquid streams

Around 25%-20% of TP in sludge on the lab scale and 35%-30% of Epe sludge ends in the alkaline, acidic liquid streams, respectively, as orthophosphates. The phosphate concentration is 600 mg PO4-P/L, comparable to concentrations reported for mature technologies of the full-scale phosphate recovery processes for municipal and industrial wastewater (Desmidt et al., 2015). Chemical precipitation by metal addition as magnesium, calcium, and iron is the most common straightforward technology for orthophosphate recovery from liquid streams. The acidic stream has a low pH=2.2, requiring intensive chemical addition for pH adjustment to form commercial P-recovery products such as struvite, calcium phosphates, or vivianite. On the other side, it is a byproduct stream that would not interfere with the Kaumera production as the EPS is already removed, and the organics interference with the final P-recovery product would be minimal compared to the alkaline liquid stream. The acidic stream seems more promising, so current research is ongoing to validate the possibility of phosphorus recovery in the acidic stream. Orthophosphate fraction in the AD effluent was calculated to be 12% (Epe)-15% (lab) of sludge TP with concentrations ≈700-900 mg PO_4-P/L, showing feasible recovery.

Ammonium Recovery

The concept of recovering ammonium from the alkaline liquid stream is attractive since it has high pH and high temperature, which are required for commercial ammonium recovery technologies as air stripping and membrane stripping. Ammonium recovery should not require more energy than ammonium production by the Haber-Bosch process, so it is highly dependent on concentration. Ammonium concentration in the alkaline supernatant at pH=9 is 105 mg NH4-N mg/L which is too low to be energy efficient recovered (Maurer et al., 2006). However, the ammonium fraction in the anaerobic digestion effluent was calculated to be 17% (Epe) and 25%(lab) of TN in sludge with a concentration of around 2600 mg NH4-N/L, which would make it feasible for nitrogen recovery.

CONCLUSIONS

The modified laboratory protocol developed in this study is an excellent base to predict demonstration /large-scale practice. It can be used for futural experimental work focused on nutrient recovery or to test the effect of different extraction conditions and predict the consequences on a large scale. Mass balances allowed for the quantification of recoverable products, and concentrations allowed for evaluating the technology selection. It was shown that combined EPS, methane, phosphorus, and nitrogen recovery is promising in AGS WWTPs by integrating anerobic digestor, P-chemical precipitation unit and air/membrane stripping for ammonium recovery.

Abstract
The sanitation problem in the small population centers in the Consorci Besòs Tordera (CBT) presents various problems due to the diversity of parameters that govern these systems: the changing orography throughout the basins, the isolation in the headwaters in mountainous relief, among other issues. A set of methods are used that can give us answers to the difficulties presented. Decision support systems (DSS) that produce synergy between the experience of experts and varied information such as that of a database, in silico systems to work this information efficiently.

KEYWORDS
CBT, DSS, environmental management, small population centers, wastewater.

INTRODUCTION

Our priority is the CBT and to analyze the sanitation problem of its small population centers. For this, it is important to identify these nuclei in their varied orography, especially in the mountainous area where the headwaters of the basins are located (ecologically sensitive areas). These nuclei are normally isolated and dispersed, these particularities are what delimit the action of any type of sanitation, which constitutes a challenge to adapt to the relief and isolation. On the other hand, there are other characteristics such as the seasonality of the population, that presents an increase in the number of inhabitants throughout the year (weekends, summer, winter holidays, etc.) which considerably alter the characteristics of the discharges; such as in restaurants and hotels.
This environmental problem has led to the application of a set of tools that, under the heading DSS propose an improvement to decision-making.
It should be added that wastewater treatment will be Nature-based solution systems (NBS) innovating in wastewater treatment in small population centers.

THEORETICAL BACKGROUND

In the 1980s, and due to the complex problem posed by an environmental system with biological variables, DSS were perceived as a tool that offered a large degree of freedom, since it took it to a higher level than where computer models were at that time. At that time, since they did not integrate qualitative knowledge, they presented limitations when dealing with knowledge referred to in situ practice. Today, all the models are integrated, mathematical, statistical, and emerging technologies, as well as artificial intelligence applied to the DSS. In all his context, we are designing a customized DSS for the small nuclei in the CBT through the search for NBS, which are designed systems that imitate and use natural environments with a minimum dependence on mechanical elements, to carry out the water sanitation process.

OBJECTIVES

-Design a decision support system for wastewater treatment in small seasonal population centers in the Consorci Besòs-Tordera.
-Exclusively use the NBS for the treatment of wastewater treatment systems.

METHOD

The database of the CRAI (Learning and Research Resource Center) of the University of Barcelona is used as the main tool to identify relevant publications, while academic search engines are used to complete the search for possible non-inventoried works. In addition, the data from the Catalan Water Agency (ACA) website is used to have an updated base of the CBT nuclei.

DISCUSSION

After the characterization, it is necessary to find out what is done with the tributary: do we pour it into the river? (In one place or in several), do we pour them on the ground? What kind of soils do we have? Agricultural soils or riverside soils? We will also consider a recharging of aquifers and for this it is necessary to know the type of soils and subsoils that exist, ideally gravel, or think about infiltration-percolation systems. In an ideal scenario, it is necessary to look for floodplains that are close to the treatment plants. The problem arises when it arises in the headwaters of the rivers where there is not plain. On the other hand, by eliminating the effluent we have positive and negative impacts that need to be quantified. Among the positives, we have the Ecosystem Services that provide less erosion capacity, bring more clean flow to the river, recover the riverside forest, floodplain and maintenance or formation of lateral wetlands.
In relation to economic considerations, it is necessary to ask about the type of treatment plant. If an aeration system is developed, it could be economically unaffordable because there are few inhabitants. Therefore, we must consider NBS or others. It is necessary to consider parameters such as the price of the analysis and confirm if the reuse or controlled application to the medium is feasible. With this, the SAD is built, which will take into account the main thing that is debugging, as well as all these secondary parameters.

Finally, it is necessary to carry out a scientific diffusion, such as, for example, through nearby schools where the SAD is explained and the motivations for their choice and its benefits are expressed. The general population must be provided with training, information, and communication, also considering the cost that this has.

In summary, with the design and evolution of the SAD, it is concluded that it must go beyond the choice of wastewater treatment technology, and that, in addition, it will have a favorable environmental effect that contributes to the development of more resilient.

Assessment of the role of the solubilization time in the P-recovery process in the Murcia-Este WWTP

The adaptation of already existing wastewater treatment plants (WWTP) aiming phosphorus (P) recovery from sewage is an essential strategy considering its limited mineral reserves and its key role in the food supply chain. The already full-scale implemented recovery systems are mainly focused on the recovery after anaerobic digestion. However, they are limited due to the uncontrolled precipitation of P in the digesters. In the Murcia-Este WWTP (Spain) this limitation was overcome by implementing a two-step process in the sludge line to promote the solubilization of the polyphosphate (poly-P) stored in the sludge and the obtention of liquid stream enriched in orthophosphate (PO_4) after elutriation in the gravity thickening together with the primary sludge. After six months of operation under stable conditions, with 47.8% of average enhanced biological phosphorus removal, the 18.8 ± 6.9 % of the WWTP influent P load was extracted through the recovery stream with a PO_4-P concentration of 41,1 ± 8.8 mg L^{-1}. The sludge retention time (SRT) during the solubilization stage was pointed as a hot spot of the process as longer SRT promoted the fermentation and the poly-P solubilization but also reported a decrease in the settling rate in the gravity thickening.
This affection to the settleability after mixing both sludges in the gravity thickening was found to play a key role in the successful operation of this WWTP.

Keywords: Elutriation, Fermentation, Full-scale, Phosphorus recovery, Settleability

INTRODUCTION

The upgrade of already existing WWTPs with the arising technologies plays a key role in the mitigation of the worst effects of the current scenario of climate change and resources depletion (Robles et al., 2020). Regarding to P, it is an essential raw material for the food supply chain and is expected to deplete in the next decades and because of this was included in the last List of Critical Raw Materials. This situation has driven to a broad agreement among the different stakeholders about the relevance of its recovery from wastewater as a promising strategy to improve its sustainability.
Most of the full-scale implemented technologies are focused on the recovery from the centrifuge centrate after the anaerobic digestion, however, the efficiency of these technologies is limited by the uncontrolled precipitation in the digestersAiming the recovery before anaerobic digestion is considered as an option to increase the efficiency whilst mitigating the uncontrolled precipitation issue (Roldán et al., 2020)..
The sludge line of the Murcia-Este WWTP (Spain) was modified to promote the obtention of a PO_4-enriched liquid stream before anaerobic digestion for its subsequent recovery. This work resumes the main operation results and the influence of the SRT during the solubilization in the global process performance.

MATERIALS AND METHODS

The new sludge line of the Murcia-Este WWTP was implemented to enable the bio-sludge distribution between the original and the new sludge management handlings. During the 6 months period of operation under stable conditions a flow-rate of 100,000 m^3 d^{-1} was treated with a low EBPR efficiency of 47.8 ± 20.6 %. The PO_4 extraction was carried out in a two steps process: 1) bio-sludge storage in the 'Elutriation Tank' under anaerobic conditions to promote the poly-P solubilization after volatile fatty acids uptake (VFA) and 2) elutriation of the resulting and the primary sludges over gravity thickeners to obtain the PO_4-enriched liquid overflow. The whole sludge line was controlled with a new fuzzy-logic control system whose core relied on controlling the sludge blanket level in the gravity thickening by wasting and controlling the bio-sludge distribution between the current and the previous configurations before anaerobic digestion (see Figure 1).
In lab-scale tests, the effect of the duration of the poly-P solubilization in the VFA production, the PO_4 concentration in the bio-sludge and the settleability in the gravity thickening were studied in order to understand the affection of this parameter to the proper WWTP operation.

RESULTS AND DISCUSSION

Figure 2 shows the ability, during a representative 24 h period under stable conditions, of the fuzzy logic based-control system to keep the sludge blanket level in the gravity thickening near to the setpoint by wasting from the bottom of the thickener and opening the control valve to reduce the bio-sludge flow entering into the elutriation tank at excessive blanket levels. After operating the new sludge line for 6 months, the PO_4-P concentration in the overflow increased from 6.7 ± 0.7 mg L^{-1}, (represents the 3.0 ± 0.5 % of the influent P load operating the original configuration), to 41.1 ± 8.8 mg L^{-1} (represents the 18.8 ± 6.9 % of the influent P load). This concentration occasionally increased up to 60 mgP L^{-1}.
In lab-scale tests was observed the VFA accumulation in the elutration tank (Figure 3), whose concentration increased up to 410.1 ± 94.2 mg L^{-1} after 22-24 h. This fermentation promoted the poly-P solubilization and the increase of the PO_4-P concentration in the bio-sludge stream (see Figure 4) from 88.0 ± 49.2 mg L^{-1} to 277.0 ± 59.8 mg L^{-1} in this period.
A negative effect was observed in the settleability when increasing the solubilization HRT, which led to a higher fermentation but also to slower settling rates. Despite the lack of differences between 12 and 24 h of solubilization, a significantly slower settling rate was observed at 40 h of solubilization (see Figure 5).

Abstract
FORWARD-FACTORY project aims at transforming urban wastewater treatment (WWTP) into a resource recovery factory (RRF) to foster and reinforce the resource revolution thanks to forward osmosis (FO) combined with advanced biological processes. Seawater (SW) is used as draw solution to make use of osmotic driving force for water extraction and nutrients concentration. Then diluted SW is passed through reverse osmosis process allowing for combining desalination and water reuse at lower energy costs. Our recent works studied various aspects of the proposed concept. It was demonstrated that FO could improve anaerobic digestion efficiency (with granular biomass), could be used for microalgae concentration with limited fouling propensity and allow for retrofitting of existing desalination plant allowing production of pure water at lower than 1kWh.m^{-3}.

Keywords
Forward osmosis; nutrients recovery; microalgae treatment; water reuse; desalination

INTRODUCTION

The conventional urban wastewater treatment WWTP apply activated sludge systems which are energy intensive and current approach is limited to the removal of valuable nutrients from the water stream, not optimizing their recovery. FORWARD-FACTORY project aims at transforming WWTP into a resource recovery factory (RRF) to foster and reinforce the resource revolution. FORWARD FACTORY proposes (1) to move from WW discharge to water recovery and reuse, (2) to promote to organic matter value recovery processes (to produce biogas, valuable organic compounds and/or fertilizers) and (3) to move towards nutrients recovery (especially N and P). One limitation for RRF concept is the low concentration of organic matter, nitrogen and phosphorus and the high inflow rate to be treated which negatively impact the efficiency of resource recovery bioprocesses (fermentation, anaerobic digestion, microalgae production). Thus, a pre and post-concentration step are required. Forward osmosis (FO), an innovative membrane technology, features unique properties by combining high rejection rate, low fouling propensity and driven by salinity gradient energy. Seawater is used as extracting solution for the FO steps allowing also to dilute the seawater stream and therefore the energy costs for downstream desalination. As such, the forward factory concept also allows for integration of water reuse and desalination (Figure 1).

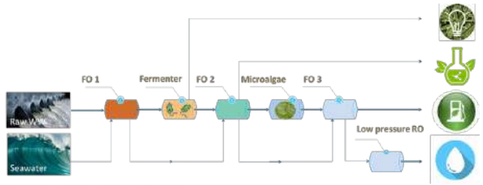

Figure 1: FORWARD-FACTORY concept.

MATERIALS AND METHODS

To validate this concept, our recent work focused on the integration and evaluation of FO with biological processes such as granular anaerobic bioreactor (G-AnMBR) and microalgae photobioreactor. Also, a design study was performed to evaluate the potential of FO to dilute seawater and decrease desalination energy costs below 1kWh.m^{-3} so to assure safe water production at affordable costs. Granular anaerobic membrane bioreactor (G-AnMBR): Forward osmosis membrane were integrated to a G-AnMBR. Kubota microfiltration modules were step by step replaced by FO Submerged FO plate and frame modules. Microalgae cultivation and concentration: Chlorella vulgaris was grown in a BG11 media under controlled illumination and CO_2 injection. Then, 8L batches of microalgae suspension were concentrated 4 times through submerged FO and MF membrane to evaluate fouling propensity and impact of aeration. Retrofitting of RO desalination plant: LewaPlus (Lanxess) water treatment design package was used for simulation work. As a reference, a baseline desalination plant (with 35 g/l feed salinity) was modelled to a capacity of 1,800 m3/h of permeate production. The same plant design was simulated with varying salinity (5, 10, 20 g/l) in the feed to evaluate the impact of required energy for water production, water quality and potential increase in water production.

RESULTS AND DISCUSSION

G-AnMBR: FO membranes proved to be less prone to fouling and increased COD degradation was observed when operating with FO (above 90%). However, increasing FO membrane share in the reactor, led to salinity increase and to enhanced fouling propensity probably due to salinity shock on the active biomass, releasing extra polymeric substance in the mixed liquor.

Microalgae concentration: Both MF and FO submerged membrane led to a complete rejection of chlorella vulgaris. Under aeration, negligible fouling was observed for both membranes leading to a microalgae recovery above 90%. Fouling layer removal proved to be easily reversible in FO thanks to osmotic backwash allowing for almost full recovery of microalgae biomass.

The simulation results from LewaPlus states that, thanks to FO predilution of SW (down to 5g/L), an existing desalination plant could be retrofitted allowing for decrease of energy consumption by 65.5% (below 1kwh/m^3) and leading to potential competitive advantages like significant reduction of the Total Dissolved Salt content (TDS) and Boron in the permeate stream.

CONCLUSION

Tests with G-AnMBR and microalgae demonstrated the capacity to concentrate WWTP streams and optimise biological reactor efficiency. However, salinity increase remains a limiting factor that should be considered for optimised biological reactor and efficient resource recovery. Using SW as extracting solution in FO before RO desalination demonstrated several advantages both in terms of energy savings and produced water quality and the potential for FO-RO hybrid to combine water reuse and desalination.

Abstract

New technologies you be implemented to the concentration of volatile fatty acids (VFAs) produced from organic waste. This fact is related to the current commercial processes presented several drawbacks, such as (i) several ions compete with the VFAs to be adsorbed onto the matrix, reducing the effectiveness of the adsorption and (ii) high energy requirements for heating to achieve VFAs separation by distillation and evaporation. To solve these problems, membrane technologies appear as a important player, due to low energy demand, specific separation and easy scalability. To develop a concentration process based on membranes, VEnvirotech Biotechnology and Lequia joint efforts to develop and implement an innovative technology for VFAs concentration. Preliminary results show that VFAs concentration by membrane is technically feasible and nanofiltration, reverse osmosis and forward osmosis processes have the capacity to concentrate a solution of volatile fatty acids. The effects of different operational conditions are under study.

Keywords (maximum 6 in alphabetical order)
Concentration; forward osmosis; membrane; purification; volatile fatty acids; reverse osmosis

INTRODUCTION

Nowadays, volatile fatty acids production from organic waste is attracting great interest as a sustainable approach for implementation of circular economy. VFA are a subgroup of fatty acids, ranging from 2 to 5 carbon atoms, including acetic, propionic, isobutyric, butyric, isovaleric and valeric acids. Its current main applications are related to building blocks in several industries, such as pharmaceutical, food and chemical[1]. In recent years, VFAs have become important players in the production of bioplactics, such as polyhydroxyalkanoates (PHA). Thus, it is expected that the market will increase. The current commercial production of VFAs is based on chemical synthesis from petroleum-based compounds. Thus, economic and environmental issues are related to this production pathway. To move forward a circular economy approach, new technologies should be considered to apply organic waste.

VEnvirotech Biotechnology is a Spanish company devoted to the sustainable transformation of organic waste into bioplactics and it's developing a revolutionary (bio)technology to produce bioplastics using VFAs as building block. The current technology under development needs high concentrations of VFAs to achieve feasible technical, environmental and economic benefits.

On a commercial scale, the current concentration technologies for VFAs are adsorption, distillation and evaporation. However, these processes presented several drawbacks, such as (i) several ions compete with the VFAs to be adsorbed onto the matrix, reducing the effectiveness of the adsorption process and (ii) high energy requirements for heating to achieve VFAs separation by distillation and evaporation processes.

Due to the detected limitation of the current technologies, new processes should be studied and developed for VFA concentration. The mentioned drawback can be solved by the implementation of membranes, including electrodialysis (ED), microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), reverse osmosis (RO) and forward osmosis (FO)[2]. Membrane technology allows the use of different kinds of effluent to be treated, lower energy demand in comparison to current concentration technologies, specific separation and easy scalability[2].

Currently at full-scale, membrane processes are key elements for water reuse and desalination. RO is a consolidated technology for seawater desalination. Another developed membrane technologies are NF and UF and they have been applied in different fields such as chemical compounds recovery, water treatment, WW reclamation, juice concentration, dairy industry or medical usage. Other membrane processes is forward osmosis (FO), it is a novel technology in comparison to the other processes and it had gained interest in the last two decades.

Nowadays the implementation of membranes, such as RO and NF, are mainly related to desalination and water reused. However, for VFA concentration the investigation is limited. Thus, research should be applied to evaluate membrane technology as a potential key player in the concentration field. Thus, researchers and engineers from VEnvirotech Biotechnology and Lequia are working together for the implementation of a novel process based on membrane to achieve concentration of VFAs from biotransformed waste. The joint efforts from both entities have been achieved in the implementation of the ConcentrA project, to study, develop and scale-up a membrane-based technology for VFAs concentration. To achieve this goal, different membranes and operational parameters will be evaluated.

MATERIALS AND METHODS

The study has two main tasks. The first one will be performed at bench-scale in Lequia facilities, where different membranes at laboratory scale (0.01 m^2 of filtration area) will be tested. A flat-sheet membrane cell testing equipment will be used to assess the permeability and the rejection of the membranes. In this way, different kinds of membranes can be characterized to evaluate their potential implementation and to identify properly their concentration capacities. At the same time, operational conditions for each membrane will be determined with synthetic and real effluents. The focus will be on the flux, pressure, conductivity, temperature, pH and water concentration factor. Thus, design parameters can be obtained. Besides, knowing the capacity of the membranes, a concentration train can be defined and proposed for scale-up.

The second task of the project is the scale up of the membrane technology for VFA concentration. The proposed technology will use commercial membrane modules (2-3 m^2 of filtration area) and will be tested on a real environment at VEnvirotech facilities.

RESULTS AND DISCUSSION

The ConcentrA project is ongoing, and the first task is under development. Preliminary results show that VFAs concentration by membrane is technically feasible and nanofiltration, reverse osmosis and forward osmosis processes have the capacity to concentrate several times a solution of volatile fatty acids. The effects of different operational conditions are under study.

ACKNOWLEDGMENTS

ConcentrA project is funded by the catalan agency for business competitiveness (ACCIÓ) through the NUCLIS call.

Abstract

Gel-forming extracellular polymeric substances (EPS) were extracted from aerobic granular sludge, then fractionated according to their net surface charge using preparative anionic exchange chromatography. The fractions eluted by increased NaCl concentrations were collected and their gel formation capacity was analyzed using a gelling factor (GF) obtained through a miniaturized screening test based on the level of the molecular interactions and the volume of gel formed after calcium-induced gelation. Initial EPS solution extracted from granules exhibited interesting gelling capacity, approximately half of that of alginate (GF of 0.2 ± 0.02 and 0.45 ± 0.06 respectively). The GF correlated with the polymer's charge: a GF of 0,04 ± 0.03 was measured for the first eluted molecules (with NaCl 0,25M) and a GF of 0,26 ± 0.1 for the lastly eluted molecules (with NaCl 0,75M). The size distribution of the molecules participating in the gelation was analyzed by Size Exclusion Chromatography allowing the determination of the % of reactivity corresponding to the area that disappeared from the chromatograms. High molecular weights were implied in the gelation whatever the charge of the polymers was (between 65% and 100% of reactivity). Concerning low molecular weights their participation was limited (<40%). Therefore, the obtained results show that both charge and molecular size are important factors for gelation. With the goal of selecting gel-forming EPS, these results underline the necessity to modulate the extraction and purification methods towards the selection of molecules having the appropriate negative charge and also towards the preservation of their molecular weight during the extraction steps.

Aerobic granular sludge; calcium-induced hydrogels; gel-forming EPS; molecular weight; resource recovery; surface net charge

INTRODUCTION

Polymers with gelling properties, in presence of divalent cations, can be extracted from aerobic granular sludge which are emergent promising biofilms that are used in wastewater treatment [1]. These polymers called gel-forming Extracellular Polymeric Substances (EPS) are interesting because they are from renewable sources and fall within the circular economy concept. Using alkaline and heating treatments, gel-forming EPS can be recovered from granules as a mix of biopolymers (proteins and polysaccharides are the major ones) with yields representing 23% of the total organic matter. Therefore, wastewater treatment plants using aerobic granular sludge technology treating domestic wastewater (COD ≈ 600 mg/L), with a flow rate of approximately 3.0 m^3/s, could produce approximately 1 ton/day of gel-forming EPS [2]. Bio-hydrogels are valuable materials with diversified mechanical properties and their characteristics are influenced by the molecular properties of the involved biopolymers. In the case of alginates from seaweed, a higher molecular weight was shown to improve gel formation kinetics and to increase fluid hydrogels viscosities [3]. It was also observed that the charge of molecules influences their gelling capacity[4]. However, there is a lack of knowledge concerning molecular weight and/or net surface charge involvement in the gelling process of the very complex EPS fraction extracted from aerobic granules. The implication of these two factors in the gelation will be addressed in this study.

MATERIALS AND METHODS

Biomaterial and gel-forming EPS extraction

Aerobic granular sludge was recovered from sequencing batch reactors fed with synthetic wastewater (equal COD fractions of acetate and propionate) [5]. After freeze-drying, aerobic granules were solubilized at 80°C in Na_2CO_3 0.2 M and gel-forming EPS were precipitated by reducing the pH to 2 [6].

Preparative Liquid Chromatography

EPS fractionation according to their net surface charge was performed using a Resource™ Q column grafted with a quaternary ammonium ligand. Equilibration was done by using Tris HCl 50 mM pH=12±0.02, and elution was performed by the sequential addition of NaCl 1 M. Absorbance was monitored at 280 nm and peak areas (mAU×mL) were processed using the UNICORN 5.31 software. The fractions were collected, dialyzed against distilled water and then freeze-dried for further analysis. Fractions from the Resource Q column were prepared at 0.5% (w/v) volatile solids (VS), incubated without or with 0.1 M calcium for one hour. Then the supernatant was collected after a 15 min centrifugation at 14 000 g for further analysis by SEC using a Superdex 200 column as described in [6]. The MW reactivity (%) for each MW group was calculated using the formula 1.1:

$$MW\ reactivity\ (\%) = \frac{(total\ area\ without\ calcium - total\ area\ with\ calcium)*100}{total\ area\ without\ calcium} \quad (1.1)$$

Test for evaluation of gelling capacity

Dialyzed solutions at a final concentration of 1 % (w/v) VS were incubated for 1h with 0.1 M calcium chloride then centrifuged at 14 0000g for 15 min. The volume of the supernatant was measured and therefore the gel volume (Vg) for samples with calcium was deduced allowing to calculate a gel volume percentage (%Vg). UV-vis spectra between 220 and 500 nm were measured to determine a reactivity (%R) corresponding to the percentage of area that disappeared from the spectra after addition of calcium. Both factors were combined to obtain a gelling factor (GF), as seen in equation 1.2, that help in comparing solutions capacities to form hydrogels.

GF = % Vg * %R (1.2)

This method allows the detection of gelation using only 2 mg of the sample to be tested and could be very beneficial in lab scale experiments where this material availability is limited.

RESULTS AND DISCUSSION

What are the effects of the net negative surface charge on the gelling capacity?

As shown in figure 1, the fractionation of gel-forming EPS through a sequential elution strategy (NaCl steps with increasing concentrations from 0 to 1 M) allowed to clearly separate groups of molecules with different negative surface charges. It can be noticed that the majority (91.5 ± 5 %) of the molecules present within the EPS solution are negatively charged (figure 1) similarly to other studies [7].

The collected fractions were analyzed for their gelling capacity using a miniaturized method based on the analysis of the soluble molecules remaining in the supernatant after addition of 0,1 M calcium. As shown in Table 1, the initial EPS solution extracted from granules by sequential alkaline and acidic treatment exhibited interesting gelling capacity, corresponding approximately half of that of alginate (GF of 0.2 ± 0.02 and 0.45 ± 0.06 respectively). In order to select biopolymers with interesting gelling capacities the fractions eluted from the anionic exchange column were screened for their gelation capacity after calibration at 1% VS. As shown in Table 1, the unbound Cat/N exhibited the highest GF at 0.37 ± 0.03 due to a good %R to calcium and a high %Vg. Further analysis showed that in fact Cat/N fraction has a global neutral charge (data not shown) and this neutral charge is due to the formation of strong associations between positively and negatively charged polymers, these anionic polymers being able to react with calcium and form hydrogels. Concerning the negatively charged polymers, the GF increased with charge from 0.04 ± 0.03 for LAC to 0.26 ± 0.1 for HAC. However, upon reaching a very high negative charge (i.e., VHAC) the gelling capacity decreased abruptly reaching 0.02 ± 0.0005. Indeed, the presence of a lot of negatively charged polymers could hinder the hydrogel formation capacity due to an increased repulsion of polymers as described for carrageenan hydrogels [8,9].

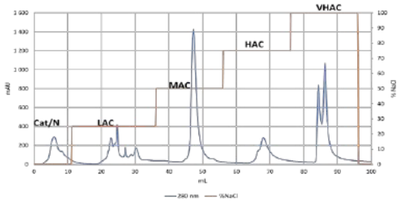

Figure 1. Anionic Exchange Chromatography of gel-forming EPS extracted from aerobic granules and eluted with gradual NaCl concentrations. Cat/N=cationic/neutral molecules, LAC= low anionic charge molecules, MAC= medium anionic charge molecules, HAC= high anionic charge molecules and VHAC= very high anionic charge molecules.

Table 1. The gel volume (%Vg), reactivity (%R) and gelation capacity (GF) of the different samples. The results were obtained through three gelation replicates.

sample	%Vg	%R	GF
Alginate	54.2 ± 5.2	83.3 ± 2.5	0.45 ± 0.06
Unfractionated EPS	30 ± 2.5	65.4 ± 1	0.2 ± 0.02
Cat/N	41.7 ± 1.4	87.90 ± 4.6	0.37 ± 0.03
LAC	12.33 ± 4.5	32.08 ± 10.1	0.04 ± 0.03
MAC	19.83 ± 0.3	54.73 ± 1.9	0.11 ± 0.00
HAC	34.67 ± 10.7	74.38 ± 6.6	0.26 ± 0.10
VHAC	2.50 ± 0.0	97.62 ± 2.1	0.02 ± 0.00

Which molecular weight groups are the ones responsible for the gelation?

No matter what the net negative surface charge is, the HMW group always participates in the gelation with a % of reactivity going from 65% for the MAC fraction to values as high as 100% for the LAC fraction (figure 2). On the contrary, participation of MMW molecules to the hydrogel formation is dependent on the net negative surface charge. Indeed, for the LAC and MAC, the % of reactivity is below 25% while for the fractions with high negative charge (HAC and VHAC), the participation of MMW is above 95%. Surprisingly the Cat/N fraction has a % of reactivity for MMW at 87%. When it comes to LMW molecules, their participation is always limited, reaching 27%, 14% and 11% respectively for Cat/N, LAC and MAC and around 40% for HAC and VHAC.

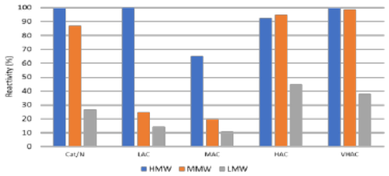

Figure 2. The % of reactivity for Molecular weight groups showing their respective participation in the gelation.

CONCLUSION

The miniaturized screening method is capable of comparing gelling capacities of different solutions obtained either by different processes/extraction protocols/fractions of EPS... Fractions of gel-forming EPS from aerobic granular sludge obtained through anionic exchange chromatography showed that both the charge and size of the polymers are essential factors for the gelation of EPS. Different gelling capacities were nevertheless measured for polymers exhibiting more or less important anionic charges indicating that a process based on anionic exchange is relevant for further purification of these valuable biopolymers.

Abstract
Globally, a large amount of solid waste is produced, including sludge generated in wastewater treatment plants (WWTP). Due to the high production of sludge, different strategies have been proposed to enhance its reuse, preferably with low-cost strategies friendly to the environment. For this reason, constructed wetlands (CWs) have been proposed as a solution indeed, in such systems, sludge can be treated to obtain a dry, mineralized by-product (biosolid) that can be reused. Two CW facilities were studied by measuring biological and physicochemical parameters to check the stabilization and hygienization of these biosolids. Dry biosolids content of 50% total solids (TS) was obtained, with a decrease in organic matter between 38% and 49% volatile solids (VS); a decrease in pathogenic microorganisms, and a high content of essential nutrients for plant growth respect to the influent. According to these properties, biosolids could be reused in agriculture as a possible organic fertilizer, potentially increasing crop yield and replacing commercial fertilizers.

Keywords
Agriculture, constructed wetlands, sludge, sludge drying beds, wheat

INTRODUCTION

The global population has led to an increase in solid waste production from industrial, residential, and public sources. Every year, 4 billion tons of waste are generated, and municipal waste accounts for 1,6 to 2 billion tons. Wastewater treatment facilities produce sludge, which is a type of solid waste containing organic and inorganic materials. The amount of sludge produced depends on the parameters of the effluent and the type of treatment used, typically ranging from 60-80 g TS/person/day when using standard activated sludge processes (Andreoli, et al., 2007). Stabilized sludge (also known as biosolid) typically has between 50-70% organic matter, 3-4% nitrogen, 1-3% phosphorous, and trace levels of heavy metals like Cr, Zn, Pb, Ni, and Cd. Sludge management strategies should focus on both pollutant removal and biosolids reuse to reduce potential health and environmental risks and make the material harmless and more reusable.

Developed and developing countries are searching for ways to manage sludge produced in WWTP. Solutions such as thermal processing, composting, disposal, and agricultural use are being explored. Agricultural use is gaining more attention since sludges contain components that can act as soil conditioners or fertilizers, providing an alternative to commercial fertilizers and adding value to wastewater treatment by-products. However, the sludge must be treated before to be reused. For these reasons, constructed wetlands (CWs) are gaining more attention as a solution due to their ability to treat sludge in a sustainable, low-energy, and low-maintenance manner and obtain a by-product suitable to be reused in agriculture. The aim of this study was to evaluate the capacity of CWs to generate stabilized biosolids after different periods of rest (without feeding) and to test their compliance with the requirements established by European legislation for agricultural reuse (European Commission 2000). Moreover, agronomic essays were carried out in agronomic crops (i.e. wheat) to test biosolids properties as organic fertilizer.

MATERIALS AND METHODS

The facilities studied in this work are located in the WWTP Sentfore-La Guixa (1000 PE) and the WWTP Santa Eulàlia de Riuprimer, (2000 PE), both located in Vic (Barcelona, Spain). **Sampling methods and sludge characterization**

Three sampling campaigns have been carried out during 6 months starting one week after the CWs received the last feeding (June 2022). Samplings were carried out in June 2022, September 2022, and December 2022. In order to obtain a composite sample of the sludge, in each facility one representative bed was selected and divided into 4 sections, 1 sample was collected in each section and then carefully mixed. Samples were analysed in triplicate using standard techniques in accordance with the Standard Methods (APHAAWWA-WPCF, 2001). The following parameters were analysed: pH, Electrical Conductivity (EC), Total and Volatile Solids (TS and VS), Chemical Oxygen Demand (COD), Total Kjehldahl Nitrogen (TKN), nutrients, heavy metals, faecal bacteria indicators (*Salmonella spp*, *E. coli*, faecal coliform and nematode eggs).

Experimental design of the agronomic essay

The agronomic essay was carried out at the Tona WWTP located in the Osona region of Barcelona province. Three fertilizer treatment were considered: biosolids from CW applied directly to the soil (T1), biosolids from CW after crushing (T2) and commercial inorganic fertilizer (T3). The doses of sludge and commercial fertilizer were calculated with respect to the nutritional needs of the crop and the concentrations of total nitrogen in biosolids and fertilizer. For biosolids, 2 $t \cdot ha^{-1}$ of T1 and 3 $t \cdot ha^{-1}$ of T1 and T2 were applied in the agronomic assay. Each treatment was carried out in triplicate in smallholdings of 3x8 m^2 (figure 1). All fertilizers were homogeneously mixed with the soil at the beginning of the experiment, then 200 Kg ha^{-1} of wheat seeds (KWS ultim) were planted in each smallholding. During the testing period (6 months), samples of the plants and soil were taken to measure the different parameters stablished by the directive AAA/1072/2013 (MAGRAMA 2013).

RESULTS AND DISCUSSION

The physicochemical characterization of the sludges from CW during three sampling campaigns is shown in table 2. The pH and EC values were similar to those previously reported for biosolids quality (Stehouwer et al. 2022). The sludge after 6 months without feeding has reduced its moisture from 33%TS to 50%TS in the system of La Guixa and 35%TS to 50%TS in St. Eulàlia. The organic content of the biosolids in all basins studied was quite uniform (40-49%SV) and in accordance with previous studies (Uggetti et al., 2009). Biosolids contain a large amount of nutrients (4,6% TKN/TS for La Guixa and 5,7%TKN/TS for St. Eulàlia).

Finally, the concentration of the heavy metals was evaluated to verify their potential in agricultural application (table 3). In all basins there was a small accumulation of metals, such as Cu, As, and Mn in the three basins; and Zn and Cr in the St. Eulàlia basin. However, despite the slight accumulation of these metals, concentrations do not exceed the thresholds established in the European Directive (European Commission 2000). Lastly, indicators of faecal contamination were analysed, in particular to evaluate the quality of the final product for its application in agriculture. According to the results, *Salmonella spp* was not detected in any samples. *E. coli* was present in the three sampling campaigns and their presence increased along the sampling period. Nematode eggs were present just in the first campaign, but in the third campaign it was not detected (table 3).

Crop trials are currently taking place, and it is expected that the sludge will favour the wheat crop performance due to its high content of nitrogen and other nutrients, thus it could be considered as an organic fertilizer. It is expected that, the addition of biosolid (organic fertilizer) will increase the plant weight compared to the inorganic fertilizer as reported by Bouzerzour et al. (2002) in their pot studies. Indeed, they detected an increase in leaf diameter, leaf area index, accumulated dry matter on the soil, tiller number, and plant height of crops such as barley and oats. Latare et al.(2014) reported a wheat yield of 39.21 $g \cdot pot^{-1}$ using a sludge concentration of 40 $t \cdot ha^{-1}$. According to these studied, good results are expected with biosolids from CW.

Abstract
Volatile organic compounds emitted by anthropogenic sources contribute to increasing tropospheric ozone concentration and the formation of secondary organic aerosols, as well as being harmful to human health. This work presents a novel solution for the removal of these pollutants, based on their biotransformation into market value compounds: polyhydroxyalkanoates (PHAs), expanding their production beyond conventional organic feedstock and making use of the gaseous pollutants while supporting their mitigation. Different nitrogen limitation strategies were tested for the continuous abatement of toluene and PHA synthesis. Promising results have been obtained so far, achieving PHA accumulation values of 25-30% (w/w) and up to 53% (w/w) under nitrogen feast-famine cycles of 24:48h.

Keywords (maximum 6 in alphabetical order)
Atmospheric pollution, polyhydroxyalkanoates, *Rhodococcus opacus*, volatile organic compounds, waste gas valorization.

INTRODUCTION

Atmospheric pollution has a massive impact on human health, causing millions of deaths every year along with imposing a heavy burden on ecosystems and social resources (Almetwally et al. 2020). Volatile organic compounds such as benzene, toluene, ethylbenzene, xylene and styrene (namely BTEXS) are among the most harmful pollutants emitted by anthropogenic sources.

Although environmental strategies promote preventive measures, they are often insufficient or technically and/or economically unfeasible, thus it is necessary to implement end-of-pipe treatment solutions. Biological treatments have been promoted in recent decades for air pollution control as they present lower investment and operating costs and lower environmental impacts. In addition, these biological technologies are capable of partially or totally degrading the pollutants into biomass, CO_2 and water, and not merely transferring them from one phase to another (Alfonsín et al., 2015; Mudliar et al., 2010). Numerous studies have demonstrated the ability of several bacterial strains to degrade BTEXS, however, scarce studies have investigated their potential bioconversion to valuable end products (Akmirza et al. 2017).

In this context, the valorization of BTEXS via bioconversion into polyhydroxyalkanoates (PHAs), a group of biodegradable and biocompatible polymers that can substitute oil-based plastics, appears as an attractive alternative due to their environmental and commercial interest (4-20 € kg^{-1}_{PHA}). The industrial manufacture of PHAs currently relies on the use of refined agricultural feedstock, such as glucose or fatty acids from sugar cane and palm oils, with high associated costs that can reach up to 40-50% of the total production costs, limiting PHA industrialization due to a low competitive price. Thus, the development of cost-effective technologies for the production of biodegradable and biocompatible polymers from waste sources could alleviate our heavy dependence on fossil plastics (Borrero et al. 2022).

However, only few studies have investigated to date the feasibility of bacterial conversion of BTEXS into biopolymers. For example, *Rhodococcus Aetherivorans IAR1* has been shown to accumulate short-chain-length PHA during degradation of aromatic compounds (Hori et al. 2009). Similarly, *Pseudomonas* genus synthesizes medium-chain-length PHA using BTEX as substrate (Narancic et al., 2012; Ni et al., 2010). Nevertheless, despite the promising results obtained so far, the potential of continuous removal of BTEX coupled with PHA synthesis has never been investigated. This work reports for the first time a comparative analysis of different nitrogen supply strategies to optimize PHA production by *Rhodococcus Opacus* using gaseous toluene as the only carbon source.

MATERIALS AND METHODS

Inoculum and mineral medium

Rhodococcus opacus (DMS 43205, Leibniz-Institut DSMZ, Germany) was cultivated in 120 mL serological bottles with mineral medium supplemented with 20 mL L^{-1} of a glucose solution (200 g L^{-1}). The mineral medium was composed of (g L^{-1}): NH_4Cl, 5; Na_2HPO_4, 75.2; KH_2PO_4, 30; NaCl, 5; 1 mL L^{-1} of a $MgSO_4{\cdot}7H_2O$ solution (1M); 0.3 mL L^{-1} of a $CaCl_2{\cdot}2H_2O$ solution (1M); 10 mL L^{-1} of a trace element solution composed of (g L^{-1}): EDTA, 5; $FeCl_3 \cdot 6H_2O$, 0.83; $ZnCl_2$, 0.168; $CuCl_2{\cdot}2H_2O$, 0.13; $CoCl_2{\cdot}2H_2O$, 0.01; HBO_3, 0.01; $MnCl_2 \cdot 4H_2O$, 0.0016; 1 mL L^{-1} of a biotine solution (1 g L^{-1}) and 1 mL L^{-1} of a thiamine solution (1 g L^{-1}). After growth, this pre-inoculum was transferred to 1.2 L bottles and growth in 200 mL of mineral medium also supplemented with glucose. The bottles were incubated under controlled temperature of 25ºC and continuously agitated at 200 rpm.

Experimental setup and operating procedure

An automatic stirred tank reactor (Biostat ® A, Sartorius Stedim Biotech GmbH, Germany) was used for the degradation of toluene and the production of PHA. The working volume was 2 L. The reactor was continuously stirred at 300 rpm, maintained at a constant temperature of 25ºC and the pH of the cultivation broth was controlled at 7 using a 4 M NaOH solution.

The toluene laden stream was obtained by injecting toluene with a syringe pump (Chemyx, Fusion 100) using a 5 mL syringe (Hamilton 1005RN) into an air inlet flow of 200 mL min^{-1}. Thus, the final inlet concentration was ~4 g m^{-3} and the gas residence time 30 s. The polluted stream was continuously fed to the bioreactor via a stainless steel fine bubble diffuser with a pore size of 2 µm. The reactor was filled with MSM and inoculated with the pre-inoculum to an initial concentration of 0.24 g L^{-1}. The reactor was then operated for 95 days in three different stages, as described in Table 1.

Table 1. Description of the different N-limitation strategies during the experimental period.

Stage	Days	N-feeding regime	N load
I	1-14	N added at the beginning of the stage (6 days limitation)	-
II	15-41	N addition upon depletion in the cultivation broth	Days 15-27: 100 mg N Days 28-41: 2.5 g N
III	42-95	Feast-famine N cycles	Days 42-68: 24h:48h (feast-famine, continuous N feeding) Days 69-88: 24:72 h (feast-famine, pulse N-feeding) Days 89-95: 120 h famine

Analytical methods

The concentration of VOCs was daily analysed by gas chromatography in a GC-FID (GC-FID Agilent 8860). Biomass concentration was quantified using Standard Methods (APHA 2018) as total suspended solids (TSS) and culture absorbance using a UVmini-1240 spectrophotometer at 600 nm (Shimadzu, Japan). pH measurements were performed using a pH meter Basic 20 (Crison, Spain), inlet pressure was daily monitored by an electronic pressure sensor PN7097 (Ifm Electronic, Germany), and gas flowrates were verified using the water displacement method. Total organic carbon (TOC) and total nitrogen (TN) concentrations were determined in a Shimadzu TOC-LCSH/CSN analyser equipped with a TNM-1 unit (Shimadzu, Japan).

Biomass samples were collected and refrigerated for preservation prior to extraction and PHA characterization. For extraction, 10 mL of sample was taken, centrifuged at 9000 rpm for 10 min at 4°C, with the resulting biomass pellet washed and dried for 12 h at 90°C. Then, 4 mL of pure chloroform was used for extraction by incubation for 4 h at 100°C, to finally recover the solvent and quantify PHA. The bacterial PHB content was measured using a GC–MS (GC System 7820A MSD 5977E, Agilent Technologies, Santa Clara, USA) equipped with a DB-wax column.

RESULTS AND DISCUSSION

After the initial acclimation period, complete toluene removal was recorded under N-sufficient conditions regardless of the operating stage. During N limitation, a slight deterioration of the toluene removal performance was observed, with minimum values of 92% (Figure 1). During stage I, a maximum PHB concentration of 39.7% (w/w) was obtained after 5 days of N limitation. On the contrary, feeding N upon depletion during stage II did not result in a significant accumulation of PHB, with maximum values of 28.2% recorded by day 27. It is also worth to mention that the biomass concentration during these stages was relatively low, reaching maximum values of ~1.7 g TSS L^{-1}. Biomass concentration significantly increased during stage III, with average values of 3.2 g TSS L^{-1}. The maximum PHA concentration of 53.0% (w/w) was also recorded in this stage when N was supplemented during 24h followed by a 48h famine period.

Overall, the capacity of *Rhodococcus Opacus* to continuously biodegrade toluene from a gaseous stream and produce PHB was demonstrated. Further optimization of the N-feeding strategy is being performed to promote biopolymers synthesis.

Abstract
Purple phototrophic bacteria (PPB) can be used to convert gaseous streams (e.g., H_2 and CO_2) into single-cell protein. Here we have determined, for the first time, the specific uptake rates of enriched PPB cultures under different environmental conditions (i.e., temperatures, pH and light intensities), using a mechanistic model considering relevant biological and physico-chemical processes. The model accurately represented results from batch tests with different gas-transfer kinetics (i.e., k_La values), providing similar biological uptakes rates. Optimal rates of 1.9-2.0 g COD·g COD^{-1}·d^{-1} were reached at pH 7, 25 ºC and light intensities over 30 W·m^{-2}, with biomass yields of ~1 g COD·g^{-1} COD. The influence of light and temperature on the uptake rates was modelled using the Steele's equation and the cardinal temperature model with inflection. The obtained rates are similar to those for pure PPB cultures and those achieved via photoheterotrophy.

Keywords
Autotrophy; gas valorisation; modelling; purple phototrophic bacteria; resource recovery; single-cell protein

INTRODUCTION

Processes based on purple phototrophic bacteria (PPB) are a promising option for resource recovery due to the high biomass yields that their phototrophic metabolism allows. PPB can efficiently generate a wide range of value-added products (*e.g.*, single-cell protein (SCP), fertilisers, or polyhydroxyalkanoates) at biomass yields up to 1 g COD·g COD^{-1} (Capson-Tojo et al., 2020).

While their photoheterotrophic capabilities have been considerably studied in the past few years for resource recovery from wastewater (Hülsen et al., 2022a, 2022b, 2022c), their photoautotrophic capabilities have barely been researched. PPB grown autotrophically could allow the efficient conversion of H_2 and CO_2 into SCP, generating a pathogen-free high value-added product usable as feed/food (Delamare-Debouteville et al., 2019). If the H_2 and nutrient sources are sustainable (e.g., from bioH_2 and anaerobic digestate), this approach could be a game changer for valorising gaseous effluents in a biorefinery, while recovering remaining nutrients. The proof of concept of H_2 conversion by PPB has been recently realised using pure cultures (Spanoghe et al., 2021). Recent results from our group have shown than enriched PPB cultures can valorise H_2 and CO_2 at higher yields than pure cultures (unpublished). The specific rates (crucial for implementation) are still to be determined using dedicated models.

The mechanistic models available to represent resource recovery by PPB are the Photo-anaerobic model (PAnM) (Puyol et al., 2017) and its extension, the ePAnM (Capson-Tojo et al., 2023), which have been successfully applied for wastewater treatment. Photoautotrophic uptake is included in both models, but they do not consider detailed gas-transfer kinetics. This is essential for modelling gas-fed processes, as models must account for rate limitation by mass transfer due to the low solubility of gaseous substrates.

Results from dedicated batch tests have been used here to calibrate a mechanistic model considering PPB as biomass component. Once we confirmed that the model could account for both physical and biological rate limitations, the model was used to determine the specific uptake rates of enriched PPB cultures under different environmental conditions (e.g., pH, temperature (T) and light intensities). The impact of these variables on the rates was studied and modelled.

MATERIALS AND METHODS

Photoautotrophic enrichments were grown in Schott flasks of 500 mL using the mineral synthetic medium (MSM) proposed by Ormerod et al. (1961) but modified to provide CO_2 as C source (as carbonate) and providing H_2 in the headspace. The flasks were filled with 190 mL of MSM and 10 mL of PPB enrichment as inoculum. After, they were closed and the headspace was flushed with N_2 prior to H_2 addition. The initial headspace pressure was adjusted to 1.30-1.35 bar. The flasks were covered with UV/VIS filters (Hülsen et al., 2022c) and incubated under continuous illumination using infrared LED lights (850 nm). Two tests at different mixing intensities (and thus gas transfer rates) were performed, at 150 and 600 rpm. Assays at initial pH values of 6, 7 and 8.5, T of 15, 25, 38 and 50 °C, and light intensities of 0, 5, 15, 30 and 50 W·m^{-2} were carried out at 600 rpm (in triplicate). Gas composition and pressure were monitored 4-5 times per day. Liquid samples were drawn to determine biomass yields, crude protein contents and microbial communities.

The model considered PPB as single biomass component and growth on H_2 and CO_2 and biomass death as biological processes. Table 1 shows the corresponding Petersen matrix. Mass transfer processes and chemical equilibria were modelled as in the ADM1 (Batstone et al., 2002), modifying the model to account for gas consumption and for relevant chemical species for pH calculation. The model was structured following IWA standards. Stoichiometric parameters were either determined experimentally (yields) or gathered from the literature. Matlab was used to perform the simulations. Estimation of parameters related to H_2 uptake (K_m and K_{H2}) was performed as in Puyol et al. (2017). The effect of T and light on uptake rates was modelled using the cardinal temperature model with inflection (CTMI) (Ruiz-Martínez et al., 2016) and The Steele's equation (Wágner et al., 2018).

Table 1. Petersen matrix of the proposed model. The nomenclature is the same as in Capson-Tojo et al. (2023).

RESULTS

Figure 1 shows, as example, the results for one of the batch tests at 150 rpm. Despite the change in limiting rates, the model was able to represent the whole process, predicting accurately biomass and hydrogen concentrations. Before 0.9 d, H_2 was sufficient, and the consumption rates were limited by biological uptake (typical exponential curve, soluble H_2 concentrations much higher than the saturation constant for H_2 (K_{H2}; below 0.05 mg COD·L^{-1} in all experiments) and uptake rates increased with supply). After 0.9 d, the H_2 transfer rate became limiting due to the high biomass concentration and the low k_La (28.7 d^{-1}), a situation that did not change despite the injection of extra H_2 in the headspace. After this point, the concentration of H_2 in the liquid was always close to zero, the growth curve became linear, and the uptake rate was limited by the supply rate. The model predicted accurately this behaviour, confirming its applicability for rate determination.

The tested environmental conditions affected considerably the H_2 uptake rates. Optimal rates of 1.9-2.0 g COD·g COD^{-1}·d^{-1} were achieved at initial pH values of 7, 25 ºC, and light intensities over 30 W·m^{-2} (Table 2). Lower or higher pH values and T resulted in decreased rates (Table 2, Figure 2). No photoinhibition was observed at 50 W·m^{-2}. With R^2 values of 0.97 and 0.91, the Steele's equation and the CTMI when able to represent these impacts accurately (Figure 2). The biomass yields close to 1 g COD·g^{-1} COD confirmed effective phototrophic growth. The optimal conditions are similar to those reported for photoheterotrophic PPB growth, confirming these values and suggesting that the growth mode does not affect optimal conditions (Capson-Tojo et al., 2022, 2020). Optimal specific uptake rates are close to those for photoheterotrophic processes (2.3-2.7 g COD·g COD^{-1}·d^{-1}; (Capson-Tojo et al., 2023; Puyol et al., 2017)) and similar to those reported for pure PPB cultures grown autotrophically (below 2.3 g COD·g COD^{-1}·d^{-1}; (Spanoghe et al., 2021)).

1. k_La_{H2} of 28.7 d^{-1} at 150 rpm and 70.4 d^{-1} at 600 rpm.
2. Results also for the tests at pH 7 and 25 ºC.

CONCLUSIONS

Here we show for the first time that enriched PPB cultures can be grown autotrophically from H_2 at similar rates than pure cultures, proving that axenic conditions are not needed. Optimal values of 1.9-2.0 g COD·g COD^{-1}·d^{-1} were reached at pH 7, 25ºC and light intensities higher than 30 W·m^{-2}. The developed model was able to represent the overall kinetics of the process, accurately predicting rate limitations. The Steele's equation and the CTMI represented accurately the variations in the specific uptake rates due to light and T. The high yields and rates achieved confirm the great potential of enriched PPB cultures for H_2 valorisation. Volumetric production rates must be assessed and the model must be validated using continuous bioreactors.

Abstract
Biological methanation is seen as one key technology which might enable long-term renewable energy storage in the chemical form. When applied to a WWTP biogas stream, it is capable of substituting a conventional upgrading step, with the advantage of increasing the total biomethane produced by 40 to 80%. An ex-situ biological methanation process is tested at demonstration scale to supply biomethane to a public transportation bus.

Keywords (maximum 6 in alphabetical order)
Biomethane, biological methanation, green hydrogen, power-to-gas, regenerated water, sustainable mobility

INTRODUCTION: THE NEED OF ENERGY STORAGE IN THE PATH OF DECARBONIZATION

As Europe progresses towards de-carbonization of the energy sectors as well as invests in renewable investments, the gap between instantaneous production and consumption of electricity becomes more crucial and harder to manage for grid operators. Storage of surplus renewable electricity in the chemical form is expected to be a key bridge in the decarbonization of the several sectors, transportation among them. Hydrogen has been gaining most of the attention since it can be readily produced out of water and electricity, however, it is well known that storing energy in the form of hydrogen comes with a number of unsolved issues, among them: low energy volumetric density, high corrosivity, high fugacity and very high explosive mixtures range with air.

Processing the H_2 molecule into another species is seen as the next logical step, in spite of the potential losses. Among the candidates, there is methanol, ammonia, synthetic long hydrocarbon chains as well as methane. Methane, or biomethane, has the advantage that it can be readily injected into existing infrastructure, however, in order to produce methane, as the reaction of Sabatier shows (see Equation 1), CO_2 is needed as a reactive, and, if possible, biogenic CO_2.

$$CO_{2(g)} + 4\,H_{2(g)} \rightarrow CH_{4(g)} + 2H_2O_{(g)}$$

Equation 1. Sabatier methanation reaction

Biogas upgrading to biomethane consists of the separation of CO_2 from CH_4, either by membrane separation, or chemical or physical absorption, or pressure swing adsorption, or cryogenically. In the case of methanation, hydrogen can be directly injected into the biogas for its methanation and upgrading into biomethane. The volume of biomethane obtained is also increased compared to conventional upgrading, in-between 40% and 80% depending on the on-site composition of the biogas.

Methanation can either be carried out biologically or catalytically. Catalytic methanation requires high temperature and pressure (pressure enhances reaction kinetics due to Le Chatelier's principle) which leads to very low residence times and enables coupling with heat integration (district heating, steam generation, etc.). However, although the maturity of catalytic methanation is very high, it has a weak point: catalyst poisons quickly due to remaining pollutants such as H_2S in the biogas, ppb traces accumulate over processed volume flows and render the operation inviable.

Biological methanation on the other hand, is at a lower degree of maturity and requires much longer residence times, but it does not suffer from catalyst poisoning, as microbes regenerate and are much more tolerant to pollutants. Pressure and temperature requirements are lower, which ease construction of reactors although it makes heat integration less attractive. Biological methanation can be done ex-situ (on a separate reactor) or in-situ (in the anaerobic digester itself). Literature seems to suggest that in-situ methanation is limited in terms of the maximum achievable concentration of methane in the off-gas.

MATERIALS AND METHODS

In the LIFE NIMBUS (LIFE19 ENV/ES/000191, http://www.life-nimbus.eu) project a biological methanation ex-situ process has been developed to upgrade on-site biogas produced in an anaerobic digester of WasteWater treatment plant sludge at the Baix Llobregat WWTP. The process has been scale up to build a demonstration plant with a nominal capacity of 7,4 Nm^3/h of biomethane, enough to cover the daily needs of a urban transportation bus which covers a distance of 150km daily. The biogas is scrubbed of H_2S and pressurized into the reactor up to 4 barg, where it mixes with the hydrogen and CO_2 reacts to CH_4. The biomethane is conditioned and pressurized up to 300 bars for its storage and refuelling of a public transportation bus (see Figures 1 and 2).

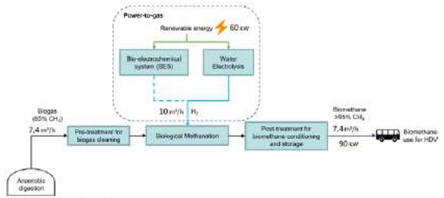

Figure 1. Flowchart of the biological methanation implemented process.

This process is not only presented as an alternative to a conventional biogas upgrading to biomethane such as membrane upgrading or chemical absorption; it really is a hybrid between a biogas upgrading process as well as a power-to-gas process, for it stores renewable electrical surplus energy in the form of biomethane. The hydrogen necessary to methanate the biogas will be supplied by an on-site alcaline electrolyzer (60 kWe, 10 Nm^3/h H_2) powered by renewable electricity. A Biological Electrochemical System is also implemented at pilot scale. This type of electrolyzer obtains part of its energy needs from organic matter from a wastewater stream, greatly improving the efficiency of electrolysis. The electrolyzer requires deionized water with a very high purity (no salts nor organic content), regenerated water will be treated so as to obtain this demineralized water.

Figure 2. Public transportation bus from TMB fuelled by biomethane produced in the LIFE NIMBUS project

Both the methanation plant (see Figure 3) as well as the Biological Electrolyzer System pilot plants have been designed based on laboratory experimental data on microbial activity as well as other aspects such as mass and heat transfer, which can become limiting when scaling up from laboratory/bench scale. Both pilot plants will start its operation in February 2023, and operational data will be collected to assess both technically as well as economically the scale-up of the process to commercial nominal capacities, in order to determine the technology viability. Furthermore, the bus engine and tanks will be analysed to see any detrimental effects by remaining Siloxanes and H_2 traces.

Figure 3. View of the biological methanation plant

RESULTS AND DISCUSSION

The first results of the operation of the pilot plant will be presented at the congress.

Abstract
Nitrogen recovery from wastewater appears as a feasible alternative to produce ammonia fertilisers with a lower impact than the conventional process, increasing the nutrient circularity and reducing the external EU dependence on fertilisers. For that aim, a treatment train formed by an ion exchange unit and a hollow fibre membrane contactor unit was evaluated in this work for the recovery of nitrogen from wastewater. The results show its capacity to recover nitrogen as marketable ammonium salts with high efficiencies (91%) which will be blended with recovered struvite and Plant Growth Promoting Bacteria to produce a Smart Bio-based fertiliser.

Keywords
Biofactory; circular economy; hydrophobic membrane; ion exchange; nitrogen recovery; smart fertiliser.

INTRODUCTION

Nitrogen is an essential nutrient for plant growth. Its demand to produce fertilisers to be applied in agriculture has increased drastically in the last decades. Conventional production of nitrogen as fertiliser is carried out by the Haber-Bosch process, which is an energy-intensive process and fossil fuel dependent. More sustainable ways to obtain nitrogen fertilisers have been developed recently. In this framework, Horizon 2020 WalNUT project came out, developing new alternatives to produce fertilisers from wastewater and brine, increasing the nutrients' circularity as well as reducing the external EU dependence of these products by the application of different technologies to recover nitrogen, phosphorus and salts such as sodium, chloride or potassium.

Nitrogen is usually removed from wastewater treatment plants (WWTPs) by the nitrification-denitrification process. This two-step process has high energy requirements in terms of aeration to oxidise ammonium to nitrate, and also needs organic matter to reduce the nitrate to nitrogen gas. A more sustainable alternative is to recover the nitrogen from wastewater instead of removing it. In particular, nitrogen can be recovered from reject water, which is the most nitrogen rich stream from WWTPs, reducing the energy demand and the carbon footprint from WWTPs (Noriega-Hevia et al., 2021). For that purpose, gas-permeable hollow fibre membrane contactors (HFMC) are one of the best technologies to applied because of its low energy requirements, modularity, high ammonia selectivity and its hydrophobicity, which avoid the pass of hazardous substances such as heavy metals or organic micropollutants (Licon Bernal et al., 2016). These membranes offer a surface to favour the pass of free ammonia gas from a feed solution with a high ammonia concentration to an acid solution, usually sulphuric acid or nitric acid. This free ammonia is captured in the acid solution due to the low pH producing an ammonia salt which is marketable as fertiliser. The driven force is the free ammonia concentration in both sides of the membrane. In some applications it is advisable to add a unit of ion exchange to concentrate the ammonia of the reject water before feeding the membranes in order to maximise the salt production.

Although the ammonia salt produced is a marketable as fertiliser, in this project the final aim is to produce a NPK smart bio-based fertiliser (BBF), that is, a nitrogen, phosphorus and potassium fertiliser in which is possible to modify the release of the nutrients by biological or chemical techniques (Raimondi et al., 2021). This fact favours an adaptive application of fertilisers depending on the soil requirements, increasing the sustainability and improving its management. In this case, selected Plant Growth Promoting Bacterias (PGPBs) are going to be added to the NPK fertiliser. In this work, it is shown the performance of the nitrogen recovery process from reject water by the application of HFMC and IE jointly as the first step to produce a smart BBF in the framework of WalNUT project. Different operational conditions have been tested to determine the optimum conditions in terms of recovery efficiency, recovery rate and ammonia content in the acid tank.

MATERIAL AND METHODS

The treatment train applied for the recovery of nitrogen consisted of two units: an ion exchange unit, to concentrate the ammonia content of the reject water; and two hollow fibre membrane contactors in series to extract the ammonia of the feed and to produce an ammonia sulphate solution (Figure 1). Ion exchange columns have a bed volume of 1 litre using natural zeolites (ZEOCAT- 0-1 mm) as exchangers. HFMC were two modules of Liqui-Cel® 3M with an unitary surface of 1.4 m2.

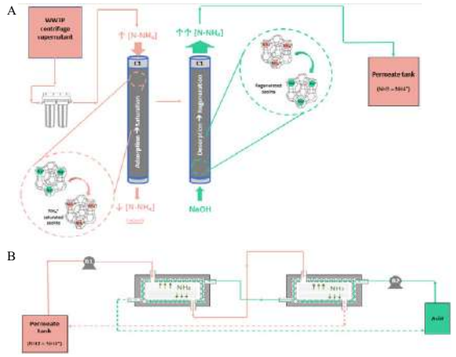

Figure 1. Nitrogen recovery set-up: A) ion exchange unit; B) membrane unit.

The feedstock was reject water from the full-scale Ourense WWTP located in the Northwest of Spain. This stream has an ammonia concentration of 1307±146 mg NH4-N/l and a SST of 2.3±0.3 g/l. Although the amount of solids of this stream is not dangerous, a pre-treatment of two filters in series (20 µm + 5 µm), was also included in order to remove the big solids that could be present.

Different tests were carried out to characterise and evaluate the performance of the treatment train to define the optimum operational conditions in each part of it. Regarding the IE unit, to obtain the maximum concentration of ammonia in the regeneration with the minimum losses and, in the case of the HFMC unit, the maximum recovery efficiency to obtain a concentrated ammonium salt.

RESULTS AND DISCUSSION

The treatment train proposed in this research has been validated, proving its capacity to recover nitrogen from wastewater. In this section, the results obtained in the different units are shown.

Ion exchange unit

Different operational conditions have been tested in order to characterise the column and to determine the optimised operating conditions. Figure 2 presents the ammonia evolution in the column outflow with an HRT of 23 minutes. The cation exchange capacity (CEC (mg/g)) obtained by the zeolites in the different tests carried out was 15 mg N-NH_4/g zeolite.

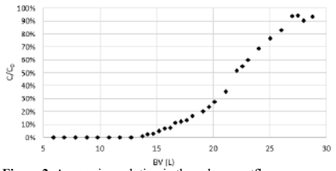

Figure 2. Ammonia evolution in the column outflow.

Another important parameter to evaluate is the concentration of the regenerant, in this case sodium hydroxide. Different concentrations were tested. A more concentrated solution reduced the regeneration time and offered the possibility to obtain higher ammonia concentrations (Figure 3). However, a higher concentration of NaOH led to a higher pH, which increases the risk of free ammonia losses by stripping. This is an important parameter to evaluate for the best performance of the treatment train due to the reagents costs.

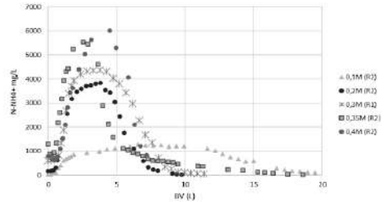

Figure 3. Effect of NaOH solution in the regeneration.

Membrane unit

Regarding the membrane, different flow rates were tested to evaluate the effect of this parameter on the recovery rate. Figure 4 shows the ammonia evolution in the feed tank during the recovery process.

The feed concentration was 1285±102 mg N-NH_4/l and pH was 12.4±0.2. As it can be seen, an increase in flow rate leads to a higher recovery rate but, at values higher than 400 ml/min, the rate is similar. These results suggest that applying a higher flow rate, the turbulence reduces the boundary layer resistance but, at a certain flow rate, this resistance is minimum, and the turbulence could not be more reduced. In these tests, the recovery efficiency was 91±3%. The nitrogen recovered was stored in the acid tank as sulphuric acid. At this moment, only a sulphuric acid concentration of 0.09M has been tested, obtaining an ammonia sulphate solution with 2.5 g N-NH_4/l.

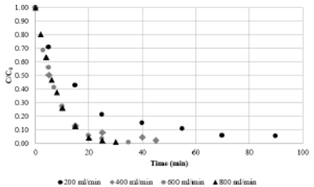

Figure 4. Ammonia evolution during the recovery rate at different flow rates.

Next steps will be focused on the increase of the ammonia sulphate nitrogen concentration and the optimization of both units jointly as the previous step of the production of a NPK Smart fertiliser in the WalNUT project framework. This Smart fertiliser will be the blend of recovered ammonia salt and struvite with a selected PGPB to maximise the soil nutrient uptake.

CONCLUSIONS

The treatment train proposed is able to work as a unique unit maximising the nitrogen recovery and reducing costs due to the previous concentration with the IE. Furthermore, it presents high recovery efficiencies (91%) producing a concentrated ammonia sulphate solution. However, the optimization of both units working together as well as the raised product ammonia concentration will be aspects to work on to produce the final Smart BBF.

Abstract: Pharmaceutical active compounds (PhACs) have been detected in the environment for several years. These substances, even at low concentrations can have an impact in the ecosystems. Therefore, it is crucial to develop new methodologies to track these concentrations in the environment. A suitable selection of pharmaceuticals is a critical step and it can be achieved through a prioritisation strategy. In this work, PhACs occurrence data were obtained from monitoring studies of our group in the last 10 years in hospital and urban wastewater, river, and sea. The data were used to determine the most relevant pharmaceuticals in terms of occurrence and an analytical method upgrade to analyse them was performed. The new methodology was then applied and validated with water (wastewater, river, and sea water), soil, and crops samples from Greece and Spain suffering from water scarcity.

Keywords: Emerging contaminants; Hospital wastewater; Transformation Products; Wastewater.

INTRODUCTION

Pharmaceutical active compounds (PhACs) have been widely detected in wastewater. Wastewater treatment plants may not achieve their total degradation and, therefore, they are released in the environment (Čelić *et al.*, 2019). These compounds, even at low concentrations, can have an impact in the ecosystems. Thus, it is critical to develop up-to-date analytical methods to determine their occurrence. To obtain accurate information a target analysis is required. Nonetheless, the fact that analytes must be selected in advance is a major drawback, and, in some cases, no-preselected analytes could remain unspotted while other selected ones might not be present. Therefore, properly selecting the most relevant analytes through a prioritisation is a critical step. In this work, an occurrence-based prioritization was performed using an in-house research group database of 30 publications in hospital and urban wastewater, river, and sea. A new multi-residue analytical methodology was upgraded, applied, and validated with wastewater, river, and sea water from Catalonia and Greece, areas suffering from water scarcity (EU HYDROUSA project, www.hydrousa.org).

MATERIALS AND METHODS

Studies performed by the group in the last 10 years in river, hospital, and urban wastewater in Catalonia (NE Spain) were gathered. The generated database (30 publications) provided the occurrence data of 157 pharmaceuticals and transformation products (TPs). Compounds were ranked based on their mean concentrations and 4 different lists were generated (hospital and urban wastewater, treated wastewater, and river water). A list of 50 compounds was generated combining the 4 lists considering each compound ranking. Current analytical methodologies of the institution based on SPE and UHPLC-MS/MS (5500 QTRAP hybrid triple quadrupole-linear ion trap mass spectrometer) were combined to obtain an upgraded method for the analysis of the selected compounds in both positive (HSST3 column) and negative (BEH column). The methodology was validated with real samples from Spain and Greece.

RESULTS AND DISCUSSION

Therapeutic classes with the highest concentrations in water bodies of Catalonia in the last 10 years were analgesics and antiinflammatories (30%), antibiotics (24%), and psychiatric drugs (20%). Other compounds with high concentrations in water belong to β-blockers, histamine receptor antagonists, or calcium channel blockers. On the other hand, 12 TPs were detected and represented 24% of the 50 more ubiquitous compounds, highlighting how important it is to include them in monitoring programs. Figure 1 depicts the 25 compounds occupying the first positions of the selection.

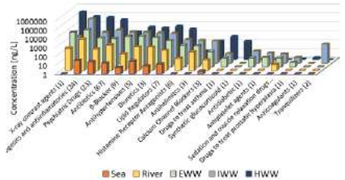

Figure 1: Concentration (ng/L, logarithmic scale) of the first 20 occurrence based prioritised PhACs in IHWW, IWW, EWW, and river water.

Sampling campaigns were carried out in Catalonia and Greece water samples (2019-2020) with the upgraded analytical method. Similar concentration profiles were observed in both areas in influent wastewater (338 and 351µg/L in Greece and Catalonia, respectively). Furthermore, the concentrations did not strongly differ in most of the therapeutic classes. Nevertheless, some compounds presented different concentrations in wastewater influent: levamisole, gemfibrozil, and iopromide were detected at higher concentration levels in Catalonia; whereas ranitidine, venlafaxine, and valsartan presented higher values in the Greek Islands. These results may suggest there might be some preference in the usage of certain pharmaceuticals based on the country. Results obtained in Catalonia followed the same patterns of the in-house database but with higher concentrations for some TPs, especially of ibuprofen.

CONCLUSIONS

Data coming from 30 publications in the last 10 years in Catalonia was gathered to select the 50 most ubiquitous pharmaceuticals in surface and wastewater. More than 20% of the selected compounds correspond to TPs. A new analytical method was developed based on the in-house methods for these 50 compounds and applied to water samples of Catalonia and Greece. Both countries showed similar therapeutic classes concentration profiles, with some differences for some compounds: levamisole, ranitidine, gemfibrozil, venlafaxine, iopromide and valsartan. Further studies are required to confirm the hypothesis of different prescription/use/preferences in the usage of certain pharmaceuticals in different countries.

Abstract
Phosphonate contamination of water bodies has drawn much attention. Advanced oxidation combined with phosphorus recovery from phosphonate-contaminated waste water bodies is considered as a promising solution to but the development of a cost-efficient process remains challenging. This work demonstrates an effective two-step process including a plasma degradation step followed by granular filtration with iron-coated sand (ICS). In the first step, a tandem reactor configuration, which consists of a dielectric barrier discharge (DBD) plasma chamber and an ozonation chamber was used to transform 1-hydroxyethane-1,1-diphosphonic acid (HEDP), a phosphonate widely used in textile industry, to Ortho-phosphate (Ortho-P). Ozone gas produced in the dielectric barrier discharge (DBD) reactor was introduced in the ozonation chamber. Experiments were performed with and without lava rock packing in the ozonation chamber. The addition of lava rock as packing material increased the Ortho-P production efficiency by 15-35%, because the presence of lava rock increased the exposures of reactive species (O_3, ·OH and $O_2^{\bullet-}$) by 120%, 20% and 30%, respectively. The effects of carrier gas composition as well as waste water composition was also evaluated in the operational model of plasma & packed ozonation chamber. The use of O_2 resulted the highest Ortho-P production efficiency (86 %), followed by Ar (48%), N_2 (21%) and air (13%). Humic acids present in waste water can compete with phosphonates for reactive species, decreasing the Ortho-P production efficiency by 30%. In the second step, ICS granules were used to adsorb produced Ortho-P. The final recover efficiency of Ortho-P from real textile and synthetic wastewater was 53% and 85%, respectively.

Abstract
The biosynthesis of polyhydroxyalkanoates (PHAs) from fish-canning wastes by mixed microbial cultures is a promising technology to replace conventional plastics. However, the dynamics of the key populations involved in the PHA are not well known, limiting the feasibility of PHA yield. Hence, the aim of this study was to determine the shifts in the bacterial communities in lab-scale sequencing batch reactors (SBRs) fed with fish-canning waste under a double growth limitation (DGL) strategy. The analysis of the bacterial communities was determined by Illumina sequencing of 16S rRNA genes, and the bioaccumulation of PHA was measured by gas chromatography in two SBRs using different NaCl concentrations (SBR-N, 0.5 g NaCl/L, and SBR-S, 10 g NaCl/L). The imposition of the DGL strategy resulted in broad successions of the dominant genera, being *Calothrix*, *Gordonia*, and *Chryseobacterium* the most abundant PHA-accumulating bacteria in the SBR-N, whereas *Qipengyuania, Corynebacterium*, and *Dokdonella* those in SBR-S.

Keywords (maximum 6 in alphabetical order)
Bacterial diversity; fish-canning waste; Illumina sequencing; mixed microbial cultures; PHA accumulation; sequencing batch reactors

INTRODUCTION

The production of conventional plastics, which involves the use of crude oil and natural gas, produces major damage to the environment due to its high CO_2 emissions. Hence, there is an urgent need to develop biodegradable, compostable, and environmentally friendly substitutes for traditional petroleum-based plastics. In this sense, bioplastic production is the most promising strategy in the replacement of the high contaminant conventional plastics. Among the different alternatives, polyhydroxyalkanoates (PHAs) production by mixed microbial communities (MMC) using industrial wastes stands out as a promising biotechnology against fossil-fuel-derived plastics. In this regard, the PHA biosynthesis by using an MMC requires a robust enrichment in the bacterial populations carrying the enzymatic machinery to achieve a high level of synthesis and accumulation of PHAs. However, the successional patterns of the key genera involved in the effective establishment of PHA-accumulating communities are not well known. Hence, the main objective of this work was to determine the dynamics of PHA-accumulating bacteria within the MMCs in two SBRs using fish-canning waste as a substrate using two different levels of salinity.

MATERIALS AND METHODS

Two lab-scale (4 L) sequencing batch reactors (SBRs) were operated using two different levels of salinity (SBR-N, 0.5 g NaCl/L, and SBR-S, 10 g NaCl/L) for the enrichment of PHA-accumulating bacteria for 331 and 122 days, respectively. Both SBRs were operated under a double growth limitation (DGL) strategy, in which C (added in the feast phase) and N (added in the famine phase) were incorporated separately. The accumulation of PHAs was determined by gas chromatography in biomass samples (Argiz et al., 2021). High-throughput Illumina MiSeq sequencing of the V3-V4 region of the 16S rRNA gene was performed according to Correa-Galeote et al. (2022). The corresponding statistical analyses were carried out in the XLSTAT software (Addinsoft, USA).

RESULTS AND DISCUSSION

The main physicochemical parameters showed few statistical differences among sampling times and reactors. Regarding the PHA accumulation, the maximum yields were 22.03 wt% and 26.33% for SBR-N and SBR-S, respectively, without statistical differences in the PHA yield between reactors. Regardless of the SBR and sampling time, the most abundant bacteria were *Gordonia* (8.88%), *Qipengyuania* (6.19%), and *Acidovorax* (5.65%). Significant differences of the relative abundances of several main bacterial genera were found after the imposition of DGL strategy in both bioreactors. The broad successions of the dominant bacteria found throughout the operational time in both SBRs, suggest that the DGL strategy for the enrichment in PHA-accumulating bacteria strongly affected the structure of the bacterial communities. In this sense, *Calothrix* (20.88%), *Gordonia* (18.15%), and *Chryseobacterium* (7.72%) were the PHA-accumulating bacteria with higher-than-average relative abundance at the end of the operation of SBR-N; whereas, *Qipengyuania* (57.09%), *Corynebacterium* (17.33%) and *Dokdonella* (11.62%) were the most abundant genera at the end of the experiment for SBR-S. According to these results, the operation strategies imposed resulted in the implementation of different well-established PHA-accumulating potential capacities in each SBR. This suggests a broad functional redundancy in the PHA accumulating capacity within the bacterial communities of both SBRs. Finally, the multivariate statistical analysis carried out showed that increasing the salt concentration from 0.5 g NaCl/L to 10 5 g NaCl/L had no influence on the PHA-accumulating capacity.

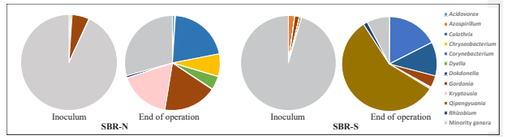

Figure 1. Structure of the dominant bacterial genera (relative abundance > 0.5%) from two PHA-accumulating SBR reactors operated using two different levels of salinity (SBR-N, 0.5 g NaCl/L, and SBR-S, 10 g NaCl/L).

Abstract
A next-generation fit-for-use water reclamation treatment scheme is being operated since January 2023 with the aim of demonstrating innovative technologies to treat and valorize urban wastewater in the form of energy, nutrients and water for different purposes. The pilot plant is treating 400 L/h of wastewater coming to La Llagosta WWTP (Barcelona, Spain) using a treatment train composed of an anaerobic membrane bioreactor followed by a partial nitritation reactor and an anammox reactor. In May 2023, additional units will be in place to incorporate phosphorous recovery in the form of vivianite and a reverse osmosis module using recycled membranes. The design of the plant has followed the Value Sensitive Design (VSD) principles. Interested stakeholders have been involved in the project from its beginning through meetings of the so-called "Community of Practice" (CoP) where topics related to the implementation of the Water Mining technologies are analysed and expertise is exchanged.

INTRODUCTION

The Water-Mining project is a H2020 funded project started in September 2020 with the aim of contributing to the circular economy in the water sector. It is a highly collaborative project (38 partners) coordinated by Technical University of Delft, The Netherlands) (www.watermining.eu. The different technologies that will be demonstrated within the project are spread into different case studies and living labs in five European countries. In this abstract, Case Study 5 is presented, which is taking place in a pilot plant located in the wastewater treatment plant (WWTP) of la Llagosta (Barcelona, Spain). In this plant, the recovery of nutrients, energy and water for different purposes will be evaluated using novel technologies.

THE PILOT PLANT

The CS5 Water-Mining pilot plant is being commissioned in January 2023 and will be in operation for 18 months. It will be treating 400 L/h municipal wastewater using a flexible wastewater reuse treatment scheme described in Fig. 1. The first unit of the treatment train consists on a granular anaerobic membrane bioreactor (AnMBR) with the configuration of an EGSB (expanded granular sludge bed) reactor followed by two hollow fiber ultrafiltration modules (Thermally Induced Phase Separation (TIPS) PVDF UF membranes from Scinor, China). From this unit, biogas will be produced and quantified and the water coming from it could be either directly applied to agriculture in the form of fertirrigation or pass the N and/or the P removal systems located afterwards. The N removal is comprised by a granular partial nitritation reactor and an anammox reactor. Anammox is the oxidation of ammonium with nitrite as the electron acceptor and dinitrogen gas as the product (Kumar *et al.*, 2017). In the partial nitritation reactor, approximately 50% of the ammonium contained in the influent will be oxidized to nitrite. Afterwards, the ammonium and nitrite of the influent will be converted into nitrogen gas via an anammox reactor where anammox bacteria will be cultivated in the form of granules.

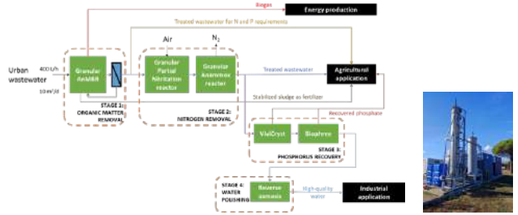

Figure 1. Water-Mining CS5 treatment scheme (left) and picture of the pilot (right).

After the N removal step, the ViviCryst and Biophree technologies from Wetsus will be operated in order to recover P in the form of vivianite ($(Fe)_3(PO_4)_2$ $8H_2O$) via precipitation (ViviCryst unit) and to eliminate the remaining P using adsorption (Biophree unit) that can lead to severe fouling in the RO membranes afterwards. The RO modules will be recycled using oxidative treatment by Eurecat (Fig. 2).

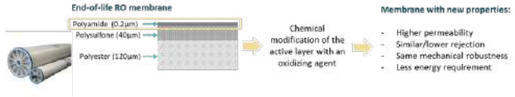

Figure 2. Regeneration process of the RO membranes.

SOCIAL INNOVATION: THE COMMUNITIES OF PRACTICE

A group of relevant stakeholders was selected at the beginning of the project that included water authorities, NGOs, private water companies and research centres. This group conform the so-called "communities of practice" (CoP), which participate in meetings along the project in order to incorporate their opinions, values and expertise in the design of the technologies and their further applications. Two meetings have been held to date, where approximately 15 people have given their insights about the Water-Mining project analysing the market, policy, technological and economical barriers of the implementation of the technologies and provided recommendations for optimization.

Abstract
Climate change and environmental degradation increasingly represent a threat to the entire world, and therefore the safe recovery of resources is crucial in order to encourage the use of what is now considered as waste as a real resource. In this context, risk analysis is the main element to ensure the safe reuse of wastewater and grey water. For this purpose, a semi-quantitative approach was followed for risk assessment in wastewater reuse, while a QMRA calculation tool was developed for a quick assessment of the risk of re-use to support stakeholders in making decisions about possible restrictions.

Keywords (maximum 6 in alphabetical order)
FMEA; QMRA; risk assessment; run-off; stormwater management; water reuse.

INTRODUCTION

Water scarcity and water stress are issues of growing concern at international and European level (Delli Compagni et al., 2020). Freshwater availability is getting scarcer due to effects related to climate change issues, like heatwaves or drought periods. Apart from limiting water resources for human consumption, water scarcity implies some environmental impacts such as increasing contaminants concentration and water pollution. Potential contamination sources include also diffuse inputs, such as urban and agricultural run-offs, which may occur during precipitation and flooding events. Extreme rainfall events may impact on sewer overflows and thus on surface water quality, since they may increase bacterial loads and concur in environmental contamination, affecting both human health and ecosystem. Reclaimed wastewater and greywater can contribute to compensate water needs, providing regular supply (Deviller et al., 2020), reducing the exploitation of natural water resources and alleviating the pressures of wastewater treatment plants (WWTP) discharges into sensitive areas. In this context, risk assessment represents a crucial task to ensure health and environmental protection for water reuse applications. Regulatory frameworks are including this aspect, even if detailed procedures are still lacking, especially for alternative sources, such as greywater. The work carried out aimed to face risk assessment, both for wastewater and for run-off water reuse.
Considering wastewater reuse, a semi-quantitative risk assessment has been developed and detailed for a full-scale water reuse system in Italy. Moreover, a specific methodology has been developed for safe stormwater management and reuse of greywater, during the European project WATERUN.

MATERIALS AND METHODS

Risk assessment has been developed according to existing international guidelines, such as Australian Guidelines and WHO Manuals (QMRA 2016).

Table 1. QMRA methodology.

Step	Description	Formulas
1	**Dose-response relationship** (dose of pathogens with which the exposed group enter in contact)	*d = pathogen concentration × log reduction × exposure* *Exposure/event = volume (mL) with which people enter in contact in a single event of exposure during a certain activity*
2	**Probability of infection** (Pinf) related to each event of exposure to the target pathogen	$P_{inf} = 1 - (1-d/\beta)^{(-\alpha)}$ *Beta Poisson model* α,β = dose response constants
3	**Total probability of infection in one year** (of each pathogen)	$P_{inf\,(year)} = 1-(1-P_{inf})^{N}$ 1 activity N=number of exposures/year
4	**Probability of illness** (Pill) in one year	$P_{illness\,(year)} = P_{inf\,(year)} \times$ ratio of illness to infection
5	**Disability-adjusted life years (DALYs)**	DALY/year = $P_{illness\,(year)} \times$ DALY per case × susceptibility fraction

Risk assessment includes uncertainties, due to not reliable data or lack of information, which might lead to errors in the overall result (WHO, 2016). Data analysis may support the development of a robust dataset, which allows to increase the numerosity but also to include extreme events characterised by lower probability of occurrence, which are more difficult to detect by standard measures. Literature research may also be useful to define typical ranges of concentration and characteristic ratios between parameters, in case local measures are not available, not sufficient or not trustable. Models and analysis, such as multi-criteria decision analysis, fuzzy and stochastic analysis or Monte Carlo based models can help to deal with uncertainty, but their application requires specific skills. Simpler models, such as Failure Mode and Effects Analysis (FMEA) can also be used to assess water systems. FMEA analysis allows to identify the critical parameters that may have an impact on water quality, by comparing the 95th percentile with intervals defined between the lab detection limits and quality standards (ISS, 2019). The approach and the level of detail are strictly dependant from the site-specific characteristics, the available information and the required results. The methodology for risk assessment should thus be flexible and reshaped to be fitted with the specific application in exam.

Wastewater reuse

The water utility ACEA manages the territorial district of ATO2 in Lazio, Italy, and Fregene WWTP was selected to provide safe reclaimed water for irrigation purposes, since the surrounding area is voted to horticultural cultivation. The WWTP is characterised by pre-treatment, biologic CAS process, secondary sedimentation, sand filtration and UV disinfection. Data from the routinary lab analysis for the characterisation of influent and effluent wastewater were acquired, together with information on the design and operative parameters of each unit.

Run-off reuse

In order to support risk assessment for run-off water reuse, an innovative tool for stormwater management, based on a risk-based approach, is being implemented, in the context of the EU project WATERUN. Hence, a python tool (β -version) for QMRA calculation has been developed, which is able to calculate the microbiological risk for specific reuse scenarios (e.g., garden irrigation, toilet flushing) and for three different pathogens (Campylobacter, Rotavirus, Cryptosporidium). Furthermore, a preliminary version of a graphical user interface (GUI) has been created to allow the communication of a stormwater management model (SWMM) outputs with the phyton tool.

RESULTS AND DISCUSSION

Proposed methodology for risk assessment

A detailed and specific methodology for risk assessment has been developed to be implemented in water reuse applications.
The steps detailed for safe wastewater reuse (Figure 1) included a preliminary phase of system description and asset management, where the design and operative parameters of each operative unit were verified and compared with the literature working ranges, in order to define indicators for the resilience of the treatment layout. Then, a phase of data analytics was performed, in order to detect anomalies or critical conditions occurred in the plant. Once all the information was elaborated, risk assessment must be performed. A first semi-qualitative approach has been carried out, with the definition of a risk matrix that included all the hazardous events identified for each unit, according to the evaluations of the previous data analysis. A quantitative approach could be furtherly performed, in case from the previous phase a deeper analysis would be required. In that case, QMRA and QCRA could be performed to evaluate microbial and chemical risks, respectively. After that, control measures and digital support tools could be applied and implemented in the monitoring. Finally, communication and emergency procedures should be implemented.

Figure 1. Proposed methodology for risk assessment.

The presented approach has been followed to perform the risk assessment of Fregene water reuse system. Data from the WWTP has been analysed and the possible hazardous events have been identified. The FMEA has been then implemented, in order to evaluate effluent quality and identify the most critical parameters. A semi-quantitative approach was followed and a risk matrix has been developed. Scores have been attributed to the probability and the severity of each identified hazardous event, according to the results of data analysis, expertise judgement and considering the control measures applied in the plant.

A more detailed approach has been followed to assess the risks for run-off reuse. In order to provide a more quantitative information on the health outcomes from run-off water reuse and since information on pathogens in urban stormwater were available from literature, a quantitative assessment has been developed and implemented into a tool that could support users to perform a QMRA. More in detail, the developed tool allowed to perform QMRA for each pathogen and for each rainfall event that generate overflow (DWA A-118 (2006) guidelines), implementing Monte Carlo analysis for statistical reliability. This tool will provide information about water quality, indication for safe reuse practices and thus restrictions needed in the districts of the urban catchment for reuse or recreational activities after the simulated storm water event. Moreover, this risk-based tool will allow to evaluate the reduction of the health-risk after the implementation of different preventive measures through the application of different log removals.
This tool will enable stakeholders to quickly assess the risk for different activities following weather events and thus make decisions on possible reuse.

Abstract
Recovering plant essential nutrients from wastewater and converting them to value-added products is an important step for society to transition to circular nutrient management. We have developed a process that separately collects human urine and converts it into solid bio-based fertilizers containing >10% N, 1% P & 4% K. It involves adding alkaline chemicals to freshly excreted urine to stabilise nutrients like urea and ammonia so that they are not lost when urine is concentrated by evaporation. In this study, our objective was to evaluate the possibility of formulating alkaline chemicals into a multilayer tablet that is enclosed using a water-soluble or water-swellable polymer layer. We evaluate the degradation and erosion of Polypropylene (PP), Polylactic Acid (PLA), Polycaprolactone (PCL) and Polyvinyl Alcohol (PVOH) in two types of urine: $Ca(OH)_2$ treated fresh urine and $Ca(OH)_2$ treated concentrated urine, with a control using Milli-Q water. We performed destructive sampling on days 1, 2, 4, 8, 16 and 32, and analysed COD, pH and EC as proxy parameters for the degradation of polymers. Further tests such as ICP, FTIR, DSC, GPC and SEM were also conducted to determine the degradation mechanisms. PLA and PVOH were identified as the most promising polymers for urine treatment. A follow-up investigation was also done to evaluate the effect of the thicknesses of PLA films (0.05 mm to 0.25 mm) on the breakthrough time at two temperatures, 21 °C and 45 °C. Here, we demonstrated that polymer films with lesser thickness and kept at a higher temperature degraded the fastest in urine.

INTRODUCTION

Domestic wastewater fractions such as human urine contain plant-essential nutrients that can be recovered and recycled as crop fertilizers. Recovering nutrients from waste and converting them to value-added products is an important step for society to transition to circular nutrient management. Irrespective of the type of sanitation system, today most of the nutrients, energy, and water present in human urine are not recovered. A better approach to valorise resources present in human urine is to first collect urine and faeces separately using a urine-diverting toilet. When the collected urine is treated further by alkaline dehydration, a solid bio-based fertilizer with the following composition can be produced: 10% N, 1% P & 4% K on a dry matter basis (Simha et al., 2020).

To prevent urease-catalysed hydrolysis of urea present in human urine, the pH of fresh human urine needs to be increased. Several different alkaline chemicals can be added to urine to achieve this and many have already been evaluated (Simha et al., 2018). However, in present system designs, the chemicals must be added manually from time to time to a urine stabilisation reactor. These chemicals could be can be formulated into a multilayer tablet (e.g., dishwasher detergent) and enclosed using a water-soluble or water-swellable polymer layer. The dissolution rate of polymers depends on their chemical composition, properties, and thickness, as well as the composition of the solution in which they are placed. Therefore, the objective of this study was to evaluate the degradation and erosion rates of different polymers when they are added to alkalised fresh human urine.

MATERIALS AND METHODS

Fresh human urine was collected anonymously in 500 mL polypropylene bottles. The donors were both male and female and aged between 20-65 years. The total number of donations was 51 which were collected over 3 days. The total volume of urine collected was 25 L (pH= 6.05, EC= 13.7 mS/cm). To the collected urine, 10 g/L of $Ca(OH)_2$ was added and mixed for 30 min using a mechanical stirrer until the urine pH was >12. The $Ca(OH)_2$ treated urine was then put in two separate buckets, buckets A and B. Bucket A contained 8 L of the alkalised fresh urine. Bucket B contained 17 L of alkalised concentrated urine and was dried in a CO_2-free dryer (Electrolux Day Care Eco) for 48 h at 40 °C till the volume was reduced to 9.04 L. The concentrated urine (CONCU) thus produced had a concentration factor of 1.88, pH of 12.5 and EC of 26.1 mS/cm.

Laboratory grade Polypropylene (PP) pellets, Poly Caprolactone (PCL) flakes, Poly Vinyl Alcohol (PVOH) powder and Poly Lactic Acid (PLA) pellets were used to fabricate 2 mm thick polymer samples. PP, PCL and PLA samples were prepared by heat. PVOH samples were fabricated via solution polymerization technique using deionised water as the solvent. No additives were used during the fabrication process. The samples were then cut into 2 cm diameter pieces and weighed.

A follow-up experiment was conducted using a PLA sheet with 0.05 mm thickness. The sheet was moulded into 2 different thicknesses (0.1 mm and 0.25 mm) using the pressure moulding technique. CU was the only media used for the follow-up investigation and milli-Q water was used as a control. The investigation was carried out at two different temperatures: 21 °C and 45 °C.

Experimental Setup

The experiment evaluated the degradation and/or erosion kinetics of polymers in different types of urine over 32 days. All the samples were made into duplicates. 80 mL of urine was put in Petri dishes using a pipette, after which the polymer samples were placed. The setup was then kept undisturbed and covered with opaque boxes. Destructive sampling was done on every sampling day, namely day 1, day 2, day 4, day 8, day 16 and day 32, respectively.

The follow-up experiment evaluated the effect of the temperature and thickness of the polymer film on the breakthrough time and erosion. 100 mL urine was put in an airtight container containing the polymer samples. The containers that were kept at 21 °C were kept undisturbed and covered with opaque boxes. The containers that were kept at 45 °C were put in an incubator. Destructive sampling was done on every sampling day, namely day 2, day 4 and day 8.

RESULTS AND DISCUSSIONS

In the first experiment involving 2 mm thick polymer samples, there was no visually noticeable degradation or erosion. However, evaluating the proxy parameters showed signs of erosion and degradation of the samples in both types of urine concentration of COD in both types of urine. There was also loss of sample weight and a decrease in thermal properties for every polymer on every sampling day.

The second experiment demonstrated the effect of temperature and pH on the breakdown of PLA films. Films with 0.05 mm thickness broke down in 2 days at both the evaluated temperatures in CU, while 0.1 mm and 0.25 mm thick films broke down in 4 days at 45 °C (H) but did not break down at 21 °C (R). In milli-Q water, none of the polymers broke down. However, there was a decrease in the transparency of the film and they became more brittle. All the samples have been sent for further analyses, namely FTIR and GPC to gain more insight into the degradation mechanism, and the results will be presented at the conference.

PP break down into a mixture of alkanes and alkenes which will further undergo reduction due to the presence of ammonia and other ionic salts to form alkanes which are slightly basic (Gewert et al. 2015). PLA is most likely to degrade into the oligomers and monomers such as lactic acid or other compounds such as sodium lactate. These compounds are slightly acidic (pH ~ 6.5 to 7.3) (Siddiqui et al. 2020). PCL degrades to carboxylate anion and diloxanide which have a pH close to 7 (Bartnikowski et al. 2019). PVOH degrades to various hydrolases, ketones and acetic acid. While hydrolases and ketones do not change the pH or EC of a media unless introduced in a significant amount, acetic acid is a weak acid and can reduce the pH of the media (Halima, N. B. 2016).

Li et al. studied the effect of pH on the erosion and degradation of PLGA films. At pH 10.1, the breakdown of the polymer was the fastest but the decrease in molecular weight was slower than in acidic conditions. This explains the breakdown of the PLA films in urine (pH >12) evaluated in this study, and also why they are intact in milli-Q water. Literature also points to faster degradation of PLA at higher temperatures. This is because at elevated temperatures (close to the glass transition temperature of PLA) the coils of the polymer start to untangle, making it more susceptible to water intake (Teixeira et al. 2021). This explains the breakdown of all PLA films, irrespective of their thicknesses at 45 °C, while 0.1 mm and 0.25 mm thick films do not break at 21 °C. All the samples collected in our experiments have been sent for FTIR, GPC, DSC and SEM analysis, and the results will be presented at the conference.

Abstract
The use of drinking water treatment residuals (DWTR) as an adsorbent has raised attention as a sustainable option to remove emergent compounds (EC). The objective of this study was to analyse a DWTR with high activated carbon content, without any reactivation process, as adsorbent of estrone, 17β-estradiol and 17α-ethinylestradiol. The DWTS characterization results showed that it is a heterogenous material with high surface area and pore volume, which may suggest high adsorption potential. Adsorbent dosage study suggested that 0.2 g guarantees high adsorption capacity with the possibility of compounds quantification. Adsorption kinetics study points to an adsorption equilibrium at 24 h contact time. The concentrations tested for adsorption isotherm modelling where not enough to reach the maximum adsorption capacity, implying the need of further analysis with higher concentrations. DWTR showed promising results, already supported by the literature, to adsorb estrogens, and to be further tested with other types of EC.

Keywords
Adsorption processes; drinking water treatment residuals; emergent contaminants; estrogens

INTRODUCTION

The presence of emergent contaminants (EC) in aquatic environment has raised global concern. Among this group of compounds, estrogenic action hormones, such as estrone (E1), 17β Estradiol (E2) and 17α Ethinylestradiol (EE2) have been detected in concentrations ranging from ng/L to mg/L in water bodies and wastewater discharges (Tran et al., 2018). These compounds enter into the aquatic environment mainly through wastewater treatment plants (WWTP), since these are excreted through urine and faeces (Martins et al., 2022). Their presence in the aquatic environment has been well documented due to observed adverse consequences, such as the feminization of male fish and the induction of vitellogenin synthesis in fish plasma (Kasonga et al., 2021). Even though hormones are normally detected in low concentrations, these cannot be removed by conventional wastewater treatment systems, becoming crucial the development of new, easy to implement, environmentally friendly and affordable technologies to ensure their removal (Tiwari et al., 2017). According to recent reviews there is a scientific consensus which settles adsorption process as the most promising one, since it does not entail the operational and energetic costs of other treatments such as the advanced oxidation processes or the membrane processes (Rout et al., 2021). Within the scope of adsorption processes and the vast possibilities of low-cost materials for this purpose, drinking water treatment residuals (DWTR) have been tested as a suitable adsorbent material for estrogens (Dias et al., 2021; Martins et al., 2022). The objective of this study was to analyse a DWTR with high content of activated carbon (resulting from the raw water treatment and subsequent decantation), further on referred as PAC-DWTR, as adsorbent of three estrogen compounds, E1, E2 and EE2 that are commonly present in water bodies and wastewater effluents.

MATERIALS AND METHODS

Drinking water treatment residuals preparation and characterization

DWTR from a Portuguese drinking water treatment plant was used to assess their adsorption potential of E1, E2 and EE2. The procedure and results were presented by Dias et al. (2021) where the sample was air-dried and sieved to obtain a particle size of 45/60 mesh. Within the DWTR characterisation, the determination and results of elemental analysis, ash content, the pH at point zero charge and thermogravimetric analysis procedures were presented by Dias et al. (2021). The BET surface area (S_{BET}), the total pore volume (V_{total}), microporosity (V_{micro}) and mesoporosity (V_{meso}) volumes were determined according to the methodology presented by Bernardo et al.(2020). The elemental composition and surface morphology of the PAC-DWTR were analyzed by Scanning Electron Microscopy with Energy Dispersive Spectroscopy (SEM-EDS) and energy dispersive X-ray spectrometer light elements detector attachments. Functional surface groups were analyzed by Fourier Transform Infrared Spectroscopy (FTIR).

Stock Solution and Determination of The Emerging Pollutants

The stock solution preparation and the determination of the estrogens followed the procedures reported by Dias et al. (2021), where the extraction and detection of the target compounds was performed using solid-phase extraction (SPE), with Oasis HLB cartridges (200 mg, Waters), and high-performance liquid chromatography tandem mass spectrometry (HPLC-MS-MS), respectively.

Analysis of the adsorbent dosage

Four PAC-DWTR doses were prepared, 2.5 g/L, 1 g/L, 0.5 g/L, 0.2 g/L and 0.05 g/L, in 250 mL flasks, in horizontal agitation (160 rpm) to which distilled water spiked with 1000 ng/L of the stock solution was added. The adsorption capacity (*qe*) that is the amount of estrogen absorbed (ng) per mass of PAC-DWTR (g).

Adsorption kinetic and isotherms

The adsorption kinetic study was performed using a PAC-DWTR dose of 0.2 g/L in 250 mL flasks, in horizontal agitation to which milli-Q water spiked with 1000 ng/L of the stock solution was added. The adsorption kinetics was evaluated at 0, 0.08, 0.25, 0.5, 1, 2, 6, 8, 18, 24, 48, and 72 h. The kinetic data were modelled through pseudo-first-order (PFO) and pseudo-second-order (PSO) rate equations to describe adsorption data obtained under non-equilibrium as described in the methodology presented by Bernardo et al.(2020). The adsorption isotherm study was performed using a PAC-DWTR dose of 0.2 g/L in 250 mL flasks, for 24 h contact time to which milli-Q water spiked with 200, 400, 600, 800 and 1000 ng/L of the stock solution was added. The data was analysed through Langmuir and Freundlich nonlinear models to describe the maximum adsorption capacity of the material.

RESULTS AND DISCUSSION

Drinking water treatment residuals characterization

Surface characterization parameters, such S_{BET} stood out with 352 m^2/g, higher than the one presented by Martins et al (2022), without any type of structural modification. However, V_{total} obtained was lower 0.174 (cm^3/g), though 66% of the V_{total} corresponds to V_{micro}. In SEM image (Figure 1- a)) it is possible to observe the PAC-DWTR heterogeneity and the rough surfaces, which may indicate the presence of mineral matter at their surface. Which is in accordance with the PAC-DWTR's high ash content and mineral composition (Dias et al., 2021). EDS analysis to the selected area within the particle (Figure 1 – b)), indicates four major peaks, corresponding to higher percentages of oxygen (O), carbon (C), aluminium (Al) and silica (Si). Carbon high percentage could be related to the presence of PAC in the DWTR, as corroborated by Lee et al. (2020). The FTIR spectrum shows four major peeks. The stretching of -OH functional group emerged at 3436 cm-1 and in the 1638 cm-1 the bending vibrations of HO-H, due to adsorbed water molecules and hydroxyl groups presence, respectively (El-Kammah et al., 2022). The 1421 cm^{-1} stretching can be related to C=C double bond of aromatic organic matter (He et al., 2022). The peak identified at 968 cm^{-1} band can be related do OH bending or with structures bonded with Al (Lee et al., 2020) and finally, an O-Al-O stretching at 543 cm^{-1} (Hamadeen et al., 2021).

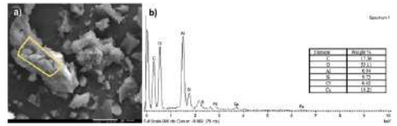

Figure 1. SEM-EDS results: a) SEM image; b) EDS spectra of the selected area of the SEM image.

Analysis of the adsorbent dosage

The three target compounds presented greater adsorption capacities at the lowest adsorbent dosage (0.05g). This behaviour is expected due to mass transference phenomena (El-Kammah et al., 2022; Martins et al., 2022). Even though, the selected adsorbent dosages for the subsequent experiments was 0.2 g, to allow full quantification of the selected compounds.

Adsorption kinetic and isotherms

The results obtained using PFO and PSO models for the three compounds showed similar determination coefficients (R^2). However, for both E1 and E2, the equilibrium time was obtained slightly sooner (around 20 h) than EE2 (closer to 24h). Therefore, the contact time selected for the adsorption isotherm study was 24 h. Different initial concentrations were not tested, and so the difference between models could not be addressed, since PFO is normally related to adsorption processes with initial concentration dependence and PSO to chemisorption processes (Martins et al., 2022). The results obtained showed that the concentrations used for each of the three compounds, where not sufficient to reach the maximum adsorption capacity. Nevertheless, the R^2 was also similar for both models (for each compound). A similar situation was described by Martins et al. (2022), who used heterogenicity parameter of the Sip isotherm model for adjustments to the Langmuir (monolayer adsorption) and Freundlich (multilayer adsorption) model. If the parameter is closer to one, the phenomena is described by Langmuir, and the opposite is related to Freundlich. Further assessment is needed within the adsorption isotherms modelling to reach maximum capacity and to better relate each adsorption model to each compound.

Though there are aspects on isotherm modelling still under assessment, this material showed to have potential for adsorption of estrogens, which is also supported by the study developed by Martins et al. (2022) and therefore, provides a possible sustainable wastewater treatment option, especially when considering wastewater reuse. Nevertheless, the use of low-cost adsorbents should always be assessed due to their leaching potential and possible ecotoxicological risks.

Abstract
In this study, it has been tested the treatability of gin spent wash in UASB reactors through anaerobic co-digestion, as a way to recover bioenergy by the production of biogas. Results showed that gin spent wash can be efficiently treated by anaerobic co-digestion with wastewaters that provide alkalinity and nutrients. At the same time, the spent wash was valorised through an efficient and stable production of biogas. Overall, this process can contribute to the generation of energy in the distilled gin industry, turning an environmental problem into a recoverable resource.

Keywords (maximum 6 in alphabetical order)
Anaerobic co-digestion; biogas; distillery wastewaters; gin spent wash; over-acidification; UASB

INTRODUCTION

The industry of production of alcoholic beverages is a very important source of wastes worldwide. In particular, distillery spent wash (DSW, the liquid fraction of the residual waste after distilled liquor production) is considered the major liquid stream from the distilled beverage production due to its high Chemical Oxygen Demand (COD) and low pH (Acharya et al., 2008). Anaerobic digestion has been suggested as a feasible treatment process for DSW, since its organic content is highly biodegradable, and in addition the spent wash is produced at high temperature (70-80ºC) (Goodwin et al., 2001). On the other hand, distilleries are high energy demanding factories, mainly for heating purposes, which increases the motivation for producing valuable biogas through the anaerobic digestion of the organic pollution of the DSW. Thus, anaerobic treatment could become of crucial interest for the distillery industry, in order to valorise the organic matter of waste, recovering resources as bioenergy in a circular economy approach.
The aim of this study was to evaluate the valorisation of DSW through biogas production in Upflow Anaerobic Sludge Blanket (UASB) reactors. The spent wash was co-digested with swine wastewater (SWW) in order to provide nutrients and alkalinity to help the anaerobic process avoiding external chemicals and alkalinity supplementation.

MATERIALS AND METHODS

Experimental setup

A cylindrical lab-scale UASB reactor with a useful volume of 1 L, made of PMMA, was used for the experiments. The reactor was maintained at 36±1ºC and the produced biogas was collected in gas bags for the determination of gas volume and methane concentration. Granular sludge from an industrial UASB reactor was used as inoculum. More details about the experimental setup and methodology can be found in Montes et al. (2019).

Substrates and mode of operation

The DSW was collected at a local gin distillery while the SWW was obtained from a closed-cycle pig farm. The UASB reactor was fed in a semi-continuous mode with a constant HRT of 3.3 days. The feed consisted of a mixture of SWW (16.7%), diluted DSW (33.3%), and effluent recycled from the UASB effluent (50%) to dilute the influent and to reuse alkalinity. The DSW was diluted with dechlorinated tap water. The experiment was divided in 8 experimental periods, increasing the organic loading rate (OLR) by increasing the content of DSW in the diluted DSW, starting from 10% dilution in period 1 and eventually achieving an 80% dilution in period 8.

RESULTS AND DISCUSSION

Biogas and methane production

The production of methane over the experimental period is shown in Figure 1(a), as the volumetric methane production rate (VMPR) versus the OLR. A very good correlation was obtained between the OLR and the VMPR until period 7, indicating that the efficiency of the process did not decrease with the increasing OLR up to 28.5 kgCOD m^{-3} d^{-1}. The reactor was able to produce a maximum stable mean VMPR yield of 8.4 m^3CH_4 m^{-3} d^{-1}, when it was fed with a highly concentrated DSW (70% dilution). When the last period was set (80% DSW in the diluted DSW), the biogas and methane production started to drop and fell to minimal values.

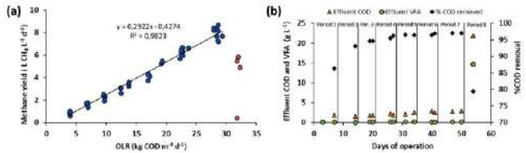

Figure 1. (a) Volumetric methane production rate (VMPR) at different organic loading rates (blue circles represent operation for periods 1–7; red circles represent the period 8); (b) COD and COD_{VFA} in the effluent and removal percentage of COD

COD removal efficiency

The content of acetic and propionic acids in the effluent, during experimental periods 1-7, was minimal with concentrations lower than 200 mgCOD_{VFA} L^{-1}, while the effluent COD ranged between 1.5 and 2.8 gCOD L^{-1}, as shown in Figure 1(b). The COD removal efficiency increased with the OLR because of the higher biodegradability of the DSW compared to that of the SWW, eventually achieving a removal efficiency of 97%. In period 8, the VFA concentration in the effluent raised to 14.7 gCOD_{VFA} L^{-1}, evidencing that the reactor failure was due to over-acidification. The last increment in the OLR caused an organic overloading that could not be compensated with the alkalinity in the medium, causing VFA accumulation, along with a big drop in the pH and inhibition of methanogenesis. To keep reactor stability, additional alkalinity should be provided by increasing the proportion of SWW in the feed or by increasing the effluent recirculation to influent ratio. In a different approach, the operational conditions of period 8 could be explored to produce and recover VFA as another valuable resource from the spent wash.

Abstract
WWTPs aim to remove and redirect nutrients from wastewater to energy generating processes efficiently. A newly built WTTP with capacity of 480 m^3/d was operated to maximize Carbon recovery while minimizing GHG (N_2O) emissions. Briefly, the plant consisted of: HRAS Biosorption, BNR, MBR for solids separation, and MBBR for pharmaceutical removal. The impact of autotrophic-driven denitrification (Anammox) and heterotrophic denitrification (conventional AS) was evaluated against the C-recovery load. Excessive C-recovery (>70% influent) lead to significantly higher N_2O emission factors (0.35 – 0.89%), compared to lower C-recovery loads (0.01 – 0.09%). Full-scale results agreed with offline analysis of specific activity for key N-removing microbes and Biomethane potential tests.

INTRODUCTION

The ambitious target for net-zero in 2030 in the water industry remains challenging. The positive effect of energy and nutrient recovery are insufficient if greenhouse gas emissions are not targeted. Within the HEPWAT national project, the municipality of Assens (AssensForsyning, Denmark), built and operated a 3.000 PE WWTP to investigate novel strategies for resource recovery, and nutrient, pathogen, and pharmaceutical removal. Experience and results would inform the design of a new 100.000 PE WWTP for the region, currently under construction. The objective of this study was to quantify N_2O emissions and the potential C-recovery as CH_4. The influent to the WWTP lies within a catchment that receives mainly municipal but also industrial wastewater (Dairy, and potentially also a brewery). The hypothesis was that increasing C-recovery also increases N_2O emissions as denitrification becomes C/N-limited (Peng, Carvajal-Arroyo, et al., 2017). Also, while autotrophic N-removal would maximize C-recovery it also poses the largest threat for high N_2O emissions. Focusing on the BNR processes the aims of this study were:

- Maximize the C-recovery load while minimizing N_2O emissions targeting either autotrophic or heterotrophic nitrogen removal.
- Perform offline analysis to elucidate the effect of operating variables for maximum C-recovery on N_2O production, on the potential N-removing activity (AOB, NOB, Anammox), and on the potential for C-recovery via Biomethane Potential tests.

MATERIALS AND METHODS

WWTP configuration

A WWTP was operated for over 300 days treating 15-20 m^3/h (3000 PE) and process performance was monitored online, and 24h samples several times per week (**Figure 1**). *BioSorption HRAS*: Aerobic MBBR (50 m^3, K5-carriers) followed by Fe and polymer dosing, and primary solids retained by a drum filter (40 µm). *IFAS*: The operational strategies adapted to lower aeration, intermittent aeration, and lower biomass set points compared to conventional activated sludge processes. *Anammox*: The filling ratio of K5 carriers was 9%, significantly lower than conventional biofilm systems (30-40%), economic reasons. *MBR*: The solids separator (52 m^3, 1500 m^2, 0.4 µm).

Experimental campaign: N_2O monitoring and offline analysis

N_2O production: The N_2O measuring campaign lasted 260 days while operation strategies for C-recovery were implemented. Two variables varied during the campaign: the total flow of wastewater treated, and the fraction of the flow considered for C-recovery in the BioSorption unit. N_2O was measured in the liquid phase in two of the Activated Sludge / IFAS reactors. Additionally, the influent, effluent, and BioSorption effluent were monitored with a lab-scale N_2O liquid sensor. The kLaO2 was estimated from the online DO data (corrected for the response time of the DO sensor) and percentage of valve opening from the blower, which was then converted into kLaN2O values. *qPCR*: Functional genes were quantified for total bacteria, 16S AOB, 16S Anammox, 16S Nitrobacter, 16S Nitrospira, Typical nosZII Atypical nosZII. *C-recovery*: The COD content was analysed for different particle sizes (<0.45, 0.45-0.70, >0.70 µm). The quantity of COD to be recovered as methane (CH_4) was studied via biomethane potential (BMP) tests after incubation period of 40 days at 35 °C and volatile fatty acids (VFA). *Offline tests*: Test the effect of (BOD/N ≫ 1) and (BOD/N ≈ 1) on the N_2O production (aerobic), and N_2O consumption (anoxic). Standardized batch tests at varying temperatures (10 – 20 – 30 °C) to monitor changes in potential Anammox activity, AOB, NOB and OUR activity.

RESULTS AND DISCUSSION

Key process performance and nutrient removal parameters

Industrial wastewater: The industrial wastewater contributed to 10% of the influent but 30-35% of COD and TN load. The COD load was comprised of particulate (39%), colloidal (18%) and soluble (43%). The BMP potential of industrial origin (dairy and brewery) was higher than that of the BioSorption unit, on-site recovery was recommended.
Anammox and IFAS: Because of the low Anammox biomass mass abundance the contribution of Anammox to the overall Nitrogen removal was difficult to distinguish and was significantly dependent on temperature (**Figure 5**), while no significant specific activity was lost for four months. Specific nitrification rates decreased over time as the Bypass flow increased, because more COD was loaded, and heterotrophic bacteria increased. The nitrifying capacity remained in excess and the total nitrogen removing capacity also increased. A 25-75% ration of Bypass-Biosorption flows at maximum influent rate (20 m^3/h) allowed for good removal of COD, BOD, SS, TP and TN (< 8.5 mgN/L). The membrane bioreactor (MBR) (TSS > 7gSS/L) acted as solids retention unit and additional nitrifying reactor (DO > 4mg/L) and hampers NOB suppression.

Nitrous oxide emissions

Increasing N_2O concentrations were observed when aeration occurred and NH_4^+ concentration was higher than ≈ 2 mgN/L (**Figure 2**). With respect to N_2O consumption, aerobic conditions slowed down, but not stopped, N_2O reduction, indicating the possibility of simultaneous N_2O production and consumption (Domingo-Félez and Smets, 2019). The daily-average N_2O emissions varied significantly, from below the detection signal of the sensor (≈ 0% emission factor) to 8.31% during an MBR process malfunction. During 41% of the days analysed N_2O emissions in the MBR were larger than in the Activated Sludge reactors, indicating that, contrary to settling tanks, MBRs are hotspots of N_2O emissions and should be considered in new WRRF designs. The higher the ratio [Bypass / Total flow], the lower the C-recovery of the process, where the [Bypass/Total flow] is, approximately, an indicator of the C/N levels in the influent to the Activated Sludge reactors (**Figure 3**). The N_2O emission factor was significantly higher when the influent to the Activated Sludge reactor consisted of C-depleted wastewater from the Biosorption unit (0.35 – 0.89%), compared to when a fraction of the raw influent was bypassed (0.01 – 0.09%). Also, the higher the wastewater load was, the higher the N_2O emission factor (**Figure 4**). Additionally, the highest N_2O emission factors corresponded to periods with the lowest TN removal efficiency. Hence, a balance between efficient C-recovery and low N_2O emissions must be found.

Conclusion: Regardless of the total flow rate treated, a C-recovery flow ratio of more than 30% resulted in high TN removal efficiencies (> 80%) and low N_2O emission factors (< 0.1%).

Abstract
Legislative developments are triggering a race against time to upgrade and optimize technologies in the wastewater treatment sector. Detailed diagnosis of aspects such as greenhouse emissions, elimination of emerging pollutants, resource recovery and energy efficiency are central elements in wastewater management. Based on this premise, this study advances a roadmap for the evaluation of the operation of wastewater treatment plants under circularity indicators.

Keywords
Circular economy; Wastewater treatment performance; Indicators; Roadmap

INTRODUCTION

The updating of Directive 91/271/EEC has just started with the aim of extending its scope and aligning it with current sustainable and circular actions. The most recent proposal was revised in October 2022 to include aspects related to greenhouse gas emissions, removal of emerging micropollutants, efficient use of energy, water reclamation and recovery of valuable resources (i.e., organic matter and nutrients) (European Commission, 2022). In this context, wastewater treatment facilities are nowadays considered not only as the focus of wastewater treatment but also the recovery of nutrients as biofertilizers and water reclamation. To this end, facilities must be subjected to rigorous scrutiny in order to obtain a complete diagnosis of their performance. Indicators can be useful as tools for the measurement of the circularity as they can be used at various implementation scales. Since the indicators provide a single score result, they are not able to provide full insight of a treatment process and the analysis should be encompassing different understandings (Moraga et al., 2019). Therefore, a system of indicators is required to assess the successful development and implementation of CE. Other studies related wastewater treatment have tried to provide a background for evaluation within the sector. For example, Preisner et al. (2022) have collected indicators for resource recovery in wastewater treatment, but they have not created a thorough framework beyond that application. Kayal et al. (2019) have designed a composite indicator monitoring the 3Rs and Kakwani et al. (2022) another one for the urban water cycle. It is perhaps the study of Nika et al. (2022) the one providing a full multi-indicator analysis (17 indicators). However, they have taken an approach very linked to the specific design of facilities and does not advocate for a top-down approach to detect needs from the legislation and the state-of-the art. For this reason, this study provides a review and roadmap based on holistic criteria extracted from legislation aimed at the quantitative measurement of the circular economy performance of wastewater treatment plants under different topic areas (i.e., water quality and energy efficiency).

MATERIALS AND METHODS

The circularity assessment can be approached on the basis of a multidisciplinary analysis, so that it is possible to identify a set of circular indicators that would quantify various dimensions of a wastewater treatment plant or technology. The assessment tool is based on three different steps: (1) review, classification and adaptation of water sector indicators for the purposes of wastewater treatment facilities, (2) identification of all possible inflows and outflows of the selected scenarios, as well as the variables needed to calculate each selected indicator, and (3) gaps and proposal of new indicators to fulfil the circular actions and products. The analysis was framed for the operational phase of wastewater treatment facility, leaving the construction and long-term maintenance of the infrastructure outside the system boundaries. It should be noted that the study provides a process or mesoscale perspective, therefore, the indicators related to the transport, storage and consumption of drinking water or those associated with the sewerage system were disregarded.

RESULTS AND DISCUSSION

Bibliographic data analysis and classification of indicators

Two types of documents were considered for revision: grey literature (reports and initiatives) and scientific articles. The result was a total of 103 water-oriented indicators (76 for the environment, 15 for economy and 12 for governance), being around 87% of them from papers. The truth is that, despite the large efforts of OECD to compiled 474 indicators different sectors (report "The OECD Inventory of Circular Economy indicators"), the concept of circular economy and the increase of interest of the scientific community in the measurement of the circular actions taken for the processes has led to a blooming of ideas and creation of indicators. In fact, by the end of 2022 the Scopus database shown that around 56% of the articles associated to the keywords of "circular economy" and "wastewater treatment" belong to the last two years. On the other hand, consensus has not been reach regarding to the classification of the indicators. The report of the OCDE arranged the indicators into 5 categories and 27 subcategories while Seghezzo et al. (2014) proposed 20 different criteria grouped within the three pillars of sustainability (5 environmental, 7 social and 4 economic) and technical aspects (4). Singhirunnusorn y Stenstrom (2009), instead, grouped them in 7 principles allocated within the technical, socioeconomic and environmental pillars and 14 more specific criteria. It is also worth mentioning the document named as "*Categorization system for circular economy*", which highlighted 14 categories assembled in circular design and production, circular value of the recovery, circular use and support. The thing is, in relation to the outcomes of this study, the quantitative indicators measuring the circularity of the wastewater sector facilities can be classified according to the pillar of sustainability around topics of design, water quality, water reclamation, energy performance nutrient traceability, sludge valorization, waste treatment, product quality, employment, education, perception and innovation. Some examples of circular economy indicators are shown in Table 1 for the theme of water quality.

Identification of inflows and outflows

The study had a two-side approach: top-down regarding to the collection of indicators and bottom-up to consider the specific needs to the facilities (both novel and conventional design) which helps detect gaps while adjusting the assessment to the process. The registered indicators required the measurement of a total of 100 variables to complete the estimation of the indicators. Some of them such as the plant influent flow rate or nitrogen and phosphorus content of the wastewater are already quantified to comply with legislation while others like the content of Al_2O_3 and the total incomes from the produced bio-based products are not usually provided.

Detection of gaps and new indicators

A list of principles, criteria and sub-criteria were extracted from 17 European directives and regulations (shown in Table 2) with the main goal to verify if the actual legislation in force, very oriented to performance and sustainability, is also adapted to the upcoming circular economy framework for indicators. The directive 86/278/EEC for the protection of the soil against sewage sludge, 2020/741 related to minimum requirements for water reclamation, 2010/75/EU about industrial emissions were the 3 of the 17 analyzed showing some advancements in circular economy. However, their focus is on monitoring (establishment on management plans, awareness campaigns, traceability of the documentation and prevention and recovery programs, among others) which is more related to a qualitative measurement than quantitative. Besides, and from the second stage of the assessment provided within this study (identification of in-out flows of wastewater treatment plants), gaps have been detected in the current dataset of indicators from literature regarding to human health and biodiversity as well as other topic under assessment for the proposal of the new wastewater treatment directive: emerging micropollutants and resource recovery (i.e., polyhydroxyalkanoates, volatile fatty acids for butanol manufacturing and celluloses).

Table 2. List of principles, criteria and sub-criteria from directives and regulations.

Pillars	Principles	Criteria	Sub-criteria

Abstract
A two-population model, implemented by modifying the Guyer matrix of the model 2C in Sumo software, was calibrated through the experimental dissolved oxygen (DO) profile to highlight the mechanisms of microbial competition and selection occurring in a mixed microbial community (MMC) comprising PHA-accumulating heterotrophic and ordinary heterotrophic microorganisms. The model takes its cue from the work of Marang et al. (2015), and further details the biomass decay processes to better represent experimental data obtained from monitoring a lab-scale bioreactor set to select PHA storing microorganisms. The model made it possible to hypothesise new control strategies for effective selection of PHA storing rich cultures.

Keywords
Calibration; dissolved oxygen; mixed microbial community; modelling; polyhydroxyalkanoates

INTRODUCTION

Polyhydroxyalkanoates (PHAs) are a wide category of bio-based and biodegradable polymers, produced intracellularly by several microorganisms, as a carbon and energy storage compounds. Currently, its industrial production process consists of using pure cultures of natural or genetically modified microorganisms as they can accumulate high amounts of PHA (up to 90% of their cell dry weight), but the costs are also high, and not competitive with conventional plastics. To reduce process costs and with the perspective of valorising specific wastes, mixed microbial communities (MMCs) instead of pure cultures are a promising alternative. Lab-scale trials have demonstrated that the MMCs can achieve cellular PHA content comparable to that of pure cultures, depending also on the complexity of the substrate. Nevertheless, the overall yields are still lower, probably due to the lower cell density (or biomass concentration) of the MMC compared to the pure one. The selected MMCs presumably consist of both conventional and PHA-accumulating heterotrophic bacteria. So far, the most robust strategy to select PHA-accumulating bacteria is the alternation of feast and famine phases, in aerobic conditions, and using selected volatile fatty acids (VFA) as substrates (Estévez-Alonso et al., 2021). To better highlight the dynamics between PHA-accumulating and ordinary heterotrophic populations and as a basis for the development of future control selection strategies, in the present study a two-population ASM-like model was developed and calibrated using of experimental data collected from a laboratory-scale sequencing batch reactor (SBR) and data taken from literature (Dias et al., 2005, Jiang et al., 2011, Marang et al., 2015). This study aims to extend the two-population model developed by Marang et al. (2015) by detailing the decay processes on the basis of preliminary experimental results reporting non-negligible concentrations of slowly-biodegradable residual-soluble organic matter (in terms of chemical oxygen demand-COD-) and predation phenomena.

MATERIALS AND METHODS

Experimental set up

An aerobic lab-scale SBR with a maximum working volume of 1.4 L has been running from 6 months. It was fed with 1 gCOD $L^{-1}d^{-1}$ of VFAs (80% acetate and 20% propionate), 30 mgN_NH_4^+ $L^{-1}d^{-1}$ of ammonium and 7 mgP_PO_4^{3-} $L^{-1}d^{-1}$ (C:N:P =100:6:1.5 in w/w proportion). The reactor operates with 12 h cycles, for a hydraulic retention time (HRT) of 1 day and with a volume exchange ratio (VER) of 50%. The feast-famine (F/F) ratio was set to 0.3 and an intermediate settling and effluent discharge has been introduced between feast and famine phases. Selection was forced by applying an uncoupled feeding: the VFA solution was dosed at the beginning of the feast while the nutrient solutions (N, P and micro-nutrients) were dosed at the beginning of the famine. The sludge withdrawal was made at the end of the cycle under mixing conditions (in the represented model, due to the need to respect the constraints imposed by the model structure, purging is immediately following the supernatant discharge) to maintain the sludge retention time (SRT) at 3.6 d. The temperature in the reactor was controlled at 27 ±0.5 °C, while pH varied between 8.4 and 8.9. The dissolved oxygen (DO) profile, obtained by monitoring with an optical probe (S423/C/OPT/T, Chemitec), has been used to calibrate the model.

Activated sludge model

The model Sumo 2C, developed by Sumo (Dynamita S.A.R.L., France), was modified for including the PHA-storage heterotrophic organisms (X_{PHO}), not available in the library (different from the polyphosphate- and glycogen-accumulating organisms, PAO and GAO, respectively), to simulate the competition with the ordinary heterotrophic organisms (X_{OHO}). In the modified model X_{OHO} and X_{PHO} populations are the only two microbial populations. The reactions involved are as follows and represented in the schematic in Figure 1: storage of VFAs (S_{VFA}), growth on VFAs, growth on PHA (X_{PHA}) and decay for X_{PHO}, growth on S_{VFA}, growth on readily and soluble biodegradable substrate (Ss) and decay for X_{OHO}.

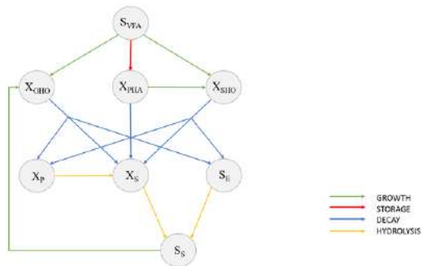

Figure 1. Schematic of the processes involved in the model (only the carbon cycle is reported).

Both X_{PHO} and X_{OHO} decay were defined in three different compounds: particulate slowly hydrolysed (X_P), particulate readily hydrolysed (X_S) and soluble-decay-products slowly-biodegradable (S_E) compounds. The hydrolysis processes convert X_P in X_S and both X_S and S_E in S_S. Table 1 shows the stoichiometric and kinetics parameters picked up for the simulations.

Table 1. Overview of the model input: stoichiometric and kinetic parameters for OHO and PHO.

Stoichiometric parameters	**Description**	**Value**		**Reference**
$Y_{PHO,VFA}$	Yield of PHO on VFA	0.4	g COD. g COD-1	Dias et al., 2005
$Y_{PHA,VFA}$	Yield of PHA on VFA	0.55	g COD. g COD-1	calibrated

Kinetic parameters BIO	**Description**	**Value**		**Reference**
$K_{NHx,BIO}$	Half-saturation of NHx	0.1	mgN L^{-1}	calibrated

RESULTS AND DISCUSSION

Figure 2 shows the calibration results of a simulated DO profile along the experimental one. The VFA and ammonium concentration profiles reflect experimental trends, while PHA concentration has a profile consistent with that predicted; VFA decreases and it is totally consumed before the end of the feast phase, meanwhile accumulating PHA and consuming oxygen. During the famine phase, after ammonium dosing, PHO grow on stored PHA, consuming nutrients and oxygen (Fig. 3). The volatile suspended solids (VSS) concentration provided by the model are approximately 430 mg L^{-1} (consistent with the experimental value, 490 mg L^{-1} ca.). The most abudant population selected on average is that of PHA-accumulating microorganisms (250 mgCOD L^{-1}), the rest are OHOs (200 mgCOD L^{-1}). The effluent mostly contains both S_E and S_S (for a total of 70 mg sCOD L^{-1}), representative of the residual experimental COD measured at the end of the famine phase. Calibrating the model on the basis of the experimentally monitored DO profile seems to achieve the purpose. Moreover, many DO data are easily obtained from the bioreactor monitoring; collecting several DO values over time is relatively simple, provided the bioreactor is equipped with a DO probe. Several insights emerge from the results of the simulations. For instance, the feast and famine phases duration is not perfectly optimised, thus still favouring the OHO rather than the PHO. Adjusting the duration of the two phases could lead to richer communities of accumulating PHA microorganisms.

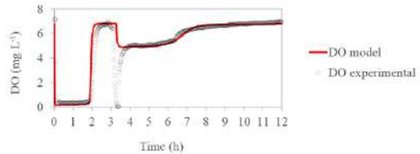

Figure 2. Model calibration results: comparison between experimental and modelled DO profile.

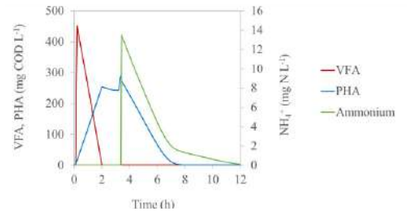

Figure 3. Results of the simulation: VFA, PHA and ammonium (as representative nutrient) profiles along one cycle.

Improvement of activated sludge systems: should we pay more attention to the role of EPS?

Abstract
Understanding links between bioflocculation, settling and extracellular polymeric substances (EPS) in activated sludge (AS) systems presents a challenge, but is necessary to describe and optimize bioprocesses. This study provides a comprehensive approach, including new insights to characterize the role of EPS in AS systems, to reduce energy and environmental treatment costs. AS samples were taken in a wide range of full-scale facilities including conventional AS (CAS), high rate AS (HRAS) and densified sludge processes. Complementary and innovative protocols were selected to analyse EPS content and nature, as well as bioflocculation and settling efficiencies. Links between EPS, bioflocculation and settling were observed under different operating conditions. One sampling and analysis campaign on two full-scale plants and a pilot plant is presented in this abstract. More investigations on six other processes will be scheduled in four sampling campaigns in the forthcoming months.

Keywords: Bioflocculation, Biological process, EPS, Settling

INTRODUCTION

The transition from wastewater treatment plant to wastewater resource recovery facilities requires solutions to optimize energy efficiency of activated sludge (AS) processes and to reduce their overall environmental footprint. Current solutions such as carbon capture and valorisation (using chemically enhanced primary treatment and/or high rate activated sludge) or the use of sludge densification enable to reduce treatment costs, but there is still a need to maximise organic matter capture for recovery and to reduce energy needs. Better understanding the role of extracellular polymeric substances (EPS) and their link with bioflocculation and settling mechanisms was recently highlighted as a way to optimize AS processes (Ngo et al., 2022; Van Winckel, 2022, Yang and Li, 2009). EPS are produced by bacteria, they are composed mainly of proteins and sugars that form a matrix around cells, which interact with the external environment. Results related to the role of EPS in AS available in literature show no consensus. Some studies demonstrate that EPS are responsible for good bioflocculation (Ngo et al., 2022; Van Winckel, 2022), others that EPS generate poor settling (Liao et al., 2001), and a study even conclude that there is no link between EPS and process performances (Kinyua et al., 2017).

The first challenge is to quantify EPS concentrations, which is linked to their complexity and the lack of standardised protocols. This explains the difficulty to reach a consensus in addition to the very large range of experimental conditions (scale, processes and wastewater types).

The objective of this study was to analyse samples of mixed liquor simultaneously for EPS characterisation, bioflocculation and settling with the aim to develop complementary insights.

A comprehensive approach has been followed, consisting of:

- Selection of robust and easily applied protocols accepted by the scientific community as well as recently developed ones to a general understanding of the mechanisms;
- Sampling of full-scale systems to characterise processes ongoing under real conditions;
- Sampling of a large panel of AS processes (CAS, HRAS, densified sludge) in several campaigns to characterise mechanisms under a wide range of conditions.

One sampling and analysis campaign on two full-scale plants and on one pilot plant is presented in this abstract. A full series of data including six more plants investigated with four more campaigns as well as several other parameters measured will be available in June 2023.

MATERIALS AND METHODS

Biological processes

AS samples were collected from the biological reactor of one full-scale CAS system, one full-scale densified AS system and one HRAS pilot plant (as presented in Table 1) and analysed for bioflocculation and settling within 30 minutes and for EPS within 4 hours after sampling.

EPS

Total EPS (EPSt) were extracted by using the cation exchange resin (CER) extraction method developed by Frølund et al. (1996). This protocol enables a good extraction while limiting cell lysis. Loosely Bound (LB) and Tightly Bound (TB) EPS were extracted by using a heat extraction method modified based on Li and Yang (2007). This method is complementary to the first one by giving information on EPS structure; both are easily performed even under field conditions. Once extracted, EPS were quantified by measuring the total COD content using WTW® micro-methods.

Bioflocculation and settling

Conventional methods as diluted Sludge Volume Index (dSVI), Effluent Suspended Solids (ESS) measured by the TSS (Total Suspended Solids) of the dSVI supernatant, and initial settling velocity were determined with standards methods (APHA 2005). Limit Of Stokesian Settling (LOSS) was determined by using the method of Mancell-Egala et al. (2017). LOSS provides the minimal sludge concentration at which flocculent settling transitioned into hindered settling. The combination of these macroscopic physical behaviours of sludge with the biochemical characterisation of EPS enable to better understand the link between EPS, bioflocculation and settling mechanisms.

RESULTS AND DISCUSSION

As expected, HRAS sludge presents the lowest settling velocity and the largest ESS reflecting the presence of weak flocs having a low density (Table 1). The observed dSVI and LOSS of HRAS are in between those measured for CAS and densified process.

Densified sludge presents a low dSVI and a high LOSS, corresponding to a good compression capacity, and a high settling velocity. This can be the consequence of a greater sludge density that settles faster with higher compression capacity. ESS is not significantly different from that of CAS.

Table 1. Operating parameters, bioflocculation and settling performance of full scale and pilot reactors

	CAS	Densified	HRAS
SRT (d)	15	20	1.5
Organic loading rate (gDBO/gVSS/d)	0.09	0.18	3
TSS (g/L)	2.97	2.94	2.30
VSS (g/L)	2.39	2.43	1.92
dSVI (mL/g)	151	81	129
ESS (g/L)	0.005	0.010	0.061
Settling velocity (m/h)	1.8	4.1	1.2
LOSS (mg/L)	1060	1580	1079

EPSt concentrations (Figure 1) are similar to those obtained in other comparable studies (Ngo et al., 2022; Van Winckel, 2022).

EPSt and LB-EPS are larger for HRAS. As LB-EPS make flocs less dense, their settling velocity is lower. LB-EPS have relatively low cohesion strengths. Their high concentration makes flocs more sensitive to deflocculation, they can break down easily, which is likely to corroborate the high ESS. The positive correlation between LB-EPS and ESS was also observed by Yang and Li (2007) in a 2 L AS reactors (SRT ~ 5-20 d) fed with synthetic water.

With this high LB-EPS, one can expect a larger dSVI and a lower LOSS. Therefore, the following hypothesis can be formulated: the good compressibility observed is related to isolated particles, generated by deflocculation, rather than diffuse flocs. This initial floc structure is due to the short sludge retention time, which does not allow flocs to aggregate strongly.

More TB-EPS would be expected in the densified sludge, as TB-EPS are presumably responsible for strong aggregation. However, there is no significant difference in the concentration and structure (i.e. TB and LB-EPS) of the EPS between densified and CAS sludge. This can be a consequence of EPS extraction. The protocol developed for flocs may have limits to extract EPS from robust aggregates. More aggressive methods might be required. Therefore, there is still a need to develop a method enabling to compare EPS in flocs and granules.

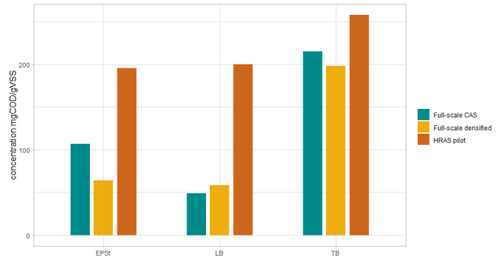

Figure 1. EPSt, LB-EPS and TB-EPS concentration in full-scale and pilot reactors

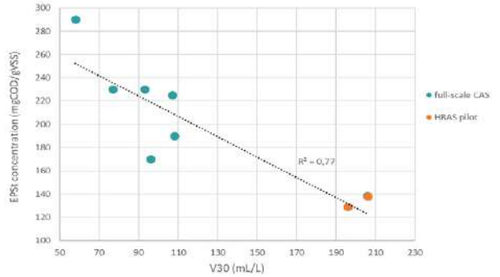

Figure 2. Relation between V30 and EPSt in HRAS pilot and CAS processes

Results were analysed to draw correlations between EPS, bioflocculation and settling efficiencies. As an example, a correlation was observed between V_{30} and EPSt (Figure 2). This suggests that the presence of more EPSt increases the capacity of flocs to aggregate and, therefore, the overall compressibility. Investigations are still under progress, a larger set of data will enable to perform more statistical tests and to highlight other potential correlations.

CONCLUSION

These preliminary investigations provide the following conclusions:

- Links between EPS, bioflocculation and settling can be observed under different operating conditions.
- Protocols for EPS extraction still need to be adapted for specific sludge types (e.g. densified sludge).

Other results are expected both in terms of investigated parameters, such as bioflocculation characterisation (e.g. Threshold of Flocculation (TOF)), EPS composition (e.g. ratio protein/sugar), floc investigation (particle size and morphology analysis) and additional data sets in the upcoming campaigns.

Abstract
The new European policies to achieve a carbon neutral Europe in 2050 are increasingly strict and call for increasing the use of renewable energy and implementing technologies based on hydrogen, biogas and biomethane. The BIOUP project will offer a "power-to-gas" solution for the use in the form of biomethane ((above 90% in CH_4 content) of green hydrogen from surplus renewable energy, which cannot be used at certain times of the day. For this purpose, an in situ pilot plant and ex situ pilot plant (biotrickling filter) will be integrated into the sludge line of a WWTP. Thus, the conversion of biogas into biomethane will be studied and optimized, evaluating a series of scenarios, also studying the different energy supply options for the generation of green hydrogen through the HOMER and XENDEE energy simulators.

Anaerobic digestion; biogas; ex situ; in situ; power-to-gas

INTRODUCTION

The new European and national policies to achieve a carbon neutral Europe in 2050 are increasingly strict and call for increasing the use of renewable energy and implementing technologies based on hydrogen (H_2), biogas and biomethane. The BIOUP project will offer a "power-to-gas" solution not available until now, for the use in the form of CH_4 of green H_2 from surplus renewable energy, that may exceed conventional demand at certain times of the day. To this end, it will develop a technology that will biologically enrich WWTP anaerobic digested sludge biogas (60% in CH_4) from the anaerobic digestion of sewage sludge through the biomethanation of CO_2 contained in it, with renewable H_2, so that the upgraded biomethane generated have sufficient quality to be injected into the natural gas network (> 95% in CH_4) or used directly in transport vehicles (> 90% in CH_4). The BIOUP project aims to develop and validate a technology for the biological transformation into CH_4 of H_2, from renewable sources, and carbon dioxide (CO_2), generated in the anaerobic digestion of organic matter. This technology fits the particularities of WWTP, which have large volumes of anaerobic digestion of sludge and a clear need to increase the energy efficiency of their operation.

MATERIAL AND METHODS

BIOUP will address the assessment of in situ and ex situ biomethanation technologies. In the case of the in situ technology, laboratory tests will be carried out to determine the technical feasibility and the optimal design conditions and parameters of the biomethanation process, in order to determine the best operating conditions, together with the potential effect of the codigestion and different alternatives to improve H_2 transfer. The study of microbial populations of the processes will also take place through the project, in order to offer a deeper insight of the biodynamics of the system. Subsequently, with the data obtained, a 5m^3 prototype will be designed and built for the validation of the technology on a pilot scale. It will be installed in a real WWTP, to use real sludge to feed the in situ biomethanation digester. For ex situ biomethanation, biotrickling filter (BTF) technology will be assessed as a way to support the specialized biomass that will metabolize the H_2 and CO_2 contained in the biogas, potentially coming from a conventional digester, or in the eventually poor biomethane coming from a previous in situ system with incomplete conversion. Again, the study of this technology will be addressed from lab and pilot scales approaches. To start with, the feasibility of using the centrate from the AD of sludge, rich in ammonium and micronutrients, as nutrient source for ex situ biomethanation will be evaluated so that the use of chemicals for biomass subsistence is minimized. Together with this one, other operational conditions will be explored to obtain the best operational strategy and design for a 150L pilot plant that will also be installed in a real WWTP. In this case, biogas coming from the real scale anaerobic digestion or the eventually poor biomethane produced in the in situ pilot plant with incomplete conversion would be fed to the pilot BTF. Daily monitoring of the pilots will be carried out, analysing the critical physicochemical parameters to know the evolution of the process, measuring the quality of the biogas obtained. Thus, the conversion of biogas into biomethane will be studied and optimized. In parallel to the empiric work to be carried out in the project, BIOUP will also study the different energy supply options for the generation of green H_2 through HOMER and XENDEE energy simulators, in order to design a competitive strategy to implement this kind of technology in a real scale, depending on the renewable energy scenario of different locations.

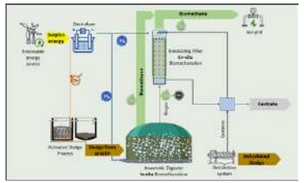

Figure 1. Concept of the BIOUP project for the generation of CH_4 in the WWTP.

EXPECTED RESULTS

The conclusions obtained in the project will make it possible to establish the application settings of the BIOUP technology in a real environment in existing or newly built WWTP. Among the main aspects and improvements to be achieved with the project, the following stand out:

- Through one stage or two stage strategies, to produce biomethane that meets the specifications for use as transportation fuel (>90% CH_4) and for injection into the network (>95% CH_4).
- Obtain a "power-to-gas" system that allows improving the energy performance of the WWTPs, generating 0.4 kW/m^3, with the aim of promoting the energy self-sufficiency of these facilities or becoming a source of extra income by injecting biomethane (which price ranges between 50 and 150 €/MWh) into the gas network.
- Demonstrate that an energy improvement of up to 25% per kg of TSS treated can be achieved compared to conventional systems by enriching the biogas stream and reducing the aeration needs to remove nitrogen.
- Contribute to the circularity of water sector by boosting the energy recovery of WWTP sludge, producing an energy vector from residual biomass that helps the use and production of renewable energy in a WWTP.
- Advance in the decarbonization of the energy system and the water treatment sector.
- Expand the portfolio of ACCIONA technologies applicable in a WWTP, which allow flexibility and maximize the use and recovery of resources.

Energy recovery from olive mill waste streams

Abstract
The lack of cost-effective strategies for the treatment of Olive Mill Waste Streams (OMW) compromises the sustainability of the olive oil sector and hinders the transition towards a circular economy. In the present study, the anaerobic digestion of OMW and its co-digestion with pig manure were investigated in semi-continuous reactors. Results showed that the co-digestion with pig manure improved the methane yield 3.5-fold, which was attributed to an increase in the buffer capacity, dilution of phenolic compounds concentration and nutrients balance. Moreover, an energy balance showed the feasibility of scaling-up the process. Therefore, this consolidated technology appears as a promising solution for the co-treatment and bioenergy recovery from agro-industrial waste streams.

INTRODUCTION

Olive oil production is of great economic importance for the Mediterranean region. However, this agro-industrial sector still lacks sustainable, cost-efficient strategies for the management of generated waste streams (OMW). In Spain only, being the first olive oil producer worldwide, over 10 million tons of olive mill by-products are generated every year (ANEO 2019).

Anaerobic digestion arises as an effective technology for the treatment of organic wastes, such as OMW, with the added benefit of renewable energy generation in the form of biogas. Nonetheless, specific characteristics of OMW, i.e., high concentration of solids and lignin presence, phenolic content, low alkalinity, and high C/N ratio, can constrain the anaerobic digestion performance. Thus, anaerobic co-digestion with nitrogen-rich co-substrates has been investigated to enhance the process stability and biogas outcome.

Despite the energy production from agro-industrial waste streams is not a new process, the industrial implementation and execution continue to be a challenge. The aim of this work is to evaluate the anaerobic digestion of OMW and co-digestion with pig manure in terms of biogas production using semi-continuous lab-scale reactors and the feasibility scaling-up the process.

MATERIALS AND METHODS

OMW and pig manure were obtained from an integrated storing and drying facility and a local farm, respectively, located in Seville, Spain. The physicochemical characterization of both substrates is shown in **Table 1**.

Two semi-continuous reactors with 1.7L of effective volume were inoculated with an adapted inoculum and operated for 126 days. The reactors were operated at an organic loading rate of 1 g VS/L·d, a hydraulic retention time of 21 days and mesophilic temperature (37°C), in accordance with previous experiments (Serrano et al., 2017).

The methane production was daily measured by water displacement, after removing CO_2 from the biogas stream using a 3N NaOH solution. The pH was daily monitored, but not controlled. Soluble samples of the digester effluents were analyzed in terms of chemical oxygen demand (sCOD) by the colorimetric standard method 5220D (APHA 2017) (daily) and volatile fatty acids (VFA) by gas chromatography (three times per week). Effluent samples were also analyzed two times per week in terms of total alkalinity (TA) using pH titration to 4.5; total and volatile solids (TS and VS) by APHA procedure 2540G; ammonia nitrogen by APHA 4500-NH_3 C; and total and soluble phenols following the Folin-Ciocalteu method (Box 1983; APHA 2017).

Experimental results were used to perform a feasibility study for an industrial scale plant for the co-treatment of both residues. Theoretical energy balances considered thermal and electric power requirements of the proposed system (anaerobic digestion coupled to a 120kW combined heat and power (CHP) facility), and the energy produced upon steady-state operation of lab-scale reactors.

RESULTS AND DISCUSSION

OMW anaerobic mono-digestion

During the first experimental period (day 1 to 63) the anaerobic mono-digestion of OMW was evaluated. The methane yield was in average 51 mL CH_4/g VS (**Figure 1a**), a poor value resulting from low organic matter removal (11%), as indicated by the accumulation of VS and sCOD towards the end of this experimental period. These results are far below those reported for the anaerobic digestion of OMW in batch reactors, i.e. 321 mL/g VS (Fernández-Rodríguez et al. 2014) and semi-continuous reactors, i.e. 220 mL/ g VS (Stoyanova et al. 2017).

Process instability was suggested by low pH values (5.5-6) (**Figure 1a**) and a concomitant increase in VFA concentration, which raised from 3,731 to 6,053 mg COD/L (**Figure 1b**), acetic and propionic acid being the most abundant. Moreover, the average concentration of total phenols in the reactor was 1,406 mg gallic acid/L, which is close to the proposed methanogenic activity inhibition threshold of 1,500 mg/L (Monlau et al. 2014).

OMW anaerobic co-digestion with pig manure

During the second experimental period (days 64 to 126) the co-digestion of OMW with pig manure was assessed. The results showed that the methane yield increased by 3.5-fold as compared to the mono-digestion (from 50 to 175 mL CH_4/g VS). This was attributed to the alkalinity increment, the balance of nutrients (C/N ratio decreased from 33 to 28) and dilution of phenolic compounds by 70%.

Energy balance

Based on experimental data, it was estimated that the proposed digester produced 966 Nm^3 CH_4/day to be fed to a CHP plant. The energy balances showed that the CHP plant was able to provide enough thermal and electric energy for the anaerobic digestion facility to be self-sufficient and excess green electricity to be fed to the grid (**Figure 2**). Moreover, the stabilized digestate could re-enter the olive oil production cycle as a biofertilizer or be used in different agro-industrial applications.

These findings support the anaerobic digestion technology as a promising solution for the sustainable co-treatment of OMW along with other agro-industrial waste streams in Mediterranean countries, and contribute to the transition towards a circular economy in the olive oil sector.

Table 1. Physicochemical characterization of the substrates (olive mill waste stream (OMW) and pig manure)

Parameter	OMW	Pig manure
pH	4.58 ± 0.10	6.53 ± 0.12
Total alkalinity (mg $CaCO_3$/L)	n/a	25.79 ± 1.01
Electrical conductivity (mS/cm)	1.41 ± 0.03	1.29 ± 0.02
Total solids (g/L)	252.60 ± 3.00	374.44 ± 4.65
Volatile solids (g/L)	236.85 ± 3.12	218.43 ± 10.01
Chemichal Oxygen Demand (g O_2/L)	351.17 ± 3.55	263.62 ± 4.58
Soluble chemical oxygen demand (g O_2/L)	135.35 ± 1.75	51.96 ± 4.88
C/N	34.59 ± 1.18	16.89 ± 1.17
N-NH_4^+ (g /L)	147.93 ± 7.85	832.85 ± 24.98
Total phenols (g gallic acid/L)	10.18 ± 0.35	n/a
Soluble phenols (g gallic acid/L)	4.82 ± 0.58	n/a
3,4-dihydroxyphenylglycol (mg/L)	295.80 ± 5.79	n/a
Hydroxityrosol (mg/L)	2749.65 ± 64.75	n/a
Tyrosol (mg/L)	798.63 ± 10.64	n/a

Abstract
Technologies for nutrient recovery have generated industrial and academic interest as part of the circular economy strategy, since they contribute to an efficient management of available resources and to the environmental sustainability. Among the different technologies to recover ammonia, bioelectrochemical systems (BESs) are innovative systems with lower energy consumption and less chemicals requirements than traditional methods. Nevertheless, several limitations may hinder its industrial development such as the development of a resilient electroactive biofilm on the electrode surface with tolerance to high ammonia concentrations, and the need for electrode and membrane materials that could perform at long term operation and at high current density. This research seeks to provide information on the progress made in recent years to obtain high performance BESs for ammonia recovery. Details of the different configuration of the reactors and main performance parameters are described. Finally, this work will provides conclusions and future perspectives of this technology when compared to the current state-of-the-art.

INTRODUCTION

The fundamental transformation towards a circular economy creates a demand for an efficient recovery of energy and nutrients (e.g. N, P) from wastewater. In urban and industrial wastewaters, the inorganic nitrogen is mainly represented by total ammonia nitrogen (TAN) in two forms of reactive nitrogen, NH_3 and NH_4^+ (Kuntke et al., 2018). The different approaches used to recover TAN from wastewater can be classified into chemical, physical, and biological processes. The chemical and physical processes include struvite precipitation (Li et al., 2012), ammonia stripping (Kim et al., 2021), reverse osmosis (Shin et al., 2021), ion exchange (Ding & Sartaj, 2016) and the use of gas-permeable membranes (Hou et al., 2018). Biological processes for NH_3 recovery are based on the use of BESs (Kuntke et al., 2018). BESs are biologically catalyzed electrochemical systems that consist of two connected electrodes. The biological catalysts are electroactive microorganisms capable of exchanging electrons with a solid electrode. The electrons released in the organic matter oxidation on the anode surface travel through an external circuit to the cathode and the electrons are donated to a terminal electron acceptor. The electron flow can drive the transport of TAN through a cation exchange membrane (CEM) and thus allow its recovery with a minimal dosage of chemicals for pH control and with simultaneous production of other valuable compounds such as electricity or hydrogen (Kuntke et al., 2018; Rodríguez Arredondo et al., 2015). The most relevant BESs configurations for TAN recovery are the Microbial Fuel Cells (MFCs), Microbial Electrolysis Cells (MECs), Microbial Desalination Cells (MDCs) and Bioelectroconcentration Cells (BECs) (Figure 1). If the oxidation and reduction reactions are spontaneous and electrical energy is produced, this system is called MFC. In MECs, external energy is applied to drive the oxidation and reduction reactions. MDCs are MFCs modified with an anionic and a cationic membrane placed between the cathode and anode chamber, which allows ionic species to be recovered in a middle chamber without electrical energy input (Cao et al., 2009). BECs are similar to MDCs, with the major difference that BECs require electrical energy input that can be used to recover ionic species in a concentrate chamber. The bioelectrochemical NH_3 recovery in BESs occurs in three main steps (Iddya et al., 2018) (Figure 1): i) the electric current resulting from the microbial oxidation drives the transport of NH_4^+ cations from the anode to the cathode chamber to maintain the charge neutrality; ii) conversion of NH_4^+ to NH_3, since the reduction reaction on the cathode surface increases the pH above 10, where NH_3 dominates *vs* NH_4^+ (pKa 9.24 at 25 °C); and iii) NH_3 is recovered, e.g. by stripping and gas diffusion membranes (Kuntke et al., 2018).

Many advances have been made with the reactor configurations, scaling up and recovery/removal efficiencies and new challenges have been encountered (Lee et al., 2022, Kuntke et al., 2018; R. Sharma et al., 2022; Xiang et al., 2020) since previous reviews focusing on bioelectrochemical NH_4^+removal and recovery were published. The aim of this work is to provide a comprehensive overview of the current state of these systems, benchmark them with other existing methodologies for TAN recovery and to provide recommendations for its design. This work revises the last manuscripts related to bioelectrochemical NH_3 recovery and focuses on comparing its performance results obtained in the past studies as a function of the configuration of the reactors and the influent wastewater. The focus is set to TAN recovery (e.g. stripping or precipitation) and the inclusion of innovative materials as gas diffusion electrodes.

RESULTS AND DISCUSSION

Forty-eight manuscripts related to bioelectrochemical NH_3 recovery in two scientific databases (Web of Science and Scopus) between 2019-2023 were reviewed. Most of them were related to MECs. MECs require an energy input, but the NH_3 recovery rate can be increased in this configuration using different strategies (Kelly & He, 2014). For example, Cerrillo et al. (2021) reported a NH_3 recovery rate of ~36 g N m^{-2} d^{-1}, coupling a MEC and a hydrophobic membrane. So, the use of this hydrophobic membranes could be an interesting strategy for the improvement of NH_3 recovery in MECs reactors. About the electrical current density produced in MECs, Wu & Modin (2013) reported a high electrical current produced in MECs (28 A m^{-2}) with an ammonia recovery efficiency of 94 %. This value could be considered interesting, nevertheless, more efforts should be done to improve the electrical current density produced in MECs, as the NH_4^+ transport through the CEM is driven by the current that is produced in the reactor. Regarding MFCs, the highest NH_3 recovery rate reported for Kuntke (2013) was 9.6 g N m^{-2} d^{-1} with an electrical current density of 2.6 A m^{-2}. However, this MFC rate was less than a half of the MEC rate reported by Cerrillo et al (2021). Zhang et al. (2022) reported an MFC coupling with a stripping unit for NH_3 recovery with a current density of 1.2 A m^{-2} and a NH_3 recovery rate of 6.9 g N m^{-2} d^{-1}. Low NH_3 recovery rates in MFCs can be increased by changing them into MECs, which produce more current due to the applied power (Kuntke et al., 2014).

Finally, innovative configurations such as MDCs and BECs have gained interest for nutrient recovery. Particularly, the BECs used mainly with urine for NH_3 recovery shows an interesting performance. Ledezma et al. (2017) reported an ammonia recovery rate of 430 g N m^{-2} d^{-1}, which is the highest value of NH_3 recovery determined until today for BESs. This high value is related to the high current density of 37.8 A m^{-2} reached by the system. MDCs reactors have also achieved high recovery rates. Zhang et al. (2015) reported a recovery rate of 80 g N m^{-2} d^{-1} using a novel submersible MDC. In this case, an electrical current density of 2.85 A m^{-2} was produced. All these results are interesting in comparison with the values obtained for the other configurations reviewed. Moreover, more critical analysis will be presented about other parameters related to the performance of BESs. For example, the electrode materials. Electrodes with high conductivity and biocompatibility allows to reduce the internal resistance in the system. The NH_3 concentration is relevant since high concentrations can be toxic. Thus, acclimation of the biofilm may be necessary. The load ratio (ratio between the current density and the TAN loading rate) shows whether the current density of the system is limiting NH3 transfer rate. Finally, the presence of other cations that can compete with ammonium when balancing electroneutrality will be detailed and discussed.

Abstract

Alterations in the parameters that allow controlling the quality of the water, such as excess contaminants in it, appear more and more frequently. There are many areas with problems of excess concentration of nitrates, nitrites, phosphates, ammonia, etc., which reach concentration levels higher than those allowed and which can affect human health. As well as potentially toxic elements (PTEs) V, Cr, Zn, Co, Pb, Ni, Cu, As and Cd. In addition, there are cases of contamination with Enterobacteria and Coliform bacteria, present in the aquifers used for crop irrigation and in the food itself.
In this study, the potential of microalgae for the elimination of contaminants and pathogens in wastewater has been simulated. For this, a photobioreactor has been used, simulating temperature and light conditions similar to those existing outside.
The concentration of the main contaminants in the water at the entrance and exit of the photobioreactor has been monitored. It has been analyzed: COD, phosphates, ammonium, organic matter. The disinfection capacity of microalgae has been studied by analyzing pathogens such as E. coli and total coliforms present in the water. As well as monitoring the algar biomass concentration.

Keywords
Contaminants; disinfection; microalgae; pathogens; photobioreactor; simulation.

INTRODUCTION

There is an increasing deficit of pure water suitable for consumption, as a result of climate change, which is affecting temperature and rainfall. Greenhouse gases are the main drivers of global climate change (Hu et al., 2021). There is less and less rainfall or it is in the form of a storm, affecting the availability of pure water. The main causes of contamination depend on human use in mining and the misuse of commercial fertilizers applied in agriculture and intensive agriculture (Liu et al., 2021). Alterations in the parameters that allow controlling the quality of the water, such as excess contaminants in it, appear more and more frequently. In drinking water, problems of excess concentration of nitrates, nitrites, phosphates, ammonia, etc. appear in many places, which reach concentration levels higher than those allowed and which can affect human health (Wang et al., 2022). As well as potentially toxic elements (PTEs) V, Cr, Zn, Co, Pb, Ni, Cu, As and Cd (Liu et al., 2021). In addition, there are cases of contamination with Enterobacteria and Coliform bacteria, present in the aquifers used to irrigate crops and in the food itself. According to the WHO, it is estimated that one in ten people contract diseases from eating spoiled food. Every year 420,000 people die from consuming food contaminated by microbial agents (Bari & Yeasmin, 2018). By the year 2050, it is expected that the demand for water will increase by 40%, and the demand for energy will increase by 50%, this is influenced by the need to increase food production by 60% (FAO, 2015).
That is why it is necessary to apply an economical and more environmentally friendly solution, using purification systems with low energy consumption (Chong et al., 2021). The cultivation of microalgae for wastewater treatment can be an alternative solution to conventional purification systems, since it can remove inorganic nutrients such as nitrogen and phosphorus present in wastewater through photosynthetic activity (Dolganyuk et al., n.d.). In addition, in this process it is possible to fix carbon dioxide (CO_2), the main compound that causes the greenhouse effect. (Fthenakis & Kim, 2012). The digestate from anaerobic digestion can be used for the cultivation of microalgae since it has nutrients that allow the growth of microalgae (Chong et al., 2021).

MATERIALS AND METHODS

The cultivation of microalgae is carried out in a continuous photobioreactor. Using pig slurry diluted with distilled water with a concentration between 1:20 and 1:40 as a substrate to adjust the concentration in order to maintain a COD in the range of 0.5 and 1.0 g/l.
The photobioreactor is a stainless-steel cuvette that simulates a small-scale raceway-type photobioreactor. It can work at different heights of water column 20, 25 and 30 cm deep. Simulating standard conditions in microalgae lagoons. This has a pump programmed for the introduction of residual water. And a pumping agitation system, to maintain the homogeneity of the microalgae culture.
As a light source for the development of photosynthetic activity and growth of microalgae, a Philips LED light source is used, simulating the intensity of sunlight. For this the lamp is connected to a microcontroller. In addition to light, in order to simulate outdoor conditions, a SELECTA Frigiterm brand thermoregulator is used, through which the temperature can be adjusted to simulate the desired season of the year.
In addition, different parameters are monitored by sensors: temperature, pH, dissolved oxygen (D.O), solar irradiation (PAR).

Figure 1. Stainless steel photobioreactor for microalgae cultivation with light and temperature simulation.

RESULTS AND DISCUSSION

Under winter conditions, a lower elimination of ammonia 20.72% is achieved than in summer conditions 78.26%. Regarding the elimination of phosphorus, a greater elimination is achieved in summer 69.83% than in winter 34.83%. This is since algar biomass grows faster with high temperatures such as those typical of summer. However, higher total solids and COD removal values are reached in winter than in summer. The percentage of elimination of total solids in winter and summer is 96.20% and 50.18% respectively. And the COD removal percentage in winter and summer is 91.08% and 65.34% respectively.
Under winter conditions, a lower elimination of ammonia is achieved, 21% than in summer conditions, 78%. Regarding the elimination of phosphorus, a greater elimination is achieved in summer 70% than in winter 35%. This is since the algar biomass has greater activity and greater growth with high temperatures such as those typical of summer. Achieving a greater absorption of nutrients by the algar biomass. However, slightly higher values, although not very significant, of organic matter removal are reached in winter than in summer. Being the percentage of COD removal in winter and summer of 91% and 65% respectively. In summer there is greater bacterial activity in the wastewater compared to winter, due to the temperature. In both conditions, high disinfection values are reached. To determine the level of disinfection, the regulations focus on the presence of E. coli bacteria, resulting in this study an elimination percentage of 99.6% and 100% in winter and summer respectively.

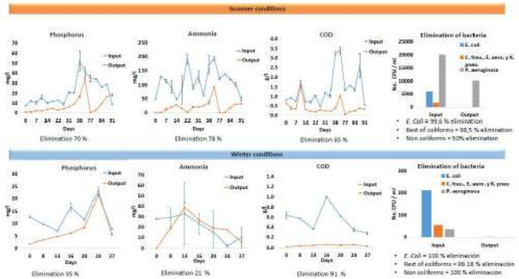

Figure 2. Results in inlet and outlet water of the concentration of phosphorus, ammonium, COD and elimination of coliform bacteria, in summer and winter conditions.

Abstract
Polyhydroxyalkanoates (PHAs) are biopolymers synthesised by microorganisms in the presence of nutrient-limiting environments that are suitable as source for bioplastics production. To make to overall process economically and environmentally sustainable, waste streams are often evaluated as feedstock for PHAs production. The aim of this study is the use of a real fermented cheese whey feedstock as carbon source for the selection of a PHA-accumulating mixed microbial culture, operating under a saline concentration equal to 30 gNaCl/L. A stable and acclimatized culture was obtained in a sequence batch reactor operating in a Feast/famine regime with an organic loading rate of 60 Cmmol/(L d). The accumulation capacity of the culture was tested, reaching a maximum content of 76.5% (weight/weight, on volatile suspended solids basis).

Keywords
Acidogenic fermentation; Cheese whey; Halotolerant microorganisms; Mixed microbial cultures; Polyhydroxyalkanoates; Saline wastewaters.

INTRODUCTION

Sustainable industrial practices such as circular economy are nowadays primary important to reduce the environmental impact of human activity. Resource recovery from waste streams is strongly encouraged to reduce raw material extraction and processing as well as to limit the impact of waste disposal. Saline side streams from agri-food industries are characterized by a high cost in their treatment for safe disposal, as the conventional biological processes are often inhibited by the high saline concentration. Among others, fishery and dairy industry are a relevant source of saline wastewaters (Lefebvre and Moletta, 2006; Chen et al., 2018). Therefore, the development of biological processes able to produce secondary raw materials from saline wastewaters as feedstock is favourable to promote both environmental and economic sustainability for the agri-food industry.

PHAs are biodegradable polymers produced by certain microorganisms as intracellular energy and carbon reserves. The production of this polymer is of growing interest as they are viable substitutes of conventional plastics (Kourmentza et al., 2017). Nevertheless, PHA production process is characterized by high costs that make bioplastics more expensive that petroleum-based polymers.
PHA production by open mixed microbial cultures (MMC) comprises three distinct stages: (i) acidogenic fermentation, where the organic matter is converted into Volatile Fatty Acids (VFAs) which are the PHA precursors; (ii) culture selection, where the aerobic MMC is enriched with PHA-storing organisms under selective pressure conditions; (iii) PHA production, where PHA accumulation is carried out using the culture selected in stage (ii) and fed with fermented stream produced from stage (i). The use of industrial by-products or waste streams as feedstock for VFAs production and thus for PHA synthesis is being investigated for the overall process cost reduction. In this framework, saline conditions might be applied as a direct consequence of using salty waste streams or, in the cost reduction and environmental perspectives, due to the use of seawater for dilution instead of freshwater.

In the present study, the valorisation of salted fermented cheese whey, a by-product from the dairy industry into PHA by MMC was investigated. The main challenges were to enrich an efficient PHA-accumulating MMC and attain good PHA productivities under high salinity (30 g_{NaCl}/L). In addition, PHA accumulation batches using the salted fermented stream supplemented with valeric acid as feedstock was investigated.

MATERIALS AND METHODS

A sequence batch reactor (SBR) with a 2 L working volume was used for the culture selection. The culture was enriched with PHA-accumulating organisms by applying a F/f regime strategy as selective pressure. The SBR was operated with 3 cycles/day of 8 hours each, with a hydraulic retention time (HRT) and a solids retention time (SRT) of 14.5 h and 3 d, respectively. The pH was controlled bellow 8.5 through automatic dosing of 0.5 M HCl . The reactor was operated under aerobic conditions, with mechanical stirring (150 RPM) and at room temperature (20°C ± 1.5 °C). The organic loading rate – OLR – was set at 60 Cmmol/(L d), and the C/N/P ratio selected was 100/5/2. The feed solution was obtained from an acidogenic fermenter reactor, with the typical composition reported in Tab.1. As the C/N/P ratio of the fermented solution was 100/1/2, the remaining amount of ammonia was fed after the exogenous carbon was depleted (uncoupled feeding), approximately one hour after the carbon feed. Together with the fermented stream, a mineral solution with allitiourea, to inhibit nitrification, and micronutrients was fed to the SBR as described in (Carvalho et al., 2022). The salted conditions (30 g_{NaCl}/L) were artificially imposed to SBR, through salt addition in the fermented and mineral solutions, to mimic a real salted fermented stream.The feeding was composed of 111 mL carbon solution and 889 mL dilution mineral solution. . PHA-accumulation performance of the culture was assessed through a pulse-wise feeding strategy in a 2 L reactor. Accumulation-A was carried out with the same fermented stream used in the operation of the selection reactor, while the feed of Accumulation-B was supplemented with valeric acid (H.Va) to reach a relative concentration of 30% $Cmmol_{H.VA}/Cmmol_{VFA}$.
Total and volatile solids (TS, VS) and total and suspended solids (TSS,VSS) were determined according to standard methods (APHA, 2005). Volatile fatty acids (VFAs) were quantified in filtered samples (0.20 µm) using a high-performance liquid chromatography (HPLC) in a VWR Hitachi Chromaster chromatographer. Ammonia and phosphate concentrations were determined in filtered samples (0.20 µm) using a segmented continuous flow analyzer (Skalar SNA++). Lyophilized biomass was weighted and incubated with 1 mL chloroform and 1 mL acidic methanol (20% H_2SO_4) through digestion at 100 °C for 3.5 h. After the digestion, the organic phase was extracted and injected into a gas chromatograph (GC-FID, Brucker).

RESULTS AND DISCUSSION

The results obtained in the culture selected with PHA-accumulating organisms are summarized in Tab.2 while in Fig.1 and Fig.2 is depicted a representative F/f cycle. A complete VFA consumption was observed after ~ 0.6 h, with a greater preference for the consumption of butyric acid (-qBut = 0.397 ± 0.055 Cmol/Cmol X.h). This resulted in a F/f ratio equal to 0.076 ± 0.016 on average, which is considered adequate to boost the selection of a good PHA-storing biomass (Kourmentza et al., 2017). At the end of the feast phase, it is reached the maximum PHA content (39 ± 5 %wt., VSS basis), where the co-polymer accumulated was composed of 94% of 3-hydroxybutirate and 6% of 3-hydroxyhexanotate. Overall, a stable halotolerant PHA-accumulating mixed culture with a good PHA storing capacity ($Y_{PHA/S}$ = 0.75 ± 0.03 Cmol/Cmol X.h) was selected under high salinity.

Regarding PHA accumulation, Accumulations A (fermented stream) and B (fermented stream + 30% H.Va) showed a good storing capacity of the culture as it was reached a maximum PHA content of 73.0% and 76.5% (wt., on VSS basis), respectively. For Acc-A the maximum storing capacity was reached after 4 pulses while for Acc-B after 5 pulses. It is worth noting that even though the culture was selected without the presence of H.Va, a higher maximum PHA content was observed under the presence of this VFA. The capacity of the biomass of consuming the H.Va. in Acc-B was showed also by its consumption rate (qSvale) greater than acetic and hexanoic acids

Abstract
Modelling wastewater treatment plants (WWTP) is a very extended and useful tool for the analysis, management and optimisation of urban WWTP. However, the development of new innovative processes and technologies urges to adapt and validate these models to simulate the innovative technologies. Based on the results from the PHERTILIZER project, the software BioWin® was used in the study to simulate different WWTP configurations to increase phosphorus (P) recovery as struvite, yielding up to 119 kg/d of recovered struvite and reducing almost all of the uncontrolled precipitation inside the anaerobic digestion process, thus optimising the related operational processes. Additionally, this study offers a new methodology that can be transferred to other WWTPs to optimise the phosphorus recovery plant location in a WWTP to minimise associated problems with uncontrolled precipitation and hydrogen sulphide (H_2S) emissions.

Key words
WWTP, struvite, phosphorus, nutrient recovery, simulation

INTRODUCTION

Phosphorus (P) is an essential nutrient and limited resource. With an increasing demand for P, therefore, the PHERTILIZER project has the objective of recovering P as struvite from WWTPs and increasing its value as fertiliser. Moreover, the uncontrolled precipitation of P in the anaerobic reactors in WWTPs leads to operational problems and increases operational costs. It has been demonstrated that these problems can be reduced by the implementation of phosphorus precipitation and its recovery as struvite (De-Bashan and Bashan, 2004), obtaining a product not only rich in P but also with nitrogen (N).

In order to recover P as struvite from WWTPs, it is imperative to obtain a flow with a high concentration of P. Therefore, the study of the optimal P-recovery plant location is critical in order to obtain the highest efficiency. Likewise, the elutriation of the sewage sludge process reduces up to 43% of the P loses by uncontrolled precipitation (Bouzas, et al., 2019). Hence, all the WWTP configurations studied are based on the elutriation of sludge flows to produce a high P concentrated flow to be fed into the crystallizer to produce a controlled precipitation. The simulation study of these configurations allows determining the optimal location and the evaluation of the side effects related to the implementation of P-recovery technologies.

METHODS

The simulation model (figure 1) developed with the BioWin® software was based on the experience and results from the P-recovery plant used in the PHERTILIZER project. In order to get representative results, the model was calibrated and validated with the results from the experience at the WWTP, with and without the crystallization process.

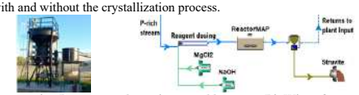

Figure 1. Demonstration P-recovery plant, picture and layout on BioWin software.

Using this model, the study of the different scenarios was focused on comparing the optimal location for the P-recovery plant, the effects and the recommendation of including the elutriation process to improve the results, and the effects of each configuration on the whole WWTP. Three different configurations were compared: Layout 1: elutriation of mixed sludge in primary thickener; Layout 2: elutriation of mixed sludge on secondary thickener; Layout 3: elutriation of secondary sludge in secondary thickener.

RESULTS AND DISCUSSION

The main difference in between the three scenarios was the elutriation of the sludge. Consequently, this is the critical point to control the P-recovery process and improve the WWTP operation. Thus, the combination of elutriation and a P-recovery process results in a reduction of between 11-18% of the total sludge production and 10% of the aeration ratio.

Table 1. Significant parameters obtained for each scenario.

		Layout.0	**Layout.1**	**Layout.2**	**Layout.3**
Biogas	m^3/h	61.39	50.85	53.37	57.40
H_2S MC	kg/d	27.41	28.39	3.90	0.01
H_2S Digestion	kg/d	24.83	20.14	22.84	37.74
Sludge production	kgDM/d	1,850	1,514	1,644	1,594
Aeration energy ratio	kWh/m^3	0.21	0.18	0.18	0.18
P-precipitation in anaerobic digestion	kg/d	181	143	142	0.23
Struvite recovery	**kg/d**	**-**	**98.03**	**71.18**	**118.85**

However, in addition to a remarkable struvite production (almost 119kg/d) in Layout 3, it is important to emphasise the reduction of uncontrolled precipitation of P in the digester by almost 100% and the minimisation of H_2S emissions in the plant (figure 2). These H_2S emissions, linked to elutriation, will be favoured if the WWTP initially had this problem.

Figure 2. Operational results. (A) H_2S emissions (kg/d). (B) P distribution in the WWTP (kg/d).

From this study, the simulation methodology is transferred to other WWTPs, analysing the combination of sewage sludge elutriation and struvite recovery process to validate the optimal location and the most favourable configuration for P-recovery and WWTP management. To this end, improving the biological P removal process at the WWTP and having anaerobic conditions along the sludge line to increase P-release is essential. Moreover, simulation studies are useful to validate the design of the P-recovery process including not only the volume of the crystalliser but also the addition of reactants.

CONCLUSIONS

The recovery of P combined with the elutriation of the sewage sludge increases the amount of struvite recovered and decreases the operational costs at WWTPs. In addition, if only the secondary sludge is elutriated, the uncontrolled precipitation of P will be almost totally reduced. This study shows a new simulation methodology transferable to other WWTPS for evaluation.

Abstract

This study is focusing on evaluation in-situ biological hydrogen methanation in mesophilic continuous stirred-tank reactor (CSTR) for biogas upgrading. Two CSTRs was installed with effective capacity of 5 L and loaded with inoculum sludge with VS concentration of 1.5% and fed with mixed waste sludge with organic loading rate (OLR) of 1.9 g VS/L and sludge retention time (SRT) of 14 days at mesophilic condition with temperature of 37 °C. One of the reactor was operated as control while the other one was injected with H_2 through micro-ceramic membrane diffuser at H_2:CO_2 ratio of 4:1. The quantity of produced biogas was monitored continuously via gas counters and gas chromatography. The results showed a good performance of bio-methanation process in the upgraded CSTR as the average methane yield increased to 215 mL/g VS compared with 135 mL/g VS methane yield in the control reactor. Also, gas constituent analysis showed good improvement of biogas quality as the % CH_4 reached 68% starting from 52% without H_2 injection. The results showed also utilisation of about 88% of the hydrogen injected to the reactor in the bio-methanation process. Based on this results, the upgrading of biogas produced from sewage sludge is promising and furthers studies will be carried out on the effect of gas recirculation and the performance in thermophilic conditions to reach maximum utilisation of H_2 for high performance bio-methanation.

Anaerobic digestion; biogas; Bio-methanation; CSTR; hydrogen

INTRODUCTION

Biogas is a product of anaerobic digestion process (AD) of organic wastes and it is composed of methane (CH_4) with about 50–70% and carbon dioxide (CO_2) with 25–45% while minor amounts of other compounds, such as nitrogen (N_2) (0–3%), oxygen (O_2) (0–1%), and hydrogen sulfide (H_2S) at concentrations of 0-4% (Golmakani, et al., 2022). Except CH_4, the other gasses in biogas are not wanted and are considered as biogas pollutants and this reduce the energy content of biogas described by lower calorific value (LCV) from 36 to 20 MJ/m^3. The biogas could be utilized as an alternative of natural gas. However, European Commission has recently issued a mandate for determining harmonized standards for gas quality which must contain about 95% methane (Angelidaki, et al., 2018). Accordingly, the biogas should be treated to increase the methane content through conversion of CO_2 contained in the raw biogas to CH_4 by reaction with H_2 (Kougias, et al., 2017). The biogas can be upgraded in the same reactor through injection of H_2 during the AD process and it is called in-situ upgrade. The other method is ex-situ upgrade in which the mixing of biogas and H_2 in another external anaerobic reactor is occurred. The aim of this study is to evaluate in-situ upgrade of biogas produced from anaerobic digestion of sewage waste sludge by H_2 injection inside CSTR system.

MATERIALS AND METHODS

Reactors set-up and operation

Two laboratory-scale AD reactors were fabricated with a capacity of 5 L for each one of the reactors is injected with H_2 gas while the other acts as control. The reactors were stirred with the use of paddle-type mixers, and the temperature was kept at level of 37–38 °C by means of a water jacket connected to circulating water baths with digital temperature controller (VWR International, USA). For H_2 supply inside one of the reactors a precision digital mass flow controller (MFC) model DPC07 (AALBORG, USA) was used to inject the H_2 through a ceramic membrane micro-bubble diffuser ED 60 (Enviro Ceramic Co., Ireland) made from ultra-fine nano porous aluminum oxide. The reactors were loaded with inoculum from anaerobic digester of a municipal waste water treatment plant (WWTP) from southern part of Poland with VS content of 1.5 % while substrate used was collected from the mixed sludge waste at the same treatment plant with average VS contents of 2.7%. Both reactors were operated at OLR of 1.9 g VS/L and fed with sewage sludge substrate every 24h and SRT of 14 days. Figure 1. Shows the reactors configurations.

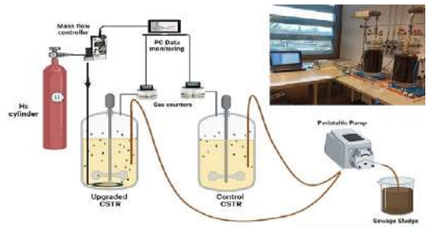

Figure 1. Schematic diagram of in-situ methanation system

Analysis and measurements

pH and temperature measurements were carried out in the reactors on daily basis. The volume of produced biogas was measured continuously with use of gas counter (RITTER MGC-1 V3.4, Germany) PC software. The composition of biogas was measured by collecting gas in Tedlar bags and injection to gas chromatography (Agilent). Also, the composition of substrate and digestate from each reactor was monitored weekly in terms of soluble COD, TS, VS, TN, ammonia, VFA and alkalinity.

RESULTS AND DISCUSSION

Reactor operation

The operation of the reactors was started in normal mode and same conditions for both reactors for three months till reaching the steady state. During this period, the performance of both reactors was monitored for gas quality and quantity as well as analysis of digestate effluent. The results of this stage showed stable pH value in the reactors (6.9-7.1) and the produced gas ranged between 240-280 mL/g VS. The gas contents in both reactors were 50-55% CH_4, 25-32% CO_2, 5-11% N_2 and 2-4% O_2. After the steady state, the hydrogen was injected to one of the reactors through micro-ceramic membrane diffuser. The amount of H_2 injected to the reactor was calculated to be H_2:CO_2 ratio of 4:1 based on literature studies on biological hydrogen methanation (Wahid and Horn, 2021). To reach this ratio, gradual increase in the amount of H_2 injected to the reactor was performed starting from 1:1 then 2:1 and 3:1 till 4:1. It was noticed that the %CH_4 was slightly increasing with increasing the H_2: CO_2 ratio with the sequence of 55%, 57% and 60%.

Evaluation of in-situ hydrogen bio-methanation

The H_2 was injected to the CSTR reactor with a flow rate of 1.4-1.5 mL/min according to the gas flow rate of the control reactor to achieve H_2: CO_2 ratio of 4:1. Table 1 summarizes the performance of bio-methanation process during the study period. The average amount of hydrogen added was 3150 mL/d and the average produced biogas in the control reactor was 2510 mL/d. The average amount of upgraded biogas from bio-methanation process is 3100 mL/d of which 11 % H_2. The results depicted in Figure 2 showed the variation of CH_4 yield over time in the control and upgraded CSTRs. The results showed an increase in CH_4 yield by 59% (from 135 to 215 mL/g VS) and the methane production rate was 415 mL/L_{VT} .d compared to 260 mL/L_{VT}. d without hydrogen addition. Also, the H_2 conversion rate high and ranged from 83 to 92% with average rate of 88%. Analysis of gas composition showed acceptable increase in the % CH_4 (Figure 3) as it reached to 68 % compared with 52% in the control reactor. The achieved yield was satisfactory compared to similar studies on in-situ bio-methanation in CSTR reactor. Luo and Angelidaki (2013) investigated the biogas upgrading by hydrogen bio-methanation in 1L CSTR for digestion of manure at thermophilic condition (55 °C) with H_2: CO_2 ratio of 4:1. They obtained CH_4 content of 68% at retention time 92h and methane production rate of 1.2 L/L_{VT}.d which considered high production rate due to the high organic load and thermophilic conditions. The achieved results in our study could be improved through investigation the increase of H_2 to CO_2 ratio to more than 4:1 via circulation a part of biogas in the reactor headspace and application of thermophilic conditions in the reactor.

Table 1. Process performance variables in control CSTR and upgraded CSTR with H_2 addition.

Reactors	Control CSTR	Upgraded CSTR
H_2 addition	No	Yes
H_2:CO_2 ratio	--	4:1
H_2 added (L/L_{gas}. d)	-	1.3
% CH_4	52	68
% CO_2	32	18
%H_2	--	1
CH4 production rate (L/L_{VT}.d)	260	415
CH_4 yield (mL/g VS)	135	215
% H_2 consumption	-	88

CONCLUSION

This study demonstrated the feasibility of biogas upgrading through in-situ biological hydrogen methanation using a two CSTRs system where one was control, and the other was injected with hydrogen with H_2: CO_2 ratio of 4:1 through ceramic diffuser. The results showed a good performance of bio-methanation process in the upgraded CSTR as the average methane yield increased to 215 mL/g and the gas constituent analysis showed good improvement of biogas quality as the % CH_4 reached 68% with utilisation of about 88% of the hydrogen injected to the reactor. Based on these results, the upgrading of biogas produced from sewage sludge is promising and furthers studies will be carried out on the effect of gas recirculation and the performance in thermophilic conditions to reach maximum utilisation of H_2 for high performance bio-methanation.

Abstract
Ammonia (NH_3) is a valuable resource used in various industries and is commonly produced from H_2 and N_2, while researchers have tried to recover directly from wastewater. In this study, a facile synthesis procedure was developed for preparing high-performance ammonium adsorbent via in-situ immobilization of Prussian blue analog, viz. copper hexacyanoferrate (CuHCF) on a weakly acidic cation exchange resin (WAC). From the analysis of the physicochemical properties of the synthesized CuHCF-based adsorbents, it was confirmed that CuHCF was successfully immobilized on the surface of WAC, allowing access to NH_4^+ for adsorption. The maximum equilibrium adsorption capacity was 47.07 mg NH_4^+ per g of WAC-CuHCF at pH 6.5 by fitting the Langmuir isotherm model. The optimal pH was 8, and the competition effect of K^+ and Na^+ on the capacity was not severe (<10%). The ability of WAC-CuHCF to regenerate was assessed in the column test, and the regenerated adsorbent was found to adsorb and desorb NH_4^+ to essentially the same extent.

INTRODUCTION

Ammonia is a useful chemical substance in various industrial fields but could be a problematic pollutant causing eutrophication and so on when emitted into nature. Various technologies have been developed to remove it, but a significant amount of energy is required. Therefore, numerous studies for recovering ammonia from wastewater have been performed using non-biological methods. Adsorption is preferred because of its environmental sustainability and economic feasibility. Prussian blue (PB) and its analogs (PBAs) are materials in which metal ions and metal cyanide ions combine in a specific ratio to form a lattice structure that is known to capture monovalent cations (Cs^+ of which ionic radius is similar to ammonia). In this study, we aimed to develop a method for producing CuHCF-based composites as adsorbents for the adsorption of ammonium ions from wastewater. In this case, the production process was simplified using a commercial IX resin rich in carboxyl groups as the substrate for PBA immobilization.

MATERIALS AND METHODS

Copper sulfate pentahydrate and potassium hexacyanoferrate trihydrate were coated on the surface of weakly acidic cation exchange resin (WAC). The physicochemical properties of the synthesized CuHCF-based adsorbents were analysed using various methods (PXRD, FT-IR, BET, HR-SEM etc.). To evaluate the ammonium ion adsorption characteristics of the synthesized CuHCF-based adsorbents for ammonium ions in water, batch and column tests were performed. The experimental results were fitted by the kinetics equations, adsorption isotherms, and Thomas model.

RESULTS AND DISCUSSION

The WAC-CuHCF was successfully prepared with the facile preparation method suggested in this study. The BET surface area of WAC-CuHCF decreased by 16 %, but its average pore size increased to 282.3 Å compared to one of WAC. The WAC-CuHCF exhibited different thermal behavior and fewer intra-particle pores than WAC and WAC-Cu. The ammonium adsorption capability of WAC-CuHCF was approximately 62 and 7 times higher than one of WAC and WAC-Cu, respectively. It was revealed that the primary adsorption mechanism for WAC-CuHCF was the chemical action of the monolayer, and its maximum adsorption capacity was 47.07 mg/g, which was significantly higher than one of the other adsorbents in the previous studies (Table 1). Within the pH range of 4–9, the optimal pH for ammonium adsorption was 8.0, and the competition effects of K^+ and Na^+ against ammonium ions were not severe (<10 %). The adsorption-regeneration process was successfully demonstrated in the continuous column test with high ammonium loading conditions (1,200 mg/L). Furthermore, the amount of ammonium from the regeneration process was similar to the amount of removed ammonium by adsorption, implying outstanding recyclable performance and high stability. The WAC-CuHCF may be a promising candidate for highly effective ammonium recovery from wastewater. Ammonia, which gains attention as a hydrogen carrier in the future society, is highly likely to be produced in specific regions, so long-distance transportation to the consumer is inevitable.

Abstract
The hydrolysis of a lipid-containing wastewater was studied using two different hydrolytic strategies, enzymatic and alkaline. The enzymatic hydrolytic strategy achieved a 98% triglycerides (TAG) hydrolysis, and it was used in an acidogenic fermentation process performed in a lab-scale stirred, temperature and pH-controlled reactor, obtaining a maximum yield of 0.46 g short-chain carboxylic acids (SCA)/g chemical oxygen demand (COD).

Keywords

INTRODUCTION

In a circular economy process, the treatment of industrial wastewaters is aimed at generating products of interest while, at the same time, preserving the environment from receiving damaging substances. Conventional biological technologies, including anaerobic digestion, have been satisfactorily used for treating high-strength waste streams generated, for example, from food manufacturing industries (Mendes et al., 2006). The first step of an anaerobic digestion process involves hydrolysis and acidogenic fermentation of the feeding stream to generate short-chain carboxylic acids (SCA) to be used in a second step by methanogenic bacteria. Recently, the hydrolysis-fermentation step, namely acidogenic fermentation, has been seen as a promising alternative itself inside a circular economy process as it is able to efficiently manage high-strength waste streams, and also to obtain high-value by products (SCA) that can be used as a carbon source for producing, for example, polyhydroxyalkanoates (PHA), a high-value bioplastic (Silva et al., 2013). On the other hand, the management of high-strength wastewaters from food manufacturing industries involves some inconveniences, such as a high fats concentration, that affects negatively the acidogenic fermentation due to mass transfer limitations that will affect the hydraulic retention time (HRT) and will promote the formation of fat scum at the surface of the reactors, resulting as the rate limiting step of the process. High fat concentrations can also affect the use of some industrial equipment, for example, by pipe clogging. To overcome such limitations, several hydrolytic strategies have been proposed, in order to degrade the lipid content prior to an acidogenic fermentation process. On the one hand, some authors report chemical strategies, such as lipid saponification as an effective way to improve anaerobic digestion by increasing the bioavailability of fatty wastes. On the other hand, biological-based strategies, such as the use of enzymes that specifically hydrolyze complex organic matter have gained interest over the last years (Domingues et al., 2015). Lipases (triacylglycerol ester hydrolases EC 3.1.1.3) are able to catalyze the hydrolysis of triacylglycerides (TAG) into glycerol and free fatty acids (FFA). For this reason, these enzymes seem to be a promising alternative to efficiently achieve the degradation of lipid-rich waste streams (Cammarota et al., 2001). Regarding the acidogenic fermentation, there are several parameters that influence the SCA yield, such as the pH, the temperature or the volumetric organic loading rate (vOLR) (Vázquez-Fernández et al., 2022). It has been reported that increasing the vOLR raises the VFA production. However, at very high vOLR the acidogenic fermentation process is unstable, affecting the acidogenic microbial communities. For this reason, determining the optimal vOLR is important to assess a high SCA yield. In this sense, the aim of this work is to compare two different hydrolytic strategies, an alkaline and an enzymatic one, to hydrolyze the lipid content of a lipid-rich wastewater. The hydrolyzed wastewater was then used as the substrate to obtain an SCA-rich effluent through acidogenic fermentation in order to evaluate its effect over the SCA yield.

MATERIALS AND METHODS

A wastewater liquid waste stream was obtained from a food processing industry located in Vic (Girona). The characterization of the wastewater is shown in Table 1.

Daily samples were stored in the fridge (4ºC) for further analysis and the parameters of interest were analyzed. Commercial lipase obtained from a non-GMO strain. The optimal enzyme conditions were pH between 7 and 11, and temperature in a range between 25 and 65ºC, being its optimal at 40ºC. Anaerobic sludge was obtained from acidogenic fermentation reactors previously adapted to the wastewater tested and it was used as inoculum for the acidogenic fermentation.

Table 1. Characteristics of the wastewater. pCOD: particulate Chemical Oxygen Demand; sCOD: soluble COD; tCOD: total COD; TAG: triacylglycerides; TSS: Total Suspended Solids: TS: Total Solids.

Parameter	Value	Unit
pCOD	76.5 ± 12.9	g L^{-1}
sCOD/tCOD	33.0 ± 2.2	%
TAG	19.7 ± 0.1	g L^{-1}
TSS/TS	44.6 ± 3.0	%
Protein	3.00	g Kg^{-1}
Density	1000.0	g L^{-1}

Alkaline hydrolysis was carried out in 3L stirred reactors and the temperature was controlled at 37ºC. Raw wastewater was added to the reactors and pH was adjusted to 12 using NaOH (25%w/v). The optimal alkaline conditions, regarding the optimal dose, time and temperature were found in previous experiments (data not shown). Enzymatic hydrolysis was also performed in 3L reactors. The pH and temperature were adjusted according to the optimum for the enzyme activity stated by the manufacturer, and it was dosed at 1% w/v, as found in previous experiments (data not shown). Samples were taken at the beginning and at the end of each experiment for the quantification of TAG, total and soluble Chemical Oxygen Demand (tCOD and sCOD). The hydrolysis of the organic matter was determined as sCOD/tCOD, and the TAG hydrolysis was analyzed and quantified according to the initial and final concentrations. The pH of the hydrolyzed effluent was adjusted to 8 before starting the acidogenic fermentation.

Acidogenic fermentation was performed in lab-scale mechanically stirred reactors, mesophilic conditions were maintained, and pH was controlled at 8. Previously acclimated anaerobic sludge was used as inoculum, and the enzymatic hydrolyzed wastewater was used as substrate. Sludge retention time (SRT) was set in 10 days. The test was carried out over 46 days, maintaining the same conditions, except the organic vORL, that was adjusted in order to maximize the production yield. The vORL was defined as the amount of organic material fed, quantified as Total Solids (TS) per volumetric unit of the reactor per unit of time. Concentrations of TAG, SCA, tCOD and sCOD were analyzed periodically to determine the stability of the process and the fermentation yield. The production yield or SCA yield (Yp/s) was calculated as SCA produced in terms of sCOD per tCOD fed into the system (Ramos-Suarez et al., 2021). Degree of acidification (DA) was calculated as the amount of SCA produced in terms of COD over sCOD of the fermented broth (Girotto et al., 2017).

TS and COD were determined according to the procedures described in the Standard Methods of Water and Wastewater (APHA, 2012). Concentration of SCA was determined using an HPLC SCA analyzing method (Agilent Hi-plex H column). Six types of metabolites and SCA were analyzed: lactic acid (HLac), acetic acid (HAc), propionic acid (HPr), iso-butyric acid (HiBt), n-butyric acid (HBt) and valeric acid (HVc).The SCA concentrations were expressed as theoretical equivalents of COD (Naresh Kumar & Venkata Mohan, 2018). TAG concentration was analyzed performing a lipid extraction and determined using RMN.

RESULTS AND DISCUSSION

Hydrolysis of wastewater

Enzymatic and alkaline hydrolytic strategies were carried out in order to evaluate the most convenient hydrolytic strategy. Table 2 shows the composition of the hydrolyzed wastewater and samples were obtained after 24h assays. Initial and final TAG concentrations are shown, and TAG hydrolysis was also calculated from the concentration difference.

The sCOD/tCOD is also represented to assess the reached solubility. An increase of the soluble fraction (sCOD/tCOD) from a 33% to a 59% and 54% in the alkaline and enzymatic strategies, respectively, was observed. These results showed that both strategies are able to solubilize the organic matter present in the wastewater, by achieving almost the same solubilization. On the other hand, the TAG hydrolysis was also quantified. Total TAG concentration decreased up to 24% in the alkaline strategy, while 98% TAG concentration decrease was obtained in the enzymatic pretreated wastewater. The TAG hydrolysis is credited to the effect of the lipase in the enzymatic strategy. This behavior was not observed in the alkaline strategy, as little TAG hydrolysis was achieved.

Table 2. Hydrolytic strategies results

Assay	TAG			
	Initial concentration (g L^{-1})	Final concentration (g L^{-1})	TAG hydrolysis (%)	sCOD/tCOD (%)
Alkaline hydrolyzed wastewater	19.97 ± 0.23	15.39 ± 0.62	24%	59%
Enzymatic hydrolyzed wastewater	19.97 ± 0.23	0.45 ± 0.05	98%	54%

The solubilization of the pCOD, involving an increased in the sCOD/tCOD ratio, can be attributed to the pH effect, as both the alkaline and enzymatic pretreatment were adjusted to pH 10 and 12, respectively, involving the addition of NaOH (Li et al., 2012). However, the TAG hydrolysis can only be related to the lipase action, as the alkaline hydrolysis has no potential effect in the lipid hydrolysis, and only the lipases hydrolyze specifically the TAG present in the wastewater. Based on the results presented herein, the enzymatic pretreatment was significantly more effective for the TAG hydrolysis, achieving an equal percentage of sCOD solubilization. For this reason, this enzymatically hydrolyzed residue was chosen to be used as the substrate in the subsequent acidogenic fermentation, in order to study the SCA yield obtained from this residue.

Acidogenic fermentation results

The acidogenic fermentation of the enzymatic hydrolysate to produce SCA from lipid-rich wastewater was performed, and the fermentation parameters were set according to the literature (Yin et al., 2016). DA (%), SCA concentration (gCOD L^{-1}) and SCA yield (Yp/s) are shown in Figure 1A, as well as the vOLR of each period. The vOLR was set at 22.1 g TS L^{-1} d^{-1} during the first days of the acidogenic fermentation (day 0 to day 16, period 1). During this period, the SCA yield was, on average, 20 ± 8 % and the total SCA concentration achieved was 24 ± 6 gCOD L^{-1}. Since operation during this period was very unstable regarding the Yp/s and SCA concentration, the vOLR was therefore reduced. According to the literature, vOLR higher than 16 g TS L^{-1} d^{-1} was considered to cause instability in the process, while lower vOLR, such as 5 or 11g TS L^{-1} d^{-1} was considered optimal for SCA production from food wastes (Jiang et al., 2013). Therefore, the vOLR was set at 12.6 g TS L^{-1} d^{-1} from day 16 to the end of operation (Period 2). After the vORL adjustment, the production yield increased up to 38 ± 5%. In this second period, which lasted 30 days, the average SCA concentration was 30 ± 3 gCOD L^{-1}. In comparison to the first stage, the DA increased from 29 ± 6% to 62 ± 8%, showing the vOLR adjustment had an effect on the process performance. Regarding the sCOD/tCOD, it was 48 ± 9 % during period 1, and then it was 47 ± 7 % for the rest of the acidogenic fermentation process. No significant variation was observed as the sCOD/tCOD parameter depends on both the hydrolytic strategy and the characteristics of the substrate itself. Moreover, no variation in this parameter shows stability in the hydrolytic process. Regarding the TAG concentration, and due to a high hydrolytic yield in the enzymatic pretreatment strategy prior to the acidogenic fermentation, it was 0.49 ± 0.05 g L^{-1}, showing that the low TAG concentration is preserved during the fermentation stage. Modifying the vOLR affects the acidogenic fermentation performance in terms of SCA concentration, and subsequently, the SCA yield and DA, indicating that vOLR is a key parameter to consider to achieve high production yields.

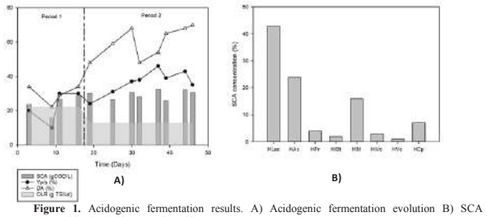

Figure 1. Acidogenic fermentation results. A) Acidogenic fermentation evolution B) SCA composition in the fermentation effluent

In case of a subsequent PHA production, the composition of the SCA obtained is a parameter of paramount importance as a direct correlation between SCA and the type of PHA biosynthesized can be predicted. In general, it is expected that fermented SCA-effluents with higher odd equivalent acids, such as propionic or valeric, lead to higher Hydroxy-valerate (HV) composition in the final PHA (Albuquerque et al., 2011). In this sense, Figure 1B shows the SCA composition (%) in the acidogenic reactor, during the second period of the fermentation. The most abundant SCAs in the second period were lactic acid (43%), acetic acid (24%) and butyric acid (16%). In this fermentation effluent, low concentration of propionic (4%) and valeric acids (1%) were detected, leading, in principle, into hydroxy-butyrate (HB) polymers. A modification of the operational parameters should be considered in order to modify the SCA composition to drive the PHA production into PHV. Acidogenic fermentation of high-strength wastewaters can be limited by the lipid hydrolysis. In this work, the use of a commercial lipase has shown to promote a great TAG hydrolysis, enhancing also the solubilization of the particulate organic matter. Moreover, the acidogenic fermentation of the enzymatic hydrolyzed waste was studied, and, by adjusting the vOLR, better acidogenic yields were achieved. The results show that coupling the enzymatic hydrolysis with an acidogenic fermentation done at an appropriate vORL might be an attractive alternative for the valorization of lipid-rich waste streams.

Heavy metals uptake with energy crops biomass depending on soil amendment

M. M. Kharytonov*, M.G.Babenko* and N.V. Martynova**

* Department of Soil Sciences and Farming, Dnipro State Agrarian and Economic University, 25 Serhii Yefremova st. Dnipro, 49600, Ukraine (E-mail: *kharytonov.m.m@dsau.dp.ua)*
** Department of Nature Flora, Botany Garden, Dnipro National University, 72 Gagarin Avenue, Dnipro, 49044, Ukraine (E-mail: *nadiamartbg@gmail.com*)

Abstract
The application of various amendments leads to an increase in the parameters of vertical and horizontal growth from 2% to 40%. The greatest effect is the use of sewage sludge. The content of heavy metals in the above-ground biomass is quite low and varies from 4.2-4.5 to 129.5-159.9 mg kg^{-1}. The content of heavy metals in the biomass of Miscanthus was higher than in Switchgrass by 20-30%.
Keywords: energy crops, sewage sludge, heavy metals.

INTRODUCTION

The issues with utilization of wastewater sludge are not resolved for decades in Ukraine. Hygienic properties and high content of heavy metals in wastewater sewage sludge are the main problems that hinder the use of biosolids in agriculture, including technical crops for production of biofuels (Singh and Agrawal, 2008; Stietiya and Wang, 2011; Antonkiewicz et al., 2018). Main objective of this case study was to estimate heavy metals uptake with energy crops biomass depending of kind and rate of soil amendment.

MATERIALS AND METHODS

The field experiment was established on phytomeliorated loess-like loam at the DSAEU research station located in the south of Ukraine (47°39′N, 34°08′E). The following five amendments were used to determine the effect of various additional fertilizers: ash of sunflower husk in amount 10 t ha^{-1}, municipal sewage sludge (10 t ha^{-1}), mixture of ash and sewage sludge (10 t ha^{-1}), a double rate of sludge (20 t ha^{-1}) and mineral fertilizer with a balance of nutrients $N_{60}:P_{60}:K_{60}$ kg ha^{-1}. All amendments were put into the soil in dry form annually once in spring. The biometric parameters and biomass productivity were defined at the end of vegetation season (second part of September).

RESULTS AND DISCUSSION

The application of amendments led to an increase in the parameters of vertical and horizontal growth from 2% to 40%. The use of ash had the least effect, and the influence of double dose of sewage sludge was the strongest. The thickness of the shoots has also increased. In Switchgrass, the stem diameter under the influence of ash and a mixture of ash and sludge changed slightly, up to 5%. The application of sewage sludge and mineral fertilizer increased this indicator by 11-18%. In Miscanthus, only a double dose of sludge had an improving effect (13.9%), other amendments did not have a significant impact (1-1.6%). In this way, the response of Switchgrass plants to amendment application was better than Miscanthus, which contributed to an increase in biomass yield from 7 t DM ha^{-1} (control) to 15-17 t DM ha^{-1} (sewage sludge). In Miscanthus, the maximum yield (12.4-13.3 t DM ha^{-1}) was achieved using mineral fertilizer and double dose of sludge. Thus, for Switchgrass, the most promising amendment is only sewage sludge. For Miscanthus, the use of sewage sludge in amount of 10-20 t ha^{-1} and mineral fertilizers is optimal. In the control plot, the content of heavy metals in the biomass of Miscanthus was higher than in Switchgrass by 20-30%. On the plots with amendments, the content of Mn and Zn was also higher in Miscanthus. At the same time, Cu and Pb accumulated more intensively in Switchgrass biomass. It was detected that the amendment application modified the physicochemical properties of soil, thereby enhancing the availability of heavy metals in the soil and increasing their accumulation in biomass. The mineral fertilizer use had the least effect (from 0.1% to 90% for Miscanthus and from 32% to 48% for Switchgrass). The addition of double dose of sewage sludge had the most significant effect and caused an increase in content of heavy metals by 90-165% for Miscanthus and by 124-333% for Switchgrass compared to the control. It was detected during analyzing heavy metals content in the Miscanthus biomass that amendments affect Mn accumulation most intensively. Greatest effect was noted for Cu in the Switchgrass biomass. The application of the amendments led to an increase in heavy metal uptake by the Miscanthus and Switchgrass biomass (Fig. 1).

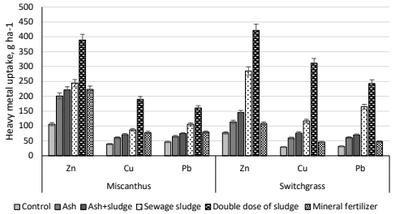

Fig.1. Heavy metal uptake (Cu, Zn and Pb) by the 3-year-old plants of Miscanthus and Switchgrass

In control, the level of heavy metals uptake was higher in Miscanthus compared to Switchgrass. The introduction of amendments has changed this ratio. The introduction of mineral fertilizers, ash and mixture of ash and sewage sludge contributed to an increase in the uptake of Zn, Cu and Pb by the biomass of both plant species on average 1.5-2.6 times. The application of single dose of sewage sludge enhanced the uptake of these metals by the Miscanthus 2.2-2.7 times, whereas for Switchgrass the uptake level increased 3.7-5.2 times. The applying of double dose of sewage sludge had the greatest effect. However, while in Miscanthus the uptake capacity was increased by 3.4-4.8 times, in Switchgrass it was augment by 5.5 (Zn), 7.7 (Pb) and 10.6 (Cu) times.

kasrakm@kth.se, zeynepcg@kth.se

Abstract
Bio-based plastic production can be a prominent contributor to the development of a circular economy. Using volatile fatty acids acquired from anaerobic digestion of municipal wastes as substrate, two different strategies were compared for microbial polyhydroxyalkanoates (PHAs) production: 1) Long-term enrichment of activated sludge-161 days- with bioaugmentation of *Cupriavidus necator* and *Burkholderia cepacia* 2) Short-term enrichment of activated sludge-5 days- with bioaugmentation of *Cupriavidus necator* and *Burkholderia cepacia*. The highest PHA accumulation was obtained from bioaugmentation of *Cupriavidus necator* (52 % PHA/VSS) followed by bioaugmentation of *Burkholderia cepacia* (36 % PHA/VSS) after 154 days of enrichment (long-term enrichment). Whereas, maximal PHA content in the short-term enrichments was 17% PHA/VSS obtained from the non-bioaugmented activated sludge.

Keywords
Activated sludge; microbial community; polyhydroxyalkanoates; resource recovery; volatile fatty acids

INTRODUCTION

Environmental pollution such as the accumulation of plastic waste is a consequence of global population growth which needs to be addressed. Resource recovery from waste is deemed one of the pillars of transitioning into a circular economy and fulfilling the United Nation's environmental sustainability goals.
Polyhydroxyalkanoates (PHAs) are biodegradable intracellular biopolymers that are synthesized under environmental stress conditions. Having comparable characteristics, PHAs can be an alternative to conventional petrochemical plastics (Sohn et al., 2022). However, their commercial production is yet impeded due to the high costs of substrates, low yields, and downstream processing. Conversion of organic wastes into value-added materials such as PHAs not only presents an opportunity for waste management and resource recovery but can also, decreases the high production costs (Mannina et al., 2020).

Mixed microbial culture (MMC) production of PHAs requires three steps: substrate provision, biomass enrichment, and accumulation (Cakmak et al., 2021). One of the possible ways to increase the desired activity in the existing population of a microbial community is bioaugmentation; which is the introduction of particular consortia or microbial strains in the system (Khatami et al., 2020). In this study, we combined the conventional biomass enrichment for the PHA production process with the bioaugmentation of synthetic cultures of renowned PHA producers over both short (3 and 5 days) and long (161 days) periods, while using municipal waste (food waste and primary sludge) as the cheap substrate.

MATERIALS AND METHODS

LONG TERM EXPERIMENTS
In the long-term experiments, the activated sludge was taken from the Hammarby Sjöstadsverk wastewater facility in Stockholm, Sweden. The biomass was enriched in 5L sequencing batch reactors for 161 days with a cycle length of 12 h, and hydraulic (HRT) and solid retention (SRT) times of 1 day. The effluent of an anaerobic digester treating food waste and primary sludge, rich in volatile fatty acids (VFAs), was used as the substrate. The composition of the VFA effluent was adjusted to maintain the same composition of the feedstock throughout the experiments (Table 1).

Table 1- Composition of the utilized volatile fatty acids as the feedstock

Volatile fatty acid	Percentage (% w/w)
Acetic acid	67
Propionic acid	20
Butyric acid	5
Isovaleric acid	6.5
Valeric acid	0.75
Hexanoic acid	0.75

Each cycle initiated with the replacement of half of the reactor working volume with mineral medium and VFAs broth (2 g L^{-1}). The medium contained: K_2HPO_4 3.2 g/L; KH_2PO_4 1.6 g/L; 0.2 g/L $MgSO_4.7H_2O$ and 5 mM NH_4Cl and 2 ml/L of trace elements. Temperature and pH remained uncontrolled in the reactors. The contents of each bioreactor were continuously stirred. The dissolved oxygen level was kept above 20% through an air pump sparging into each bioreactor.
The wild-type species *Cupriavidus necator* and *Burkholderia cepacia* were grown separately in a minimal medium. These species were bioaugmented (10% v/v) as mono- and co-culture modes in the different MMC bioreactors biweekly throughout the enrichment at the beginning of every other cycle. During the enrichment period, three fed-batch PHA accumulations were performed for 55 h to determine the biopolymer production capacity after 91, 154, and 161 days.

SHORT TERM EXPERIMENTS
In the short-term experiments, three different activated sludges were collected from the aerated tanks of the Hammarby Sjöstadsverk wastewater facility, Käppala, and Henriksdal wastewater treatment plants in Stockholm, Sweden. The biomass was enriched in 2L sequencing batch reactors for only 5 days with a similar substrate, cycle conditions, and the bioaugmentation strategy as the long-term experiments. To comprehend the influence of bioaugmentation over short-term operations, fed-batch accumulations were conducted after 3 days of enrichment for the activated sludge obtained from the Hammarby Sjöstadsverk for 12 h. In the case of sludges taken from Käppala and Henriksdal wastewater treatment plants (WWTPs), two separate fed batches were performed for 48 h after 3 and 5 days of enrichment.

RESULTS AND DISCUSSION

In the long-term experiments, the highest PHA accumulations were obtained in the second fed batch; after 154 days of enrichment and bioaugmentation. Maximum PHA accumulation of 52% (PHA/VSS) was obtained from the *C. necator*-bioaugmented reactor after 52 h, followed by 36% (PHA/VSS) with *B. cepacia*-bioaugmented reactor after 49 h (Figure 1). The maximum PHA accumulation in the control and co-culture reactors were 34% and 28% (PHA/VSS), respectively (Figure 1).
Higher PHA accumulations were obtained from the *C. necator*-bioaugmented reactor in all three fed batches, increasing the PHA production capacity by 29%, 52%, and 53% compared to the control reactor in fed-batch one, two, and three, respectively. Meanwhile, the rate of PHA accumulations was faster in the *B. cepacia*-bioaugmented reactor. By prolonging the enrichment period from 98 to 154 and 161 days, the PHA accumulation capacity did not increase significantly (between 0.2-11 %) taking into account the reactor's operation and costs over longer periods.

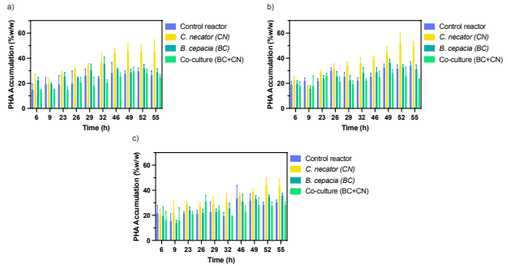

Figure 1-Polyhydroxyalkanoates production in the long-term experiments: fed batches (a) after 91 days of enrichment), (b) after 154 days of enrichment, and (c) after 161 days of enrichment

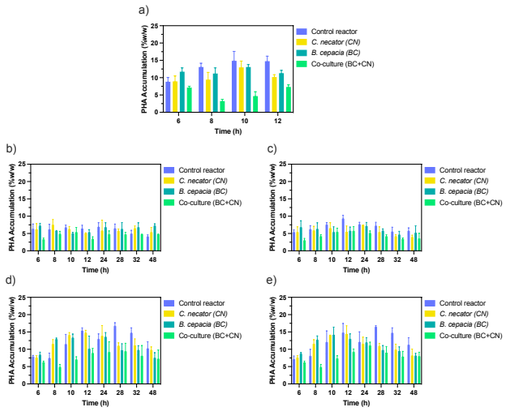

Figure 2-Polyhydroxyalkanoates production in short-term experiments: fed batches (a) after 3 days with activated sludge from the Hammarby Sjöstadsverk, (b) after 3 days of enrichment with activated sludge from the Käppala WWTP, (c) after 5 days of enrichment with activated sludge from the Käppala WWTP, (d) after 3 days of enrichment with activated sludge from the Henriksdal WWTP and (e) after 5 days of enrichment with activated sludge from the Henriksdal WWTP

In the short-term enrichments, the maximum PHA accumulations were acquired from the non-bioaugmented reactor for all the different setups regardless of the origin of the activated sludge (Figure 2). The highest PHA accumulations were 17% PHA/VSS after 28 h in the activated sludge from Henriksdal WWTP. Similar yields were obtained after 3 and 5 days of the enrichment. It is clear that the prolongation of the enrichment and bioaugmentation did not have any impact in the short-term period.

Waste-derived VFAs are suitable carbon sources that can be successfully utilized in MMC PHA production. PHA up to 52% cell dry weight was produced in the *C. necator* bioaugmented bioreactors; increasing approximately 1.6 times the accumulation capacity of the control bioreactors in the long-term enrichment experiments. In the short-term operations, the bioaugmentation did not have any influence on the PHA accumulation capacity of the activated sludges. This can probably be attributed to the short duration, meaning the synthetic cultures were not stabilized by the MMCs. The detailed results and discussions of the PHA production, VFA consumption, and changes in the microbial structure of the MMC will be presented at the conference.

This study indicated the successful influence of the bioaugmentation in MMC PHA production as a robust tool to manipulate the microbial community and to increase PHA production yield.

Abundance of biogenic compounds; Internal loading; Wastewater stabilization ponds; Wastewater reuse

INTRODUCTION

One of biggest challenges of our times is constantly growing water stress, induced by global climate crisis [UN - Water, 2019; EEA 2021, 2019]. In Europe in year 2021 the effects of drought and water scarcity affected 20% of its area and 30% of its population [EEA, 12/2021].
According to the European Environmental Agency (EEA) [EEA, 2021], we observe rapid decline in European biodiversity due to global climate change. [EEA, 2021]. Thus, there is a need to implement new solutions to mitigate water stress. EEA indicates Natural Based Solutions (NBS) as recommended solutions for global warming water stress mitigation, and reduction of its fallback on Earths biosphere [Almuktar i inni, 2018; EEA 2021, 01/2021].

Treated wastewater is seen as “endless”, reliable source of water, and as they contain number of organic material and biogenic compounds, they could also help limit usage of fertilizers.
One of possible NBSs consistent with Regulation EU 2020/741 goals are Waste Stabilization Ponds (WSPs). Wastewater stabilization ponds are widely described in literature [EPA, 2011; Butler i inni, 2017; Ratsey, 2017] However, there is lack of research done about WSPs in Central Europe climate conditions.
Researchers indicate that there is wide possibility of water reuse from wastewater, although there is need for solutions that would allow feasible fit-for-purpose treatment of wastewater, transportation, and storage of treated, ready for reuse wastewater [Ungureanu, Vlăduț i Voicu 2020; Hristov i inni, 2021; Hashem, Qi, 2021]. Wastewater stabilization ponds give good perspective for wastewater reuse, for crops irrigation, taking into account listed above limitations [Ungureanu, Vlăduț i Voicu 2020; Hristov i inni, 2021; Hashem, Qi, 2021].

MATERIALS AND METHODS

Scope of this paper is to evaluate changes of biogenic compounds concentrations in two stage waste stabilization pond (WSP) system, located in Sobótka wastewater treatment plant (WWTP). Sobótka is city located in lower Silesia voivodship. WWTP spatial plan is shown in Fig.1.

Sampling campaigns were carried out from 06.05.2021 to 14.10.2022, in month intervals (16 sampling campaigns). During sampling campaign samples were collected from sampling points shown on Fig.1 to 1.5L polyethylene containers and analysed in Environmental Engineering Institute Laboratory of Environmental Research using methods shown in Table.2.

Fig.1 Spatial plan of Sobótka WWTP

Table.2 Parameters and methods used in this research.

Parameter	Method
Nitrate nitrogen (N-NO_3^-)	Spectrophotometric method: PN-82C-04576/08
Ammonium nitrogen (N-NH_4^+)	Spectrophotometric method: PN-ISO 7150:2002
Nitrite nitrogen (N-NO_2^-)	Spectrophotometric method: PN-EN 26777:1999
Phosphates (P-PO_4)	Spectrophotometric method: ISO 6878/1:2006
pH	Potentiometric method: PN-90/C-04540.01
Turbidity	Nephelometric method: PN-EN ISO 7027-1:2016-09
Dissolved Oxygen (DO)	Insitu measurments (portable oxygen meter with galvanic probe)
Total Organic Carbon (TOC)	Supercritical Water Oxidation (SCWO) method, laboratory device TOC analyzer Sievers InnovOx by GE Analytical Instruments
Total suspended solids (TSS)	Weight method: PN-EN 872:2007

RESULTS

WSP system consist of two ponds, area of first pond is 0.47 ha and second pond area 1.35 ha, depth of both ponds is 1.1 m. Approximated HRT (Hydraulic Retention Time) of this WSP system is 8 days. As result of malfunction WSP I was skipped in treatment process and treated sewage from WWTP were directed directly into the WSP II in period 18.05.2021 to 26.07.2021 (Fig.1).
Performed statistical tests shown no difference on statistical importance level between sampling points on both waste stabilization ponds. As for turbidity and N-NO_3 differences between sampling points are on statistical importance level.
Ammonium nitrogen shows seasonal trends. With its maximal values in summer months (August 2021 – median 35.64, July 2022 – median 42.57, August 2022 -median 42.86), and minimal values in autumn and winter (November 2021– median 8.90, March 2022– median 6.28) (Fig.2).
Phosphates just like ammonium nitrogen shows seasonal trends, with maximal values in summer months. With their median values in July 2021 4.63 mg/dm^3 and 6.80 mg/dm^3 in July 2022. And minimal median values in January 2022 0.89 mg/dm^3 and after summer peak in October 2022 with median 2.29 mg/dm^3 (Fig.2). TOC concentrations raised at the beginning of sampling campaign as result of WWTP malfunction (Fig.3). Turbidity shows seasonal trends, as it raises in summer months, as result of raising sediments and WWTP malfunction (Fig.3).

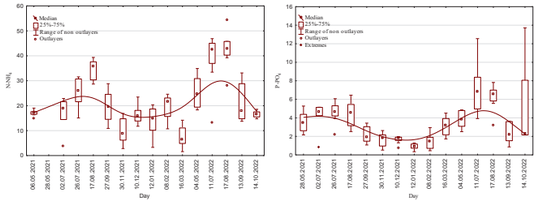

Fig. 2 Seasonal changes of ammonium nitrogen (N-NH_4) and phosphates (P-PO_4) in WSP treatment pond system

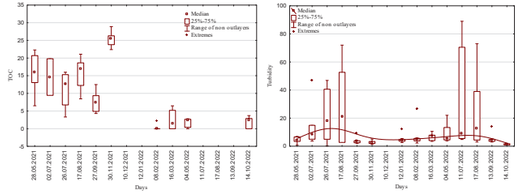

Fig.3 Seasonal changes of Total Organic Carbon (TOC) and turbidity in WSP treatment pond system

DISCUSSION

During sampling campaign at day 28.05.2021r. foamed activated sludge flowed out to the WSP I, and covered its surface with blanket like structure over sampling points no. 3 and 4. Created structure settled down in next few days. In seasons with higher temperatures, settled parts of “activated sludge blanked” emerged to the surface again.
Increased biological activity during spring and summer months connected with overload of organic material from WWTP malfunction depletes dissolved oxygen. Which changes redox potential, allowing reduction of compounds in sediments to dissolvable forms (internal loading), and intensification of methanogenic decomposition of organic matter [Søndergaard, Jensen, Jeppesen, 2001; EPA, 2011; Keffala, 2011; Butler i inni. 2017; Augustyniak i inni, 2017]. Moderate positive correlation between N-NH_4 and P-PO_4; moderate correlation between N-NH_4, P-PO_4 and temperature. High negative correlation between TOC and DO, high negative correlation between DO and mean temperature. All those correlations, and sampling point observations support occurrence of internal loading with methanogenic decomposition.
Due to described phenomenon’s there is degradation in quality of treated wastewater on ponds in terms of biogenic compounds due to processes described above. Although there is improvement in terms of turbidity and TSS due to the buffer capacities of ponds.

CONCLUSIONS

- Main factor shaping changes of phosphates concentrations (and thus, total phosphorus concentrations) in WSPs is phenomenon called internal loading in the period of biggest biological activity. Correlation between biological activity and temperature indicates seasonality of internal loading.
- Main source of ammonium nitrogen in ponds is effluent from WWTP. Although in period of increased biological activity, internal loading with methanogenic decomposition elevates ammonium nitrogen concentrations.
- Changes in N-NO_2 and N-NO_3 nitrogen forms is in line with the nitrification and denitrification intensity described by other researchers.
- Thanks to buffer capacities of WSPs limit shifts in quantity and quality of treated effluent, in case of turbidity and TSS there is improvement in quality of final effluent in comparison to WWTP effluent.

Abstract
As the amount of sewage sludge continues to increase, sludge volume reduction through dewatering is essential. In sludge dewatering, EPS (Extracellular Polymeric substance) is known as a parameter that inhibits sludge dewatering. To evaluate the effect of EPS on the dewaterability of the sludge, two types of digested sludge (sewage sludge alone and sewage sludge mixed with food wastewater) were dewatered by the filter press method. As a result, the concentrations of LB-EPS and TB-EPS in the digested sludge of 'S' WWTP were lower than those of 'N' WWTP. In addition, as a result of filter press dehydration, the discharge rate of the dewatering filtrate of 'S' WWTP was faster than that of 'N' WWTP, and the water content after 30 minutes of dehydration was about 76%, which was lower than that of 'N' WWTP. It was confirmed that the higher the EPS content, the lower the dewatering.

Keywords: Dewaterability of sludge; Extracellular polymeric substances; Filter press

INTRODUCTION

According to domestic sewerage statistics in South Korea, the annual amount of sludge generated by sewage treatment plants is 4.22 million tons, a 71.7% increase over the past 10 years. As the amount of sewage sludge generated continues to increase every year, considerably high coasts are being spent on sludge treatment due to the limitation of sludge treatment capacity of local governments. In order to reduce sewage sludge treatment costs, sludge reduction is essential. Accordingly, many studies are being conducted to improve sludge dewatering.

Many studies have shown that the characteristics of extracellular polymeric substances (EPS) play an important role in the sewage sludge dewaterability. EPS is composed of a variety of organic substances including carbohydrates and proteins as the major constituents and humic substances, uronic acids and nucleic acids in smaller quantities. There are not many analyses on the EPS effect on dewaterability of digested sludge [1]. In addition, there is a possibility of EPS accumulation due to aboudant microbial residues in the organic waste digestive fluid after digestion [2].

In this study, we compared and analyzed the digested sludge of the two WWTPs to confirm the relationship between EPS content and dewaterability.

MATERIALS AND METHODS

Material

The sludge samples was collected from the 'N', 'S' wastewater treatment plant (WWTP) in the Busan, South Korea. In case of "S" WWTP, food waste and process water are mixed in a ratio of 1:4, and treated food wastewater and sewage sludge are mixed in a ratio of 1:5. Table 2-1 shows the characteristics of sludge samples.

Experimental procedure

Prior to the experiment, sludge conditioning was conducted by a jar test and conditioned using following procedure: (1) Coagulants addition (PAC, 100 mg/g TS), (2) 200 rpm stirring for 1 min, (3) 50 rpm stirring for 10 min.
After conditioning, 300 mL of digested sludge was injected into the filter press device, and the compression pressure was 1 MPa.

Table 2-1. Characteristics analysis results of WWTPs sludge.

Samples		pH	TCOD (mg/L)	T-N (mg/L)	T-P (mg/L)	VS/TS (%)	Water content (%)
"S" WWTP	Mixed sludge	5.15 ± 0.03	32,536 ± 5235	904 ± 175	469 ± 98	75.73 ± 6.03	96.45 ± 0.06
	Digested sludge	6.95 ± 0.03	17,929 ± 458	1,534 ± 92	586 ± 42	46.50 ± 3.61	98.27 ± 0.01
"N" WWTP	Mixed sludge	5.61 ± 0.06	29,098 ± 5,894	1,328 ± 806	672 ± 201	94.95 ± 6.82	96.19 ± 0.01
	Digested sludge	7.08 ± 0.02	31,443 ± 3,355	2,368 ± 325	1,040 ± 74	40.58 ± 5.40	97.42 ± 0.01

EPS extraction

A thermal method was used to extract different fractions of sludge EPS. In this case, two types of EPS were separated: the loosely bound EPS (LB-EPS) and the tightly bound EPS (TB-EPS). The first one was extracted by adding an 0.05% NaCl buffer solution at 70°C and mixing it for 1 min. After the mixture was centrifuged, the tightly bound EPS was extracted by adding an 0.05% NaCl buffer solution at room temperature and placed in a water bath at 60 °C for 30 min.

Analysis

TCOD, SCOD, TS, and VS were analyzed according to Standard Methods. Total A polysaccharide (PS) was analyzed using the phenol-sulfuric acid method. Glucose was used as standard. Protein (PN) was determined to used Protein Kit (Sigma-Aldrich, TP 0330) based on Lowry's description, but modified by Peterson. The Kit includes a standard solution. For the determination of absorbance, a spectrophotometer (K-LAB, Optizen pop) was used. The pH was measure using a pH meter (HI 9124, HANNA, USA).

RESULTS AND DISCUSSION

Concentration change of mixed-disgested sludge

Table 3-1 shows the measured SCOD and extracted EPS content of proteins (PN), polysaccharide (PS) from two WWTPS of digested sludge. After mixed sludge digestion in 'S' WWTP, the removal rates of SCOD and TS were about 97% and 51%, respectively, and the removal rates in 'N' WWTP were about 78% and 32%, respectively. As a noteworthy feature, the concentrations of PN and PS in the thickened sludge of the 'S' WWTP were higher than those of the 'N' WWTP, and the concentrations of PN and PS in the digested sludge were lower in the 'S' WWTP than in the 'N' WWTP.

The concentrations of SCOD, PN, PS, and VS of the food wastewater (FWW) of 'S' WWTP were 94,721, 130,783, 11,791 and 151,291 mg/L, respectively, indicating a high biodegradable organic matter content. Many studies have reported that food wastewater is suitable for use as a common substrate for digesters due to its high biodegradable organic matter content [3]. Therefore, it is believed that the high PS and PN concentrations of 'S' WWTP are due to the soluble carbohydrates and proteins derived from FWW. The higher removal efficiency of SCOD and TS of the 'S' WWTP indicates a higher efficiency of the digester.

Table 3-1. Organic content of WWTPs sludge.

Samples		SCOD (mg/L)	VS (mg/L)	TS (mg/L)	PN (mg/L)	PS (mg/L)
"S" WWTP	Mixed sludge	10,957 ± 510	26,887 ± 2,574	35,475 ± 556	979 ± 46	9,218 ± 1,403
	Digested sludge	289 ± 8	8,016 ± 611	17,275 ± 63	179 ± 10	57 ±2
"N" WWTP	Mixed sludge	2,389 ± 14	36,130 ± 2,592	38,053 ± 116	751 ± 95	201 ± 69
	Digested sludge	532 ± 32	10,474 ± 1,357	25,820 ± 102	257 ±12	127 ± 36

Concentration change of LB-EPS and TB-EPS

Figure 3-1 shows the concentrations of LB-EPS and TB-EPS in the digested sludge of the two WWTPs. The concentrations of LB-EPS and TB-EPS in the digested sludge of 'S' WWTP were lower than that of 'N' WWTP. In previous studies, the concentrations of LB-EPS and TB-EPS tended to gradually decrease with the increase of HRT in the early stage of digestion (1–17 days). The contents of PN and PS were decreased by the activity of hydrolase and the growth of bacteria decomposing organic matter. In 'S' WWTP, it is judged that the digester efficiency was high by FWW, so the reduction of PN and PS contents was more pronounced.

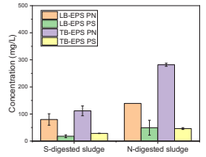

Figure 3-1. EPS content extracted from two WWTPs of digested sludge.

Dewaterability evaluation

Figures 3-2 and 3-3 shows the water content and filtrate discharge rate measured by the filter press system for two types of digested sludge. The rate of discharge of dewatering filtrate in 'S' WWTP was faster than that of 'N' WWTP, and the water content after 30 minutes was about 76%, which was lower than that of 'N' WWTP.

It is known that high EPS content can trap water molecules inside the EPS floe, increasing polymer demand and reducing dehydration [4]. This is because when the content of LB-EPS or TB-EPS is high, the relative hydrophilicity of the digestive fluid is strengthened by generally covering the bound water, resulting in low dehydration and coagulation effects [5].

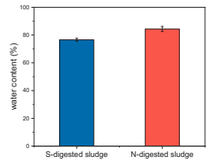

Figure 3-2. Water content of two type of digested sludge according to filter press system dewatering.

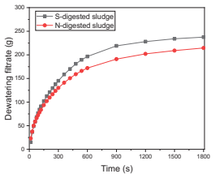

Figure 3-3. Cumulative dewatering filtrate amount of two types of digested sludge using filter press system.

CONCLUSION

The results of EPS extraction and dewaterability evaluation by two WWTPs of digested sludge are as follows. The concentrations of LB-EPS and TB-EPS in the digested sludge of 'S' WWTP were lower than those of 'N' WWTP. In addition, as a result of filter press dehydration, the discharge rate of the dewatering filtrate of 'S' WWTP was faster than that of 'N' WWTP, and the water content after 30 minutes of dehydration was about 76%, which was lower than that of 'N' WWTP. It was confirmed that the higher the EPS content, the lower the dewatering.

Abstract

Two enrichment units with mixed microbial cultures (MMCs) were operated: R1 fed with oleic acid and R2 fed with the oily fraction of a fish-canning industry effluent from canned tuna. The reactors operated stable at 30 ºC for more than 60 days and then the temperature was increased to 35 ºC, to favour the hydrolysis of the oily substrates. This increase of temperature did not change the main characteristics of the reactor's effluent in terms of pH value and soluble COD. However, the ratio PHA:TAG changed from 77:23 to 9:91 in R1 and from 74:26 to 6:94 in R2, indicating that the increase of the temperature promotes the preferential growth of TAG producers over PHA ones.

INTRODUCTION

The fat, oil and grease (FOG) fraction present in wastewater is difficult to treat by conventional biological processes and for this reason it is normally separated in a first step in wastewater treatment plants (WWTPs), either municipal or industrial (Wallace et al., 2017; Frkova et al., 2020). This separated FOG fraction can then be valorised to obtain biopolymers like polyhydroxyalkanoates (PHA) and/or triacylglycerides (TAG). These biopolymers can be intracellularly accumulated by certain microorganisms using as carbon source the FOG fraction (Argiz et al., 2021). Normally the production of biopolymers by mixed microbial cultures (MMCs) requires two units: a first reactor to promote the enrichment of the MMC with the ability to accumulate PHA and a second reactor to maximize the accumulation of the biopolymers. Therefore, an adequate enrichment is crucial to have high accumulation percentages. In the case to use the FOG fraction as carbon source the uptake of the substrate by the accumulating microorganisms can be limited by its hydrolysis. As it is well known the increase of the temperature favours the hydrolysis of FOG compounds, however little is known about the effect over the microorganisms and their ability to accumulate preferentially PHA and/or TAG. Therefore, the objective of the present research work is to understand how an increase in the operational temperature from 30 to 35 ºC affects the process in two different enrichment units: one fed with a synthetic medium (oleic acid) and other fed with an industrial FOG residue.

MATERIALS AND METHODS

Two enrichment laboratory sequencing batch reactors (SBRs), R1 and R2, with a useful volume of 4 L were used for the experiments. The SBRs were fed with different oily carbon sources: R1 with oleic acid and R2 with the oily fraction of the industrial effluent from tuna cookers. These reactors were operated under the feast/famine (F/F) regime, in cycles of 12 hours and with the enrichment double growth limitation (DGL) strategy via separated C and N feedings. At the beginning of the cycle half of the volume (2 L) was removed and replaced by a single pulse of new culture media containing the carbon source (1.28 g COD/L in R1 and 0.83 g COD/L in R2). After 5 hours nitrogen source was introduced in the form of ammonium chloride (26 mg NH_4^+-N/L). The hydraulic and solids retention times (HRT and SRT) were of 24 h. Both SBRs operated stable at 30 ºC for more than 60 days and then the temperature was raised at 35 ºC.

RESULTS AND DISCUSSION

In both enrichment units (R1 and R2) the increase of the temperature neither affect the soluble COD concentration nor the pH value in the reactor's effluent, with values around 200-300 mg COD/L and 6.2-6.4, respectively. However, in R1 the nitrogen concentration increased from values close to zero (at 30 ºC) to 10 mg N/L (at 35ºC) indicating a decrease in the nitrogen consumption and, consequently, in the microbial growth. While in R2 the nitrogen concentration remained close to zero at both temperatures, except in punctual days when it reached values of 5-10 mg N/L. In this reactor after the increase of temperature to 35 ºC, an increase of the substrate's hydrolysis was observed in the first minutes after the carbon source feeding, as the soluble COD concentration rose up from 116,66 ± 3,93 to 169,43 ±3,93 mg/L. This increase was not observed at 30 ºC. In R1 the increase of soluble COD after carbon source addition was not observed neither at 30 nor at 35 ºC.

The improvement of the hydrolysis of the substrate resulted in a slight increase of the amount of active biomass and the percentage of compounds accumulated (Table 1). The active biomass raised in both systems; however, it was less significative in the case of R1, which correlates with the lower nitrogen consumption at high temperature. The maximum PHA storage capacity of the MMC increased in R1 from 34% to 41% and in R2 from 39 to 41%, at 30 and 35 ºC, respectively. Regarding the moment in which the maximum storage occurred (Figure 1) in R1 it was after 5 hours of carbon source feeding at both temperatures, that corresponds with the moment of nitrogen source addition. However, in R2 the maximum storage takes place at 4 and 2 hours for 30 and 35 ºC, respectively. The shorter feast phase in R2 can be correlated with the lower COD addition in the feeding and the higher amount of active biomass in comparison with R1. Regarding the compounds accumulated over the 12 hours of cycle in the enrichment units (Figure 1) the increase of temperature from 30 to 35 ºC promoted a higher accumulation of TAG in detriment of PHA (Table 1). The results showed that the PHA:TAG ratio changed from 77:23 to 9:91 in R1 and from 74:26 to 6:94 in R2. Despite that at 35 ºC the production of PHA is lower it is important to highlight that the ratio PHB:PHV changed (Table 2) and that the temperature increase favoured the production of PHV, which can be desirable for some PHA applications. Finally, despite using two different carbon sources (synthetic oleic vs industrial FOG waste) the behaviour of both enrichment units with the increase of the temperature was similar, mainly regarding the ratio of PHA:TAG accumulated, which indicates that the operational parameters, instead of the carbon source, can drive the preferent compound accumulated.

Abstract
Next generation wastewater treatment plants (WWTPs) have to deal with energy scarcity. High-rate activated sludge (HRAS) processes produce higher amounts of sludge than conventional activated sludge systems, thus they offer an opportunity to increase the production of biomethane. The objective of this study is to find the operational conditions able to recover a higher fraction of organic matter into sludge to later determine the energy savings in comparison to conventional WWTPs. With this purpose, two HRAS reactors were operated at two levels of dissolved oxygen (DO), respectively, and four hydraulic retention times (HRT), keeping the sludge retention time at 4 d. Results suggest that low levels of DO do not impair the recovery of organic matter, and decreasing the HRT might slightly reduce the total removal of organic matter but not the recovered fraction, which was around 30% at a HRT of 8 h.

Biomethane, COD mass balance, energy recovery, high-rate activated sludge, wastewater

INTRODUCTION

High-rate activated sludge (HRAS) processes are considered as an opportunity to transform the wastewater treatment plants (WWTPs) paradigm from energy consumers into producers, or at least self-sufficient facilities. Its main advantages, in comparison to the conventional activated sludge system, are the lower energy consumption in terms of aeration, no need of primary clarifier and the higher sludge production that can be anaerobically digested and converted into biomethane (Carrera et al., 2022). Therefore, HRAS should be operated under conditions that allow to meet the standards of effluent quality, but also a high production of sludge. To achieve both objectives the fraction of organic matter removed by oxidation into CO_2 should be restricted in benefit of a higher recovery into sludge. This study aims to determine the optimal conditions of dissolved oxygen (DO) and hydraulic retention time (HRT) that maximize the fraction of organic matter recovered into sludge. This will allow us to determine the energy savings of a WWTP configuration with a HRAS system in comparison with a conventional WWTP.

MATERIALS AND METHODS

Description and operational conditions of the HRAS units

Two HRAS lab-scale systems (2 L reactor + 1 L sedimentation tank) were inoculated with biomass from a conventional activated sludge reactor and operated for ~ 5 months at room temperature, which varied between 18 and 23 ºC. The sludge retention time (SRT) in both HRAS reactors (R1 and R2) was kept at around 4 d. Aeration was monitored and controlled so that the reactors operated at two different levels of DO, as shown in Figure 1. The 5-month operation of each HRAS system was divided in 4 periods with different HRT (12 h, 8 h, 4 h and 2 h) to assess the effect of this parameter and DO in COD recovery (Figure 1).

The biological reactors were continuously fed with real wastewater, taken from the municipal WWTP of Santiago de Compostela (Spain) after the pretreatment step (just before entering the primary clarifier). Due to dilution during rainy periods, a synthetic concentrate was additionally added to ensure a minimum COD concentration of 400 mg O_2/L (Table 1).

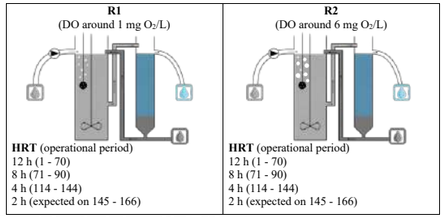

Figure 1. Operational scheme of the HRAS reactors

Table 1. Composition of the synthetic concentrate.

Compounds	mg/L
Sodium acetate ($CH_3COONa \cdot 3H_2O$)	84
Acetic acid (CH_3COOH)	36.2
Yeast extract	63.5
Ammonium chloride (NH_4Cl)	120.6
Potassium dihydrogen phosphate (KH_2PO_4)	6

Analytical methods

The reactor performance was monitored twice per week in terms of pH, TS, VS, TSS, VSS, COD, NH_4^+, NO_2^- and NO_3^- collecting samples from the influent and effluent and analysing them according to the Standard Methods by triplicate. Sludge from the purge and samples from the reactor were characterised every week in terms of TSS and VSS. Temperature and pH were daily monitored inside the reactor while DO was continuously monitored.

Calculations

Sludge purge flowrate was controlled daily to achieve a SRT of 4 days according to Table 2. The COD recovery and the COD mass balance (Table 2) was calculated in a five-day period assuming a ratio of 1.42 kg O_2/kgVSS (Carrera et al., 2022).

In order to address the implication of a HRAS system on energy recovery of a WWTP, an energy balance is conducted on an innovative WWTP scheme (HRAS + partial nitritation-anammox) in comparison with the conventional WWTP (primary clarifier + conventional activated sludge). Moreover, the influence of operational parameters, such as HRT or DO, on this energy balance is assessed.

Table 2. Definition and calculation of the COD mass balance and SRT.

COD in the influent (COD_{inf})	$mCOD_{inf} = Q_{inf} \cdot tCOD_{inf}$
COD in the effluent (COD_{eff})	$mCOD_{eff} = Q_{eff} \cdot tCOD_{eff}$
COD recovered (COD_{rec})	$mCOD_{rec} = \left(\sum Q_{sl} \cdot VSS_{sl} + \sum Q_r \cdot VSS_r\right) \cdot \frac{1.42\ mg\ O_2}{1\ mg\ VSS}$
COD balance	$mCOD_{inf} = mCOD_{eff} + mCOD_{ox} + mCOD_{rec}$

$$SRT = \frac{V_{reactor} \cdot VSS_{reactor}}{Q_{purge} \cdot VSS_{purge} + Q_{effluent} \cdot VSS_{effluent}}$$

m: mass flow rate (mg O_2/d); *Q*: volumetric flow rate (L/d); *tCOD*: total COD concentration (mg O_2/L); *sl*: sludge purge; *r*: reactor sampling

RESULTS

HRAS performance

The first two operational periods were carried out at a HRT of 12 h and 8 h. The third campaign (HRT 4 h) is ongoing and will be followed by the fourth and last period with an HRT of 2 h, which is expected to be finished by the end of February. From day 40 (Figure 2), real sewage was mixed with the synthetic concentrate due to the low COD observed during the previous rainy days. Therefore, from that moment 70-90% of the tCOD was soluble.

A stable operation was achieved in both reactors during the first two operational periods, reaching total and soluble COD removals of 80 – 90% and 75 – 95%, respectively, in both reactors (Figure 2). pH values varied between 6.5 – 7.5 and low nitrification values were observed through the operation (<1% NO_3^- and <5% NO_2^-). VSS were maintained during the first operational period at 1200 and 1500 mg/L in R1 and R2, respectively. During the second period, biomass concentration increased up to 1800 and 2400 mg/L in R1 and R2.

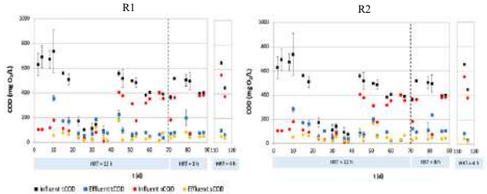

Figure 2. Total (t) and soluble (s) COD concentrations in influent and effluent on both reactors during the different operational periods.

Effect of HRT and DO in COD recovery

Figure 3 shows the distribution of the total COD among the different fractions at each operational period. During the first period (HRT = 12 h), DO seems to be a key parameter in COD recovered as sludge. Although a higher aeration appears to slightly increase COD removal from 87% in R1 to 93% in R2, this COD is not recovered but mineralised, as COD recovery decreases from 34% to 18%, respectively. During the second period of operation (HRT = 8 h), DO does not have a clear effect on COD recovery (27% in R1 versus 32% COD in R2). Therefore, these results suggest that higher DO levels in HRAS systems do not have a positive impact on COD recovery or COD removal.

Concerning the effect of HRT, it was observed that lower COD eliminations were achieved when reducing the HRT in both reactors (i.e., higher COD values were measured in the effluent, Figure 3). This might be due to biomass inability to completely metabolise the organic matter at such rate. The data from the next two operational periods will contribute to confirm these preliminary conclusions regarding the effect of HRT and DO on the COD recovery.

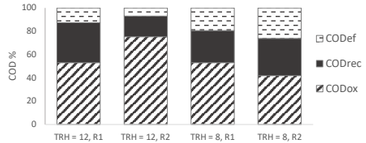

Figure 3. COD distribution (effluent, recovered into sludge and oxidized) in each operational period.

Abstract
Carbon recovery from sewage sludge by anaerobic fermentation is usually modest due to low volatile fatty acids yields. The potential of anaerobic fermentation in the wastewater treatment plants in a region was carried out, integrating the management of sewage sludge with possible co-substrates issued from local organic waste producers. The co-fermentation blends were defined using computer-aided methods and compared to sludge monofermentation, demonstrating the potential of co-fermentation to increase the yields of volatile fatty acids and their composition.

Keywords
Anaerobic co-fermentation; arrested methanogenesis; carboxylate platform; organic waste; sewage sludge; volatile fatty acids.

INTRODUCTION

While anaerobic digestion is the most common technology for recovery of organic carbon from sludge, other novel schemes based on anaerobic fermentation can lead to higher added-value products. The so-called carboxylate biorefinery is a set of processes whereby a substrate rich in organic carbon is first converted into volatile fatty acids (VFA) and, subsequently, into other products including medium-chain carboxylates, biopolymers or energy carriers.

Sewage sludge, produced annually at approximately 23 kg total solids (TS) per person-equivalent in wastewater treatment plants (WWTP) can be a substrate for the carboxylate platform. However, anaerobic fermentation of sewage sludge often leads to low VFA yields, e.g., between 10%-32% in mesophilic conditions (Esteban-Gutiérrez et al. 2018). A successful strategy aimed at increasing the conversion of sewage sludge to biogas consists of blending sludge with other organic wastes which are more readily degradable and may complement the composition of sludge. As other organic wastes are normally not produced or collected in municipal WWTPs, transporting large volumes of waste over long distances would offset the profit and possible environmental benefits of sludge co-fermentation. Therefore, candidates for co-fermentation should be collected at a limited distance from the WWTP.

In this study, an evaluation to the potential of carbon recovery by anaerobic co-fermentation was carried out for a number of WWTPs. First, the conversion to VFA was assessed in batch tests. To increase the VFA yield, a number of co-fermentation blends were proposed where the available wastes were selected using two different computer-aided methods.

MATERIALS AND METHODS

Approach. For each of the 7 WWTPs in the region that counts with anaerobic digestion on-site, an inventory of organic waste producers was elaborated based on available information on the net and direct inquiries. The inventory includes the distance to the WWTP, nature of the organic waste, volume of waste produced and potential seasonality. Wastes were characterized by measuring solid contents, chemical oxygen demand (COD), total Kjeldahl nitrogen, percentage of potassium and phosphorus and concentration of the main cations and anions.

Acidification tests. Sludge acidification tests were carried out in 0.5 L bottles at 37ºC gently mixed in orbital shakers. In each bottle, 5 g/L of volatile solids (VS) of anaerobic digester biomass was used as inoculum and mixed with 5 gVS/L of sewage sludge. Experiments were replicated with different inoculum to ensure the independence from the sampled biomass. Sewage sludge was sampled from the feed to the anaerobic digester. Methanogenesis was inhibited in these tests by addition of 0.5 g of 2-bromo-ethane sulfonate (BES) per g of substrate. At the beginning of the test, pH was adjusted to pH 7.5 and, if needed during the test, manually readjusted by addition of concentrated HCl or NaOH. Tests were carried out in duplicates, lasted for 11 days monitored by the following parameters: pH, alkalinity, total and soluble COD, VFA and total and volatile solids.

Co-fermentation tests. To increase the acidification yield, co-fermentation tests were carried out. The candidate wastes were selected for each WWTP out of those in the inventory located at less than 30 km from the WWTP. Then, two computer-aided tools were used to define the optimal mixture of sludge and organic wastes: the Optiblender (Garcia-Gen et al. 2014), which aims at defining the blend that maximizes the yield of methane (taken here as a proxy for VFA yield) and the method proposed by Saavedra del Oso et al (2022), specifically tailored to predict the VFA yield and spectrum of organic wastes mixtures, but limited to two substrates. Blends were required to have a minimum of 80% sludge (weight basis) as the main goal of the study is to assess alternatives to sludge valorisation. An additional constraint was not to exceed the available waste volume produced in the surroundings of the WWTP. To provide a fair comparison of the results, the sum of the sludge + organic wastes was kept at 5 gVS/L in all the experiments.

RESULTS AND DISCUSSION

The first acidification tests showed significant variability among the WWTPs (Figure 1) that could not be directly related to the WWTP process characteristics, with acidification yields ranging from 8% to 50% (COD basis). Testing different inocula, i.e. the biomass from each WWTP digester and as a common biomass the one from WWTP A digester, did not lead to significant differences in acidification yields.

To increase the acidification yield, co-fermentation blends were proposed and tested experimentally. As an example, the blends for WWTP C are shown here (Figure 2). The proposed blend by Optiblender for one of the WWTPs included (in weight basis) 89% of sludge, 4% of bread and pastry waste, 3.8 % of dairy sludge, 1.6% of dairy waste and 1.2% of slaughterhouse waste. This blend was appropriate as it would not exceed the production of each of the organic waste streams. It was seen that the VFA yield was more than doubled for the same amount of VS used in the substrate (although different substrate COD content). Even more, for the same VS, the concentration of VFA is higher than for the any of the individual substrates showing the goodness of co-fermentation for reaching higher conversions. Finally, substrate blending leads to higher fractions of longer chain VFA and branched VFA which may be of interest if VFA are to be further processes, e.g. to produce biopolymers such as polyhydroxyalkanotes.

As a conclusion, although VFA yield from sludge is, in general, modest, anaerobic co-fermentation with suitable substrates can lead to higher VFA yields and a spectrum richer in longer-chain VFA, demonstrating the potential of integrating sludge management together with other organic wastes.

Mechanisms of Hexavalent Chromium Reduction by *Rhodococcus qingshengii* strain SC26

A. Melzi*, M. Colombo* and L. Cavalca*

* Department of Food, Environmental and Nutritional Sciences (DeFENS), University of Milan, Via Celoria 2, I-20133 Milan, Italy (E-mail: *lucia.cavalca@unimi.it*)

Abstract
Chromium represents a serious threat for both human health and ecosystems equilibrium. It is mainly present in two stable inorganic forms: trivalent (CrIII) and hexavalent (CrVI), the latter one being more toxic due to its high solubility and mobility in biological systems. The major pollution sources are electroplating and tannery industries. Among possible remediation strategies, the use of biological systems can be proposed since microorganisms interact with metals by passive adsorption processes and active enzymatic reactions.
In the present study, *Rhodococcus quingshengii* strain SC26 was characterized for its ability to resist Cr(VI) (MIC of 300 mg L^{-1}) and reduce Cr(VI) to Cr(III) in growing cells conditions. *R. quingshengii* strain SC26 was able to reduce Cr(VI) to Cr(III) up to 51.14 mg L^{-1} and the reduction was always paralleled by cell growth. Part of the metal was present on cell pellet (1.9 mg g^{-1}). Not proliferating cells were not able to reduce/adsorb Cr(VI), thus excluding passive adsorption processes. Trials conducted with contaminated wastewaters from the electroplating industry are ongoing to assess the bioremediation potential of *Rhodococcus qingshengii* strain SC26 in close-to-real scenarios.

Keywords (maximum 6 in alphabetical order)
Heavy metal removal; hexavalent chromium reduction; *Rhodococcus qingshengii*; wastewater bioremediation.

INTRODUCTION

Nowadays the presence of heavy metals in water bodies represents a serious environmental and human health threat. Chromium (Cr) is known for its widespread utility in various industrial processes such as industrial welding, dyes and pigments manufacturing, electroplating processes, leather tanning and wood preservation (Pushkar, *et al.,* 2021). Therefore, it is one of the most hazardous heavy metals discharged into surface water (Roşca, *et al.*, 2023). Cr is present in the environment mainly in two inorganic stable forms: trivalent (CrIII) and hexavalent (CrVI). Cr(VI) is the most hazardous one, being considered 1,000 times more toxic than Cr(III) (Diaconu, *et al.,* 2020). In some electroplating effluents, Cr(VI) concentration ranges from 6 to 887 mg L^{-1}, being the Cr(VI) and total Cr limits of 0.005 and 0.05 mg L^{-1}, respectively, in surface and ground waters (Directive 2000/60/CE). Therefore, the implementation of strategies to reduce Cr(VI) to Cr(III) and to remove total Cr from industrial wastewater is fundamental to reduce heavy metal pollution (Roşca, *et al.*, 2023). Among these strategies, the use of microorganisms can represent a sustainable alternative to conventional physico-chemical processes (Demarco, *et al.,* 2023). Beside Cr adsorption processes, bacteria can reduce Cr(VI) to the less toxic Cr(III) by intracellular or extracellular reduction mechanisms mediated, respectively, by aspecific ROS-scavenging and Cr(VI)-specific reductase systems (Diaconu, *et al.,* 2020).
The aim of the present study was to characterize Cr(VI) reduction and Cr adsorption mechanisms in *Rhodococcus qingshengii* bacterial strain SC-26, in order to envisage the most promising set-up for the development of a biological system useful to reduce Cr pollution in wastewater.

MATERIALS AND METHODS

Bacterial strains

Nine strains [As3-5a(1), As3-5a(3), As3-5a(4), As3-5a(5), SC5III, SC37, SC3I(2), SC23, and SC26] previously isolated from arsenic- (Cavalca *et al.,* 2010a) and petroleum hydrocarbon-(Cavalca *et al.,* 2010b) contaminated soils, were tested to assess their Cr(VI) resistance and reduction.

Determination of Cr(VI) Minimum inhibitory concentration

Cr(VI) Minimum inhibitory concentration (MIC) was determined on different minimum mineral media: M9 (Kunz and Chapman, 1981), DF (Dworkin and Foster, 1958) and TMM (Mergeay *et al.*, 1985). Na-gluconate (0.6 % *wt/vol*) was added as carbon and energy source. Increasing concentrations of Cr(VI) were tested between 25 and 500 mg L^{-1}, in the form of $K_2Cr_2O_7$ (VWR BDH Chemicals, Radnor, Pennsylvania, US) at pH of 5.67. Bacterial growth was determined by spectrophotometric analysis (OD_{600nm}).

Not-proliferating cell experiment in the presence of Cr(VI)

In biofilm-based system, 4 and 8 mL of bacterial suspensions (OD_{600nm} of 2), prepared in distilled water, were separately deposited onto 0.2 µm cellulose acetate filter (Millipore, Burlington, MA, USA). 50 mg L^{-1} Cr(VI) prepared as $K_2Cr_2O_7$ (VWR BDH Chemicals) solution added to MilliQ water, were vacuum-forced across the biomass-activated filter, with a few seconds of contact. Metal content of the flow through was analyzed by inductively coupled plasma spectrophotometry (ICP-MS).
In planktonic cell system, biomass was resuspended in 12 mL of 50 mg L^{-1} Cr(VI) solution added as $K_2Cr_2O_7$ (VWR BDH Chemicals) and stirred in plastic tubes (100 rpm at 23 °C). The effect of contact time on Cr(VI) reduction and biosorption was determined on cell biomass and supernatant after 0, 4, 72, and 168 h of incubation. Bacterial suspensions were centrifuged (15 min at 10,000 rpm) and the biomass total Cr and the supernatant Cr(VI) were analyzed by ICP-MS and by diphenyl carbazide (DPC) spectrophotometric methods, respectively. Each experiment was conducted in triplicate and the abiotic controls were always analyzed.

Growing cell experiment in the presence of Cr(VI)

R. qingshengii strain SC26 (inoculum 2% *vol/vol*, $OD_{600\ nm}$ of 2) was separately incubated for 7 days in DF mineral medium and in Luria Bertani (LB) rich medium, in the presence of approximately 50 mg L^{-1} Cr(VI) prepared from $K_2Cr_2O_7$ (VWR BDH Chemicals) solution. At subsequent incubation times, bacterial growth was determined (OD_{600nm}). Total Cr present on cell pellet was determined by ICP-MS analysis. Cr(VI) in the supernatant was determined by DPC spectrophotometric method (OD_{540nm}) according to Dean and Beverly (1958). Each experiment was conducted in triplicate and the abiotic controls were always analyzed.

RESULTS AND DISCUSSION

Cr(VI) MIC of isolated strains

Cr(VI) MIC was found to be 25 mg L^{-1} for most of the tested strains, the only exception being represented by *R. qingshengii* strain SC26 with a MIC of 300 mg L^{-1} Cr(VI). Resistance towards Cr is very variable in bacterial isolates. The MIC value of strain SC26 is consistent with Cr tolerance previously reported by Sevak *et al.* (2023) who found that only a few tested bacterial isolates were resistant to 300 mg L^{-1} Cr(VI) and only one isolate could tolerate up to 500 mg L^{-1}. Due to Cr resistance and the ability of the *Rhodococcus* genus to cope with different pollutants (Nazari, *et al.,* 2022), strain SC26 was chosen for further study.

Cr(VI) reduction to Cr(III) by SC26 not-proliferating cells

Not-proliferating cells didn't perform Cr removal or Cr(VI) reduction in biofilm-based and planktonic cell experiments (Table 1), being the amount of Cr present in abiotic solution always close to that of biotic ones. Total Cr biomass content was negligible.

Table 1. Cr (VI) concentrations in biofilm-based and planktonic cell experiments.

	SC26 biofilm		SC26 planktonic			
	OD_{600nm}=2	OD_{600nm}=4	0 h	4 h	72 h	168 h
Cr(VI) (mg L^{-1})	49.55 ± 1.01	49.88 ± 0.64	50.706 ± 3.737	51.065 ± 5.457	51.245 ± 4.609	49.807 ± 2.549

Cr(VI) reduction to Cr(III) by SC26 growing cells

Growing cell experiments performed in the presence of increasing concentrations of Cr(VI) from 32 to 146 mg L^{-1} (Figure 1) showed that Cr(VI) reduction to Cr(III) was inversely related to bacterial growth: increasing metal concentrations exerted cell toxicity thus affecting SC26 ability to reduce Cr(VI). These preliminary experiments evidenced that Cr(VI) transformation was strictly related to the growth of SC26 bacterial cells.

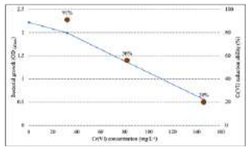

Figure 1. Cr(VI) reduction ability (%) ● of strain SC26 in growing cell experiment ⟷ at increasing Cr(VI) concentrations (32, 82 and 146 mg L^{-1}).

Analysis performed at increasing incubation times conducted in the presence of 50 mg L^{-1} Cr(VI) (Figure 2) confirmed that the reduction of the metal was parallel by cell growth, either in DF mineral minimal medium and in LB rich medium. After 7 d incubation, Cr(VI) present in the supernatant was 31.59 and 4.45 mg L^{-1} in DF and LB media, respectively, and the specific total Cr content of cell biomass was 7.62 and 1.92 mg g^{-1} cell d.w.. These data permit to determine that the strain was able to reduce 16.46 and 51.14 mg L^{-1} Cr(VI) to Cr(III), respectively. Abiotic controls did not show any Cr(VI) reduction. The ability of reducing Cr(VI) to Cr(III) while increasing in biomass and cell density was also reported by Guatam *et al.,* (2022), who observed the secretion of chromate reductase in the culture medium and intracellular enzyme activity.

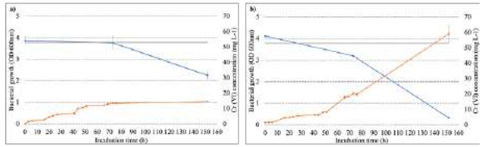

Figure 2. Cr(VI) reduction in *R. qingshengii* strain SC26 growing cell experiment performed in DF (a) and LB (b) media, in the presence of 50 mg L^{-1} Cr(VI) OD_{600nm} , Cr(VI) and total Cr concentrations — over seven days (152 h) of incubation.

The data obtained suggest that *R. qingshengii* strain SC26 is able to lower Cr toxicity either by reducing Cr(VI) to Cr(III) and by adsorbing Cr onto the cell biomass. Further analysis will determine the adsorbed Cr form. Experiments in the presence of real wastewaters are on-going.

Vinyl Chloride Biodegradation In Contaminated Aquifer Undergoing Stimulation Treatment

M. Bertolini*, S. Zecchin*, A. Melzi* and L. Cavalca*

* Dipartimento di Scienze per gli Alimenti, la Nutrizione e l'Ambiente (DeFENS), Università degli Studi di Milano, via Celoria 2, 20133 Milano, Italy, martina.bertolini@unimi.it, sarah.zecchin@unimi.it, lucia.cavalca@unimi.it

Abstract
Vinyl chloride is chloroethenes. It is very toxic for human because of its carcinogenicity. Vinyl chloride accumulations are widely present in chlorinated solvents contaminated area due to it hard transformation in anaerobic conditions by microorganisms. Nevertheless, it is efficiently biodegraded in microaerobic and aerobic conditions by bacteria. The first enzyme involved in its oxidation is alkene monooxygenase (AkMO), encoded by *etnABCD*.
In this work, aerobic oxidation activity of vinyl chloride present in a contaminated aquifer was investigated in order to trace microbial activities involved in the decrease of vinyl chloride. Laboratory scale experiment confirmed that vinyl chloride bacterial populations were active at the site. Molecular analyses conducted *in situ* allowed to monitoring oxidation activity and to determine the effects of biostimulation on microbial community present in the aquifer.

Chlorinated ethenes; Vinyl chloride; Aerobic oxidation;

INTRODUCTION

Chlorinated aliphatic hydrocarbons are the cause of soil and groundwater contamination due to a inadequate disposal. In Europe, chlorinated organic compounds are present in10% of contaminated water and 8% of contaminated soil (JRC, 2014). European directive indicated tetrachloroethene (PCE) and trichloroethene (TCE) as priority contaminant (Directive 2006/118/EC).
Chlorinated solvents are recalcitrant to traditional treatments, but they are efficiently transformed by microorganisms. Highly chlorinated ethenes (PCE and TCE) are dechlorinated in anaerobic conditions (organohalide respiration) by bacteria that use these compounds as energy source, organo-halide respiring bacteria, OHRB (Dolinová et al., 2017). This metabolic pathway is not efficient for lower chlorinated ethenes, dichloroethenes (DCE) and vinyl chloride (VC) (Abe et al., 2009), that can be oxidated in aerobic conditions by different bacteria (e.g. *Mycobacterium, Nocardioides, Rhodococcus*). These aerobic bacteria use VC (and similarly ethene) as sole carbon source, with production of water, CO2 and Cl-. In VC oxidation pathways, only the first two enzymes are known: alkene monooxygenase (AkMO), encoded by genes *etnA, etnB, etnC*, and *etnD*, and epoxyalkane:coenzyme M transferase (EaCoMT) encoded by *etnE* gene (Coleman & Spain, 2003). It has been hypothesized that the last compound of the degradative pathway enters into TCA cycle (Mattes et al., 2005).
Accumulation of VC in chloroethenes contaminated matrix results of incomplete anaerobic organohalide respiration turns out an important problem.
In this study, microbial community of contaminated aquifer was monitored to determine the efficiency of an aerobic biobarrier in sequence of an anerobic biobarrier on stimulation of VC oxidation.

MATERIALS AND METHODS

Ethene/VC degrading bacteria isolation from enrichment culture

Aerobic microcosms were set up in order to determine the presence of ethene/VC degrading bacteria in the contaminated aquifer. Vials were prepared with groundwater from piezometers near aerobic biobarrier with addition of ethene (3 mmol L^{-1}). Abiotic control samples were set up with sterile MSM and the addition of ethene. Enrichment cultures were incubated on an orbital shaker at 30°C in the dark. Enrichment cultures were monitored for 10 days, and ethene concentrations were analysed through gas chromatography with flame ionization detector (GC-FID). Bacterial strains were isolated from enrichment cultures according to their ability to use ethene as sole carbon source, and subsequently, they were identify.

Nucleic acid extraction methods and *etnC* quantification

Groundwater biomass was filtered by using a peristaltic pump apparatus. Filters were stored at -20°C until processed. Total DNA was isolated from the pellet using the DNA PowerSoil® Isolation kit (Qiagen, Germany) in triplicate for each sample.
16S rRNA genes of total bacteria and *etnC* (gene that encodes for one of subunit of AkMO) were quantified through real time quantitative PCR.

Microbial community characterization

Effects of biostimulation treatments on groundwater microbial community were investigated through Illumina sequencing of Bacteria 16S rRNA genes. Groundwater bacterial community was characterized at January 2021 and after one year (January 2022). Sequence analyses were performed with QIIME2 (Caporaso et al., 2010). Amplicon Sequence Variants (ASVs) were created in accordance with a similarity higher than 97% using UCLUST method. ASVs were aligned to the SILVA database.

RESULTS AND DISCUSSION

Ethene enrichment cultures showed growth highlighting the presence in the aquifer of bacteria that can use ethene/VC as sole carbon source. Isolated bacterial strains were identify as: *Mycobacterium frederiksbergense, Bacillus mobilis, Ralstonia pickettii, Ralstonia solanacearum, Simplicispira hankyongi*. Ethene degradation tests were set up with the 4 strains that showed a faster growth. *Mycobacterium frederiksbergense* strain 1.1 and *Ralstonia solanacearum* strain M4 degraded added ethene after 4 days of incubation, *Bacillus mobilis* strain 2 after 5 days, and *Simplicispira hankyongi* strain 6A after 7 days (Figure 1).

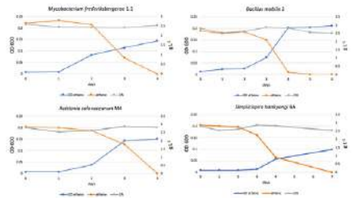

Figure 1. Growth and ethene degradation curves of isolated strain. *Mycobacterium frederiksbergense* ceppo 1.1, *Bacillus mobilis* ceppo 2, *Ralstonia solanacearum* ceppo M4, *Simplicispira hankyongi* ceppo 6A.

The gene for the first enzyme of VC oxidative pathway (alkene monooxygenase) was selected to monitoring VC mineralization activity for one year. Analysis showed that *etnC* was present in the aquifer with order of magnitude between 10^4 and 10^7 gene copies L^{-1} and it increased during the time. Statistical analysis of ratio *etnC*/16S rRNA showed that increase during the time was significant (ANOVA, $p<0.05$). At the end of monitoring year, the two piezometers downstream the biobarrier showed higher presence of *etnC* (Figure 2).

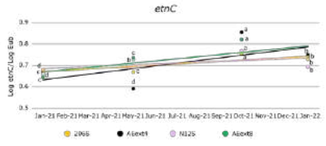

Figure 2. Ratio etnC/16S rRNA of all sampling points in biobarrier during one year. Lowercase letters indicate significant or not significant difference between different time (ANOVA, $p<0.05$).

Analysis of microbial community 16S rRNA genes sequencing in the aquifer showed that the biostimulation treatment induced a significant change in the microbial community composition (Permanova, $p < 0.05$). Indeed, β diversity of bacterial community of piezometers upstream the biobarrier were significant different than one of piezometers downstream the biobarrier (Figure 3).

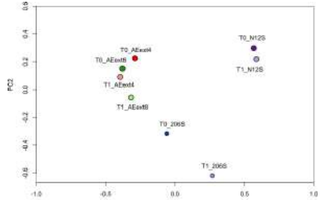

Figure 3. Analysis of bacterial community β diversity in the aquifer near the biobarrier

Treatment induced a high similarity between the bacterial community of downstream piezometers. This effect persisted after one year of treatment. The two piezometers upstream the biobarrier showed a significant diversity between them. Addition of air and nutrients induced after one year an increase of relative abundance of *Mycobacterium* and *Rhodoferax*, known VC-degrading bacteria, and *Simplicispira*, characterized for its VC/ethene degrading activity during this project (Figure 4).

Figure 4. Relative abundance significant variation at genus level in bacterial community between January 2021 and January 2022 in biobarrier.

CONCLUSIONS

In the aquifer, VC/ethene degrading bacteria were present. Presence of gene involved VC oxidative pathway was detected.
The addition of air and nutrients induced significant change in bacteria community with a selection of bacterial composition downstream the biobarrier. Treatment determined an increase of VC/ethene degrading bacteria in the aquifer.

Thermal treatment assessment to improve the phosphorus recovery as struvite from olive mill wastes

Mendoza M.*, Espejo L.**, Tey L.*, Viñas M.*, Fernández B.*

*IRTA Institute for Food and Agricultural Research and Technology, Torre Marimon, Road C59, km 12, E08140 Caldes de Montbui, Barcelona, Spain. **University of Barcelona, Barcelona, Spain. Email: marlene.mendoza@irta.cat; belen.fernandez@irta.cat.

Abstract

A thermal treatment at different pressures and temperatures was assessed for phosphorus solubilisation, before its recovery, contained in a mixture of olive oil mill pomace and olive oil mill wastewater. The highest increments of soluble phosphate, compared to the initial content were 55 % at 130 ºC & 10 bar (condition E), followed by 47 % at 100 ºC & 2.5 bar (condition C). Under any of these treatments, the soluble content of potassium and ammonium also increased thus allowing the recovery of 88-97% of the solubilised phosphate as a precipitate from hydrolysates or liquid fractions of treated mixtures; this precipitate was predominantly struvite ($MgNH_4PO_4.6H_2O$). Furthermore, mesophilic biomethanation tests of the remaining solid phase of the treated materials revealed an increment of methane production yield of +25% and +14% at conditions C and E, regarding the untreated mixture.

Keywords: olive pomace, phosphorus solubilisation, struvite, thermal treatment.

INTRODUCTION

A thermal treatment to improve the recovery of essential nutrients (N, P, K) required for olives production (Kolakovic, et al., 2021; Hadrami, et al., 2004), that were included in olive pomaces (OP) and olive mill wastewaters (OMWW), was developed as an improvement of the current valorisation strategy of a real olive oil cooperative that was already treating their mill wastes in a biogas plant. This work was designed as a proof of concept before implementing this strategy at field scale, to facilitate the closing of the olive oil production loop. Therefore, the main objectives of this study were (i) to improve the recovery of phosphorus as a salt from a mixture of OP and OMWW, and (ii) the production of biogas of the remaining material after the production of the phosphate salts.

MATERIALS AND METHODS

Two mixtures (initial-1 and initial-2) of OP:OMWW (wet weight ratio 56:44 %) were prepared. The mixture initial-1 was prepared with OP and OMWW collected in 2021 October, while mixture initial-2 contained OP and OMWW collected in 2022 January. All wastes were taken in the same industrial olive oil mill (Santa Bárbara, Tarragona, Spain) and were characterized similarly (TS, VS, COD, TN, TP, TK, pH, and soluble ions as phosphate, potassium, ammonium, nitrite, nitrate).

Both mixtures were submitted to a 60-minute thermal treatment in two ranges (Figure 1 and Table 1): low range or 50 - 75 - 100 °C at 2.5 bar (treatments A, B and C, respectively); high range or 100 – 130 - 180 °C at 10 bar (treatments D, E and F, respectively). After the thermal treatment, the treated mixtures were centrifuged (8,500 rpm, 10 °C, 20 minutes) to obtain a liquid and solid phases (L and S, respectively). The subsample L was characterised by its content in soluble ions, before the phosphorus recovery test, while all S subsamples were submitted to a biochemical methane production (BMP) test at 37 ºC for 34 days to determine their potential methane yield (Otero et al. 2021).

The solubilised phosphate was recovered by precipitation, adjusting the magnesium and phosphorus molar ratio (1:1 or 2:1), at ambient temperature (22ºC) and constant pH 10.5 (using a 40 % NaOH solution). The trials were made in batch in two steps: first, stirring at 200 rpm for 60 minutes (reaction and nucleation); then, no stirring for 60 minutes (crystal growth and precipitates settling).

The recovered phosphate as struvite was calculated based on the stoichiometric molar ratio of struvite precipitation (Eq. 1), after the experimental determination of the precipitated ions (Eq. 2). The initial and remaining content of soluble ions was determined by ion chromatography.

$$Mg^{2+} + NH_4^+ + PO_4^{3-} \rightarrow MgNH_4PO_4.6H_2O \quad Eq.\ 1$$

$$Ions_{initial} - Ions_{remaining} = Ions_{precipitated} \quad Eq.\ 2$$

RESULTS AND DISCUSSION

The mixtures initial-1 and initial-2 had a soluble phosphate content of 1,018 ±54 and 958 ±68 mg/kg, and an initial soluble potassium content of 3,923 ±67 and 3,771 ±81 mg/kg, respectively. Comparing the composition of soluble ions before and after the thermal treatments, the best phosphate solubilisation was attained with conditions C (100 ºC, 2.5 bar) and E (130 ºC, 10 bar) (Table 1), being the soluble phosphate a 47 and 55 % higher than the initial soluble phosphate respectively. Under these C and E conditions, the content of soluble potassium also increased (a 28 and 37 % higher than the initial soluble potassium in C and E, respectively) as well as the soluble ammonium content (17 and 18 % of the initial TN in C and E, respectively).

Based on the best results of phosphorus solubilisation, the hydrolysates or L phases of materials submitted to conditions C and E were selected to phosphorous recovery. The recovery assays were named C1, E1, C2, and E2, being the subscript equivalent to the Mg:P molar ratio (1:1 or 2:1) (Figure 2). In terms of phosphorus recovery, an 88% ±0 and 97% ±0 of soluble phosphate was recovered in C1 and E2 respectively. The recovery was 90% ±3 and 90% ±2 of soluble phosphate in the precipitates in C2 and E2, respectively, but some added magnesium remained not precipitated (Figure 2A); therefore, an optimisation of the combined processes of thermal treatment and precipitation would be done in a near future.

Considering the molar ratio for the formation of struvite (Eq.1), the amount of PO_4^{-3} and Mg^{+2} that precipitated under conditions C1 and E1 might indicate that struvite crystallization was completed (Figure 2B). The quantity of struvite obtained in each condition were 1.58, 1.74, 1.57 and 1.69 g-struvite/kg of initial mixtures in C1, E1, C2 and E2, respectively. Potassium struvite (K-struvite or MgKPO4.6H2O) could also be formed; however, ammonium ions competed and hindered the K-struvite precipitation based on the precipitation potential (p_{Ksp}) of struvite and of K-struvite (p_{Ksp} 12.5-13.6 and 12.2, respectively) (Xu et al., 2015).

Once the precipitates were extracted, a significant concentration of phosphate, potassium and ammonium remained available in hydrolysates (85-185 mg-PO_4^{-3}/kg, 143-193 mg-NH_4^+/kg and 3,398-4,396 mg-K^+/kg), which can be considered as hygienised liquid fertilisers due to the applied thermal treatment. The assessment as fertilisers of precipitates, and the remained fractions, through a phytotoxicity test are currently on-going.

Once the phosphorous was recovered, the S fraction of the treated mixture would be valorised in the biogas plant. The initial untreated mixtures had a methane yield of 219 and 316 NLCH4/kgVS (initial 1 and initial 2). After the thermal treatment, the methane yield was higher than methane yield of the untreated mixture for S fractions from treatments A (+16 %), C (+25 %) and E (+14 %). Other treatments showed negligible or no increment of the methane yield (+1 % from B solids; -5 and -6 % from D and F solids). The solubilisation of compounds such as polyphenols (Batista et al. 2014), or their intermediate compounds due to thermal decomposition, may have inhibited the methanogenic activity for B, D and F solids. Therefore, the best methane yield was obtained under treatment C, followed by treatments A and E (Table 1).

CONCLUSIONS

The recovery of essential nutrients NPK, together with biogas production, can be key to implement a circular economy model in the agricultural olive oil sector, obtaining non-fossil fertilisers and renewable energy from its own wastes. This study showed an improvement of soluble P (the soluble phosphate increased 47 - 55 % after the treatment under the best conditions C and E), soluble K and soluble N after the thermal treatment. This solubilisation, plus the adjustment of the Mg: P molar ratio to 1:1, allowed the recovered of the 88-97 % of the soluble phosphate, predominantly as struvite. Therefore, the best thermal treatment was C (100 ºC and 2.5 bar) considering its lower energy demand (compared with treatment E), the high phosphate recovery and the higher methane yield increment of its corresponding solid fraction (its methane yield was +25 % higher that the untreated mixture after treatment C).

Abstract
Because of high phosphorus content, the possibility of using treated anaerobically stabilised sewage sludge (digestate) as a fertiliser product is very ambiguous. The management of phosphorus in agriculture, as a critical raw material, begins at the urban wastewater treatment plant as phosphorus removal from wastewater (biological and chemical) and continues with the comprehensive characterisation of treated sewage sludge (pellets), expanded research of physico-chemical properties and the phase-mineralogical transformation of pellets' thermal residues, and researches of phosphorus bioavailability from resulted material. With a suitable technological pre-treatment of digestate and environmentally safe phosphorus recovery (preventing the unwanted possibility of heavy metals' leaching), new recycling strategies could be established to recover the valuable components of sewage sludge and strengthen the circular economy in waste processing.

Keywords
Bioavailability; pelletised digestate; phosphorus recovery; struvite; thermal residues; urban wastewater.

INTRODUCTION

In the European Union (EU), the use of sewage sludge in agriculture is regulated by the Sewage sludge framework Directive (SSD) (Directive, 1986), which is implemented differently by each EU Member State, reflected in the different limit values of critical parameters. The set of parameters for which the SSD prescribes limit values is short. It also does not specify a declaration for the content of C_{org} (organic carbon), primary nutrients (PN), secondary nutrients SN), macronutrients (MACN), and micronutrients. This shows the fact that there is an urgent need for the unification of the existing European market for fertilisers based on treated waste. In order to achieve this and to include as much recovered waste as possible in the raw material cycle, the EU has recently adopted a Fertilising Regulation (FR) (Fertilising Regulation, 2022). According to the vision of FR, the 'EU fertilising product' is a product labelled with the logo CE ("conformité européenne") when made available on the market. Also, it includes fertilisers from recovered or organic materials. The FR, which was entered in full into force on 16 July 2022, will not affect the implementation of SSD. Treated wastes that have the potential to be used as fertiliser according to the new FR are wastes that are composted or anaerobically stabilised (hygienic and with the content of polycyclic aromatic hydrocarbons below 6 mg/L), precipitated phosphate salts and derivates, thermal oxidation materials and derivates, together with pyrolysis and gasification materials. The possibility of using treated anaerobically stabilised sewage sludge (digestate) as a fertiliser product is still ambiguous. Considering the new possibilities of material utilisation of pelletised digestate, it also makes sense to reevaluate older research. A case study of the composition of treated sewage sludge generated at the Central wastewater treatment plant in Ljubljana (CWWTPL) (JP VOKA SNAGA 2006) has been performed. At the annual level, incorporated into the pellets, there are about 1,500 tons of organic matter expressed as total organic carbon (TOC), 230 tons of nitrogen, 80 tons of phosphorus, 13 tons of potassium and 16 tons of magnesium transported from the site of the plant to the location for final processing. Due to the impoverishment of natural sources of phosphorus, it is essential to find opportunities for recycling it.

MATERIALS AND METHODS

The yearly production of pellets at the CWWTPL is up to 4300 tons (designed capacity of 360,000 population equivalent) in the form of grain size diameter of 2 mm to 4 mm. We analysed non-treated digestate, centrate (technological wastewater after mechanical dehydration of digestate), pellets (annual representative samples of the years 2012 (sample Y2012), 2014 (sample Y2014), 2016 (sample Y2016), 2018 (sample Y2018), and 2021 (sample Y2021). Additionally, we prepared two types of residues, one simulating the bottom ash and a second type of residue simulating the biochar. We have used three kinds of techniques for the sample preparation: i) semi-pilot equipment for pyrolysis (sample BC 2014), ii) thermogravimetric analysis of the sample Y2012, using inert atmosphere (pyrolysis), TG/DTG in the range from 30 °C through 450 °C (sample "Pyrolysis 450 °C), iii) the ignition of pellets (sample Y2012) in the laboratory heating furnace at 450 °C (sample Ignition 450 °C), 550 °C (sample Ignition 550 °C), 700 °C (sample Ignition 700 °C), and 900 °C (sample Ignition 900 °C). In the resulting residues, we have determined the content of nutrients (TOC, P, K and Mg) and their mineralogical composition by XRD analysis and SEM-EDS technique; the proportion of water-soluble part of phosphorus with the EN 13652.

RESULTS AND DISCUSSION

The results in Table 1 show that the pellets have a reasonably reproducible composition and high nutrient content.

Elements in granules can have the function of nutrients if they are water-soluble or if they are bioavailable. This is especially important for phosphorus and potassium recovery. In this process, emphasis is needed on preventing the re-entry of heavy metals into the environment. The paper will show the bioavailability of nutrients and the potential leaching of heavy metals from pellets.

ASH utilisation

Despite anaerobic stabilisation and biogas production, the pellets still contain enough organic matter to be used for the waste-to-energy (WtE) process. In addition to energy recovery, the WtE enables the material recovery of many inorganic compounds or elements in the granules (Figure 1). In addition to carbon, nitrogen, hydrogen, sulphur and phosphorus, the inorganic content presents the major elements in pellets. Some elements are also on the critical raw material list (Communication, 2017; Critical raw materials, 2012). To evaluate ash as a suitable fertiliser or as a fertiliser additive, it is essential to study the phase-mineralogical transformations that occur during the burning of pellets (Figure 1 and Figure 2) and the bioavailability of nutrients - especially phosphorus. The contribution will show the rate of bioavailability's loss of nutrients due to thermal treatment in oxidative conditions.

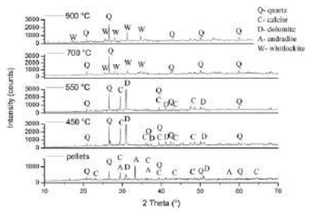

Figure 1. XRD analysis of pellets (Y2012) and their combustion residues.

PYROGEN MATERIAL utilisaton

The major part of the carbon content in pellets is bound in substances which, in an inert atmosphere when heated to 450 °C, are volatile or are thermo-chemically converted into volatile gaseous compounds. That makes sense to convert the pellets into pyrolytic products and then into fertiliser according to the FR (Figure 2), especially because the results show that phosphorus has better bioavailability in this case.

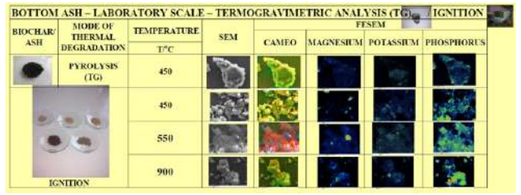

Figure 2. SEM analysis of combustion residues of sample Y2012 and its pyrogenic residue after thermal load at 450 °C.

NON-TREATED DIGESTATE utilisation

Non-treated digestate and centrate present valuable materials for struvite precipitation (Figure 3). As a spontaneous precipitation process, struvite is a disturbance, but it shows us the possibility of taking advantage of this chemical reaction. This is an essential strategy for phosphorus recovery.

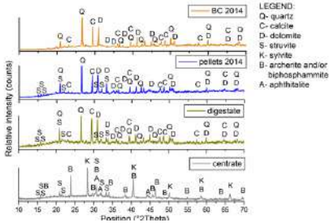

Figure 3. XRD patterns of centrate, digestate, pellets Y2014 and BC 2014.

CONCLUSION

Evaluation of the pellets and their solid combusted (ash) and pyrolytic residues according to FR is a complex procedure. New economically viable technologies need to be developed to recover the nutrients from digestate, centrate and treated sewage sludge's thermal residues to increase the extraction of essential components. Some materials recovered from treated sewage sludge are still considered as waste, even though they contain valuable nutrients that provide good market value [Position paper, 2021]. The example of the FR, explicitly defining the conditions or processes under which struvite or ashes and pyrolitic material from urban wastewater treatment plants would not longer be defined as waste and a product instead, would be a good starting point [Position paper, 2021]. In order to preserve natural sources to as large degree as possible it is especially important to find new recycling strategies.

Abstract
Gas-permeable membrane (GPM) technology is a N-recovery technology that could contribute to the mitigation of ammonia emissions while obtaining a fertilizing product. A global approach for the reduction of NH_3 emissions in a pig farm is reported in this study. Two pilot plants based on GPM technology were installed and evaluated on-farm, one plant for the N-capture in the atmosphere of the farm building and another for the capture of ammonia in the liquid manure of the manure storage tank. Nitrogen was successfully recovered as fertilizing product (i.e. ammonium sulphate) in both pilot plants. The temperature positively influenced TAN recovery rates in both systems.
Keywords
Ammonia recovery, Gas-permeable membranes, pig farm, swine manure

INTRODUCTION

Ammonia emissions reduction is of major importance for the competitiveness of the EU livestock sector. In the case of Spain, reductions of 16% are expected in 2030, in comparison to the 453 kt of NH_3 produced in 2005, the baseline year (NEC Directive (2016/2284). The agricultural sector was responsible for 3.6 million tons of NH_3 emissions in 2017, being released from the livestock buildings (44%), the manure storages (25%) and during land application (31%). Gas-permeable membrane (GPM) technology is a N-recovery technology that presents high recovery rates while not altering farm operations. Moreover, GPM technology transforms volatile NH_3 into a marketable fertiliser $(NH_4)_2SO_4$, so that this technology contributes to GHG reduction, since NH_3 production currently emits 1.5 ton of CO_2 per ton of NH_3. The LIFE Ammonia Trapping project demonstrated at on-farm pilot plant scale that the GPM technology successfully captures NH_3 from pig manure and from the air in animal buildings (TRL 6). The LIFE Green Ammonia aims at increasing the TRL of GPM technology through the design, evaluation and commercialization of improved models for N-capture. This study reports a global approach for the reduction of NH_3 emissions in a pig farm, both from the atmosphere of the farm building and from the liquid manure in the manure storage tank.

MATERIALS AND METHODS

Pilot plants configuration

Two pilot plants were designed, built and tested on farm: The NH_3-recovery pilot plant for gases (Soto-Herranz et al., 2021) and the NH_3-recovery pilot plant in liquids (Molinuevo-Salces et al., 2020). Both pilot plants were based on the GPM technology using tubular membranes made of ePTFE, with an outer diameter of 5.2 mm, a wall thickness of 0.64 mm and a polymer density of 0.95 g cm^{-3}. The NH_3-recovery pilot plant for gases consisted of a 2.6 m^3 steel structure with 32 membrane panels. The surface area of the membrane used was 7.7 m^2. The pilot plant contained a single-phase wall-mounted fan, two ammonia sensors, a recirculation pump for the acidic solution, a 0.25 m^3 tank for the storage of the acidic solution, a sealed distribution pipe connected to the 32 parallel membrane panels, a collecting pipe, pH and temperature probes, a pressure gauge to monitor the pressure of the acidic solution and a PLC system to control the equipment. The NH_3-recovery pilot plant in liquids was equipped as follows: A manure feeding pump, a 5.85 m^3 ammonia separation reactor tank with a module of 16 membrane panels, a blowing air pump for aeration, a manure recirculation pump for mixing the reactor, a 0.25 m^3 tank for ammonia concentration and for the trapping solution storage, a recirculation pump for the trapping solution, a heating blanket and a PLC control system. The surface area of the membrane used was 13.07 m^2, the ratio of membrane length per manure volume was 0.16 m L^{-1} and the ratio of the membrane area per volume of manure was 0.0026 m^2 L^{-1}.

Location

The experiments were carried out in Guardo (Palencia, Spain). The pilot plants were located in a sow farm with 2800 animals, generating a volume of swine manure of approximately 17,136 m^3 per year. More specifically, the NH_3-recovery pilot plant for gases was located inside a gestating sow house with 912 places, with a natural ventilation system. The NH_3-recovery pilot plant in liquids was installed inside a mobile shipping container, which was placed outside the farm building, next to a manure storage pit.

Experimental procedure and sampling

The NH_3-recovery pilot plant in liquids was evaluated during seven months in 2018. First, a setup period of 56 days was carried out to optimize the pilot plant operation and then the pilot plant was operated in batch mode. Five batch experiments (B1-B5) were carried out to evaluate the performance of the pilot plant at real environmental conditions. The NH_3-recovery pilot plant for gases was evaluated for eight-months in 2019. A two-month trial was first performed to optimize the performance of the equipment. Then, the plant was operated in continuous mode. Analyses of total ammonia nitrogen (TAN) were performed once per week both in the acidic solutions and in the manure. pH and temperature were daily monitored.

RESULTS AND DISCUSSION

Ammonia gas reacts with the acid of the trapping solution (sulphuric acid in this case) to form $(NH_4)_2SO_4$, that remains in the liquid phase. Ammonium sulphate is a valuable fertilizer. The TAN recovery in the acidic solution was 4108 g in 232 days for the NH_3-recovery pilot plant for gases and it was in the range of 1357-5457 g in batch experiments of 7 to 20 days for the NH_3-recovery pilot plant in liquids (Table 1). As it can be seen from the results, the amount of N that was recovered was in the same range, both in the liquids and from the atmosphere, but the latter in much lower time. This is due to the higher concentration of TAN in the manure than in the atmosphere of the farm building. In this way, and as it was previously reported by Soto-Herránz et al., (2021), the capture of nitrogen gas directly from the atmosphere would be only effective if the TAN concentration is high. So that, it seems appropriate to install GPM technology after the forced ventilation systems of the animal buildings.

Table 1. TAN recovery in the acidic trapping solution.

	Unit	Gas-recovery pilot plant	Pilot plant for ammonia recovery in liquids				
			B1	B2	B3	B4	B5
TAN acidic solution	g	4108	2198	5457	3296	1357	2301
Experimental time	days	232	11	7	20	14	20

Regarding TAN recovery rates a high variation between summer and winter months was observed. In the case of the NH_3-recovery pilot plant for gases, an average rate of 1.6 g TAN m^{-2} day^{-1} was obtained during the summer season and an average rate of 3.9 g TAN m^{-2} day^{-1} was registered during the winter season (Table 2). These results are in accordance with the higher ammonia concentrations registered in the farm house during winter, in comparison with the summer months. This is a consequence of an increase in ventilation in the animal houses during the summer season due to the harmful gases accumulated in the buildings with the high temperatures of summer. In the case of the gas pilot plant, operating the pilot plant would be more useful in winter months or in periods without natural ventilation. This it would contribute to reduce NH_3 emissions inside the buildings while recovering N in the form of ammonium sulphate.

Table 2. TAN recovery rates related to temperature.

	Unit	Gas-recovery pilot plant		Pilot plant for ammonia recovery in liquids				
		Summer	Winter	B1	B2	B3	B4	B5
TAN recovery rate	g TAN m^{-2} day^{-2}	1.6	3.9	25.2	38.2	16.1	8.4	10.9
Temperature	ºC	17.9*	5.8*	26.8**	28**	24.6**	20**	21.5**

*Temperature is referred to outdoor ambient temperature
**Temperature is referred to temperature in pig manure

On the other hand, in the NH_3-recovery pilot plant in liquids the TAN recovery rates during the different batch experiments were in the range of 8.4 and 38.2 g TAN m^{-2} day^{-1} (Table 2). These differences were in accordance with seasonal variations in manure temperature, so that a positive exponential relationship between temperature and TAN recovery (R^2=0.87) was found in this case. The higher temperature in the manure, the better TAN recovery rate.

CONCLUSIONS

Nitrogen was successfully recovered as ammonium sulphate both in the liquids and from the atmosphere using GPM technology. The temperature positively influenced TAN recovery rates in both systems. For N-recovery in gases, 1.6 g TAN m^{-2} day^{-1} were obtained during summer and 3.9 g TAN m^{-2} day^{-1} during winter. In the N-recovery in liquids, the rates ranged between 8.4 and 38.2 g TAN m^{-2} day^{-1}.

Abstract
The use of cheese whey for VFA production through anaerobic fermentation is being widely studied as a green and renewable alternative for whey valorisation. The study of kinetic models helps to predict the results of this process. Cheese whey was fermented in batch, at pH 5.5 and pH 10, and at constant temperature of 38ºC. VFA production from cheese whey shows great results. The highest production of VFA was at pH 5.5, with a yield of 9.11 g COD L^{-1}. The experimental results were analysed using two kinetic models and it was observed that to the Modified Gompertz model fits better to the pH 5.5 while the First Order model fits better to the pH 10. The best fit is for pH 5.5 using the Gompertz model, where an r^2 value of 0.9936 and a BIC value of -8.31 were found.

Keywords (maximum 6 in alphabetical order)
Anaerobic digestion; cheese whey; kinetic study; VFA production

INTRODUCTION

Cheese whey (CW) contains a high organic load, resulting in one of the main wastes to dairy industry. The cheese industry generates an average of 9L of whey for every kg of produced cheese (Guimaraes et al., 2010). CW contains mostly sugars (lactose), fat and proteins, so it is a great source of carbon and nitrogen. The current uses and management strategies for CW include animal feeding, biogas production and conversion of CW into valuable products as whey powder, lactose powder or protein concentrate (Asunis et al., 2020). The development of the dairy sector is highly dependent on the Environmental legislation, due to the GHG emissions of dairy activities (FAO and OECD, 2020). In this manner, innovative and sustainable solutions are necessary to ensure the competitiveness of dairy sector. Anaerobic digestion (AD) has proven to be a green alternative with great potential to reduce, recycle and recover various organic industrial wastes (Nguyen et al., 2019). Traditionally, investigation has been focused on maximizing methane production. However, and due to the value of the intermediate compounds, this technology is shifting to the production of volatile fatty acids (VFA) in the frame of a circular economy approach. VFA are value added molecules with a high price in the market and they are mostly produced by transformation of petrochemicals or via fermentation. Several factors influence the VFA yields and composition obtained from AD like pH (Greses et al., 2020, Yu et al. 2021), temperature, type of substrate (or inoculum), among others.
The main objectives of this study were to evaluate the influence of pH in the production and composition of VFA using CW as substrate and appling and evaluating two kinetic models (i.e. a first order kinetic model and the modified Gompertz model) to describe the kinetics and mechanisms of VFA production. A kinetic study was carried out to estimate which model presents the best adjustment and a better prediction of VFA production.

MATERIALS AND METHODS

Substrate and inoculum

Cheese whey (CW) from local cheese factories (Palencia, Spain) was used as a substrate to produce VFA. This by-product was collected and maintained frozen to avoid organic degradation. Thereafter, when was necessary, the substrate was thawed and stored at 4ºC. The inoculum was anaerobic sludge (AS) obtained from urban wastewater treatment plant of Valladolid, Spain. The CW and AS were characterized according to volatiles solids (VS), total solids (TS), total chemical oxygen demand (COD) and pH.

Experimental procedure

The experiments were conducted in a reactor with 1L of mixture substrate/inoculum (1:1, in VS proportions). The assays were performed in batch under two different conditions of pH, acidic (pH 5.5) and basic (pH 10), and at constant temperature (38ºC). The reactors were below constant mixing and the pH was adjusting every day by using 1M NaOH and 1M HCl. The temperature was maintained on the reactor glass jacket by circulation water. The VFA production assays were carried out for 14 days.

Kinetic study

Two types of kinetic model (First Order and Gompertz) were selected to predict the maximum production of VFA. The first order model Eq. (1) was selected to report the hydrolysis rate constant, while the Gompertz model Eq. (2) provides the lag phase time and the maximum VFA production rate.

First Order Kinetic model: $VFA = VFA_{max} \times [1 - exp(-kt)]$ (1)

Modified Gompertz model: $M = VFA_{max} \times exp\left\{-exp\left[\frac{VFA_{p}e}{VFA_{max}}(\lambda - t) + 1\right]\right\}$ (2)

where VFA is yield with respect to time t, VFAmax is the maximum VFA potential of the substrate, k is the hydrolysis rate constant, t is the time, VFAp is the maximum VFA production rate (g COD L^{-1} d^{-1}), λ is the lag phase time (days) and "e" is Euler's function equal to 2.7183.
The Bayesian information criterion (BIC) test Eq. (3) were used to compare the models and to determine the model that is more likely to be correct.

$$BIC = N\ ln\left(\frac{RSS}{N}\right) + K\ \ln\ (N) \quad (3)$$

where N is the number of data points, K is the number of parameters fit by the regression model, and RSS is the residual sum of the square.

RESULTS AND DISCUSSION

Production and composition of VFA

Figure 1 shows the VFA production and composition in mesophilic conditions (38ºC) and under two pH (5.5 and 10). The production of VFA was higher under acidic conditions than basic conditions, with a yield of 9.11 g COD L^{-1} and 7.01 g COD L^{-1}, for pH 5.5 and 10 respectively. The highest variety of VFA was in pH 5.5, with higher yield of propionic (2.79 g COD L^{-1}), acetic (2.58 g COD L^{-1}) and butyric acid (1.40 g COD L^{-1}). On the other hand, when operating at pH 10, the production was basically composed of acetic acid (5.78 g COD L^{-1}). Similar results, at basic conditions and using cheese whey as substrate was found in Iglesias-Iglesias et al (2020), where a higher production of acetic and butyric acid was observed. Khatami et al. (2021) corroborate the results found in this assay, where under acidic conditions also found that higher VFA produced was propionic acid and under basic condition was acetic acid.

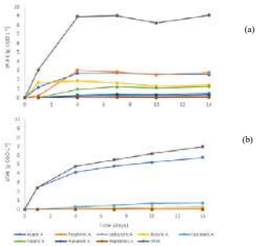

Figure 1. VFA production and composition, under pH 5.5 (a) and pH 10 (b) conditions.

Kinetic study

Figure 2 shows the graphical representation of the models indicated in equations 1 and 2. The kinetic parameters and the BIC test results are show in Table 1. High r^2 values confirm that all the models fit the experimental data. The values of k correspond to the hydrolysis rate constant. The constant k is higher for pH 5.5 than pH 10, with 0.53 and 0.33, respectively. Low k values indicate that there is a lower rate of biodegradability of the substrate and that more time is needed for VFA production to be maximum (Nguyen et al., 2019). As a result, it indicates that at pH 10 the reaction is slower than at pH 5.5. For both models, the VFA yield is higher for pH 5.5, with 9.21 g COD L^{-1} (First Order model) and 8.84 g COD L^{-1} (Modified Gompertz model), even though the first order model is closer to the experimental data.

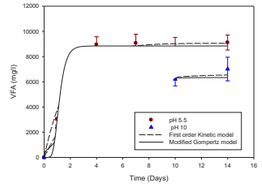

Figure 2. VFA yield from the First Order Kinetic model and Modified Gompertz model.

The VFAp is higher for pH 5.5 (9.40 g COD L^{-1} d^{-1}) than pH 10 (1.43 g COD L^{-1} d^{-1}). It indicates that the production of VFA is faster at acidic conditions than at basic conditions. The adaptation of microorganisms and the digestion response time is expressed by the lag phase (λ). The value of λ was lower for pH 10 (0 day) than at pH 5.5 (0.53 day) indicating that there is a higher adaptability of microorganisms to produce VFA at basic conditions (Pramanik et al., 2019).

Table 1. Estimated kinetic parameters for the two models.

Kinetic Model	Parameter	Units	pH 5.5	pH 10
First Order	k	day^{-1}	0.53	0.33
	VFA yield	g COD L^{-1}	9.21	6.59
	r^2	-	0.9732	0.9788
	BIC	-	-0.76	-6.34
Modified Gompertz	λ	days	0.67	0
	VFA yield	g COD L^{-1}	8.84	6.36
	VFAp	g COD L^{-1} d^{-1}	9.40	1.43
	r^2	-	0.9936	0.9437
	BIC	-	-8.31	-1.86

BIC is a statistical indicator that helps to determine the best fit between the kinetic model and the experimental data. The lowest BIC values show the most suitable kinetic model (Pramanik et al., 2019). According to BIC data, for pH 10 the best fit is for the First Order model presenting lowest values (-6.34). For pH 5.5 and using the Gompertz model, the highest value of r^2 (0.9936) and the lowest value of BIC (-8.31) were found, indicating that the Gompertz model is the best fits the experimental data at these conditions. All results of BIC are corroborated by r^2 values.

CONCLUSION

VFA production through anaerobic digestion is a sustainable way of valorization of cheese whey, using sewage sludge as inoculum. Anaerobic digestion of whey produces up to of 9 g COD L^{-1} and 7.01 g COD L^{-1}, for acidic and basic pH conditions, respectively. Under basic conditions VFA are mainly acetic acid while under acidic conditions VFA composition is more varied. First order and Gompertz kinetic models can be used to indicate the best conditions and predict the maximum production of VFA. The Modified Gompertz model fits better for pH 5.5 while the First Order model fits better for pH 10.

Aknowledgements: This study was funded by the European Union and the Rural Development Program for Castilla y León through the FEADER project LACTOCyL "Applying bioeconomy to the valorization of cheese whey for feeding, sustainable energy production and bioproducts obtention". Abstract
The thraustochytrid, *Aurantiochytrium* sp. strain L3W was applied to treat the 3 pickling (*Shisohijiki, Hiroshimana*, and *Akimurasaki*) waste liquors to remove dissolved organic carbon (DOC) and dissolved nitrogen (DN) and to produce valuable polyunsaturated fatty acids (PUFAs) such as docosahexanoic acid (DHA) and eicosapentanoic acid (EPA). The strain L3W grew on the liquid waste liquors, while adjustment of the initial pH but not sterilization was carried out as pretreatment of the waste liquors. The removal efficiencies of DOC and DN were respectively about 35-80% and 35-80%. The produced biomass contained DHA and EPA, and the DHA and EPA contents, and the *Hiroshimana* waste liquor with the initial pH7 demonstrated the highest DHA and EPA contents of 75 mg/g and 1.1 mg/g, respectively. This study provided the evidence that the thraustochytrid can be used to treat the pickling waste liquors and to produce PUFAs.

Keywords: *Aurantiochytrium* sp., pickling waste liquors, polyunsaturated fatty acid.

INTRODUCTION

Pickling waste liquors are abundant in organic compounds but hypersaline. Because of this nature, new methodologies are required to treat pickling waste liquors. Therefore, this study focused on use of thraustochytrids. Thraustochytrids are heterotrophic and halophilic microorganisms that can produce valuable polyunsaturated fatty acids (PUFAs) such as docosahexanoic acid (DHA) and eicosapentanoic acid (EPA) (Nakai et al., 2021). DHA and EPA are contained in fish oil and essential for cultured fish such as salmon (Shepherd et al., 2017). Because of issues relating to the sustainability of wild fisheries and constraints on aquaculture systems (Cadillo-Benalcazar et al., 2020), cultivation of thraustochytrids using pickling waste liquors may be beneficial via satisfying both of removal of dissolved organic carbon (DOC) and dissolved nitrogen (DN) and production of valuable PUFAs. This study aims at investigating usability of a thraustochytrid for treatment of pickling waste liquors and production of PUFAs.

MATERIALS AND METHODS

The 3 waste liquors generated from the production processes of *Shisohijiki, Hiroshimana,* and *Akimurasaki* pickles (Table 1) were collected from the pickling factory in Hiroshima, Japan. The *Shisohijiki, Hiroshimana, and Akimurasaki* pickling waste liquors were diluted with sand filtered seawater at twice, 20 times and 5 times, respectively to attain about 10000 mg/L of DOC. Adjusting to pH4 and pH7, the thraustochytrid, *Aurantiochytrium* sp. strain L3W was inoculated. To confirm whether sterilization is necessary, both autoclaved and unsterile media was tested for cultivation of the strain L3W. Growth of strain L3W was monitored by microscopic observation, and the resultant biomass was analysed by a gas chromatograph equipped with a flame ionization detector (GC/FID).

Table 1. Characteristics of the pickling waste liquors.

	Shisohijiki	*Hiroshimana*	*Akimurasaki*
pH	4.0	4.0	3.5
Salinity [PSU]	30	38	48
DOC [mg/L]	20253	192120	54970
DN [mg/L]	814	1015	7701

RESULTS AND DISCUSSION

Growth of the strain L3W

The strain L3W did grow on the unsterile *Hiroshimana* pickling waste liquor, and no difference of the growth was confirmed between the sterile and unsterile conditions at the initial pH7 (Fig. 1). This indicates that sterilization was unnecessary for treatment of the *Hiroshimana* pickling waste liquor using the strain L3W. The strain L3W grew on the tested 3 pickling waste liquors (Fig. 2), though the measured biomass may include contaminating microorganisms such as yeasts.

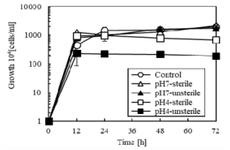

Figure 1. Growth curve of the strain L3W in the diluted *Hiroshimana* pickling waste liquor (n=3).

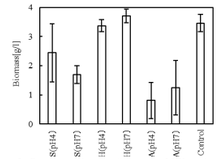

Figure 2 Biomass production of the strain L3W on the diluted *Shisohijiki* (S), *Hiroshimana* (H), and *Akimurasaki* (A) pickling waste liquors under nonsterile condition (n=3).

Removal of DOC and DN

The DOC and DN concentrations before and after cultivation of the strain L3W are compared in Fig. 3, where about 35-80% of DOC and 35-80% of DN were removed. Because the remaining DOC and DN concentrations were high, further treatment may be necessary. Possible reason for the lowest DOC and DN removal from the *Akimurasaki* waste liquor might be containment of polyphenols that can inhibit growth of the strain L3W.

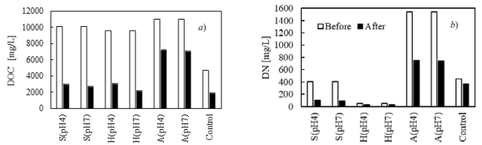

Figure 3 Dissolved organic carbon (DOC) and dissolved nitrogen (DN) concentrations before and after treatment using the strain L3W under nonsterile conditions.

PUFAs contents in the biomass of strain L3W

DHA and EPA production on the pickling waste liquors at pH7 was 15 mg/g and 0.37 mg/g for *Shisohijiki,* 75 mg/g and 11 mg/g for *Hiroshimana,* and 21 mg/g and 0.37 mg/g for *Shisohijiki,* though the cultural media were unsterile.

Abstract
Rhodobacter sphaeroides is a versatile purple non-sulfur bacteria that can be used in resource recovery to produce hydrogen, polyhydroxyalkanoates, single-cell protein and other value-added products. We developed a genome-scale metabolic model representing the primary metabolism of a denitrifying strain *R. sphaeroides* ATCC 17025. This metabolic model predicted growth, production of hydrogen and polyhydroxybutyrate, and was in better agreement with literature-based experimental values as compared to predictions from existing models for *R. sphaeroides*. We evaluated the growth, production rates and product distribution under different metabolisms and using different organic substrates. In addition, it allowed to assess the metabolic mechanisms governing the preferential generation of different products. This model can be a valuable tool to optimize the generation of value-added products.

Keywords
Hydrogen production; metabolic modelling; polyhydroxybutyrate; resource recovery; *Rhodobacter sphaeroides*

INTRODUCTION

Purple phototrophic bacteria (PPB) can be used in the resource recovery of value-added products from waste streams. The versatility, high efficiency of removal of organics and the capability of PPB to utilize sunlight as its energy source for its growth and metabolism makes wastewater treatment using PPB economically feasible. *Rhodobacter sphaeroides* is one of the commonly observed PPB and was found dominant in mixed cultures cultivated outdoor (Hülsen, Stegman, et al., 2022; Hülsen, Züger, et al., 2022). A genome-scale metabolic model facilitates better understanding of the flexible metabolism of PPB and prediction of its varying physiological behaviour with different substrates and environmental conditions. Integration of this model with the bioprocess model would improve the reliability of the model and needs less recalibration with varying composition of wastewater feedstock or operational parameters.

To the best of our knowledge, there is no curated metabolic pathway database available for *Rhodobacter sphaeroides*, that would allow integration and visualization of the metabolic pathways, reactions, enzymes, proteins and genes and other evolving information related to transcript, protein and metabolite profiling. There are genome-scale metabolic models representing the photoheterotrophic growth of *Rhodobacter sphaeroides* strain 2.4.1 (Imam, Yilmaz, et al., 2011; Imam, Noguera, et al., 2013), *Rhodopseudomonas palustris* (Alsiyabi, Immethun, et al., 2019) that were applied to study the aspects of photosynthesis, hydrogen production, different substrate uptake and redox state. However, more study is needed to understand the substrate preferences of cells for growth and production of value-products and their distribution towards different products that are relevant to resource recovery. In the current study, a curated metabolic pathway database and a genome-scale metabolic model of *Rhodobacter sphaeroides* ATCC 17025 is developed, showing better predictions than that of existing models. The model was validated with experimental data under different trophic conditions like photoautotrophic, aerobic heterotrophic and anaerobic photoheterotrophic conditions. The metabolic model was employed to study the product distribution of hydrogen, polyhydroxybutyrate, CO_2 fixation and growth under different light uptake rates.

MATERIALS AND METHODS

Development of pathway database & metabolic model

A genome-pathway database of *R. sphaeroides* ATCC 17025 was retrieved from the biochemical database, BioCyc. Pathways and reactions involved in the central carbon and nitrogen metabolism were curated by adding 111 modifications that were based on studies gathered from 42 scientific articles/reviews and genome-based evidence. The curation of the database was guided by analysis using the Metaflux module of Pathway Tools software (Latendresse, Krummenacker, et al., 2012) and thus a draft metabolic model was developed from the database. Compartments of cytoplasm, membrane space, periplasmic space, and extracellular space were also included in the Rba_sphCyc database. The metabolic model was validated qualitatively and quantitatively by comparing the predictions of the model under various trophic conditions with the experimental observations or conclusions published in 17 articles.

RESULTS AND DISCUSSION

Curation and validation of the metabolic model

The details of the curated pathway-database, RbaSphCyc, which will be published in MetaCyc, are given in

Table 1. A genome-scale metabolic model was generated from the curated pathway database. As a part of the qualitative assessment of the metabolic model, growth of *R. sphaeroides* was simulated under photoautotrophic, aerobic heterotrophic, anaerobic heterotrophic, anaerobic photoheterotrophic condition. The validation of the model was carried out by conducting quantitative assessment of flux under photoautotrophic, aerobic heterotrophic and anaerobic photoheterotrophic conditions. The predicted values along with experimental data (gathered from literature) used for validation of the model under these conditions are shown in Figure 1, Figure 2 and Figure 3, respectively.

The photoheterotrophic growth of *R. sphaeroides* on different substrates (succinate-glutamate, succinate-ammonia, glucose-glutamate and glutamate only) were simulated using the uptake rates reported by Imam et al. (2011). In the first step, fluxes were optimized to produce maximum biomass and the specific growth rates predicted by RbaSphCyc model were in agreement with that observed in the reported experiments (Imam, Yilmaz, et al., 2011)(Imam, Noguera, et al., 2013). In the second step, a light constraint was applied and the production rates for polyhydroxybutyrate, hydrogen and CO_2 were predicted, which were in good agreement with the experimental values obtained by Imam et al. (2011).

Under photoheterotrophic and NH_3 limited conditions, when the light uptake rate is above the minimum rate that is needed for maximum growth, concomitant H_2 and PHB production was predicted (shown in Figure 4). An increase in light uptake rate increases ATP production and thus increases the rate of H_2 production, thereby affecting other electron sink pathways such as PHB production and CO_2 fixation inversely. This pattern was found similar in all the four cases mentioned, but the range of light uptake rate differs based on substrate. When the activity of nitrogenase is not limited by ammonia, the main factors that affect H_2 production were found to be light and redox condition of substrate.

CONCLUSION

We developed a genome-scale metabolic model representing primary metabolism of *R. sphaeroides* ATCC 17025, that can be used to simulate photoautotrophic, anaerobic heterotrophic, anaerobic photoheterotrophic growth and predict flux distribution towards production. Under photoheterotrophic and ammonia-limited condition, a light uptake rate higher than that needed for growth, is required to produce hydrogen. Under this condition, light uptake rate plays a major role in defining the flux distribution through electron sink pathways like production of hydrogen, PHB and CO2 fixation.

Abstract
Lime is a commonly used disinfectant for fecal matters generated in a resource-oriented nonsewered sanitation system. Here, we presented a modeling approach to estimate the minimum treatment time and lime dosage to raise matrix's pH. The estimated treatment time for 3 log inactivation of RNA mammalian viruses was less than 1 h at > pH 11.5, while it was more than 12 h at < pH 10.5. This study provided practitioners with the better guidance of the lime treatment of fecal matter containing viruses for the safe reuse and disposal.

Keywords
Sanitation disinfection; slake lime; alkaline treatment; virus

INTRODUCTION

On-site excreta disinfection is needed in a resource-oriented nonsewered sanitation system to secure the microbiological safety of workers and consumers who are directly exposed to viruses by oral transmission. Lime is commonly used as a base disinfectant for high organic loading waste because it can raise the matrix pH above 10, at which most microorganisms, including surrogate phages cannot survive (Kohn et al., 2017). Requirements on disinfectant dosage and treatment time are determined based on the quantitative relationship between the disinfectant dosage and the extent of virus inactivation. This study aimed to estimate the treatment time and lime dosage to achieve certain log-inactivation values of virus, using machine learning algorithms.

MATERIALS AND METHODS

In order to collect peer-reviewed papers that contain the time-course change of virus infectivity and quantitative information on physicochemical parameters of matrices, we conducted a systematic review following the PRISMA guidelines (Moher et al., 2009). Google Scholar and Web of Science were used as search engines to collect related articles from 1950 to July 2022. The keywords were (lime OR alkali OR calcium hydroxide) AND (pathogen OR virus) AND (inactivation OR disinfection) AND (biosolids OR sludge). The time for 3 LRVs (T99.9) was then calculated by a single reviewer. In short, the Hom model (Hom, 1972) was fit to the time series data of surrogate inactivation identified through the systematic review. T99.9 was then back calculated using the fitted Hom model. We also collected the quantitative and qualitative information on matrices' properties, virus types, and experimental settings.

We employed three machine learning algorithms to estimate T99.9: random forest, light GBM, and Automatic Relevance Determination (ARD) (scikit-learn version 1.2, in Python). The features used for prediction of T99.9 were: structure of virus genome (RNA or DNA), virus type (phage or virus), matrix type (natural or synthesized), suspended solid contents, pH, temperatures, and initial concentration of virus. Eighty percent of the whole datasets were used to train a model, while the rest 20% of datasets were used to evaluate the prediction accuracy of the model. We conducted this set of data allocation and cross validation for ten times, and the mean square values of test data (MSEtest) and training data (MSEtrain) were calculated in each time. We also calculated the ratio of those MSE indicative of the degree of overfitting to training data. The better model was selected based on the mean value of MSE of the ten-time calculation.

RESULTS AND DISCUSSION

Systematic Review

We identified 1,599 records by searching in Google Scholar and Web of Science. Fourteen articles which reported the time-series decay of viruses, types of matrices, and physicochemical properties were identified. Tested alkali additives were; slaked lime, burnt lime, sodium hydroxide, alkaline buffer, and ash. The matrix's pH after alkali addition ranged from pH 8.4 to pH 13.4.

Estimation of the lime dosage and T99.9

The better prediction accuracy was obtained based on the ARD model (**Figure 1**). The pH value was the most important factor on the treatment time compared to the structure of virus genome and the abundance of suspended solids. The coefficients were positive for the variables of virus type, matrix type, and virus initial concentration, which indicated that estimated treatment time was longer for the inactivation of phage compared to mammalian virus in a natural matrix with higher initial concentration. We found a linear relationship between the pH values and the maximum dose of slaked lime (p <0.05 by nonzero slope t test).

We finally simulated the appropriate T99.9 and lime dosage on fecal matter using the better model. The estimated T99.9 was less than 1 h at > pH 11.5, and exponentially prolonged at lower pH: more than 12 h at < pH 10.5. At least 2.5%(wt) of slaked lime was needed to yield higher pH. These results indicated that precise measurement of pH and record keeping of treatment time at lower pH are critical.

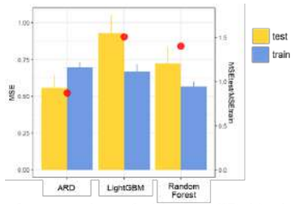

Figure 1. Mean value of mean squared error of training data (MSEtrain) and test data (MSEtest) by the three models for T99.9. Red plots represent the ratio of MSE values indicative for overfitting to training data.

Abstract
This contribution aimed to study the agronomic potential of AGS-extracted sEPS and derived hydrogels. The recovery/gelation processes were fine-tuned based on agriculture-related criteria, highlighting that the chemicals used can influence the elemental composition of sEPS and derived hydrogels. The extracted sEPS formed hydrogels having high water-binding capacity (up to 15 gH_2O/gTS_{sEPS} adsorbed by 50°C-dehydrated hydrogels upon swelling) and nutrient holding/release ability (up to 103 mgK^+ and 147 $mgNO_3^-$ per gTS_{sEPS} released in water by KNO_3-swollen sEPS hydrogels). Together with compositional properties in line with the regulatory framework, these features suggested the feasible application of AGS-derived sEPS in sustainable agro-practises.

Keywords (maximum 6 in alphabetical order)
Aerobic granular sludge; agriculture; hydrogel; resource recovery; structural extracellular polymeric substances; water and nutrient adsorption/release

INTRODUCTION

In aerobic granular sludge (AGS) microorganisms produce large quantities of highly hydrated extracellular polymeric substances (EPS) to form a hydrogel matrix (mainly consisting of polysaccharides, proteins, nucleic acids, (phospho)lipids, humic substances, etc.) in which they are self-immobilized (Flemming and Wingender, 2010; Seviour et al., 2019). Part of the AGS-derived EPS, the so-called structural EPS (sEPS), have the ability to form hydrogels which is considered well linked to the structural integrity of granules (Felz et al., 2016). sEPS can be extracted from AGS and converted into value-added biomaterials, thus contributing to a circular economy-based wastewater sector (Lin et al., 2015). In this regard, this contribution aimed to explore the agronomic potential of AGS-derived sEPS and derived hydrogels combining a fine-tuning of the extraction/gelation processes based on agriculture-oriented criteria with an integrated assessment of key properties like elemental composition, water sorption ability and nutrient release capacity.

MATERIALS AND METHODS

sEPS were extracted from AGS adapting the method reported by Felz et al. (2016) (i.e., thermo-alkaline solubilization of EPS followed by acidic precipitation of sEPS). The hydrogel-formation was carried out by Ca^{2+} diffusion from a 2.5% (w/w) Ca^{2+} cross-linking aqueous solution into the sEPS matrix through a dialysis membrane (3.5 kDa MWCO) (Campo et al., 2022). The effect of distinct chemicals on the qualitative/quantitative properties of the extractable sEPS was addressed (**Figure 1**): the agro-based methods used reagents that potentially promoted the sEPS enrichment in nitrogen and potassium, avoiding phytotoxic elements (e.g., Na, Cl). The sEPS extraction yields were determined by gravimetry, measuring Total Solids (TS) and Volatile Solids (VS) according to standard methods (APHA/AWWA/WEF, 2017). Elemental analysis of sEPS and derived hydrogels were performed through CHN-S Analyzer and Inductively Coupled Plasma-Atomic Emission Spectroscopy. sEPS hydrogels from the agro-based method were characterized in terms of swelling and nutrient uptake/release properties. To this aim, sEPS hydrogels (3 wt% sEPS concentration) were dehydrated at 50 °C and then rehydrated in both demineralized water and 0.2 M KNO_3 aqueous solution, monitoring the swelling ratio over time as gram of H_2O adsorbed per gram of 50°C-Dehydrated Weight (50°C-DW) of hydrogel. The K^+/NO_3^- release kinetics in demineralized water of KNO_3-swollen sEPS hydrogels were evaluated by means of ion chromatography and fitted by pseudo-first-order (PFO) and pseudo-second-order (PSO) models (Wang et al., 2018).

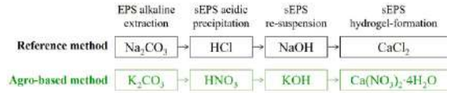

Figure 1. Chemicals used for the sEPS extraction and hydrogel-formation.

RESULTS AND DISCUSSION

As reported in **Table 1**, the agro-based protocol favoured a higher sEPS enrichment in potassium with respect to the reference method (K = 11.2 vs. 0.02 wt% as dry weight) without significantly reducing the extraction yield. By replacing Na_2CO_3 with K_2CO_3, the sodium content in sEPS considerably decreased, while the H/C, N/C and S/C molar ratios were kept almost constant and in agreement with literature data (Campo et al., 2022). Despite the extraction method applied, sEPS formed hydrogels storing up to 99 gH_2O/gTS_{sEPS}. The Ca/C molar ratio significantly increased upon gelation from 0.003 to 0.075-0.152 mol Ca/C-mol, thus indicating the inclusion of Ca^{2+} ions inside the polymeric matrix during the cross-linking reaction. The N/C molar ratio was kept almost constant from sEPS to hydrogels using $CaCl_2$ as cross-linking agent (0.187 vs. 0.134 mol N/C-mol) and considerably increased upon hydrogel-formation applying the agro-oriented method ($Ca(NO_3)_2{\cdot}4H_2O$ as Ca^{2+} source) from 0.163 to 0.972 mol N/C-mol. This evidence suggested that both Ca^{2+} and related counter ions diffused from the aqueous medium inside the polymeric matrix during gelation. The chemicals applied in the recovery and gelation processes should be hence properly selected based on application-related criteria: the use of reagents not containing phytotoxic elements is recommended for agricultural uses. The sEPS and derived hydrogels thus obtained respected the heavy metal concentrations limits of Regulation (EU) 2019/1009 on fertilizers.

Table 1. sEPS extraction yields of reference and agro-based methods and comparative elemental analysis of the recovered sEPS.

	Reference method	Agro-based method
Extraction yield ($mgVS_{sEPS}/gVS_{AGS}$)	231 ± 14	206 ± 9
VS/TS (% gVS_{sEPS}/gTS_{sEPS})	87.5 ± 1.3	84.2 ± 1.0
H/C (mol/C-mol_{sEPS})	1.620	1.702
N/C (mol/C-mol_{sEPS})	0.187	0.163
S/C (mol/C-mol_{sEPS})	0.022	0.029
Na/C (mol/C-mol_{sEPS})	0.020	0.002
K/C (mol/C-mol_{sEPS})	0.0001	0.080

Figure 2 shows the increase of the swelling ratio over time for swelling experiments carried out in demineralized water. The 50°C-dehydrated sEPS hydrogels were able to sorb up to 11 $gH_2O/g50°C$-DW upon swelling (15 gH_2O/gTS_{sEPS}). These high water-binding capacity and swelling ability are typical of superabsorbent polymers (SAPs) having high potential in sustainable agro-practises.

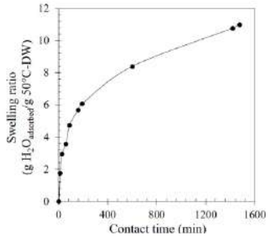

Figure 2. Experimental swelling kinetics in demineralized water of sEPS hydrogels.

Applying the agro-based method, potassium in sEPS was largely released in the cross-linker solution upon gelation likely due to ion exchange mechanisms in binding Ca^{2+}: this resulted in hydrogels poor in K (0.01 wt% as dry weight). The 50°C-dehydrated sEPS hydrogels were hence swollen in KNO_3 aqueous solution: in this case, the extent of swelling was lower (up to 5 $gH_2O_{adsorbed}/g50°C$-DW) because of the higher ionic strength of the surrounding medium. The 50°C-dehydrated sEPS hydrogels adsorbed up to 116 mgK/gTS_{sEPS} upon swelling in KNO_3: this suggested that the hydrogel elemental composition might be tuned acting on the type of swelling solution (thus providing nutrient enrichment upon hydrogel rehydration). As depicted in **Figure 3**, the KNO_3-swollen hydrogels released in demineralized water up to 103 mgK^+ and 147 $mgNO_3^-$ per gTS_{sEPS} within 8 hours (80-90% of their nutrient content): the release kinetics were better described by a pseudo-first order model (R^2=0.944), as reported for alginate gel beads (Wang et al., 2018).

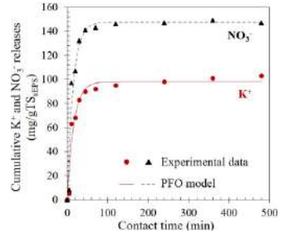

Figure 3. Experimental K^+ and NO_3^- release kinetics in demineralized water of KNO_3-swollen sEPS hydrogels and related fitting through pseudo-first-order (PFO) model.

In conclusion, paying attention to the chemicals used in the recovery process, AGS-extracted sEPS can form hydrogels having high water-binding and nutrient sorption/release properties suitable in agriculture for improving the soil water-holding capacity and/or as nutrient carriers/release agents.

Abstract Personal and home care products (PHCPs) are a potential source of micropollutants in greywater. The objective of this study was to select 2 perfuming compounds and assess their removal behaviour in a nature-based solution operating with zero-liquid discharge using different geometries and substrates. The reduced scale mesocosms showed removal of up to 72 and 64% for geraniol and linalool, respectively, using a rectangular geometry, and expanded clay as substrate.

Keywords
Greywater; emerging pollutants; nature-based solutions; reuse; treatment wetlands

INTRODUCTION

Greywater (GW) is a potential source of micropollutants (MP) due to the chemical compounds present in personal and home care products (PHCPs). Although the direct reuse, without treatment, of greywater at household level is not recommended, it seems to be a common informal practice in several countries. This raises concerns about the impact on human health and the environment. Several studies using treatment (constructed) wetlands for the removal of micropollutants have been conducted, both for conventional domestic sewage (DS) and GW (Sossalla et al. 2021 and 2022; Ramprasad and Philip, 2016, Ávila et al, 2014). Studies focusing on the selection of chemical compounds for monitoring programmes, based on consumption habits of personal care and home care products have been conducted (Paulo et al., 2018; Garcia-Hidalgo et al., 2017). For the HCPs database we screened the labels of 34 softeners (16 Brazil-BR and 18 European Union-EU) and 60 laundry detergents (liquid, powder, capsules, gel and tablets), from which 18 BR and 42 EU. Considering that 6% of the population is sensitive to ingredients present in PCPs and HCPs, especially to fragrances and preservatives (Pastor-Nieto et al., 2017), we selected linalool and geraniol, two compounds commonly used as perfuming agents in PHCPs, that are present in 17 out of 60 of the products mentioned above.

Table 1. Chemical compounds commonly used as perfuming agents in home and personal care products.

Compound	toxicological threshold value[a] (mg/kg bw[d] d)	Maximum detected value (µg.L^{-1}) greywater[a)(b)]	domestic sewage[(b)]	Possible effects on human health / environment[(c)]
Geraniol	0.030	0.8[(f)]	1.0[(e)] (influent)	allergies & immunotoxicity suspected to be an environmental toxin
Linalool	0.5	15.4	11.6 (effluent)	allergies & immunotoxicity

(a) Etchepare & van der Hoek, 2015; (b) Montes-Grajales, et al., 2017; (c) https://www.ewg.org/skindeep/; (d) bw: body weight; (e) Paxéus & Schröder, 1996; (f) https://pubchem.ncbi.nlm.nih.gov

The information shown in Table 1 is based on data retrieved from EWG Skin Deep®, which compiles a series of references used to disseminate information on ingredients regarding their effects on health and the environment. In spite of the low concentrations detected in GW and DS, studies indicate possible effects on human health and the environment. The selected products present an allergy and immunotoxicity indication, with geraniol suspected of environmental toxicity. On the other hand, none of these compounds is suspected of persistence or bioaccumulation. Considering the little information in literature regarding the removal of perfuming compounds in treatment wetlands, the objective of this study was to assess the removal behaviour of linalool and geraniol during treatment in a zero-liquid discharge system using different geometries and substrates.

MATERIALS & METHODS

The experiment was performed in reduced-scale units of CEvaT (evapotranspiration and treatment tank) which is fully described elsewhere (Magalhães & Paulo, 2021). Eight units, of which 4 square (0.5m H x 0.5m W x 0.5m L) and 4 rectangular (0.25m H x 0.5m W x 1.0m L), were built, filled with 2 different substrates: fine gravel and expanded clay. These 8 units were fed with onsite produced laundry GW and operated as zero liquid discharge systems during 1 month. The units were provided with piezometers (Figure 1) from where the samples were collected until day 7. Afterwards, samples were taken at the outlet of each unit.

Figure 1. Left: Experimental setup. Right: View of the anaerobic chamber inside the square and rectangular shaped mesocosms.

Analytical grade linalool (3,7-dimethyl-1,6-octadien-3-ol) and geraniol (3,7-dimethyl-2(E),6-octadien-1-ol) were diluted into laundry greywater to provide an inlet concentration of around 6 mg.L^{-1} for linalool and 2 mg.L^{-1} for geraniol. Concentrations were chosen based on the analysis of 4 laundry products of different brands (Table 2). For the analysis of monoterpenes, 4 mL of sample was used for extraction using 200 mg C18 solid phase extraction (SPE) cartridges (Strata® Phenomenex). The cartridge was conditioned with 4 mL of chloroform, 4 mL of methanol (MeOH) and 4 mL of 1% H_2O/MeOH, washed with 6 mL of H_2O and eluted with 1.5 mL of chloroform. The extract was analysed in a gas chromatograph (GC) with mass spectrometry (GCMS-QP2010, Shimadzu). The identification was performed based on the NIST20 mass spectra database.

Table 2. Concentration of linalool and geraniol in 3 softeners and 1 powder detergent from 4 different brands as commercialised in Brazil (BR) and in the European Union (EU).

Product type	Product	Linalool (mg.L^{-1})	Geraniol (mg.L^{-1})
Powder detergent	Brand A - EU	-	1.19
Softener	Brand A - BR	-	1.67
Softener	Brand B - EU	7.30	0.67
Softener	Brand C - EU	4.52	1.03

RESULTS AND DISCUSSION

Figure 2 shows the decrease on the concentrations of linalool and geraniol during the first 7 days of the experiment. Samples were collected until day 25, showing no further decrease in concentration for both compounds (data not shown). The total volume for both geometries is the same. In the square units, no removal occurred before day 4, however, the length of the rectangular units is twice length of the square units (1 m vs. 0.5 m), whereas their depth is half the depth of the square units (0.25 m for the rectangular units vs. 0.5m for the square units). Although the hydraulic retention time is about the same for both geometries (and actually slightly higher for the square units), the length of the units seems to play a role in the process. Possibly, in the shallower rectangular units, the less anoxic environment might favour the degradation mechanism of monoterpenes.

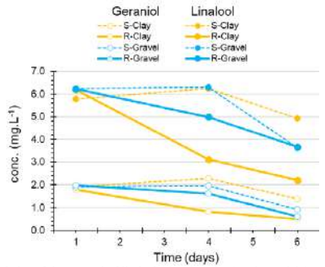

Figure 2 The evolution of the removal of linalool (closed markers) and geraniol (opened markers) in reduced scale Evapotranspiration and Treatment tanks (CEvaT) with square (dotted lines) and rectangular (solid lines) geometries, using fine gravel and expanded clay.

The rectangular shaped units (solid lines) showed the best performance when the substrate is clay, independent of the compound to be removed from the liquid phase. However, when using gravel, the removal was similar for both geometries, especially for Linalool (Figure 2 and Table 3). Thus, expanded clay seems not to be a good choice as filtering media for use in square geometry NBSs. When comparing the removal using expanded clay for both geometries, the removal in absolute values for rectangular mesocosms were 2.3 and 4.5 times higher for geraniol and linalool, respectively.

Table 3. Average concentration of linalool and geraniol at the sampling points inside the mesocosms (piezometers) and total removal for the 4 combinations tested with different geometries and substrates.

Geometry (substrate)	Geraniol P1 (mg.L^{-1})	Geraniol P2 (mg.L^{-1})	Geraniol Removal (mg.L^{-1})	Geraniol Removal %	Linalool P1 (mg.L^{-1})	Linalool P2 (mg.L^{-1})	Linalool Removal (mg.L^{-1})	Linalool Removal (%)
Square								
Gravel	1.90	0.92	0.98	51.6	6.25	3.63	2.62	41.9
Expand. Clay	1.92	1.38	0.54	28.1	5.79	4.92	0.87	15.0
Rectangular								
Gravel	1.98	0.61	1.37	69.2	6.22	3.67	2.55	41.0
Expand. Clay	1.79	0.50	1.29	72.1	6.19	2.21	3.98	64.3

The experiment was carried out 3 weeks after the start-up of the mesocosms, before introducing the plants to the system. This approach allowed to compare the two substrates before biofilm formation and without the interference of the plants. Therefore, the removal of linalool and geraniol within the mesocosms can be attributed mainly to physical and chemical removal mechanisms, with limited biological degradation. A more extensive discussion of the removal mechanisms, based on further physico-chemical monitoring, will be included in the oral presentation.

CONCLUSIONS

Linalool and geraniol were chosen to represent perfuming compounds that can pose health and environmental risks when reusing greywater. Greywater treatment can be performed in NBSs, like the CEvaT, for which the usual geometry is the square one, as it provides a higher volume, expected to result in better pollutant removal, using less area. However, the preliminary results for the removal of the tested monoterpene compounds showed a better performance of the rectangular systems, especially when using fine gravel as the substrate. Further long-term studies will allow to assess the contribution of the microbial and biochemical processes, and determine the most appropriate system configuration to deliver a better quality of treated greywater for a safer reuse.

Abstract
The complexity and the inherent interconnection of the reclaimed wastewater reuse (RWW) system requires the proper quantification of its advantages and drawbacks. In this context, water utilities and decision makers would benefit from a comprehensive risk-based framework of models aimed at the assessment of its associated impacts.
In this work, a critical literature review on the models available for the assessment of RWW reuse impacts is performed to highlight which gaps need to be filled and indicate the future research directions. A simplified approach for evaluating and integrating different type of risks was proposed to address the prioritization of critical endpoints and contaminants within regulations.

Keywords (maximum 6 in alphabetical order)
Antibiotic resistant bacteria; Impacts modelling; Literature Gaps; ONE-health approach; Risk assessment; Reclaimed wastewater reuse

INTRODUCTION

Given the interest on water as a renewable resource, the reuse of reclaimed wastewater (RWW) has been recognized as a fundamental alternative source for irrigation and is increasingly applied (de Santiago-Martín et al., 2020). Based on where the wastewater treatment plant (WWTP) effluent is discharged, the reuse can be (i) indirect, when the effluent is discharged into the surface water and irrigation water is derived downstream the point of discharge, or (ii) direct, when the effluent is directly used for crops irrigation, through a dedicated distribution network.
In both cases, it emerges that RWW reuse practices inherently connect water in numerous environmental compartments (e.g. surface water, groundwater, soil), leading to a series of impacts, either positive or negative, which need to be evaluated. As for positive impacts, besides alleviating the water stress, the reuse of RWW provides a reliable source of nutrients. On the other hand, the cross-contamination of the different environmental matrices is favored, due to the unavoidable presence of contaminants in the effluent, even after extensive treatment. RWW might be loaded with contaminants such as organic matter, suspended solids, salts, heavy metals, contaminants of emerging concern (CECs), disinfection by-products (DBPs), pathogenic microorganisms and antibiotic resistant bacteria (ARB). Besides, all these contaminants could have different effects depending on the compartment in which they occur. In fact, they can accumulate in soil, causing salinization and changes to the soils properties. From soil, contaminants can either be uptaken and accumulated by plants, negatively affecting their growth, or contaminate groundwater, where aquifers are present. Finally, the consumption of crops contaminated with, above all, pathogens, heavy metals and CECs implies a not negligible risk for human health (Delli Compagni et al., 2020). Given this system complexity, it emerges the need for a framework of models that allows a comprehensive assessment of the RWW reuse impacts, capable of quantitatively accounting and comparing all the related advantages and drawbacks, to support decision-makers and water utilities in planning, design and prioritizing the different alternatives to determine the optimum solution that minimize risks and costs.
Regarding the regulation, RWW quality aimed at direct reuse for irrigation is regulated in the European Union, and the common practice to establish minimum quality requirements is shifting towards preventive risk analysis aimed at minimizing risks (EU Commission, 2020). In this context, it becomes fundamental to define an integrated risk assessment approach, which considers all the impacts throughout all the steps of the RWW reuse chain in terms of quantitative risk for both human health and environment.
In this work, an overview of the models available for the evaluation of RWW reuse impacts is presented and a simplified approach to estimate and compare different risk assessment procedures applied to RWW reuse case studies is proposed.

MATERIALS AND METHODS

A comprehensive literature review was conducted in the field of municipal RWW reuse in agriculture, focusing on the related impacts and the models available to evaluate them. Scopus was used as database for the period 2017–2022 (documents published in 2023 were not included considering only complete annual periods). A sample of 252 articles was selected for a detailed analysis.
The RWW reuse framework was conceptualised based on four characteristics: (i) the type of RWW reuse, (ii) the analysed compartments, (iii) the models applied to evaluate the impacts, and (iv) the targeted variables in the models. For each characteristic, several categories were identified, and one or more of them were assigned to every article. Studies without at least one category from each characteristic were discarded. Ultimately, 139 articles were selected, to review the current state of the art on the available models for the evaluation of RWW reuse impacts, highlighting the gaps to be filled.
Finally, a simplified approach for comparing and prioritizing the available risk assessment procedures is proposed, focusing here on human health risk assessment due to CECs presence in crops irrigated through indirect RWW reuse. In detail, CECs concentration data in the WWTP effluent, in the receiving water body used for crops irrigation and in the irrigated crops were collected. Then, environmental risk quotient (RQ_E) and antibiotic resistance risk (RQ_R) were calculated comparing the Measured Environmental Concentrations (MEC) in rivers with the Predicted No-Effect Concentration, respectively for environmental ($PNEC_E$) and antibiotic resistance ($PNEC_R$), according to the following equations (Zhang et al., 2019):

$$RQ_E = MEC/PNEC_E \qquad RQ_R = MEC/PNEC_R$$

Details on the only 4 articles available for the comparison of human health, environmental and antimicrobial resistance risk in indirect RWW reuse practices are reported in Table 1.

Table 1. Summary of the studies used for the comparison of human health, environmental and antimicrobial risk: number of analysed CECs and antibiotics, concentration in WWTP, river and crops, indicated as average and range in brackets.

Study	# of CECs	# of antibiotics	WWTP effluent concentration [µg/L]	River concentration [µg/L]	Crop concentration [µg/g]
De Santiago-Martin et al., 2020	57	10	0.21 (<LOQ-1.5)	0.34 (<LOQ-6.5)	0.04 (<LOQ-0.25)
Delli Compagni et al., 2020	13	2	Not available	0.21 (<LOQ-0.8)	0.009 (<LOQ-0.08)
Liu et al., 2020	11	3	Not available	0.007 (<LOQ-0.025)	0.005 (<LOQ-0.03)
Meffe et al., 2021	25	3	Not available	0.25 (<LOQ-12.9)	0.001 (<LOQ-0.01)

RESULTS AND DISCUSSION

The selected studies were classified based on their characteristics and categories as shown in Figure 1, differentiated per type of RWW reuse, being (i) direct and (ii) indirect. The compartments correspond to the boundaries within which the impact is modelled and they were differentiated in (i) WWTP, (ii) environment (intended as the groundwater or surface water receiving the WWTP effluent), (iii) irrigation system, (iv) soil, (v) crops and (vi) humans. The models were differentiated between quantity- and quality-based models. Quantity-based models evaluate the impacts in terms of volumes of water available for irrigation; model as (i) water mass balances, (ii) Life Cycle Assessment (LCA), (iii) economic, (iv) energy, (v) sustainability and (vi) social assessments belong to this category. While quality-based models evaluate the impacts in terms of RWW quality, thus, concentrations or risks, and are usually specific for single compartments; here there are models assessing (vii) treatment removal, (viii) crop uptake, (ix) environmental risk and the (x) human health risk. Finally, the variables targeted by the applied models were divided again in quantity-based variables, affecting the volume of water, namely (i) water itself, and quality-based variables, affecting the water quality, such as (ii) nutrients, (iii) conventional contaminants (i.e., organic matter and suspended solids), (iv) salts, (v) heavy metals, (vi) CECs, (vii) DBPs, (viii) microbials and ARBs (ix).

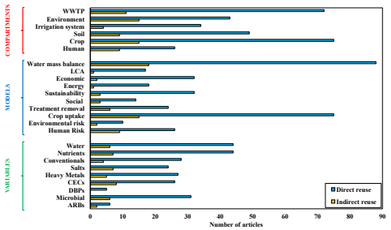

Figure 1. Number of articles mentioning the analyzed categories, differentiated per direct or indirect reuse.

Analysing Figure 1, it emerges that, on average for all the considered categories, the 85% of the studies deals with direct reuse, being the only type of reuse which is regulated so far, and being a process easier to replicate even in pilot-scale conditions, compared to indirect RWW reuse. However, there are a lot of RWW streams that are used *de facto* for indirect irrigation. Thus, studies in this field are a gap which need to be filled. Moreover, among articles addressing indirect RWW reuse practice, there are no studies considering how the dilution factor between the WWTP effluent and the receiving surface water affects the environmental impact, although the growing concern on the consequneces on the natural aquatic environment of climate change stress the importance of this evaluation.

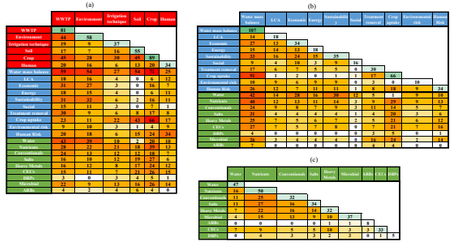

Figure 2. Heatmap reporting the paired correlations between the considered categories, differentiated per (a) compartments, (b) models and (c) variables.

Three heatmaps are reported in Figure 2 visualluy showing the paired correlations between all the considered categories, differentiated per compartments, models and variables. This visualization supports in analysing how the different characteristics (i.e., compartments, models and variables) are combined together to model the RWW reuse practice, and also permits to assess which fields are more consolidated and which ones need further research.
In particular, it is pointed out a lack of model application on ARBs, which are microrganisms of emerging concern inherently related to WWTP discharges. Regarding risk assessment models, LCA assesses human health and environmental risks through generalized standard values; if LCA studies are not considered, it emerges that only a single study applied an environmental risk assessment to a RWW reuse practice, while no studies consider both environmental and human health risk together.
In this context, given the importance of risk-based approaches to assess the impacts of RWW reuse practices, as stressed by the revision of the WW reuse Directive, the absence of studies simultaneously evaluating the environmental, antibiotic resistance and human health risks when indirect RWW reuse is applied is an important literature gap.
The analysis performed on studies dealing with human health risk assessment highlighted that environmental and antibiotic resistance risks have significant contribution to the overall risk, being higher than the human health risk for some of the CECs. This evidence stresses the importance of an holistic risk assessment, with a ONE-Health approach, to evaluate the most critical endpoint for each CEC, useful to prioritize their regulation.
To conclude, this work gave an overview of the models currently available for the evaluation of the impacts of RWW reuse practices, highlighting which are the associated literature gaps, and it might be useful in indicating future research directions, as well as to suggest which impact need to be prioritized when a comprehensive assessment is performed.

Abstract
The LIFE HIDAQUA project aims to demonstrate a sustainable water management approach in high water demanding industries, such as the EU automotive industry, by decreasing the emission of pollutants from industry and preserving the quality of natural water bodies and natural drinking water resources.

The project addresses water management in industrialized EU areas by tackling the following environmental problems: i) the depletion of natural drinking water sources, especially in areas facing water scarcity, ii) the low ecological and chemical status of natural water bodies due to the emissions of pollutants in industrial wastewater discharge, iii) burdening of the environment, especially natural water bodies, with the discharging of liquids and the landfilling of wastes from water treatment processes.

The proposed integrated management strategy is based on the following priorities for the exploitation of alternative water sources: i) industrial recycled/reclaimed water, ii) harvested rainwater, and iii) brackish groundwater. Moreover, the innovative solution focuses on a sustainable water management approach by applying the Zero-Liquid-Discharge and the Zero-Waste concepts through the recycling of all wastes generated during the water treatment process.

The system can establish recycling of highly polluted industrial wastewater (high content of oils and grease - containing on average Chemical Oxygen Demand (COD) values of 20,000 mg O_2/L). Approximately 4000 m^3 of polluted water per year with the exploitation of alternative water sources (brackish water and rainwater) can be treated simultaneously on site and produce cca 24 m^3 of cleaned water per day (with conductivity less than 0.6 mS/cm).

The incorporation of an advanced solar evaporation (ASE) pond designed as a greenhouse collects the heat for intensive evaporation of the brines. This results in production of salt products, while the waste sludge and suspensions can be recycled into building composites and produced as a ready-for-use construction products (cca 0.5 tons of salt and 1 ton of construction composites).

The involvement of an innovative interactive "Decision-Making Tool" that is being developed, will help users to decide which water needs to be treated at any time, taking into consideration the relevant technical aspects as well as the results of Life Cycle Assessment, Life Cycle Costs, Social Life Cycle Assessment and Water Footprint. In general, the Tool has integrated measures to lower the environmental impacts as much as possible.

In the initial stages of the project, the different technologies that constitute the completely innovative water treatment scheme for the automotive industry were tested and optimized at bench scale at EURECAT facilities in Spain. Figure 1 shows the proposed treatment scheme and results obtained at bench scale. Bench scale tests were carried out using real industrial wastewater (IWW) and brackish water (BW) samples provided by HIDRIA.

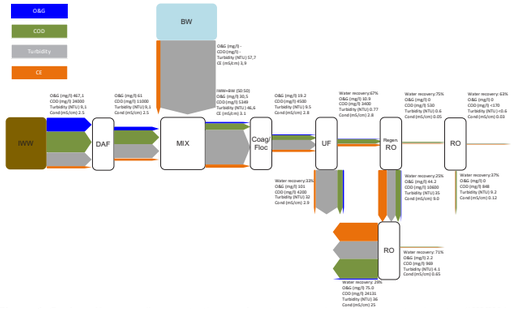

Figure 1. Sunkey diagram of concentrations and water recoveries of main contaminants of IWW in the treatment scheme at bench scale

Regarding the pre-treatment, it was decided to combine the pre-treatment steps of brackish water and industrial wastewater streams to improve the overall Oil and Grease (O&G) removal prior to continue with the rest of the treatment. The strategy chosen was to treat the industrial wastewater with Dissolved Air Flotation (DAF) to remove most of oils and COD present and then, combine this stream with the brackish water stream in a 1:1 ratio. Once both streams were mixed, a coagulation/flocculation treatment was applied to remove most of the turbidity and metals. With this pre-treatment, a removal higher than 90% was achieved for O&G and higher than 80% for COD and turbidity. The optimal pre-treatment conditions that were found were: 6 bar and 60% recirculation and no flocculant in DAF process; 5 ppm of coagulant and 0.5 ppm of flocculant for the coagulation/flocculation step with the mixed water.

The water stream resulting from the coagulation/flocculation was treated with ultrafiltration (UF) as a previous step before using a reverse osmosis (RO) with regenerated membranes to remove most of the pollutants. The UF step was able to reduce the turbidity to less than 1 NTU and a 67% of recovery rate was achieved. It is expected that higher recoveries will be obtained at larger scales due to the limitations by the dead volume of the experimental set up.

In the RO with regenerated membranes a high quality permeate was obtained with a recovery rate of 75%. A conductivity of 0.05 mS/cm was achieved, which was much less than the original goal of 0.6 mS/cm. For water reutilization purposes in HIDRIA's processes, the concentration of COD of the regenerated RO permeate was too high (~0.5 g/L COD). Different regenerated membrane modules were tested, and the results obtained where slightly different regarding the rejection of COD and final conductivity. To lower the concentration of COD in the regenerated RO permeate, a refining RO step was studied to treat the permeate achieving 87% COD removal efficiency and a 63% water recovery. The optimal regeneration conditions for RO membranes were also defined so that the RO modules for the pilot plant could be regenerated until obtaining the same NaCl and $MgCl_2$ rejection. The proposed treatment scheme would lead to a final COD concentration <70 mg COD/L in the refining RO permeate.

Finally, electrodialysis reversal (EDR) reversal was able to successfully treat the RO concentrate recovering 78% of the water in form of a dilute stream with the same conductivity as the RO influent (around 2.2-2.8 mS/cm) applying 330 Ah/m^3 (implying an electric consumption of 8 kWh/m^3). Anyway, the impossibility of treating the COD with EDR represent a limitation when using this technology for the studied wastewater. To decrease the volume of final concentrate to be sent to the ASE pond and increase the quality of the recovered water, other technologies were considered (Membrane Distillation (MD) and RO). Among these, RO gave the best results in terms of both COD, O&G and ions removal.

Afterwards, the demonstrated system at bench scale was up scaled to a pilot plant which was installed in HIDRIA factory in Koper (located in the NE part of the Adriatic Sea) in December of 2022. The results from the operation and optimization of the pilot plant are expected to be obtained during 2023.

Valorizing Methane: Methanotrophs based Biorefinery for Extracellular Biopolymers Production (CH4-BIOPOL)

Abstract
Methane (CH_4) is the second most abundant greenhouse gas (GHG) after carbon dioxide (CO_2), but it has much higher global warming potential with a heat retentive capacity over 34 times more than CO_2 in a century timeframe. Consequently, cutting off CH_4 emissions is considered the most effective strategy against the global warming. A significant amount of CH_4 is produced in the form of biogas and, due to energy increasing demands, it has been proposed as more sustainable energy source. Biogas potential, nonetheless, is currently hindered by its low conversion efficiencies. Nowadays, novel technologies are being developed to connect the reduction of methane emissions and the production of added-value substances such as designed proteins, additives, or biopolymers, in the frame of Circular Economy. Biological conversion of methane into biopolymers is highly attractive due to its efficiency under mild operating conditions and its adaptability. Also, CH_4 offers some advantages as carbon source when compared with sugars, which compete with human food supply for agricultural land and are experimenting a rapidly increasing production cost. Despite the theoretical advantages of methanotrophs for biopolymer production, this field is still very recent, with only a significant research outcome in polyhydroxyalkanoates (PHA) and its potential is impeded by intrinsic complications during the PHA extraction process. To overcome this obstacle and stablish methanotrophs as a good platform for biopolymers production, extracellular biopolymers (EPS) may emerge as an alternative. EPS possesses a structural diversity unmatched by other polymers, which makes its chemical production unprofitable, but displays interesting properties suitable for water-resistant paper coatings or fire retardants. The absence of research regarding EPS biological production, characterization and its diversity in chemical and mechanical properties encourages the approach as a potential cost-effective way for biopolymer production of this project.

Keywords: Biogas, biopolymers, biorefineries, EPS, MBfR, methane.

OBJECTIVES

The major objective of CH4-BIOPOL is to verify the feasibility of EPS production with methanotrophs. In doing so, it is expectable to understand the different pathways related to this production and how to control and optimize it. Also, characterizing methanotrophs' EPS will be key in determining whether it will be suitable for biopolymer production or not. These main aims are divided into others more specific, which constitute the different steps for them.

Proof of Concept

Until now, the different configurations for methanotrophs cultivation have encountered mass transfer limitations due to the low solubility of CH_4 in water. In this project, a different approach will be tested which is based on biofilm promotion around hollow fibres membrane, resulting in a membrane biofilm bioreactor (MBfR). Methane will be supplied through these membranes while oxygen by regular aeration to the aqueous column. Hence, CH_4 will be fed with two different streams at different concentrations: one of them will emulate natural gas so it will supply great quantities of CH_4, while the other one will mimic biogas CH_4 concentrations. This experimental set-up aims to elucidate the role of methanotrophs in the Circular Economy frame.

Identification of Key Genes

Despite methanotrophs research has already identified many genes, these findings are capitalized by the methane assimilation pathway and related ones, so EPS production genes are still quite unknown. To address this point, *Methylotuvimicrobium alcaliphilum* 20Z and *Methylomonas rubra* 15sh, two model microorganisms, have been selected and their EPS production genes will be characterized with genomics and transcriptomics techniques.

Impact of Operational Factors

There are several operational parameters that can be modified to increase cell growth, EPS biosynthesis or CH_4 uptake, according to literature in methanotrophs. Specifically, physicochemical properties of the EPS may change due to variations in such factors and these properties will be evaluated to initially characterize EPS.

EPS Regulation

Based on the conclusions reached in previous objectives, special emphasis will be placed on those genes that affects EPS production under the different operational parameters. Hence, a meta-transcriptomics analysis will show the metabolic pathway activity at the whole mixed cultures. Together with metagenomics and bioinformatics, a reconstruction of genomes and other genetic structures involved in EPS biosynthesis can be done.

METHODOLOGY

The project will last for 2 years, and it is structured into three connected Work Packages (WP). WP1 comprises those activities related to the cultivation of methanotrophs in a mixed aerobic community and will report results for the first and third sub-objectives. Within this package, it is included the design and set-up of two MBfRs, its operation to obtain enriched methanotrophic cultures, testing of different operational conditions and EPS physicochemical characterization. WP2 is only planned for the first year and addresses the second sub-objective, mainly, at unravelling the genomic expression of the two model microorganisms when producing EPS in pure cultures. Genes studies in WP2 are classified according to their major functional role in the EPS biosynthesis: NDP-sugar synthesis, glycotransferases and protein polymerization and export. For this purpose, pure cultures subjected to different operational factors will be subject to whole-genome sequencing (WGS), information from which will be used for further transcriptomic and bioinformatic analysis. Lastly, WP3 takes the knowledge generated in the previous packages to conduct several metanalysis in the mixed methanotrophic cultures.

Abstract
Volatile methylsiloxanes (VMSs) are a group of compounds used as additives in personal care products and cosmetics. Once used, part of them ends up in wastewater treatment plants (WWTP), where they can migrate to biogas, hindering the quality of this renewable resource by corroding and blocking engines powered by this fuel upon combustion. The main objective of this work is the analysis of VMSs in sludge, water, air and biogas from a municipal WWTP located in Portugal. To accomplish that, different sampling strategies were carried out to collect the above-mentioned matrices for 14 days in August 2020. Subsequently, these samples were extracted following low-impact methodologies based on green chemistry approaches, and analysed by means of GC-MS (for air, sludge, and wastewater) and GC-IMS-SILOX in case of biogas. These results were later used in conjunction with mass flows provided by the management board of the WWTP to study the fate of the different compounds in the plant. Regardless of sampling point, D3 is the prevalent VMSs in wastewater. This result is likely caused by punctual releases rather than base levels. In sludge, D5 is the predominant compound, due to its higher lipophilicity and high use as additive in cosmetics and personal care products. Air showed different VMSs profiles depending on assessed environment. Thus, outdoor samples are characterized by a prevalence of D5, while indoor samples show a predominance of D3 and D4. This phenomenon is caused by differential VMSs sources between these two environments, and the installation of air filtering systems in indoor locations. Biogas was characterized by a prevalence of D5 showing concentrations up to 8 mg/m^3, which is higher than recommended by some internal combustion engines manufacturers. By studying the WWTP as a whole, it is possible to see a reduction of VMSs levels of 81% along the wastewater treatment. Most of this VMS mass migrates to sludge and air, with some plausible degradation of D3 and D6 once volatilized. This is a giant first step to help WWTP managers to deal with the current issue of VMSs interference in the energy production from anaerobic digestion that often takes place in these facilities.

Keywords (maximum 6 in alphabetical order)
biogas; mass balance; sludge; volatile methylsiloxanes; wastewater; WWTP

INTRODUCTION

Formed by Si-O bonds with aliphatic chains attached to silicon atoms, volatile methylsiloxanes (VMSs) are cyclic or linear compounds that exhibit low chemical reactivity and high thermal stability [1]. These characteristics make them widely used chemicals in industrial processes and a vast array of consumer products such as detergents, adhesives, paints, and personal care products. Being semi-volatile, VMSs are mainly emitted to the atmosphere after use, but a considerable part enter wastewater treatment plants (WWTPs) in the untreated wastewater [2]. There, they partition among wastewater, sludge, biogas and air and can generate technical problems in internal combustion engines powered with biogas, from blockage to corrosion of parts [3]. Knowing the behaviour of VMSs in WWTPs is the first step to reduce these negative impacts and ensure the use of biogas as renewable resource to the maximum potential. Thus, this pilot study relied on an unprecedent sampling campaign to investigate 4 cyclic (D3-D6) and 4 linear (L2-L5) VMSs in a WWTP. To do so, samples of wastewater, sludge, indoor and outdoor air, and biogas were collected for two weeks and analyzed by different environment-friendly protocols to obtain the levels and mass balance of VMSs and elucidate the fate of the different VMSs.

MATERIALS AND METHODS

Wastewater, sludge, air, and biogas were collected during 14 consecutive days in August 2020 (see details in Table 1) in a municipal WWTP (about 40,000 m^3/day and 160,000 population equivalent) located in Portugal. Several points along the WWTP were chosen to collect daily 250 mL composite samples of sludge (5 points) and wastewater (4 points) were taken, plus six-hours composite wastewater samples in the first week. Point samples of biogas were collected in five days with Tedlar bags. Air samples were collected at 3 indoor, 2 semi-indoor and 4 outdoor points using two mesh cylinders with 10 g of XAD-2 resin protected with a stainless-steel case and exposed for 14 days. The analytical protocol for wastewater and sludge consisted of liquid-liquid extraction protocols, the former with n-hexane as extraction solvent under sonication and the latter with n-hexane and acetone (1:1) as extraction solvent, followed by orbital shaking for 2 h. For the passive air samples, a solid-phase extraction in separation funnels was used with three n-hexane extractions. These matrices were quantified in GC-MS. Biogas was directly analyzed by a GC-IMS-SILOX chromatograph. In order to calculate mass balances, flows from the analyzed matrices were provided by the WWTP management board.

Table 1: Sampling sites, characteristics and periodicity according to each matrix studied

Matrix	Sampling type	Number of points	Sites	Periodicity
Wastewater	Collection in 250 mL polypropylene flasks	4	Entry, Post-preliminary treatment, Post-primary decanter, Treated effluent	Daily composite samples (two weeks), Six-hours composite samples (one week)
Sludge	Collection in 250 mL polypropylene flasks	5	Primary decanter, Secondary decanter, Thickener, Pre-digester, Post-digester	Daily composite samples (two weeks)
Air	Passive sampling with 2 x 10 g of XAD-2	9	Canteen, Laboratory, Office, Workshop, Sludge thickener, Preliminary treatment, Aeration tank, Centrifuge, Background (outside the plant)	Exposure for two weeks
Biogas	Collection in 1 L Teflon bags	1	After biogas production	Every 2-3 days

RESULTS AND DISCUSSION

The level of ∑VMSs (23 ± 25 µg/L) and profiles in entry water for the sampling period as a whole were similar to results found in the literature, except for D3, which had concentrations one order of magnitude higher than reported [4]. From the daily concentrations, it was observed that this result could be related to punctual releases of this compound instead of base levels. No specific hourly-dependent pattern of VMSs was detected entering the WWTP. Regarding the wastewater mass balance, the higher losses happened in the primary decanter and the secondary treatment (31% and 29%, respectively), as a consequence of the partition between water and sludge (
Figure *1*)

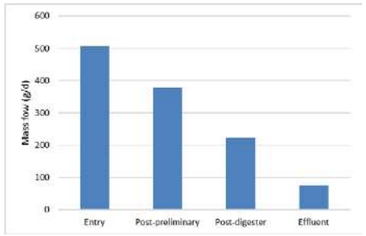

Figure 1: Mass flows of total VMSs in wastewater line

Primary and secondary sludge concentrations of ∑VMSs (8 ± 4 and 8 ± 3 µg/g dw respectively) and profiles were in line with values reported in the literature. Sludge profile was dominated by D5, followed by D6, regardless of sampling point. This outline is expectable if having into consideration the high use of D5 and the greater lipophilicity of D5-6. Concerning the mass balance of VMSs in sludge, it is possible to see a reduction along the sludge line (
Figure *2*). The digester is the treatment exerting the highest VMSs reduction in the sludge line (7% of entry levels). This result is caused by the migration of VMSs to biogas, favoured by the specific conditions in this treatment step (*i.e.*, 21 days of retention time and 37 ºC).

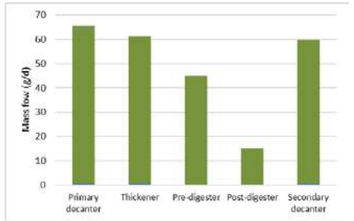

Figure 2: Mass flows of total VMSs in the sludge line

As a consequence of this migration from sludge, biogas concentrations for ∑VMSs (8 ± 0 mg/m^3) were above the limits for internal combustion engines recommended by some manufacturers (5 mg/m^3). D5 contributed with 89%, and D4 the remaining 11%.

VMSs profile in air is location-dependent, since in outdoor samples D5 was the major congener, but not indoors, where D3 and D4 prevailed. This trend, already observed in previous studies [5], is probably caused by two main reasons. On one hand, different sources are expectable between these two environments. While outdoor air is highly influenced by wastewater VMSs content, indoors may be more impacted by cosmetics and personal care products used by workers. On the other hand, the indoor air filtering systems installed in the office buildings are more prone to retain high molecular weight VMSs, such as D5 and D6.

The overall mass balance indicates a reduction of 81% in VMSs total mass is achieved along the WWTP (∑VMSs mass flows of 508 ± 530 and 96 ± 115 g/d for inputs and outputs respectively). Most of this reduction is achieved in the wastewater line, due to air migration of the VMSs. However, when comparing the observed results in air with those expected having into consideration the water/sludge partition, a lack of D3 and D6 is air is observed. This result could be indicative of atmospheric degradation and transformation processes of these compounds [2].

CONCLUSIONS

The present study highlights the importance of increased sampling periods in order to improve the representativity and time-sensitivity of VMSs monitoring and analysis. Equally, biogas and indoor air have shown their relevance as matrices to be sampled in WWTPs mass balance exercises. Future studies should aim to understand the seasonal effect on WWTP of VMSs influents and emissions.

Abstract
Despite it is well demonstrated that the presence of volatile methyl siloxanes (VMSs) in biogas hinders the quality of this renewable fuel, nowadays it is not well defined the dynamics of these compounds in methanogenic digesters. Therefore, the present work aims to study, for the first time, the distribution of VMSs within biogas digesters in different wastewater treatment plants (WWTP). Samples of sludge (both pre and post digested) and biogas were collected in five different WWTPs in Portugal. VMSs from sludges were extracted by liquid-liquid extraction with n-hexane, before GC-MS quantification. Biogas was directly analyzed from sampling bags by means of a GC-IMS-SILOX. Results show that the difference in VMSs mass between entry and digested sludge reach average values around 50%, being very variable among different congeners. Consequently, some locations showed levels of total VMSs above 5 mg/m^3 (limit recommended by some internal combustion engine manufacturers). Decamethylcyclopentasiloxane (D5) was the prevalent VMSs regardless of matrix and WWTP analyzed.

Keywords (maximum 6 in alphabetical order)
biogas; green chemistry; mass balance; sludge; volatile methylsiloxanes; WWTP

INTRODUCTION

Volatile methylsiloxanes (VMSs) are synthetic substances with a Si-O backbone saturated with methyl groups used in numerous consumer products [1]. Largely emitted to the environment, an important fraction of these compounds reaches wastewater treatment plants (WWTPs) where, depending on the congener physical and chemical properties, they can end up in biogas, often produced to fuel energy cogeneration systems. The combustion of biogas produces SiO_2 particles that settle and damage engine parts, decreasing the efficiency of the process [2]. The presence of VMSs in WWTPs has been reported in literature focusing on wastewater and sludge [3], but their behaviour in anaerobic digestors still lacks appropriate knowledge. Consequently, the objective of the present work is to study the distribution of VMSs within digesters in different WWTPs producing biogas.

MATERIALS AND METHODS

The sampling campaign occurred in 5 municipal WWTPs in Portugal in September 2021, targeting linear (L2-L5) and cyclic (D3-D6) VMSs. 250 mL of 24-hour composite samples of input and output sludge from methanogenic digesters. Biogas from every digester was taken at the same time using 1 L Tedlar® bags. Sludge and biogas flows were obtained from the WWTPs management boards. Biogas was directly injected and quantified on a GC-IMS-SILOX chromatograph. For sludge, 20 mL aliquots were mixed with 20 mL of hexane:acetone and spiked with 500 ppb M4Q (IS). Subsequently, the mixture was vortexed, orbital-shaken and centrifuged. The organic supernatant was collected, reduced to 1 mL, and injected into a GC-MS for quantification.

RESULTS AND DISCUSSION

Sludge concentrations

The ∑VMSs input concentrations (values ranging from 67.0 ± 1.76 to 395 ± 11.3 µg/L) were higher than in the output sludge (values ranging from 30.8 ± 15.1 to 94.7 ± 10.4 µg/L) concentrations in every WWTP, reflecting the partition to biogas. Cyclic VMSs were predominant in the sludge of every WWTP, with D5 representing more than 85% of the ∑VMSs regardless of the plant. L5 was the only linear VMS detected, maybe due to its more frequent use and higher lipophilicity [3].

Biogas concentrations

Cyclic VMSs were also prevalent in the biogas profile of every WWTP. D5 was the prevalent compound (representing in all cases above 78% of the ∑VMSs). L2 was the only linear VMSs detected, but only in one plant. Three of the facilities studied showed levels of ∑VMSs above 5 mg/m^3, the limit recommended as safe by some engine manufacturers [4].

Mass balance

The mass balance of all the WWTPs suggests that high molecular weight VMSs (L5, D4-D6) present a better consistency between input and output values in methanogenic digesters than low molecular weight compounds, as can be seen in Figure 1. D4 presented a total recovery of 73 ± 49%. Most of this mass partitioned to the biogas (47 ± 33%) while a smaller portion (26 ± 19%) remained in the sludge. An opposite trend was shown by D5, which yielded total recoveries of 71 ± 19%, with most mass remaining in the sludge (45 ± 24%) while approximately 26 ± 8.4% is transferred to biogas. This different behaviour can be explained by the differences in their boiling points (176 and 211 °C for D4 and D5 respectively) [3].

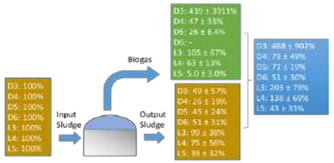

Figure 1. Overall relative mass distribution (mean ± standard deviation) of the different VMSs within the five biogas digesters

CONCLUSIONS

Cyclic VMS, and more specifically, D5 were predominant in both biogas and sludge. This outcome is a consequence of the intensive use of this compound in PCPs and cosmetics. The levels of total VMSs in biogas of three WWTPs were above the threshold proposed by some internal combustion engine manufacturers. The concentrations of total VMSs were higher in the digesters input sludge, suggesting a migration of VMSs from sludge to biogas, which was confirmed by the mass balance for most VMSs.

Abstract
Green walls and vegetated rooftops are emerging techniques for urban reconciliation ecology, and they are becoming more frequent in modern architecture. This work presents the results of the literature review done within the NICE H2020 project, regarding the state of the art of current applications of green walls and green roofs for treatment and reuse of greywater (i.e., domestic wastewater excluding toilet flush). A specific focus is adopted on the operational conditions (e.g., inflow rate of greywater), on the implementation schemes, and in the materials used as filter medium, considering that these factors are highly relevant for the treatment of greywater.

Keywords
Nature-based Solution; green wall; green roof; greywater reuse; non-conventional water.

INTRODUCTION

Green walls are vertical systems that provide vegetation cover to the external – and possibly internal – walls of buildings. According to the structure used to support vegetation growth and the classification given by Bustami et al (2018), green walls are generally classified in: Living walls, vegetation is planted in containers attached to the wall or is rooted to a supporting structure (e.g., geotextile) attached to the wall; green facades: vegetation is planted at the base of the wall and climbs either on a supporting structure (e.g., steel or plastic mesh) or directly on the wall itself. These structures can provide many valuable ecosystem services. For example, they enhance thermal regulation and increase economic value of buildings scale, and they also favour biodiversity preservation and improve air quality at urban scale (Boano et al., 2020). Moreover, they provide psychological and social benefits by lowering stress levels and enhancing people interactions. However, the implementation of green walls must take into account their water requirements, and the use of greywater has been proposed as an alternative water source to mitigate the water footprint of green walls. Moreover, green walls can also be adapted to become greywater treatment systems, becoming Nature-based Solutions that generate reclaimed water resources for non-potable reuse.

Green roofs are vegetated surfaces built on building roofs, composed of a medium layer where vegetation grows, a waterproof membrane and a vegetation layer. Green roofs are generally classified in: Extensive green roofs: medium depth up to 100 mm; Intensive green roofs: medium depth over 300 mm. Extensive green roofs are generally planted with smaller plants, usually Sedum, while intensive green roofs can be planted with larger plants and bushes, which results in heavier structures. When green roofs are integrated in buildings, they enhance thermal regulation through insulation and evapotranspiration. Biodiversity and air quality are also preserved and improved, increasing the economic value of the area in which green roofs are installed. Furthermore, rainwater can be collected, treated and reused with these systems instead of been discharged in the municipal drainage network, thus helping with the management of both extreme rain events and dry periods. Similarly to green walls, the irrigation of green roofs with greywater can support it during periods with limited rainfall and can generate treated greywater for non-potable reuse.

According with the aim of this work, the state of art of green walls and green roofs for greywater treatment and reuse is discussed in relation to new information and technologies involving these systems. For this aim, some case studies from the literature were used to derive some important data. Subsequently, statistical analyses were performed on these data to identify patterns between the relationships of different parameters in the performance of each case.

MATERIALS AND METHODS

Different literature types were investigated to obtain a suitable dataset to discuss the state of art of green walls and green roofs used for greywater treatment and reuse. Specifically, peer-reviewed and grey literature have been considered with the following rationale:

- Peer-reviewed literature – green walls: the analyzed articles were selected in cooperation with the Green Wall Cluster of the Circular City COST Action (https://circular-city.eu/) in which, POLITO and IRIDRA, partners of NICE, were involved. Eleven peer-reviewed papers have been selected and analyzed in this deliverable (for the full list of papers see section 4); all these papers consider the application of living walls for grey water treatment and reuse in real conditions. In addition, the paper of Kotsia et al. (2020) was also considered in the analysis, in order to include also the possibility to implement green wall for greywater treatment with green facades planted with climbing plants.
- Grey literature – green walls: IRIDRA experience has also been included as grey literature. Considering the design of green walls for greywater treatment and reuse for the demonstration pilots of the NAWAMED project made by IRIDRA, the data from these systems were obtained for this report. These data were presented in the 17th International Conference on Environmental Science & Technology, CEST2021, in Athens, Greece (Martinuzzi et al., 2021).
- Peer-reviewed literature – green roofs: the literature on green roofs for greywater treatment and reuse is quite limited, as reported by Boano et al. (2020); therefore, the articles have been selected considering the works citing and referred by a few key papers as Zapater-Pereyra et al. (2016); Boano et al. (2020); Cross et al. (2021); Thomaidi et al. (2022). Thirteen peer-reviewed papers have thus been selected and considered suitable for the analyses of this deliverable (for the full list of papers see section 4).
- Grey literature – green roofs: IRIDRA experience has been also included by the design approach of green roofs for greywater treatment and reuse for an installation on the roof of a resort built in Tanzania, reported in Masi et al. (2015).

The dataset obtained from the peer-reviewed and grey literature was systematized and structured according, collecting performance (e.g. TSS, BOD_5, COD, nutrients) and design values. Particular attention has been paid to collecting data in line with design parameters typical of treatment wetland technology (e.g. area, weight, HLR – Hydraulic Loading Rate, OLR – Organic Loading Rate, OTR – Oxygen Transfer Rate). When not directly reported in the papers, the parameters have been calculated from information given in the paper or from literature values (e.g., weight of the filling media).

Statistical analysis of the design parameters found in the different articles was performed to evaluate the variability of the design values within the samples. Moreover, regression analyses were performed between some key design parameters, to verify the relationship between the design and performance of green walls and green roofs.

RESULTS

The statistical analyses of the design parameters found in the different articles for green walls and green roofs are reported in Table 1 and 2, respectively.

According to the statistic parameters calculated from the literature dataset it was noted that the treatment surface per row and the medium volume per row show great variability, from 0.01 m2 to 53 m^2 (Table 1). This is due to the different scales of the green walls (laboratory scale vs. full scale) and to the different configurations of green walls, for example, from single columns of small pots to large troughs. Regarding the depth of the medium, they showed values of the order of tens of centimeters (10 – 80 cm), with an average of 40 cm. The weight per square meter of the green walls medium remained below 100 kg, with a minimum of 5 kg to a maximum of 78 kg, depending on the type of material used and the system configuration, with an average of 38 kg. The total weight per square meter, including medium and water, varied between 7 kg and 158 kg (avg. 81 kg). The observed average inflow rate was 1.4 m^3/d, with a range of 0.004 to 10.4 m^3/d. The average HLR on the first row was 411 L/m^2/d, while the average OLR on the first row was 91.5 gCOD/m^2/d with a range of 100 – 1111 L/m^2/d and 20 – 218 gCOD/m^2/d respectively. The retention time remained below two days, with an average of a day and a half (1.6 d), and with a single sample that exceeded three days (3.35 d). The OTR values varied between 3.2 and 68 gO2/m^2/d, with an average of 30 gO2/m^2/d. Green walls showed a good performance in BOD_5 and COD removal, with an average percentage removal of 87% and 73% respectively (range: 25 – 99% BOD_5, 18 – 97% COD).

Table 1. Statistical parameters of green walls design and performance from literature data.

	Unit of measure	Avg.	St.dev.	Min.	Q1	Q2	Q3	Max.	no. samples
Treatment surface per row	m^2	5.5	12.9	0.01	0.1	1.0	2.6	53	18
Medium volume per row	m^3	1.9	4.6	0.006	0.026	0.216	0.55	16.8	17
Depth per row	m	0.4	0.3	0.12	0.15	0.335	0.6	0.8	12
Medium weight	kg/m^2	37.8	25.9	5.6	14.8	44.3	55.9	78.2	16
Total weight	kg/m^2	81.2	57.7	6.9	21.9	111.8	127.4	158.2	16
Inflow rate	m^3/d	1.4	2.4	0.004	0.05	0.78	1.55	10.4	20
HLR first row	L/m^2/d	410.8	337.1	100	143.2	250	597.3	1111.1	17
OLR first row	gCOD/m^2/d	91.5	63.9	20.5	47	70.2	131.1	218.2	17
HRT	d	1.6	1.1	0.55	1	1.4	1.9	3.35	5
OTR	gO_2/m^2/d	29.9	18.5	3.2	18.4	30	39.8	67.9	11
BOD5 removal	%	87	19	25	88	95	96	99	25
COD removal	%	73	26	18	45	90	93	97	29

According to the literature dataset, in general green roofs exhibit a relatively good removal of BOD_5 and COD, with an average of 70% for BOD5 and 77% for COD. BOD_5 removal ranges from a minimum of 35% to a maximum of 97%, while COD removal ranges from 39% to 99% (Table 2). The depth of the medium layer of the green roofs in the analyzed papers varied from a minimum of 9 cm (extensive green roofs) to a maximum of 62 cm (intensive green roofs), with an average of 20 cm. The average weight of the medium layer per square meter was 203 kg/m^2, and 274 kg/m^2 with the addition of the weight of water. The observed weight range was very wide, as it depends on the depth of the medium layer and the type of filling material used, and so these values varied from a minimum of 28 kg/m^2 (88 kg/m^2 with water) to a maximum of 930 kg/m^2 (1180 kg/m^2 with water). The inflow rate varied between 0.003 m^3/d to 4 m^3/d, with an average of 0.3 m^3/d. The average hydraulic loading rate and organic loading rate that correspond to these rates are 39.2 L/m^2/d and 9.3 gCOD/m^2/d, respectively. The HRT values generally remained below two days, except for two samples, which showed an average of 1.4 days (minimum 0.5 d, maximum 3.8 d). Finally, the Oxygen Transfer Rate on average was equal to 14 gO_2/m^2/d, with a minimum of 1.1 gO_2/m^2/d and a maximum of 50.3 gO_2/m^2/d.

Other results of the statistical analyses and the regression analyses will be presented at the conference.

Abstract
Secondary sludge biomass (or WAS) produced in wastewater treatment plants is an interesting renewable resource that accumulates nutrients from these waters in the form of proteins and carbohydrates, among others. Despite recent interest in valorizing this biomass to improve the economics of wastewater treatment plants, there is still very little research focused on fractional resource recovery from this biomass. In this study, different hydrolysis processes such as chemical (acidic, AC and alkaline, ALK), hydrothermal (HT), biological (autohydrolysis, AH), physical (ultrasound, US) and sequential (US-AH) and assisted (US+ALK, HT +ALK, HT +AC) combinations were used to recover proteins in the form of peptides and carbohydrates in the form of fermentable monosaccharides from WAS biomass. The combined US+ALK treatment provided the highest solubilization yields (SY) of proteins (97.2%) with losses of less than 25%, resulting in peptide recovery yields of 75.1% with sizes ranging from 70-215 kDa. The combination HT +ALK resulted in almost complete solubilization of proteins but lower solubilization of carbohydrates (SY ≈75%) with high loss factors (47%). The combination HT +AC achieved high carbohydrate SY (94.2% 1M HCl) but lower protein SY (≈72%). The low yields obtained with the HA treatment were improved by the addition of acid, which increased protein SY by 82% and carbohydrates by 130% (0.5 M HCl) and 144% (1 M) under the same temperature (50°C) and time (180 min) conditions.

Biorefinery, peptide, pretreatments, monosaccharide, valorization, waste

INTRODUCTION

Secondary sludge is an abundant and problematic waste biomass, which accumulates nutrients from wastewater in the form of proteins and carbohydrates, among others. The handling or disposal of this sludge represents currently almost 50-60% of the total cost of wastewater treatment plants (WWTP) (Capodaglio & Olsson, 2019). In recent years, studies have been addressed to the uses of this waste biomass as source of renewable energy through processes such as anaerobic digestion. However, the fractional recovery of the biomass components could be more economically advantageous. The biomass generated in WWTPs contains various microorganisms and extracellular polymeric substances (EPS), the main component of which is protein, which accounts for about 50% of the dry weight of bacterial cells (Xiang et al., 2017). This biomass could be an important source of peptides useful in multiple applications (Zhou et al., 2017). On the other hand, the carbohydrate fraction can be used to produce different value-added products such as polyhydroxyalkanoates (PHAs), or biofuels. However, research dedicated to the fractional valorization of sludge components is very limited and this knowledge is crucial for the development of new biorefinery processes that can considerably improve the economic balance of wastewater treatment plants. In this context, the present work evaluates and compares different types of hydrolysis as chemical methods (acid, AC and alkaline, ALK), hydrothermal methods (HT), biological methods (autohydrolysis, AH), physical methods (ultrasound, US) and sequential physical-biological combinations (ultrasound-autohydrolysis, US-AH), and thermal+chemical (HT+ALK and HT+AC), physical+chemical (US+ALK) methods assisted on solubilization yield (SY) and recovery (RY) of the main components of this biomass: proteins as peptides and carbohydrates as fermentable monosaccharides (glucose and xylose).

MATERIALS AND METHODS

Raw sludge (RS) biomass used in this study was collected from local urban WWTP in Valladolid, Spain. The samples of RS were taken after the secondary settler unit of the urban WWTP. The moisture content and pH of raw sludge were 98% and 6.8. The RS was concentrated by centrifugation to achieve a concentration of total solid (TS) of 11.7% with a volatile solid fraction of 76.9 % in the centrifuged raw sludge biomass (CRS). All CRS fractions were homogenized, and the chemical composition of CRS was as follows: 43 % protein, 17.1% carbohydrates (composed by 13.6% glucose, 3.6% xylose, 1.5% cellobiose, and 1.1% arabinose), 14.3% lipid, 12.8% humic acid (percentages based on ash-free dry mass). The extraction operation conditions shown in Table 1 were selected according to the previous experience of this team working with algal biomass grown in wastewater (Martin Juárez et al., 2021) and the scarce references about WAS (Xiang et al., 2017) focused on component solubilization. After each treatment, the hydrolysate was centrifuged to separate the liquid and solid fractions. The residual solids were weighted and analyzed to calculate by difference the solubilized macro-components. The recovery as peptides and monosaccharides was calculated from the analysis of the liquid phase. Protein fraction in solid fraction was determined using the Total Kjeldahl Nitrogen (TKN) and applying the nitrogen to protein ratio (N:P) of 4.0, calculated from the amino acid profile of the CRS, determined by HPLC-UV. The size of peptides recovered from all the assays were characterized by using SDS-PAGE according to Rojo et al., (2021). The monosaccharides and amino acids recovered, in the liquid fraction, were determined by HPLC-IR and HPLC-UV, respectively. Carbohydrates, in the exhausted solid, were determined using the modified NREL protocol of hydrolysis and HPLC-IR according to Rojo et al., (2021).

RESULTS AND DISCUSSION

Figures 1 and 2 show the SY (%) and RY (%) of proteins and carbohydrates for the different treatments tested in relation to the initial mass of each component in CRS. The highest protein SY were obtained with the alkaline-based methods. Single alkaline hydrolysis (ALK, 50°C, 0.5 M and 1 M, 180 min) resulted in protein SY of 75% at both NaOH concentrations. With increasing NaOH concentration, the carbohydrate SY decreased from 65.5% at 0.5 M NaOH to 56.8% at 1 M, and the recovery of monosaccharides was slightly lower than 30%. Almost complete solubilization of proteins (≈ 97.2%) were achieved when combining thermal (HT +ALK) or ultrasonic (US+ALK) methods with alkaline medium (0.5 M or 1 M). The combination of HT +ALK conditions resulted in almost complete solubilization of proteins but lower solubilization of carbohydrates (≈78%) and high loss factors (47%) of both components. In spite of the high protein SY, HT+ALK resulted in peptide recoveries of 58.5% (1 M NaOH) and 63.5 (0.5 M NaOH) with peptide sizes around 100-150 kDa in both cases. For the US+ALK method, losses were less than 25%, resulting in a peptide recovery yield of 75.1% with sizes between 70-215 kDa and 40% essential amino acids (Eaa). No differences were observed with NaOH concentration (0.5 and 1 M). Assisted alkaline hydrolysis (US+ALK, 60 min) also achieved the highest carbohydrate SY (94.4%, NaOH 1 M) but with high carbohydrate losses, resulting in monosaccharide recovery yields of only 30%.

Even, as a single treatment, without alkali support, ultrasound (US, 60 min, 50°C) resulted effective achieving SY of 43.7% for proteins and 44.6% for carbohydrate, values much higher than the 19.6% and 24% SY for proteins and carbohydrates, respectively, obtained in the 180 min AH assay at identical pH (6.5) and temperature (50°C) conditions. The application of 20 minutes of US also improved the autohydrolysis results (US-AH, 20 min), remarkably for proteins, reaching SY of 35.1% for proteins and 25.2% for carbohydrates. In both assays (US and US-AH), protein recovery was 46.5%, but with peptide sizes lower than 70 kDa.

The effect of temperature as single hydrolysis method (HT) was also notable, especially for proteins. The solubilization yield after 60 min under hydrothermal conditions was 184% higher for proteins and 55% higher for carbohydrates than that after 180 min of autohydrolysis at pH 6.5 and 50°C. Finally, combined acid and hydrothermal hydrolysis conditions (HT +AC, 60 min) achieved high carbohydrate SY (94.2% 1 M HCl and 81.4% 0.5 M HCl) but lower protein SY (≈72%). The HT+AC treatment provided 44% of peptide recovery, with so small size peptides than they were not detected in electrophoresis analysis.

Abstract
Environmental impact and costs related to the management of membrane concentrates are the main challenges from Drinking Water Treatment Plants and Reclaimed Water Treatment Plants. These types of facilities are at the same time large consumers of chlorine-based disinfectants. Two processes for brine valorisation will be demonstrated in two real case studies in Spain. Two semi-industrial prototypes have been designed using the results of laboratory scale tests and simulations for ionic and mass balances, chemicals, and energy consumption calculations based on Nanofiltration (NF), Selective Electrodialysis (SED) and Electrochlorination (EC) technologies. The prototypes will be operated until January 2024 to assess the feasibility of the solutions to produce N-rich reclaimed water and sodium hypochlorite.

Keywords
brine; chlorine; electrodialysis; electrochlorination

INTRODUCTION

Coastal areas affected by groundwater overexploitation may suffer high content of salts in groundwater and wastewater due to marine intrusion. To overcome this issue, Drinking Water Treatment Plants (DWTP) and Water Reclamation Plants (WRP) commonly rely on advanced treatments to produce desalinated water through Reverse Osmosis (RO). These technologies concentrate the salts in brines that are either managed as a waste or discharged to natural bodies, with its consequent environmental impact and high costs associated that may increase up to 0.7 €/m3. Moreover, intense agricultural activity has increased the concentration of nitrates in water bodies leading to the discharge of nitrate-rich brines and thus to eutrophication-related problems. These reasons increase the need of developing cost-effective solutions that reduce the environmental impact of membrane processes.

The present study is based on the demonstrative cases of Zarandona WRP (Murcia) and Rincon de León WRP (Alicante), where brine valorisation technologies will be applied to produce disinfectants from membrane concentrates and to benefit from nitrates as fertilizers. Current results include simulations and lab-scale trials carried out for the design of the nanofiltration, selective electrodialysis, and electrochlorination units, as well as calculation of the ionic and mass balances, and chemicals and energy consumption of the solution.

MATERIALS AND METHODS

Both proposed Brine Valorisation Treatments are shown in Figure 1.1. In Rincón de León WRP, concentrates from RO go through a SED that concentrates monovalent ions (mainly NaCl), followed by a 2D EC reactor to produce sodium hypochlorite (NaClO) in-situ. In Zarandona WRP, contaminated water with salinity and nitrates goes through a NF, producing N-rich reclaimed water: monovalent ions (mainly NaCl) from NF concentrate go through a concentration train followed by a novel 3D EC reactor to produce sodium hypochlorite.

Software design tools, such as Winflows®, were used to design the 2-stage NF for an 85% of water recovery. Lab-scale tests were performed on a set-up of 140 cm2 of active membrane area allowing determination of rejection profiles of NaCl, nitrates, and other ions.

Lab-scale tests of SED were performed on a set-up of 64 cm2 of active membrane area and a tension range of 0-36 V allowing continuous monitoring of current intensity, voltage, pressure, temperature, conductivity, flow and pH in the electrode, dilute and concentrate streams. The 2D EC setup works with one or two cells in parallel with an electrical current from 2 to 20 A that allows evaluation of active chlorine production under different conditions.

RESULTS AND DISCUSSION

Main compositions in feed streams are chloride (>88 mg/L), sodium (>500 mg/L), sulphates (>1-8 g/L), calcium (>0.3-1.7 g/L), and ammonia (>42-315 mg/L), for NF feed in Zarandona WRP and RO brines in Rincon de León WRP, respectively. Also, NF feed has nitrates (35 mg/L) and conductivity >3.5 dS/cm, while RO brines have a conductivity >8.7 dS/cm.

NF rejection values of 50-70% of dissolved monovalent salts (NaCl), 99% of divalent salts ($MgSO_4$) and 5-10% of dissolved nitrates were obtained for the membrane selected, producing a N-rich reclaimed water with conductivity below 3 dS/cm, suitable for irrigation.

SED was able to concentrate NaCl 5-10 times, whilst maintaining Ca^{2+} and Mg^{2+} below 100 mg/L for both ions, minimising the needs for pre-treatments to reduce scaling risk in the electrochlorination unit. Energy consumption of SED unit varied from 1.8 to 4.9 kWh/m^3, depending on the concentration factor, with overall energy consumption including 2D EC of 10.3 kWh/kg of active chlorine.

In Zarandona WRP, 0.2 hm^3/y of partially desalinated N-rich reclaimed water will be injected to Murcia Urban Irrigation Network, avoiding the discharge of 0.62 ton N_{eq}/y, and 26 ton/y of NaClO will be produced. In Rincon de León, up to 110 ton/y of NaClO will be produced from RO brines.

The proposed processes appear to be a cost-effective, circular economy-based alternative to conventional brine management strategies, reducing environmental impact related to brines management and N discharge, and producing in-situ sodium hypochlorite disinfectant.

Abstract
Proteins are essential for the structure, function and regulation of tissues and organs in the human body. Proteins are ingested from meat, dairy products, nuts and some grains, but conventional methods to provide the ever-increasing demand are no longer sustainable. Microbial electrochemical technologies can arise as an alternative to generate protein-rich edible biomass by feeding it with recycled carbon dioxide and nitrogen-contaminated streams, while using the reducing power of water electrolysis. In this context, the control of the operating variables is of utmost importance. Different parameters (oxygen concentration, current supply and cell retention time) were tested, monitored and controlled to find the best conditions to maximise microbial growth. Yet, will humans be able to overcome conceptual barriers and benefit from a resource that has been a waste?

Bioelectrosynthesis; CO_2 recycling; microbial food; nitrogen cascade effect; operating control

INTRODUCTION

We live in a world that no longer supports our pace. However, until we learn that de-growth is not poverty but consuming less to live better, we will need the help of technology to prevent malnutrition. Microbial electrochemical technologies (METs) normally use microbes as catalysts. Given that microbes are protein-rich organisms (content of 60-80%), METs could also be used as a platform to generate microbial biomass. A promising example is the production of hydrogen-oxidising bacteria (HOBs) from the reducing power of water electrolysis (H_2:O_2), carbon dioxide (CO_2) and reactive nitrogen (N), which in turn could be recycled from exhaust gases and N-contaminated streams. When growing HOBs in conventional fermenters, the need for external H_2 supply and the use of deionised water, certainly increase the operational costs (60% in electricity; Pikaar, de Vrieze, et al., (2018)) and the water footprint. Whereas the use of renewable energy might mitigate the first impact in the near future, METs could emerge as an attractive method capable of producing H_2 in the same medium where HOBs are cultivated (Pous, Balaguer, et al., 2022). Therefore, the main objective would be to maximise the production rate of protein-rich biomass at the same time as ensuring an efficient C and N assimilation. To this end, balancing the stoichiometry of water electrolysis and biomass production (Reactions 1 and 2, respectively) represents the key challenge.

Reaction 1. $2\ H_2O \rightarrow O_2 + 2\ H_2$
Reaction 2. $4\ H_2 + O_2 + CO_2 + 0.24\ NH_3 \rightarrow CH_{1.68}N_{0.24}O_{0.46} + 3.54\ H_2O$

MATERIALS AND METHODS

Two 1L membrane-less methacrylate reactors were designed, constructed and inoculated with a previously enriched HOBs mixed culture, while dissolved H_2 and O_2 profiles were monitored under variable current densities. The gas phase composition, pH, electric conductivity and optical density of the bulk liquid were measured daily. Meanwhile, 70 % of the medium containing urea (CH_4N_2O) as N source was periodically replaced to assay different cell retention times, and the dry cell weight (DCW), N-species and total Kjeldahl nitrogen (TKN) were determined to calculate the volumetric biomass productivity rate and close the nitrogen balance. The protein content was analysed through the N content of biomass relative to the DCW.

RESULTS AND DISCUSSION

Increased current densities led to faster gas production rates (Table 1) and subsequent microbial growth, but H_2 and O_2 profiles had to be closely monitored to guarantee a high N assimilation efficiency while providing the right amount of CO_2. The importance of retaining sufficient gases concentration in the liquid media yet ensuring a proper purge of excess O_2 was highlighted, allowing the settlement of upper and lower limits of H_2 and O_2 concentrations.

Table 1. Stoichiometric H_2 and O_2 production rates as a function of the applied current.

Current density (mA/cm²)	H_2 production (mg/Lh)	O_2 production (mg/Lh)
0.04	0.81	6.45
0.08	1.61	12.91
0.13	2.42	19.36

So far, higher percentages (>43%) of edible proteins compared to traditional routes (4-14%) have been achieved (Pikaar, Matassa, et al., 2017; Pikaar, de Vrieze, et al., 2018; Matassa, Verstraete, et al., 2016; Pous, Balaguer, et al., 2022) by reducing water use, avoiding the use of pesticides and recycling carbon and nitrogen streams.

The knowledge that this work provides in terms of the operational parameters required to enhance bacterial growth is a fundamental tool to increase the readiness level of the technology. However, the development of a stable microbiome, mass-transfer limitations and the public acceptance of the final product are still some challenges that need to be addressed. After all, it is a matter of closing cycles, and this means having to feed on what was once a waste product.
How far will we, humans, be prepared to go?

Abstract

Removal of emerging contaminants (ECCs) from wastewater has received a lot of attention because of the hazard potential of these pollutants. Different treatment techniques have been used to remove ECCs, and the low-cost and versatility of the adsorption processes has been advantageous compared to other techniques. However, due to certain limitations, the selection of adsorbents is in many cases not done properly. For that reason, this work aimed to select the best reactive media to adsorb four common emerging contaminants through different interconnected perspectives (economic, environmental, and adsorption efficiency). Therefore, adsorption kinetics tests, life cycle assessment, and life cycle cost analysis were performed to evaluate the best material as ECCs adsorbent. Among seven tested materials, coco coir and biochar SS showed most promising results. In addition, the overall results have revealed a great potential of the combination of different approaches for selecting appropriate substrate material for low-cost natural treatment systems.

Keywords: Adsorption; emerging contaminants; LCA; LCC; Nature-based Solutions

INTRODUCTION

Nowadays, the removal of emerging contaminants (ECCs) from wastewater has received a lot of attention because of the toxicities and carcinogenic nature of these pollutants. While conventional treatment methods can be effective for the removal of ECCs, adsorption is supposed as one of the best methods due to its low cost and ease of operation (Yousef *et al.* 2020). In addition, adsorption, in conjunction with biodegradation, is one of the key processes of pollutant elimination in Nature-based Solutions, which encompasses efficient treatment technologies, which due to their innovation, reliability, and economics have been increasingly applied (Castellar *et al.* 2022). However, there are many points to consider to choose a substrate as an ideal adsorbent, such as the cost, the feedstock, the hydraulic and engineering feasibility, the capacity to adsorb a large list of contaminants, the safety, and their useful life (Wang *et al.* 2020). Therefore, there is an increasing need for studies dedicated to knowledge on various adsorbents to remediate many pollutants, such as ECCs. For that reason, this work aimed to use different approaches to select the best reactive media to adsorb four common emerging contaminants, according to their physical characteristics, environmental risks, cost, and adsorption performance. Thus, this preliminary study essentially focussed on identifying the best material for ECCs adsorption through adsorption kinetics tests, physical characteristics (particle size, porosity and BET-specific surface area), and life cycle assessment (LCA), life cycle cost (LCC) perspectives. The results of this study will be helpful for selecting and identifying appropriate substrate material which can be used in an adsorption system, or as a matrix in natural treatment systems like Nature-based Solutions where the adsorption processes help to eliminate emerging contaminants (ECCs) from wastewater.

MATERIALS AND METHODS

Reactive adsorbent materials were selected according to their feedstock content and to previous adsorption performance from bibliographies. Seven low-cost materials, natural ones and by-products, were chosen to evaluate physical characteristics, environmental risks, cost, and adsorption performance, which are: chitosan, sewage sludge biochar (SS biochar), softwood pellets biochar (SWP biochar), coco coir, perlite, zeolites, and titanium dioxide. Due to the low molecular weight of chitosan and the low particle size of titanium dioxide, these materials were supported by zeolites in order to prevent their release.

Adsorption tests

To evaluate and select the best adsorbent material, concerning the adsorption of emerging contaminants, adsorption kinetics tests were performed. In these tests, aqueous samples with 400µg/L of four emerging contaminants (diclofenac, imidacloprid, estrone, and 17-β-estradiol) and ~0.1-0.5 g of each adsorbent substrate are mixed using a stirrer, and during this process, the supernatant is sampled for the evaluation of the adsorbate concentration until an equilibrium is reached. Specifically, the bottles were shaken at an orbital mixer and the supernatants from the bottles were sampled at the time intervals of 0, 0.5, 1, 2, 4, 8, and 24 hours. Determination of the concentration of emerging contaminants was performed by an LC-MS/MS following the Standard Methods for the Examination of Water and Wastewater.

Adsorbents characterization

Considering the importance of evaluating some physical parameters to choose the best adsorbent material analysis of particle size, porosity and BET specific surface area of each material was performed. These parameters were analysed through Standard Methods.

Life Cycle Assessment and Life Cycle Cost

To carry out these analyses, the stages established according to ISO 14040 and 14044 (ISO 2006a; ISO 2006b), which define the methodological steps, were followed. In this way, considering the adsorption process, through LCA and LCC the environmental impacts and the direct and indirect costs of the production of the adsorption materials used in this studied were quantified, as well as the impacts and costs associated to discharge the effluent water treated after the adsorption process. The quantities of materials that were used were listed in the Life Cycle Inventory (LCI) in which the materials were reported per tests (50 g of synthetic wastewater), that was established as Functional Unit (FU).

The process consumption data and the characterization of the treated wastewater were obtained through the adsorption experiments performed and the production data of the adsorbent materials were taken from the ecoinvent® 3.8 database (Frischknecht *et al.* 2005). The analysis was performed using the software SimaPro in which there are different characterization methods that transform the material inputs listed in LCI into environmental or economic impacts. The characterization methods selected in this study were ReCiPe Midpoint with the Hierarchy perspective for the characterization and normalization in LCA (Huijbregts *et al.* 2016), and the Environmental Prices method to the LCC (de Bruyn *et al.* 2018). In this way, regarding economic impacts, Environmental Prices method allows to quantify the economic costs as a consequence of the environmental burdens of the process. Additionally, to complete the LCC, direct costs data (price of materials, reagents and electricity) were taken into consideration.

RESULTS AND DISCUSSION

In order to choose the best adsorbent material according to kinetics results, biochar SS and coco coir showed the greatest potential to adsorb most of the emerging contaminants (Figure 1). For instance, coco coir and biochar SS presented the higher values adsorption capacity for estrone, 125 mg/g and 33 mg/g, respectively. Furthermore, biochar SS also shows a high potential to adsorb diclofenac (DFC), with a maximum adsorption capacity of 27 mg/g. While, the materials with lower adsorption capacity values were perlite, zeolite, and titanium dioxide-modified zeolite.

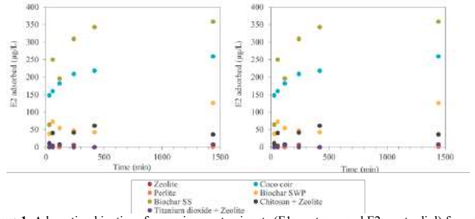

Figure 1. Adsorption kinetics of emerging contaminants (E1 – estrone and E2 – estradiol) for seven adsorbent materials (zeolite, coco coir, perlite, biochar SWP, biochar SS, chitosan modified zeolites and titanium dioxide-modified zeolites), representing the adsorbed concentration by the time.

These results could be attributed mainly to material granulometry properties. Coco coir was the material with a wider particle size range, including wide micro to macro particles, while biochar SS was the material with a higher BET-specific surface area. As expected, the material with more porosity and a variety of particle sizes has more active sites for adsorbed pollutants with different molecule sizes, which may explain the relation found. This relation was also observed for the negligible adsorbent results, the materials with the lowest adsorption capacity for most of the contaminants were the ones with the lowest BET-specific surface area.

With regard to the LCA results, Figure 2 shows the main results obtained with the 6 different adsorbents analysed in this study, after using the characterization and normalization method to quantify the environmental impact. The materials composed of zeolites and titanium and chitosan nanoparticles showed the worst values when quantifying the environmental loads. On the other hand, the material with the lowest environmental loadings was the Biochar SS. This is mainly due to the ability of Biochar SS to adsorb the contaminants used in these tests, which is generally superior to other materials. This makes the quality of the effluent (treated wastewater) better, and therefore the discharge is less harmful to the environment.

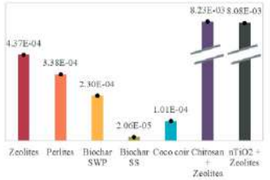

Figure 2. Results with normalized values corresponding to the environmental burdens for each adsorbent using ReCiPe midpoint method

In the case of LCC results, the direct costs were calculated on the one hand, taking into account the price of the materials, although in the case of the composite materials (Chitosan + zeolites and $nTiO_2$ + zeolites) the costs derived from their production were also considered. In this case, the materials with the highest direct costs were the composite material chitosan + zeolites ($8.77 \cdot 10^{-2}$ €/FU) and the material identified as having the lowest direct cost was coco coir ($6.21 \cdot 10^{-4}$ €/FU). However, considering the indirect costs, calculated using Environmental Prices, the material with the lowest cost was Biochar SS ($2.38 \cdot 10^{-4}$ €/FU), due to its quality as an adsorbent for the elimination of contaminants. Finally, considering the total cost, coco coir is the material with the lowest cost ($1.25 \cdot 10^{-3}$ €/FU), due to the fact that Biochar SS ($3.78 \cdot 10^{-2}$ €/FU) has a higher price.

In conclusion, with the observed results, it was possible to analyse seven materials and select the best adsorbents for removal of different emerging contaminants using economic, environmental, and adsorption efficiency perspectives. Coincidentally, the adsorption kinetics, and the LCA and LCC results indicated the same best reactive media. Coco coir and biochar SS were the materials with the lower cost, the lowest environmental loadings and with the best adsorption performance. Despite that, through a proper analysis of all factors that could affect the adsorbent choice, and consequently the efficiency of the adsorption process, this study highlights the importance of a detailed analysis of these aspects before a proper selection.

Preliminary study of anaerobic digestion of olive oil industry wastewaters in a conical spouted bed digester

M. J. San José*, S. Alvarez and R. López

* Departamento de Ingeniería Química, Universidad del País Vasco UPV/EHU, Bilbao, 48080, Spain
(E-mail: *mariajose.sanjose@ehu.eus)*

Abstract
An experimental study on operativeness of beds consisting of olive oil wastewaters was conducted in conical spouted beds reactors for anaerobic digestion of wastewater from the olive oil industry with at a temperature range of 40-55 ºC. The anaerobic digestion process of olive oil wastewater was studied in conical spouted beds digesters.

Keywords
Anaerobic digestion; biogas; conical spouted beds; olive wastewaters

INTRODUCTION

The olive oil extraction process produces a substantial amount of waste, such as olive mill solid waste, vegetable water, olive pomace, and other wastewaters. Anaerobic digestion is regarded as a sustainable way for the treatment of olive industry wastes because of the high organic matter concentration of these wastes, which converts the organic material to methane and carbon dioxide as well as a digestate (Messineo et al., 2020). Biogas generation is a major technology for promoting energy from renewable sources according to Directive (EU) 2018/2001 and is crucial to the decarbonization process (European Green Deal, (COM(2019) 640 final)).
Conical spouted bed reactors have been previously applied for thermal treatment of waste biomass (San José et al., 2013, 2014, 2018, 2019, 2021, 2023) and for anaerobic digestion of paper industry sludge (San José et al., 2015a), sewage sludge (San José et al., 2015b, 2017), and wine production waste (San José et al., 2018, 2021b). A conical spouted bed digester was developed for anaerobic digestion of beds consisting of olive waste.

MATERIALS AND METHODS

In order to design a conical spouted bed reactor for anaerobic digestion of olive industry waste, a hydrodynamic study of beds consisting of waste was conducted in an experimental plant equipped with conical spouted beds reactors of various geometric factors, Figure 1. The plant consists of an impulsion system, an electrical resistance for heating the fluid, and thermocouples to monitor bed temperature. The effect of temperature on the operating maps was determined in the spouted bed regime.
The anaerobic digestion was conducted in a battery of conical spouted beds digesters under thermophilic conditions (40-55 ºC) for 60 days. Different amounts of substrate/inoculum of methanogenic anaerobic bacteria were fed to each digester. Olive oil wastewater was obtained during the olive-oil extraction process at an olive oil processing plant. During the digestion, the biogas produced was measured by means of a gasometer through water displacement, and the biogas production was quantified by a Geotech Biogas-5000 analyzer. The characteristic parameters were quantified according to the standard methods.

RESULTS AND DISCUSSION

The proper geometric factors of the inlet diameter/particle diameter ratio and contactor angle for anaerobic digestion of olive oil wastewaters were established. Likewise, the operating conditions for beds consisting of olive oil wastewaters were determined from room temperature (25 ºC) to 55 ºC displays. by increasing fluid flow, the bed passes from the fixed bed to the spouted bed regime, which is characterized by a cyclic movement of particles and a clear distinction between the spout zone of ascending solids and the annular zone of descending solids. The system is stable for all of the stagnant bed heights studied, and an increase in bed mass leads to a higher minimum spouting velocity.

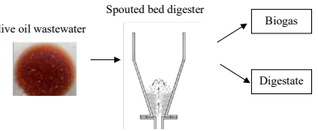

Figure 1. Scheme of anaerobic digestion of olive oil wastewater in conical spouted beds digesters.

Based on the volatiles removal and biogas production, conical spouted beds digesters are appropriate for industrial anaerobic degradation of olive oil wastewater under autothermal conditions.

Abstract
Irrigation with treated wastewater is a growing practice to surpass water scarcity in agriculture. However, this practice might pose a risk to human health allowing the entrance of wastewater-derived organic contaminants, like pharmaceuticals, in the food chain. In this work, the dietary exposure and human health risk assessment to pharmaceuticals from chronic consumption of lettuce irrigated with treated wastewater under real agricultural field conditions were estimated. All detected pharmaceuticals showed Hazard Quotient (HQ) < 0.1 and would not represent a threat to human health in terms of pharmaceuticals intake.

Keywords
Hazard Quotient; Pharmaceuticals; Risk Assessment; Treated wastewater

INTRODUCTION

Agriculture is among the sectors more threatened by water scarcity, due to an increasing demand for water in agricultural production. Different integrated water resource management measures are needed, especially in what concerns to the use of non-conventional water resources, such as treated wastewater. The reuse of treated wastewater for irrigation of agricultural fields can surpass the problem of water scarcity and compensate for nutrients needs of crop plants (Christou et al., 2019). However, emerging contaminants, such as pharmaceuticals, may persist in treated wastewater, and these practices may represent a serious threat to human health and food safety by facilitating the entrance of emerging contaminants into the food chain. Currently there is a gap of knowledge in the dietary exposure to wastewater-derived organic contaminants and their potential risks for human health due to the chronic consumption of contaminated agricultural products. In this work, exposure and human health risk from pharmaceuticals (PhACs) related to the ingestion of lettuce irrigated with treated wastewater under real agricultural field conditions were assessed.

MATERIALS AND METHODS

Lettuce sampling, sample preparation and analysis of pharmaceuticals

The experiment was performed in an agricultural field in Lesvos Island (Greece). Lettuce was drip irrigated with treated wastewater resulting from: a) Treatment 1, consisting of a UASB unit followed by saturated wetland, unsaturated wetland, and UV disinfection; b) Treatment 2, comprising a UASB unit plus tertiary treatment by UV disinfection. At the harvesting time, lettuces were collected, rinsed with deionized water, dried, and stored at -20 ºC until analysis.
At the laboratory, lettuce samples were separated into leaves and roots, freeze-dried and then lettuce leaves were extracted by QuEChERS (adapted protocol from Montemurro et al., 2020). The final extracts were analyzed by UHPLC-MS/MS (Castaño-Trias et al., 2023).

Dietary exposure and Human health risk assessment

The estimated daily intake (EDI) (ng/kg bw/day) for each PhAC was calculated by multiplying the daily intake of lettuce leaves (g/day) for the Spanish population (98.67 g/day) by the mean concentration of PhAC in the lettuce leaves, in wet weight (ng/g, ww)), and dividing by the average body weight of an adult (18-64 years) (70 kg).
The potential human health risk was estimated using the Hazard Quotient (HQ) approach. The HQ was calculated by the ratio between the EDI and the acceptable daily intake (ADI). For that, the ADI (ng/kg bw/day) was estimated by dividing the lowest therapeutic dose (mg/day) by a safety factor of 1000 and a body weight of 70 kg. A HQ > 0.1 suggests a potential human health risk due to the chronic exposure to a certain PhAC.

RESULTS AND DISCUSSION

A total of 6 PhACs were detected in lettuce leaves at concentrations ranging from 0.12 to 7.54 ng/g, ww, and from 0.70 to 7.12 ng/g, ww, for Treatment 1 and Treatment 2, respectively (Table 1).
Human exposure to each PhAC was assessed for the two tested treatments and all the detected pharmaceuticals showed a HQ < 0.1 (Table 1), indicating no human health risk due to the chronic consumption of lettuce irrigated with treated wastewater in terms of PhACs intake. In general, both wastewater treatment approaches had similar HQ.

Table 1. Estimated daily intake (EDI) of the detected pharmaceuticals based on the mean concentration detected in lettuce leaves and its associated hazard quotients (HQ)

PhAC	Treatment 1				Treatment 2			
	Conc. (ng/g, ww)	EDI (ng/kg bw/day)	ADI (ng/kg bw/day)	HQ	Conc. (ng/g, ww)	EDI (ng/kg bw/day)	ADI (ng/kg bw/day)	HQ
Acetaminophen	1.31	1.86	28,571	0.00007	0.96	1.35	28,571	0.00005

Abstract
The project proposes an innovative approach based on the circular economy in the integral water cycle. The optimised design of a bioreactor for waste air treatment is investigated first at a laboratory scale and later at an industrial scale. The potential of waste by-products from wastewater treatment plants (WWTPs) as packing materials, such as plastics and sludge turned into compost and enriched with iron, was investigated. In addition, the development of innovative configurations of bioreactors (step-feed biofilters or two-stage systems) is proposed with the aim of improving deodorization efficiency and reducing the operating costs of odour treatment in WWTPs.

Keywords
Air Treatment; bioreactor; compost; packing material; two-stage systems, wastewater treatment plant

INTRODUCTION

The treatment of urban wastewater is well known and extended. Different technologies or strategies can be used for treating the wastewater, but all with the inherent drawback of generating solid and gaseous wastes during treatment. The emission of off-gases associated with wastewater treatment causes unpleasant nuisances for plant workers and people living nearby. Some of them can be toxic and cause adverse health effects. Furthermore, malodours have negative social economic effects by reducing the price of the surrounding properties and prospects for tourism, and can also cause damage to the facilities due to corrosion.

Nowadays, there is enough experimental evidence of the potential of biofilters and biotrickling filters to achieve high removal efficiencies of air pollutants at both trace levels (Lebrero et al., 2014, 2012) and industrial concentrations with reduced environmental impacts. Estrada et al. (2012) demonstrated that biological techniques were the most cost efficient alternatives with lower sensitivity to design parameters and lower operating cost than physical/chemical treatments at typical odour concentrations.

Despite the significant advances in biological odour removal technologies in the past 20 years, packing material selection still represents the most uncertain and critical design variable in biofiltration systems. This is paradoxical since packing material ultimately determines odorant removal efficiency and process operating costs (i.e., pressure drop across the bed and frequency of packing replacement). Therefore, there is still an incipient need for research to increase the sustainability and robustness, and decrease the capital and operating costs of these biotechnologies.

This research focuses on the development of cheaper, more sustainable packing materials, with better adsorption and reactivity properties, and that provide enhanced environmental conditions for the attachment of odour-degrading biofilms. These packing materials will be obtained from by-products produced in the WWTP itself, thus reducing wastes and promoting circularity within the wastewater treatment sector. In addition, the optimization of hybrid technologies composed of biotrickling filters and biofilters will be investigated in terms of their configuration, packing material, design parameters and operation.

MATERIALS AND METHODS

The investigation will be carried out through the following stages:
1. Obtaining the materials and residues available in the wastewater treatment plants that can be used as support for the biological deodorization system, together with the assessment of the modifications required for their reuse as packing material.
2. Development and optimization of the different bioprocesses at laboratory scale (Institute of Sustainable Processes of the University of Valladolid). For this purpose, three 2.5 L biofilters packed with the plastic materials under study and 3 biofilters of 8L of packed bed volume filled with the materials derived from compost will be used. Innovative bioreactor configurations involving two-state and step fed systems will be also optimized.
3. Field validation of a pilot plant with the optimal process configuration.

RESULTS AND DISCUSSION

This research proposes an innovative concept based on circular economy within the integral water cycle that allows the retrofitting of chemical scrubbers to innovative biological systems with a moderate investment, using reused and recycled packing materials.

The project also aims at developing improved packing materials for biofilters and new bioreactor configurations for the deodorization of WWTP, waste management facilities and certain industries. The product derived from this research project is an innovative biological deodorization system with packing materials made of by-products of the integral water cycle (plastic waste and compost produced with WWTP sludge).

Abstract
Currently, residues generated in rice agriculture are burned in several locations in Spain. Considering that the burning process contributes significantly to global warming through the emission of greenhouse gases (GHG), the development of a strategy to manage this waste in an appropriate and sustainable way is paramount. The LIFE REPTES project aims to demonstrate a new circular model that will integrate the production of biohydrogen from pretreated lignocellulosic substrate and sewage sludge through a dark fermentation process. In a second phase, the fermented stream - produced in the dark fermentation - will be used for improving biogas production in a conventional anaerobic digester. Finally, the project will provide an alternative for the efficient management of this bio-waste.

Keywords
Anaerobic digestion, biohydrogen, dark fermentation, energy, wastewater

INTRODUCTION

Huge amounts of rice straw are burned annually in the rice fields situated close to Albufera Natural Park (Valencia, Spain), meaning massive emissions GHGs and particulate matter that affect the quality of life of surrounding populations with an important environmental impact. The project LIFE REPTES will allow the valorisation of the rice straw, together with sewage sludge, by the production of renewable gas biofuels (biohydrogen and biogas).

The most innovative and the core technology of the project is the dark fermentation process (DF) to produce biohydrogen, but the technical and economic success of the model is backed by an innovative methodology for pre-treating the rice straw prior to DF. Furthermore, the project will demonstrate the potential of the fermented streams as co-substrate when used in anaerobic digestion in WWTPs. The project will allow, not only improving the welfare of the citizens surrounding areas of lignocellulosic extensive cultivations, thus avoiding GHGs emissions and the bio-waste valorisation, but also creating a new profitable and bioenergy efficient business model.

MATERIALS AND METHODS

For this project, rice straw from agricultural field and sewage sludge from a WWTP, both collected in Valencia (Spain), will be used to demonstrate the viability of producing biohydrogen and biomethane in a two-stage process (Figure 1).

Before entering in the dark fermentation, the rice straw passes through a pretreatment of bioextrusion. This process is required since the presence of lignin in the structure of lignocellulosic feedstock adds to it rigidity and impermeability. Moreover, the production of fermentable sugars from cellulose and hemicellulose is extremely difficult without a suitable pretreatment (Saha et al., 2022). Regarding the sewage sludge, this matrix has to be treated in order to reduce the presence of methanogenic bacteria, which would use the hydrogen produced on their metabolic route. In this sense, a pasteurization process (70ºC) will be applied.

After the treatment of the substrates, both streams will be mixed to obtain a homogeneous content to feed the DF. The DF will operate under thermophilic conditions (55ºC) with a hydraulic retention time of around 3 days. In order to avoid the stagnation of biohydrogen production, the reactor has been specifically designed to facilitate the desorption of the gas from the liquid to gas phase. The fermented product from the DF will be used in an anaerobic digestor to produce biogas, which will be increased thanks to the pretreatment step. Then, the biogas will be used for the production of electrical energy for the WWTP.

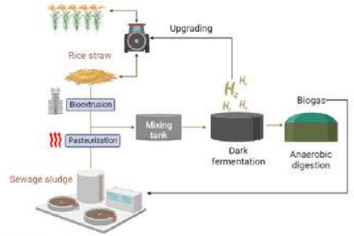

Figure 1. LIFE REPTES scheme

RESULTS AND DISCUSSION

The main expected results from this project are:

- It is expected to transform 252 tonnes of this lignocellulosic bio-waste during the demonstration, thus avoiding the inappropriately management of this waste.
- The gas stream produced by the dark fermentation process is expected to be composed of a mixture of H_2 (20-40%), CO_2 (50-60%) and CH_4 (10- 20%).
- In this innovative solution, the biohydrogen produced would be subjected to an upgrading process and later compressed for its use in agricultural machinery, or even directly used in the WWTP.
- It is expected to demonstrate an increase of the biogas production of at least 35 % in the pilot anaerobic digester module ($2m^3$) by using the fermented stream as a co-substrate.

Abstract
The Compost-UP! research project improves traditional sewage sludge composting processes, establishing a new process for the management and valorisation of this bio-waste in a more efficient, profitable and sustainable way by means of bioaugmentation techniques. The process is based on the enhancement of consortia of microorganisms specially selected for their potential to degrade volatile compounds that cause bad smells, mainly VOCs, NH_3 and H_2S. The compost obtained is valorised in compost-based bed biofilters, and when its filtering capacity is exhausted, it is reused as an improved agricultural amendment, due to its enrichment in nutrients during the filtering process.

Keywords (maximum 6 in alphabetical order)
Compost; sewage sludge; biofilter; ammonia; VOCs; H_2S

INTRODUCCION

Waste recovery is one of the most complex environmental challenges facing modern societies. Around 1,200,000 tonnes of sewage sludge are produced annually [1] and its proper management is essential to avoid its negative impacts on ecosystems, biodiversity and human health. Under this premise, Compost-UP! focuses on the development of advanced applications based on the bio-increment of compost from sewage sludge, which helps to mitigate the environmental impact and social rejection generated by the bad smell of composting plants. As a result of the process, a compost with agronomic potential is obtained, which allows improving current agricultural production systems and reducing the amount of chemical fertilisers used.

During the project, a microbial consortium was studied and selected to obtain bio-enhanced compost capable of degrading the most frequent odorous gases in the composting process (NH_3, H_2S and VOCs). The selected microbial consortium must be able to reproduce in the compost and mineralise the odorous compounds in order to give the compost improved agronomic properties. In the second phase, a pilot plant consisting of a biofilter based on a bio-augmented compost bed for odour removal was designed and constructed. This validation, in turn, is carried out using the deodorisation of a composting plant as a use case. Gas flow measurements were carried out to establish the critical operating parameters of the pilot prior to design and construction.

MATERIALS Y METHODS

Compost characterization. Compost samples were collected during October-December 2021 at different stages of maturation (from weeks 0 to 10) and characterised, analysing ammoniacal nitrogen content, conductivity, pH, moisture, organic matter, C/N ratio and presence of heavy metals. Isolation tests were then carried out, obtaining between 8-10 microbial colonies per odorant agent (NH_3, H_2S and VOCs). Subsequently, colony compatibility tests were carried out, studying the adaptation and implantation of microorganisms in mesophilic (35ºC) and thermophilic (55ºC) conditions. Finally, nutrient deprivation tests were carried out for more than 48 hours to evaluate the performance of the consortium in intermittent feed for energy savings or operational shutdowns

Gas emissions characterization in the use-case plant. Gas samples were collected and measured following the methodology detailed in UNE 13725 [2]. This method is used to determine the odour concentration in an open space using the Lindal box method, which has a wind tunnel setup. During the test, XAM 7000 equipment was used to enable the concentration of NH_3, H_2S and VOCs (isobutylene) to be measured. Chromatography was used to identify the VOCs.

RESULTS AND CONCLUSIONS

The physicochemical characterisation of the compost samples has allowed evaluation of the suitability as a filter bed of the samples from weeks 2-6, being critical parameters for this purpose are moisture (50-70%), organic matter content (higher than 55%) and particle size (particle size, higher than 5 mm). Isolation tests showed more than 200 different genera of microorganisms identified, with Firmicutes representing 96% of the microbial diversity in the thermophilic phase of the composting process (week 3), and Chloroflexi, Patescibacteria, Actinobacteriota and Bacteroidota as common phyla in the composting process.

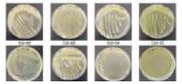

Figure 1. Microbial consortium formed by colonies of ammonia (Col A6-Col A8), hydrogen sulphide (Col S4-Col S5) and VOCs (Col-But4-Col DMDS2-DMDS5-DMDS7).

Nutrient deprivation tests performed after selecting colonies with the highest removal potential showed that ammonia-degrading colonies reduced performance insignificantly (<10%), while some VOC-degrading colonies not only withstood the test but increased their performance by 89%. Hydrogen sulphide-focused colonies did not withstand the nutrient deprivation test.

The results of the gas flow from the composting plant showed the presence of ammonia as the main compound with 40 ppm and reaching peak concentrations of 90 ppm (during turning of the compost piles), followed by H_2S and VOCs reaching concentrations of 0.6 and 15 ppm respectively during turning of the compost piles. In addition, chromatography identified 16 VOC compounds, including limonene and phenol, as a result of the degradation of organic compounds.

The results of the tests have made it possible to establish the design parameters of the biofilter, which will be able to treat a flow of 1,000 m^3/h (representing 1% of the flow of gases generated in the composting plant) and a useful surface area of $8m^2$ (4 x 2m). Finally, the validation of the bio-filter and the evaluation of its efficiency in an industrial environment will be carried out throughout 2023.

ACKNOWLEDGMENT

Compost-UP! is a project co-funded by the European Union through the Operational Program of the European Regional Development Fund (FEDER) of the Valencian Community 2014-2020 through the Business Value Chain Consolidation Program, by the Valencian Innovation Agency (AVI).

Abstract
Reclaimed water fertigation of crops is an increasingly considered solution to water scarcity. The advantage of water and nutrients reclamation can be mitigated by the possible introduction of organic contaminants in the fertigated, edible crops, posing a health risk. This work investigated the uptake of a variety of organic micropollutants by the leaves and roots of lettuce irrigated with either tap or reclaimed water. Overall, analgesics/anti-inflammatories, psychiatric drugs and β-blockers were the most detected compounds. Reclaimed water irrigation resulted in slightly higher concentrations of the same contaminants in the leaves, whereas root composition was largely different and involved compounds absent in the tap water treatment.

Keywords
fertigation; crop uptake; pharmaceuticals; endocrine disrupting compounds; water reuse

INTRODUCTION

The Mediterranean region faces significant challenges due to dry zones, increased tourist activity and wasted water resources. Water scarcity leads to new non-conventional practices that close the loops and lead towards a circular economy. In the agricultural sector, an important practice is the reuse of treated wastewater in the irrigation systems of crops, where both water and valuable nutrients can be reclaimed. However, organic contaminants of various sources are removed to different extents in wastewater treatment plants and can persist in the treated water used for fertigation (Calderon-Preciado et al., 2011). Uptake of these micropollutants by fertigated edible crops needs to be investigated, to assess their levels that correlate with food safety and ultimately human health. Most of the current studies use laboratory conditions that do not reflect field conditions. This work assessed the uptake of a variety of micropollutants, including pharmaceuticals, antibiotics and endocrine disrupting compounds, by the roots and leaves of lettuces irrigated by reclaimed wastewater.

MATERIALS AND METHODS

Lettuce sampling, micropollutants extraction and analysis

Samples from the HYDRO2 wastewater reclamation demo-site of the HYDROUSA project (www.hydrousa.org) on the island of Lesvos (Greece) involved lettuce fertigated with either: 1) tap water (TW) as a control experiment, or 2) water discharged from the wastewater treatment plant (i.e., Full Treatment, FT), which consists of an upflow anaerobic sludge blanket coupled to a constructed wetland. After harvesting, the lettuces were separated into leaves and roots, rinsed with deionized water, freeze-dried, extracted by QuEChERS (adapted protocol, Montemurro et al., 2020) and analyzed by UHPLC-MS/MS (Castaño-Trias et al., 2023) for a range of micropollutants.

RESULTS AND DISCUSSION

When lettuce was irrigated with tap water (TW), mostly analgesics/anti-inflammatories (acetaminophen, ibuprofen, indomethacin and naproxen) were detected in the leaves, with naproxen presenting the highest concentration at 121.22 ng/g extracted mass. Ciprofloxacin, an antibiotic, came second (79.55 ng/g extracted), and paroxetine, a psychiatric drug, third (53.45 ng/g extracted). 1-OH-ibuprofen, an ibuprofen metabolite, was found to be retained in the roots, whereas it was absent in the leaves.

Under reclaimed water irrigation (FT), the types of contaminants found in the leaves were the same as with the TW, with the total concentration slightly higher, mainly due to an increase in the levels of paroxetine, naproxen and caffeine. The composition of the roots for the FT treatment was largely different than in the TW one (Figure 1), with irbesartan, an anthelmintic drug, showing high retention in the roots (203.63 ng/g extracted), followed by mainly metoprolol and hydrochlorothiazide. This finding demonstrates that contaminants absent in tap water but present in the reclaimed water showed affinity for the lettuce roots rather than the edible part of the plant.

The levels of the organic micropollutants detected in this work are in line with available literature. Even though health-related risk is expected to be low, next steps of the ongoing project include dietary exposure and human health risk assessment.

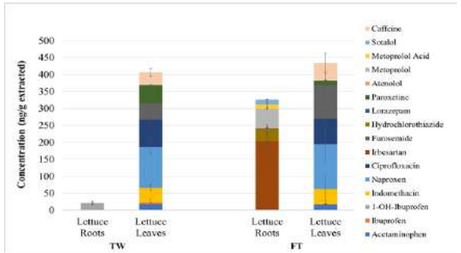

Figure 1. Concentration of micropollutants detected in lettuce leaves and roots. Irrigation type: TW: Tap Water, FT: Full Treatment

Abstract
The presence of nanoparticles in the environment is increasingly becoming common, with their wide-ranging application today. This theoretical study conducted an ecological risk assessment for the soil due to non-potable urban reuse of nanoparticle contaminated treated wastewater for irrigation of Spinach. A thorough search of the literature was carried out to gather data relevant to this work. Lognormal distribution of collected ZnO nanoparticles concentration in wastewater effluent was made as part of Monte Carlo analysis. Plant uptake models based on existing data were derived to compute uptake of Zn in the plant. Simple mass balance was used to find soil contamination. Contamination Factor, Potential Ecological Risk Factor, and Geo-accumulation index were found to be well within their respective contamination limits. This study found no risk to soil in such a hypothetical scenario. The framework demonstrated here could be well utilized again to find risk for such reuse.

Keywords
Ecological risk assessment; Nanoparticles; Wastewater irrigation

INTRODUCTION

Nanoparticles (NPs) are now being used in a variety of products and industries. ZnO nanoparticles are deployed in cosmetics, paints, etc. (Kumar Dey, Das, et al., 2018). It hence becomes inevitable that their presence has been found in different environmental compartments (Baranidharan and Kumar, 2018). Their toxicity has been documented in various in-vitro studies.

There are many studies observing the interaction of edible plant with nanoparticles containing irrigation water. But the potential of nanoparticles to contaminate soil while being irrigated with wastewater effluent contaminated with nanoparticles is not well documented. Hence this work attempts to present a framework and compute soil contamination indices as part of ecological risk assessment with respect to Zinc ion for the hypothetical scenario of Spinach plant being irrigated with Zinc Oxide nanoparticle contaminated wastewater effluent. The framework so developed could be utilised again for soil-based risks calculations in reuse for irrigation.

MATERIALS AND METHODS

Deriving log-normal distribution for ZnO NPs concentration in wastewater effluent

In the literature, ZnO NPs concentrations reported or predicted in the wastewater effluent were thoroughly searched for using scientific electronic databases. As environmental contaminants usually exist in lognormal concentration, this data was then pooled together to compute lognormal distribution for ZnO NPs concentration in wastewater, and hence 10,000 values were generated as part of Monte Carlo analysis.

Development of Plant Uptake Models

In the next step, plant uptake models to predict the uptake of Zinc ion in the shoot (C_{shoot}) and root (C_{root}) of the Spinach plant (upon its maturity) using ZnO NPs concentration in the irrigation water, were derived using literature work. It was decided to use log- logistic distribution for the plant uptake models. For this, the study by Singh and Kumar, 2020 was used as their work provides essential data on observing uptake in Spinach plant on irrigating it with ZnO NPs contaminated media for its maturity period (Singh and Kumar, 2020).

Computation of Soil Contamination Indices

Using simple mass- balance equations, remaining Zinc in the soil (C_{soil}) after the maturity of the Spinach plant was computed then. Corresponding to each of the 10,000 values of ZnO NPs concentration in irrigation water generated earlier, C_{shoot}, C_{root} and C_{soil} values were calculated. Using these values, the soil contamination indices were computed, namely Contamination Factor (CF), Potential Ecological Risk Factor (E_r) and Geo-Accumulation index (I_{geo}).

RESULTS AND DISCUSSION

The indices as part of ecological risk assessment are presented in Table 1.2. The value of the indices CF & E_r is the same here in all respect as $E_r = 1$ for Zinc element. The 99th percentile values for CF and E_r were found to be less than 1, suggesting no contamination to soil due to irrigation of Spinach with river water or STP effluent contaminated with ZnO nanoparticles. A negative value of I_{geo} denotes practically unpolluted soil, which has also been found in this study with the average value of the index varying as -14.42. Hence, no soil contamination would occur if wastewater effluent containing ZnO NPs are utilized for Spinach irrigation.

Table 2. Descriptive statistics for the computed soil contamination indices

Parameter	Average Value	90% Confidence Interval	99th percentile
CF	8.09×10^{-4}	2.48×10^{-3}	1.36×10^{-2}
E_r	8.09×10^{-4}	2.48×10^{-3}	1.36×10^{-2}
I_{geo}	-14.42	10.43	-6.79

CONCLUSIONS

This work developed plant uptake models & log-normal distribution for ZnO nanoparticle contamination in wastewater, to carry out ecological risk assessment for the hypothetical scenario of wastewater effluent containing ZnO nanoparticles being reused for irrigation of Spinach plants. At current ZnO NPs levels in the wastewater effluent, no contamination was found to occur in soil. The detailed stepwise framework developed could easily be applied to carry out ecological risk assessment due to metal that may occur due to nanoparticles-based wastewater effluent reuse, and hence making the reuse of non-potable urban water safe & informed.

Abstract
Contaminants of emerging concern (CECs) are present in water bodies, even though most of them are not regulated yet, they might bestow a risk for human health or the environment. The PRISTINE Integrated Solution aims to remove CECs in both wastewater and drinking water real scenarios using a combination of innovative and sustainable solutions. To design and optimize such solution an extensive real site characterization is needed. Thus, in the present study the occurrence and distribution of CECs in a wastewater treatment site is presented.

INTRODUCTION

Water scarcity is a current problem in many EU regions, and it is expected to be one of the main health and climate related issues in the coming years (Zal et al., 2012). Thus, water reclamation and reuse are needed to be widely implemented and are considered a priority within EU. At the same time, since drinking water will be directly impacted by water scarcity, safe drinking water must be also ensured from conventional or alternative sources. Both reclaimed water and drinking water must fulfil quality requirements that ensure both human and environment safety. Apart from the parameters already gathered for example at the Regulation (EU) 2020/741 or the Directive (EU) 2020/2184 for reclaimed water and drinking water, respectively (European Commission 2020 and European Commission 2020b), the elimination of Contaminants of emerging concern (CECs), should also be tackled in the near future.

Despite the numerous references to their negative impact, CECs presence in water bodies is not regulated yet, as their distribution, accumulation and effect are not fully understood, and there are not standard protocols affordable and available to keep detailed track of them. Still, it is generally agreed that their monitoring and elimination from the environment and water bodies will be crucial in the coming years, specially to achieve safe drinking and reclaimed water.

PRISTINE project (LIFE21-ENV-ES-PRISTINE -101074430) aims to develop an Integrated Solution to remove CECs from the water cycle. The project focuses on the elimination of pesticides, pharmaceuticals, personal care products (PPCPs), toxins, antibiotic resistance genes (ARG) and microplastics, as main CECs families, from drinking water but also to polish treated wastewater for reclamation. The proposed PRISTINE Integrated Solution consists of 3 modular technologies: i) encapsulated adsorbents, ii) hollow-fibre nanofiltration and iii) UV-LED combined with advanced oxidation processes (AOP). As depicted in Figure 1, the modular technologies that could be applied in series or individually, will be supported by a virtual artificial intelligence (AI) soft sensor and a decision support system to optimize operation parameters. The system will be adaptable, tested and optimized in both real drinking water (DW) treatment and wastewater (WW) reclamation scenarios.

OBJECTIVES

PRISTINE Integrated Solution will effectively remove >80% of the monitored CECs in wastewater and drinking water scenarios, while reducing 30% the operational costs compared of similar treatment trains based on conventional technologies (i.e., reverse osmosis), while avoiding CECs concentrated streams to be handled separately.

Parallel monitoring campaigns of both demonstration sites are crucial to design, adapt and properly estimate the performance of the PRISTINE Integrated Solution. Thus, the characterization of the water quality and occurrence and distribution of CECs is currently being performed for a full year (November 2022-October 2023). Up to date, preliminary information has been gathered for both sites. However, in the present abstract only WW results are presented.

MATERIALS AND METHODS

The wastewater demo site is located at a wastewater treatment plant (WWTP) facility in Murcia region (Spain). It serves ca. 30.600 p.e., and has a pre-treatment, a biological treatment based on prolonged aeration activated sludge followed by a tertiary treatment. A 2-month intensive campaign (November and December 2022) was performed with high sampling frequency to obtain preliminary data to start the development of the AI soft-sensor and the demonstration site characterization. During the intensive campaign, punctual samples were withdrawn from the influent (once per week) and effluent (4 times per week) of the WWTP. The river, before the discharge point of the WWTP, was sampled twice per month. 134 CECs (38 drugs, 79 pesticides, 6 haloacetic acids, 4 PFAS, 3 surfactants, 1 toxin, 3 hormones) were analysed by means of solid phase extraction and liquid chromatography coupled to tandem mass spectrometry with a triple quadruple mass spectrophotometer. Physicochemical parameters in the WW site were measured simultaneously using the applicable Hach Lange test-kit and the appropriate sensor or probe for pH, conductivity, and turbidity determination. Volatile suspended solids were measured according to standard protocols (Baird, 2012).

RESULTS AND DISCUSSION

The effluent of the secondary clarifier will be the application point of the PRISTINE Integrated solution in the WW site. Consequently, the occurrence and concentration of the CECs detected will directly impact the design and optimization of the technology. The influent of the WWTP is also another point of interest, to understand if the CECs presence in the effluent is preceded by a certain removal within the conventional treatment. Furthermore, the actual state of the Segura River upstream of the WWTP discharge point is also another factor to consider, to understand the real contribution of the WWTP itself to the general conditions of the recipient water mass.

Figure 2 shows results of CECs concentration and their detection frequencies during November 2022 in the presented points. Preliminary results of the analytical campaign showed that a total of 24 compounds were detected at least once in one of the sampled points. From the 134 analyzed, 16 were present in the secondary clarifier effluent. Drugs such as salicylic acid, ibuprofen, caffeine and ampyrone, and pesticides such as glyphosate and pyrimethanil were detected at an average concentration higher than 1 µg/L (**Figure 2A**). Other pharmaceuticals like naproxen, ofloxacin, ciprofloxacin, sulfamethoxazole, venlafaxine, diclofenac and ketoprofen, and the surfactant nonylphenol were detected at mid concentrations ranging from 0,1 µg/L to 1 µg/L (**Figure 2A**). Furthermore, most of the previously mentioned compounds (except for nonylphenol, pyrimethanil, sulfamethoxazole, salicylic acid and diclofenac) had a high occurrence, with a detection frequency over 40% in the effluent of the secondary clarifier (**Figure 2B**). In the river, ampyrone, caffeine, ibuprofen, naproxen, salicylic acid, glyphosate, imzalil and pyrimethanil were detected, as they were in the effluent of the secondary clarifier of the WWTPs. Finally, since the water quality that will need to be treated will also impact the design of PRISTINE Integrated solution, **Table 1** summarizes solids concentrations, turbidity, and concentration of UV scavengers such as COD nitrite, nitrate, among others, from all three sampling point discussed.

CONCLUSIONS AND FURTHER WORK

Preliminary results showing the persistence and occurrence of 24 CECs in a wastewater treatment site have been collected up to date. From January 2023 onwards, a reduced frequency CECs sampling campaign will take place, while microplastics and ARG will also be analyzed, gathering insight on their elimination, distribution and potential seasonal fluctuations. Furthermore, similar analysis as those presented here will be performed in a drinking water site. Results from both scenarios will be considered in PRISTINE Integrated Solution design and optimization.

Abstract
Peracetic Acid (PAA) is an organic peracid with a high oxidation potential, with by-products less harmful than chlorine or ozone. The main goal pilot-scale study was to evaluate the PAA disinfection efficiency in secondary effluents in a Portuguese wastewater treatment plant (WWTP). To this end, six disinfection conditions were studied, three PAA doses (5, 10, and 15 mg/L) and three contact times (Tr) (5, 10, and 15 minutes). After the disinfection it was observed a BOD_5 and COD increase, however, it was not proportional to the PAA dose. The PAA performance showed that doses of 10 and 15 mg/L achieved log reduction higher than 2. Results also showed that the Tr was not a determining factor for the PAA disinfection performance, however, it was considered a minimum of five minutes. This study showed that PAA can be used as an alternative wastewater disinfectant, namely if wastewater reuse is an option.

Keywords
Peracetic acid; pilot study; wastewater disinfection alternative; wastewater reuse

INTRODUCTION

Wastewater disinfection is a key treatment for the elimination or inactivation of pathogenic microorganisms (Antonelli et al., 2006), and is essential since it protects the environment and public health from pathogenic infections (Blanco-Canella et al., 2022). Peracetic acid (PAA) is an organic peracid, with a high oxidation potential, larger than chlorine or chlorine dioxide (Kitis, 2004). PAA is a wide-spectrum disinfectant with efficacy against bacteria and viruses (Cavallini et al., 2013). PAA is classified as a safe and environmentally friendly disinfectant (Freitas et al., 2021), since it has less toxic disinfection by-products than chlorine or ozone (Deng et al., 2022) There are other advantages of using PAA as a disinfectant, such as the low pH dependence, easy implementation, low corrosivity, and reasonable cost (Chen & Pavlostathis, 2019). Recent studies show promising results regarding the use of PAA in the degradation of micropollutants present in treated wastewater (Deng et al., 2022; Maurício et al., 2020). According to the latter, it seems that PAA can be the new widespread disinfectant, however, there are still uncertainties among studies that must be clarified. To do so, more studies are needed to create new knowledge to support a safe and efficient shift between the disinfection processes. The main goal of this pilot-scale study was to evaluate, in a significant and representative period, the PAA disinfection efficiency of six disinfection conditions in secondary effluents in a Portuguese wastewater treatment plant (WWTP) in the Lisbon region.

MATERIALS AND METHODS

The pilot-scale installation was set in a conventional large-scale municipal WWTP located in Lisbon area (Portugal). This WWTP has a flow above 50 000 m^3/day (more than 200 000 equivalent inhabitants) and includes preliminary, primary, and secondary treatment with conventional activated sludge and nitrogen removal. Within the WWTP, the pilot-scale installation (Figure 1) was settled after the secondary clarifiers. The pilot installation had a 5 m^3 capacity tank equipped with a vertical mixer. A 15% PAA solution was dosed to the wastewater. The work was performed during six months, from April to September, (two different weather seasons) and six disinfection conditions (Table 1) were tested. Each condition was analysed for five days (three samples per day) in which the water quality parameters and the PAA residual concentration were determined. The samples were collected before and after disinfection and the main control parameters were: Biological Oxygen Demand (BOD_5), Chemical Oxygen Demand (COD) Escherichia coli, temperature, pH, and PAA residual concentration (only after disinfection). A statistical evaluation of the results was performed using one-way ANOVA and Tukey test. The significance level was set at 5% ($p \leq 0.05$) using the software SPSS v20.ea.

RESULTS AND DISCUSSION

The statistical analysis of the results before the disinfection showed significant differences in the E. coli content between conditions. The conditions C15T10 and C5T10 had significant differences from the conditions C15T15, C10T10 and C10T15 (Tukey, $p<0.022$). These two conditions had an E. coli content lower than the other studied conditions. The disinfection with PAA increased the BOD_5 and the COD in all conditions, which was to be expected since this behaviour was already reported in the literature (Cavallini et al., 2013). According to Luna-Pabello et al. (2009) this increase is due to the organic component of PAA. Statistical analysis showed that for different PAA doses (10 and 15 mg/L), with the same Tr, there were no significant differences (Tukey, $p>0.05$). Although PAA increases the BOD_5 (Figure 2) and the COD (Figure 3), this was not proportional to the PAA dose. The disinfection with PAA resulted in a slight decrease of pH, except in the condition C5T10, in which was verified a minor pH increase. PAA is a weak acid, when combined with an alkaline effluent the impact on pH is not significant (Cavallini et al., 2013), which may explain the results obtained.

The PAA performance showed that doses of 10 and 15 mg/L achieved E. coli log reduction (LR) higher than 2, and even higher than 3 when 15 mg/L were tested with 10 and 15 minutes of Tr (Figure 4). As reported in the study of Bonetta et al. (2017), PAA doses lower than 2 obtained the E. coli LR were lower than 2. Those results were equivalent to the ones obtained with condition C5T10, which may suggest that PAA doses lower than 5 mg/L may be not efficient. However, in the pilot study performed by Pileggi et al. (2022), 4 mg/L of PAA and 35 minutes of Tr achieved an E. coli LR of 2.6, comparable with the results of the condition C10T10, C10T15 and C15T5. Those results may indicate that lower PAA needs more Tr to achieve higher LR. In the study made by Freitas et al. (2021), using the C15T15 disinfection conditions, in an effluent of a similar type of wastewater treatment, was verified a LR of 3.9, similar to the results obtained in this study. No significant differences were found between the conditions with the same PAA dose, which may suggest that the Tr was not determinant for the PAA performance, at least for the Tr used in this study. It was also observed that even with a longer Tr, a 5 mg/L of PAA would not be enough to achieve higher LR of E. coli, since almost the PAA was consumed (Figure 5). According to Chen and Pavlostathis (2019), the temperature is a parameter that may affect the PAA decay rate, and this could explain the differences verified, since those conditions on which occurred a lower PAA consumption, were the ones with lower temperatures.

Overall, the results obtained with this pilot-scale study support the use of PAA as an alternative wastewater disinfectant. The independence of this disinfectant from the Tr may be an advantage for the implementation of this disinfectant in a WWTP. Also, the residual PAA concentration, after disinfection, turns out to be an operational advantage, when considering treated wastewater storage and reuse by avoiding bacteria regrowth. Such consideration is central when countries reusing policies are in action, which is the Portuguese situation.

Abstract
Recently, large granular purple phototrophic bacteria (PPB) with good settling characteristics has been investigated. However, a sizeable flocculent component was still present. In anammox granular sludge, size classification (via hydro-cyclones) can be used to promote a larger, consistent granular biomass, and may apply to granular PPB. In this study, the effect of fortnightly size classification (biomass <200 µm) on the granular fraction was investigated. The granular fraction (~80 vol%) was high compared with previous studies (due to increased illumination) however the flocculent component regularly returned after size classification. Particle size was proportional with calcium phosphate content which suggests ballasting agents like ions are one precursor for granular PPB. Particle size was inversely proportional to organic biomass fraction (VSS/TSS ~0.53 for >1 mm diameter, VSS/TSS ~0.76 for <200 µm), and PPB relative abundance. Sieving significantly affected the PPB *Rhabdochromatium* (p=0.025), *Rhodobacter* (p=0.0218) and *Allochromatium* (p=0.052) and the non-PPB clades Desulfobacterota (p=0.0451) and Planctomycetota (p=0.0173). The change of microbial community with size was also reflected in the biomass activity which decreased with increasing particle size (e.g., biomass activity of large (>1 mm), medium (<250 µm, <1 mm), and small (<250 µm) granules were 0.63 gCOD, 1.8, and 2.8 gCOD $gVSS^{-1}$ d^{-1}, respectively)). Settling characteristics were comparable (SVI30 ~ 10 – 20 mL g^{-1}) between the different size classifications. The technology does not seem analogous to anammox as the size classification did not promote the granular fraction.

Keywords
Biological wastewater treatment; circular economy; granules; purple phototrophic bacteria; resource recovery

INTRODUCTION

The benefits of granular sludge for wastewater treatment (against conventional activated sludge) - lower capital and operational expenses and single-step removal of organics and nutrients - are well documented (Pol 1989, van der Star et al. 2007). Granular sludge mainly comprises aerobic, anaerobic and/or anammox bacteria and the high sludge disposal costs persist (Kroiss 2004). Aggregating purple phototrophic bacteria (PPB) (a promising technology in the resource recovery sphere) is incipient with only three studies performed (Blansaer et al. 2022, Cerruti et al. 2020, Stegman et al. 2021). Stegman et al. (2021) reported high flocculent biomass content, despite the growth of large (>3 mm), well-settling PPB granules. Removing the predominant flocculent fraction could be important in order to produce well-settling PPB granules with a consistent size profile. Some granular sludge technologies, such as anammox, improve the granulation rate and granule population using hydro-cyclones to select for larger granules (Wett et al. 2013). For example, in anammox systems, the anammox activity and biomass fraction increases (to an extent) as the granule size (and settling ability) increases and allows the anammox bacteria to outcompete the nitrite oxidising bacteria (Volcke et al. 2012). It is a provoking thought: could this technology translate to granular PPB? This study investigated the impact of the suspended fraction on PPB granulation and the treatment efficiency. This was tested in two PBRs on synthetic wastewater which underwent regular size classification. The physical and microbial structures of the sieved and non-sieved granular biomass' (from the two reactors and from the different particle sizes in the sieved reactor), as well as comparative performance were compared periodically.

MATERIALS AND METHODS

Two, 7 L (5 L working liquid volume), acrylic upflow photobioreactors (PBRs) were operated under anaerobic conditions. A liquid recirculation line from the 4 L to the 0 L port provided mixing in the form of liquid upflow. Synthetic media (wastewater proxy) was pumped into the reactor at the 0 L port and left the reactor at the 5 L port. The carbon source was pumped via syringe pump into the recirculation line. The reactors were covered in UV-VIS absorbing foil as per Stegman et al. (2021). Each reactor was constantly illuminated by two 150 W m^{-2} floodlamps located 15 cm from the reactor and five infrared (IR) lamps located 10 cm from reactor. The reactors were inoculated with granular PPB sludge (40 % PPB relative abundance). In the experimental reactor, undersized particles (<250 µm) were removed by sieve classification fortnightly while in the control reactor the biomass was not controlled.

RESULTS AND DISCUSSION

The PSD of the inoculum was dominated by granules (D_{50} of ~200 µm) but the reactors' biomass inventories – in terms of oversized granules (>200 µm) – increased from ~55 vol% to ~80 vol% within 60 days;**Error! No se encuentra el origen de la referencia.**. A predominantly granular system (oversized biomass >70 vol%) was maintained for the first 160 d in the control reactor, which reduced from day 174. The sieved reactor (pre-sieve biomass) contained on average ~60 vol% granular (despite fluctuations) biomass until day 160, after which the oversized granular fraction decreased to 25-35 vol%. At the HRTs used, the clear light column allowed for suspended biomass to rapidly regrow after each size classification preventing the formation of a pure granular system.

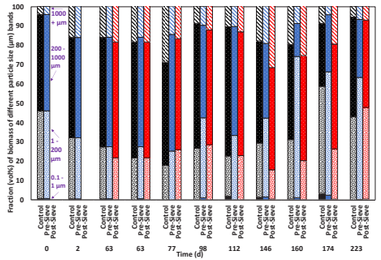

Figure 1. Volume fraction (%) of size bands of granular biomass in two reactors with time (d). The control reactor is black; the pre-sieved reactor is blue; the post-sieved reactor is red. The solid filled bar represents the biomass 0.1-1 µm; the confetti bar represents the biomass 1-200 µm; the dotted bar represents the biomass 200-1000 µm; the diagonal striped bar represents biomass >1000 µm.

Activity tests of differently sized granules (Figure 21) identified that the smaller sized particles/granules have higher SCOD removal rates compared to medium and large sized granules. Particles smaller than 250 µm had a specific COD removal rate of 2.80 gCOD $gVSS^{-1}$ d^{-1}, comparable with previously reported activities of suspended PPB (Puyol et al. 2017). The activity of medium sized PPB granules (250 µm<granules< 1 mm) was 1.83 gCOD $gVSS^{-1}$ d^{-1}, and PPB granules greater than 1 mm in diameter removed 0.63 gCOD $gVSS^{-1}$ d^{-1}. Due to the larger surface area to volume ratio, the undersized PPB have a higher activity and are more suited to phototrophic wastewater treatment.

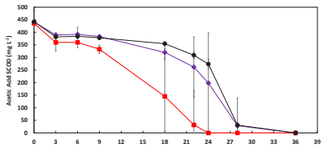

Figure 2. Activity test on consumption of acetate SCOD by granular PPB biomass of different size distributions. (-●-) undersized biomass < 250µm; (⊟) 250µm < granules < 1mm; (◆) granules > 1mm. Note: one data outlier was removed from the undersized and medium sized granules.

The undersized biomass had the lowest ash content (~20 %) and the control biomass and oversized biomass had higher ash fractions (56 ± 2.7 % and 47 ± 7.4 %, respectively). The Ca/P molar ratios of the control, oversized, and pre-sieved granular sludges were between 1-1.2, which is in line with the Ca/P molar ratios found in calcium phosphate precipitate in excess biological phosphorous removal processes (Carlsson et al. 1997) (Ca/P molar ratio of undersized biomass was ~0.8). This suggests that the calcium phosphate precipitation was a key factor in the production of large granules, likely due to it being a ballasting agent or bridging cations in EPS.

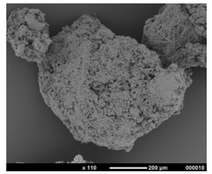

Figure 3. Ionic (calcium phosphate) compound within large PPB granules.

Inoculum was dominated by the purple sulfur bacteria (PSB) *Allochromatium* (20 %), the purple non-sulfur bacteria (PNSB) *Rhodopseudomonas* (15 %) and by a mixed group of other phyla including *Euryarcheota, Halobacterota* (*Methanobacteria*), and *Bacteroidota*. The PNSB *Blastochloris* – initially 0.3 % relative abundance in the inoculum – established itself in both reactors and persisted throughout the duration of the experiment with relative abundances of 10-20 %. The total relative abundance of PPB genera in both reactors represented on average ~50 % of the microbiota with peaks up to ~80 % and ~90 % in the control and the sieved reactors. ANOVAN indicated that the relative abundances of the PPB and non-PPB profile were not impacted by the reactor (PPB p=0.378; non-PPB p=0.532) but by time (p=0.0000 for both PPB and non-PPB) and sieving (PPB p=0.0152; non-PPB p=0.0187). Sieving significantly affected the PPB *Rhabdochromatium* (p=0.025), *Rhodobacter* (p=0.0218) and *Allochromatium* (p=0.052) and the non-PPB clades *Desulfobacterota* (p=0.0451) and *Planctomycetota* (p=0.0173) (it was potentially significant with *Chloroflexi* (p=0.056)) as the undersized biomass had a higher proportion of PPB.

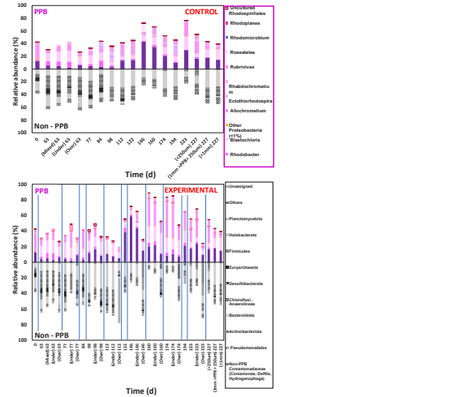

Figure 3. Relative abundance (%) of microbial communities in the biomass from the control (A) and experimental reactor (B) with time (d). PPB clades are shown with positive values (above the x-axis) in pink/purple colours and patterns and other non-PPB clades are shown with negative values (below the x-axis) in muted colours and patterns.

Abstract
The aim of this work is to characterize and monitor emerging pollutants in laundry greywater in the perspective of internal laundry water recycling. Specifically, 33 pharmaceuticals and 21 endocrine disrupting compounds were analysed in laundry greywater of three laundries of different size, clients, and services, located in France, Luxemburg, and Spain. Additionally, a novel analytical methodology was specifically developed for DEHP analysis in laundry greywater. Several pharmaceuticals were detected, including analgesics, psychiatric drugs, and antibiotics, as well as some hormones, preservatives, plasticizers, chemical biomarker (caffeine), alkylphenolic compounds, organophosphorus flame retardants compounds and DEHP at ng/L to µg/L levels. A prototype based on UV/H_2O_2 is being set-up to treat the water and remove pollutants, including organic micropollutants from laundry greywater. In this way, the effectiveness of the prototype will be determined and evaluated to establish a closed circuit and reuse 100% treated water in the same laundry.

Keywords (maximum 6 in alphabetical order)
DEHP; Endocrine disrupting compounds; Laundry greywater; Pharmaceuticals; Plasticizer; Recycled water.

INTRODUCTION

Greywater, once discharged into public sewage systems, represents a major source of pollutants in the urban wastewater. Europe has around 11,000 laundries, through which some 2,700 million kg of textile materials pass each year (Hloch *et al.*, 2012). This kind of water may contain softeners, plasticizers, emulsifiers, fatty acids, preservatives, antioxidants, surfactants, antioxidants, phthalates, phenols and solvents, pharmaceuticals and microplastics, along with many other emerging and priority contaminants (Shaikh and Ahammed, 2020; Le *et al.*, 2022). Many of these emerging contaminants are also considered endocrine disrupting compounds, carcinogens, and mutagens, representing a risk to the environment. As a specific case, DEHP and nonylphenol are currently considered priority substances under the Water Framework Directive (WFD) (EC, 2013), being limited to 25 µg/L in laundry effluents. Nevertheless, very limited information is currently available on the presence of several emerging pollutants in laundry greywater (Glover *et al*., 2021).
In addition, wastewater treatment plants are not designed for the removal of many of these substances contained in laundry greywater and these contaminants might end up in the environment. Although at low concentrations, they may have a negative impact on the ecosystems and ultimately on the human health as well.
Thus, the aim of this work is to monitor emerging contaminants in greywater of selected laundries of different size, and characteristics. In addition, greywater samples will be analyzed after an advanced oxidation treatment for the elimination of emerging pollutants for its subsequent re-use in the same establishment.

MATERIALS AND METHODS

Sampling

Greywater characterization was carried out to determine the level of pollutants in the water of three laundries located in France, Luxemburg, and Spain, differing in terms of water flow rate (25 m^3/d, 10 to 15 m^3/d and 2-3 m^3/d, respectively). Samples were collected on a weekly basis. Automatic refrigerated samplers were used to collect composite and homogenized greywater samples. Then, the water samples were kept at -20ºC till analysis. Additionally, samples were daily collected during a week in the laundry of Spain, to evaluate the inter-day variability throughout the week.

Contaminants of interest

The target pollutants assessed in this study are grouped into three groups:
- Pharmaceuticals (PhACs), including the antibiotics and psychiatric drugs from the Watch List 2020 (WL 2020/1161). Besides, clindamycin and ofloxacin included in the current Watch list (WL 2022/1307) were also considered in the analytical method.
- Endocrine disrupting compounds (EDCs), including hormones, antimicrobial, preservatives, plasticizers, chemical biomarkers, alkylphenolic compounds, anticorrosives, and organophosphorus flame retardants.
- Di(2-ethylhexyl) phthalate (DEHP), the most common phthalate which is used in hundreds of products (detergents, lubricating oils, pharmaceuticals…) and regulated by the Directive 2013/39/EU.

Analysis

For the extraction of PhACs and EDCs, laundry greywater samples were filtered (0.45 µm PVDF membrane filters). Then, the extraction was performed with a procedure adapted from Gros *et al.*, (2012) based on solid-phase extraction, followed by specific analytical methodologies for PhACs and EDCs using UHPLC-MS/MS adapted from Gros *et al.*, (2012) and Jakimska *et al.*, (2013) respectively. The analytical methodologies were validated for laundry greywater.
For the analysis of DEHP, a novel analytical methodology, based on on-line headspace solid-phase microextraction coupled to gas chromatography tandem mass spectrometry (HS-SPME-GC-MS/MS), was specifically developed for laundry greywater.

RESULTS AND DISCUSSION

Method validation in laundry greywater

In the process of analytical method development and validation for laundry greywater samples, confirmation analyses of composite laundry samples were performed. Quality parameters were assessed for each target compound in the 3 analytical methods validated, including limits of detection (LOD), limits of quantification (LOQ), and the percentage of recovery (Table 1).

Table 1. Concentration of the target pollutants in laundry greywater, LOD, LOQ and recovery (%).

Class	Compounds	Concentration (ng/L)	LOD (ng/L)	LOQ (ng/L)	Recovery (%)
Analgesics/anti-inflammatories	Acetaminophen	1,885	3	10.2	56
	Diclofenac	73	1.2	4	80
	Ibuprofen	570	3.2	10.6	72
	2OH-ibuprofen	366	10.8	36.4	120
	Ketoprofen	640	32	108	69
	Codeine	66	9	30	54
β-Blocking agents	Sotalol	18	16	54	67
	Metoprolol	4	0.3	0.9	23
Psychiatric drugs	Alprazolam	46	0.9	3	114
	O-desmethyl-venlafaxine	<LOQ	16	54	39
Lipid regulators	Fluvastatin	15	9	28	121
	Bezafibrate	38	0.2	1.0	71
Antibiotics	Sulfamethoxazole	26	0.7	2.2	47
Hormones	Levonorgestrel	1,608	79.3	381.8	119
Preservatives	Ethylparaben	25	0.2	0.8	40
	Methylparaben	636	5.5	18.4	74
	Propylparaben	164	0.16	0.53	27
Plasticizer	Bisphenol A	<LOQ	25.0	83.4	100
Chemical biomarker	Caffeine	9,285	26.4	87.8	89
Alkylphenolic compound	Nonylphenol	<LOQ	6.7	22.4	70
Organophosphorus flame retardants	Tris(2-chloroethyl) phosphate (TCEP)	767	7.3	24.8	111
Phthalates	DEHP	133,599	15.5	51.6	100

Acceptable recovery results (40-120%) were observed for all the selected contaminants, except for metoprolol (23%) and propylparaben (27%). Thus, LOD and LOQ for PhACs were found between 0.3-32 ng/L and 0.9-108 ng/L, respectively. For EDCs, values ranged between 0.2-79.3 ng/L for LOD and 0.8-381.8 ng/L for LOQ.

Characterization of laundry greywater

Greywater samples from the Spanish laundry were analyzed to validate and optimize the analytical method and allowed to have an overview of the level of contaminants (Table 1). Considering the detected concentrations in laundry greywater, caffeine (9.3 µg/L), levonorgestrel (1.6 µg/L), acetaminophen (1.9 µg/L) and DEHP (133.6 µg/L) were found at higher concentrations, while the other analytes were at ng/L level.
The concentration of contaminants in laundry greywater samples may vary depending on the day of the week, from week to week, and the period of the year because of their different cleaning treatments, different clients, and habits of the clients. Therefore, for its characterization, daily samples have been collected in a total of five samples in one week. A weekly composite sample was also analyzed to determine the variation that may exist in comparison to the collected daily samples.

FUTURE WORK

The characterization of greywater of the selected laundries will help in the further implementation of an advanced water treatment system on-site. This prototype system, based on advanced oxidation processes will allow the water reuse of laundry water by water recirculation as a water source.
Influent and effluent from the laundry will be sampled to evaluate the effectiveness of the prototype device in terms of removal of the emerging contaminants of interest.

Abstract
The biodegradability of an organic waste is a parameter that defines its possible valorisation by aerobic biological processes like those of biopolymer production. In the present study a respirometric technique was used to determine the biodegradable organic fraction (as % of the chemical oxygen demand (COD)) of four fat, oil and grease (FOG) wastes: olive pomace (78.74%), waste cooking oil (58.48%), tuna cooker oil fraction (35.24%) and FOG from municipal wastewater (11.91%). The time required for the total consumption of the biodegradable fraction of the wastes varied widely, ranging from 1.27 h (FOG from municipal wastewater) to 8.34 h (olive pomace). Considering biodegradability, the most suitable substrate for biopolymers production seems to be the olive pomace although the time required for the degradation is the longest. The less biodegradable one was the FOG from municipal sewage.

Keywords
Activated sludge; biodegradability; FOG waste; respirometry.

INTRODUCTION

The fat, oil and grease (FOG) fraction is a lipid-rich waste from private households, food industries and restaurants. It is mainly composed for free fatty acids, triacylglycerols, esters, waxes, phospholipids, sterols and sterol esters. The discharge of this fraction on the wastewater collectors provokes their complete blockage or overflow. With the proper management valuable products, like bioenergy and/or biomaterials, could be obtained from FOG wastes (Abomohra et al., 2020). One interesting possibility of valorisation is to use the FOG waste to produce biopolymers, like polyhydroxyalkanoates (PHA) and/or triacylglycerides (TAG), by a biotechnological process which certain microorganisms use this residue as carbon source to accumulate the PHA and TAG intracellularly. However, the low and/or slow biodegradability attributed to the FOG fraction may be a limiting step due to the difficulty to hydrolyse this type of substrates by microorganisms. For this reason, it is useful to first determine the biodegradable organic fraction of each FOG waste in order to select the most suitable one for this biological recovery process. Aerobic biodegradability of organic substrates is easily determined by respirometric experiments based on the measurement of the dissolved oxygen consumption (OC) rate of an aerobic microbial culture (Argiz et al., 2020; Surcis 2022). With the results obtained it is possible to control, design and protect a biological process such as the biopolymer accumulation one.

This study is part of the project ECOPOLYVER that aims to determine the biodegradability of four FOG wastes, olive pomace, waste cooking oil, tuna cooker oil fraction and FOG from municipal wastewater, to identify the best substrate to be used in a subsequent process for the production of biopolymers.

MATERIALS AND METHODS

The respirometric tests were carried out on a BM-T + analyser (Surcis, S.L) at 25 °C. Activated sludge (AS) samples used as inoculum, collected from a municipal wastewater treatment plant (WWTP), were aerated for 12 - 24 hours before the tests to remove any residual organic matter. First, the heterotrophic yield (Y_H), for the AS used as inoculum, was determined using equation 1 to check its suitability for sample degradation. *OC* is the oxygen consumed (mg O_2/L) and *COD* (mg COD/L) is the chemical oxygen demand of the sodium acetate used as substrate (325 mg COD/L).

$$Y_H = 1 - \frac{OC}{COD} \quad (1)$$

The biodegradability assays were carried out with 1 L of AS at a concentration of 1 - 3 g VSS/L, which was first aerated for approximately 20 - 60 min until oxygen saturation conditions of 7.5 - 8.0 mg O_2/L were reached. The FOG waste to be tested was then added to give a concentration of 0.14 g COD/L. During the experiments, the dissolved oxygen concentration measured with the oxygen probe was registered online to determine the oxygen uptake rate (OUR) and the analyser displayed the OC value over time (Figure 1). Four different FOG residues (Table 1) were assayed in triplicate: olive pomace (S1), waste cooking oil (S2), tuna cooker oil fraction (S3) and FOG from municipal wastewater (S4). The OC obtained was used to calculate the Biodegradable Chemical Oxygen Demand (COD_b) and the biodegradability of the substrate studied according to equation (2).

$$\%Biodegradability = \frac{COD_b}{COD} = \frac{\frac{OC}{1-Y_H}}{COD} \quad (2)$$

The AS samples used for S2, S3 and S4 were from the same collected batch, while for S1 it was collected in a different day (same origin but with different Y_H, Table 1).

RESULTS AND DISCUSSION

The respirometric assay results for the tested substrates are shown in terms of oxygen consumed (*OC*) (Figure 1). The time required to reach a stable *OC* value indicates how fast the biodegradable fraction of the substrate is degraded, with S4 being the fastest (1.27 hours) and S1 the slowest (8.34 hours). With these results the percentage of biodegradability can be calculated (equation 2). The most biodegradable substrate is the olive pomace (S1, 78.74 %), followed by waste cooking oil (S2, 58.48 %), tuna cooker oil fraction (S3, 35.24 %) and finally the less biodegradable was the FOG from municipal wastewater (S4, 11.91 %) (Figure 2). Comparing the biodegradability of olive pomace with the other food-derived substrates, its higher value may be due to the fact that it is "crude vegetable oil". However, cooking oil waste may contain recalcitrant compounds formed by the high temperatures reached during its use and similarly the tuna cooker oil fraction biodegradability is low due to the thermic process. The FOG fraction removed from municipal wastewater was collected from the supernatant of the dissolved air floatation unit, where coagulants and flocculants are used, and it has a complex composition which corresponds to its low biodegradability.

The results obtained in this study for the olive pomace are similar to those obtained for dairy wastewater from condensed milk production (79.68%) (Argiz et al., 2020) and the biodegradability of the waste cooking oil is close to that of the mixture of primary and secondary sludge from urban WWTP (63.31%) (Argiz et al., 2020). A study with different concentrations of oil and grease in fish canning wastewater shows a maximum biodegradability of 80%, lower than the maximum obtained with S1 (Cristóvão et al., 2016). A test with oily sludge showed a biodegradability of 90.7% (Cerqueira et al., 2011), higher than all the wastes evaluated in the present study. These wastes from previous studies have been already used for biopolymer production.

To conclude, biodegradability values of olive pomace and waste cooking oil are high enough to propose these wastes as substrate for biopolymer production. However, further research is needed to evaluate the possibility to decrease the biodegradation of olive pomace using an inoculum adapted to this substrate.

Abstract: This study aims at: 1) optimizing and validating the design and operation of High Rate Algal Ponds (HRAP) for wastewater treatment and biomass production and 2)assessing the effect of microalgal biomass as a biofertilizer. The design and operation of the HRAP (to be built in Aligarh, India) have been optimized and validated through a computational modelling and simulation technique. Wastewater treatment efficiency and biomass production were assessed by using a biokinetic model and hydrodynamic conditions evaluated by means of Computational Fluid Dynamics approach. Results indicate that the HRAPs with a total surface of 667m^2 at hydraulic retention time of 4 days enhanced wastewater treatment and biomass production. Agronomic bioassays were conducted on basil crop. The tests compared microalgae biofertilizers, inorganic fertilizers and a mixture of both. Results suggested that the combination of inorganic and microalgae fertilizers is suitable to reduce the use of inorganic fertilizers.

Keywords: Computational Fluid Dynamics, wastewater treatment, microalgae biomass, biofertilizers, India.

Introduction

PAVITR H2020 EU-India project (www.pavitr.net) aims to validate, deploy and/or develop cost-effective and sustainable solutions to tackle wastewater treatment challenges in India, ensuring also the provision of safe water reuse. Among the technologies considered, high rate algal ponds (HRAPs) are shallow raceways promoting the interaction between microalgae and bacteria to assimilate nutrients and organic matter present in wastewater. The low energy requirement compared to conventional wastewater treatment systems makes this solution particularly interesting for developing countries where climatic conditions are favourable. The advantages of such systems are especially evident in warm climate, with conditions extremely suitable for microalgae growth. Indeed, apart from the high efficiency in nutrients and organic matter removal, the great interest in such systems lies in the by-products that can be obtained from microalgae biomass grown in HRAPs (Yasir Arafat Siddiki et al., 2022).

In spite of the increasing interest on these systems, the optimum design of HRAPs is still not consolidated. Moreover, only few studies have been conducted on the properties of microalgae biomass as biofertilizer providing nutrients to the crops and encouraging circular economy with zero waste generation (Ronga et al., 2019).

Therefore, this study has two main objectives: 1) to optimize and validate the design and operation of HRAPs for wastewater treatment and biomass production and 2) to assess the effect of microalgal biomass as biofertilizer on basil crop.

Materials and Methods

To respond to the first objective, computational modelling and simulations were used to optimize and validate the design and operation of HRAPs to be built at one of

Abstract
Microbial Electrochemical Technologies are promising Carbon Capture and Utilization technologies toto achieve decarbonization and revalorization of carbon dioxide. Within the frame of the GAIA project, it is intended to develop a reliable, robust, and resilient electro-driven biotechnology to produce butanol and methane from feedstocks rich in organic matter, such as wastewater, and CO_2-rich gas streams.

Keywords
Butanol production; Carbon Capture and Utilization; Electromethanogenesis; Microbial Electrochemical Technology; P2G/F; Wastewater Treatment

INTRODUCTION

The bioelectrochemical conversion of renewable feedstocks such as wastewater and CO_2 into sustainable fuels is an attractive alternative to achieve decarbonization and a circular economy. These bioconversion processes embrace a power-to-gas/fuel (P2G/F) approach. Besides, they represent a remarkable option to balance the electricity grid in the forthcoming scenario of a high renewable energy source (RES) penetration. Implementation of RES is indeed required to achieve the European Green Deal objective of lowering carbon emissions from electricity supply to nearly zero by 2050. This RES deployment will require high energy storage capacity, covered by batteries and flywheels for short-term storage and P2G/F technologies for medium-long term storage. The development of innovative production routes for renewable fuels, based on energy-efficient technologies, is required.

In this context, the GAIA project aims to develop novel, energy-efficient solutions for obtaining both liquid (butanol) and gaseous (methane) biofuels using bioelectroconversion technologies. The project concept is based on the principles of Circular Economy as depicted in Figure 1. It proposes the use of electricity as the driving force (used as a source of reduction equivalents) to convert wastewater and CO_2 into green fuels promoting toto close the circle[1]. This will also ease energy transport and storage while having a positive impact on water treatment and reuse.

Within this framework, novel energy-efficient solutions based on Microbial Electrochemical Technologies (METs) are used. METs benefit from (electro)-autotrophic microorganisms that use CO_2 as the sole carbon source for the production of organic compounds, such as butanol (microbial electrosynthesis) or methane (electromethanogenesis). METs' main advantages compared to conventional CCU and P2G/F technologies rely on their innovative biocatalytic process: (i) high process efficiency under mild operation conditions; (ii) adaptability to a variety of CO_2-rich gas streams from different decentralized sources (iii) resilience to the presence of impurities; (iv) high flexibility in terms of plant size and operation power fluctuation; (v) seasonal energy storage of electricity surpluses as fuels; and (vi) positive social recognition and environmental impact due to the promotion of a circular economy. Besides, economic, social and environmental aspects are important to ensure an effective future implementation. However, principal technological challenges to tackle prior to the release of METs to the market are: (i) not competitive capital and operational costs, (ii) lack of successful upscaling attempts and (iii) low production yields even when pure substrates are used.

Figure 1. GAIA project concept.

GAIA consortium is constituted of three partners (Leitat, University of Girona and FACSA). The key contribution of Leitat is based on management and coordination activities, development of 3D metal electrodes, design of electromethanogenesis reactors with improved hydrodynamics and promoting start-up, optimization, and deep characterization of MET reactors for the conversion of CO_2 to CH_4. UdG's contributions to the project are focused on the design, development and construction of microbial electrosynthesis reactors, the start-up process and further optimization for butanol production, and the study of electrode-microorganisms interaction. Lastly, the role of FACSA in the project is to provide its expertise in the management of biogas production facilities in Wastewater Treatment Plants (WWTP). This allows us defining the best scalability and replicability in different facilities and identifies possible synergies to integrate MET into WWTPs streams and processes.

All in all, MET, the central CCU technology in GAIA, is a technology of major interest because it successfully links biofuels production, RES (and its surpluses), wastewater treatment and CO_2 emissions abatement.

Abstract
The presence of microplastics in the environment has become a worrisome issue in recent years. In this context, wastewater treatment plants could be considered microplastics hotspots, since they are not designed for their removal. However, the literature regarding their determination in the different points of these facilities is not consistent, primarily due to the lack of a standard methodology for sampling and identification. The aim of this work was to assess the occurrence of microplastics in different wastewater treatments in Galicia, Spain. For this, the optimization of a sampling and cleaning protocol was optimized, and three samplings were carried out in different wastewater treatment plants. The results show the presence of microplastics in water and sludge lines, being polystyrene, polypropylene and polyethylene the most abundant polymers.

Keywords
Microplastics, Sewage sludge, Wastewater

INTRODUCTION

In recent years, microplastics (MPs) released to different aquatic systems has aroused great interest. MPs are plastic particles with size ranging between 1 µm and 5 mm, that can be potentially harmful once released into the environment. MPs can be classified into primary MPs (those that enter the environment in small sizes, like microbeads in cosmetics) and secondary MPs (those that are produced by the degradation of larger fragments) (El Hayani et al., 2022).

Nowadays, many studies have focused on MPs in different environments. In addition, Wastewater Treatment Plants (WWTPs) have been identified as an important source of MPs since the occurrence of them in the effluent and sludge has been clearly demonstrated. However, a standard protocol for cleaning and identifying MPs has not been developed yet, and the methodology followed varies within authors (Löder et al., 2017).

Because of this, the main objectives of this work were 1) to develop an efficient protocol for determine the presence of MPs in wastewater and sludge 2) to assess the occurrence of MPs in various WWTPs.

MATERIALS AND METHODS

Optimization of sampling and cleaning protocol

An essay was performed to assess the efficiency and recovery rates of the sampling method. Particles of different size (50-100 µm; 100-500 µm; 500 µm -1 mm) of high-density polyethylene, polypropylene and polystyrene were added to distilled water and filtered using sieves of different mesh size (1 mm, 500 µm, 100 µm and 50 µm). The weight loss for each fraction of plastics was registered after filtering.

The first step of sampling treatment is the removal or organic matter and other materials that could interfere with the identification methods. Some of the most common protocols were tested: use of hydrogen peroxide, Fenton reagent (El Hayani, 2022) and enzymatic solutions (Löder et al., 2017).

Sampling campaign

Three samplings were carried out in three WWTPs in Galicia, Spain. The WWTPs were chosen considering each of them as an example of different size facilities, as well as for being representative of different treatment systems.

Samples from different points of water and sludge lines were taken and filtered using sieves as previously explained. For cleaning the samples, the optimized protocol developed was applied. Fourier-transform infrared and Raman spectroscopy were applied for polymer identification.

RESULTS AND DISCUSSION

Optimization of sampling and cleaning protocol

The recovery rate for the sampling method was 54,9 ± 3,9 %. It is important to note that the recovery efficiency was nearly 100 % for the fraction between 500 µm and 1 mm, and diminished with particle size. These results evidence the need of large volumes of sample, especially for water line samples. Liu et al., 2021 indicated that a limited sample volume in those cases could lead to experimental errors.

Regarding the cleaning protocol, the Fenton reagent was discarded since it resulted in a degradation of some polymers. Complete enzymatic protocol was discarded due to the high cost and time required even though it demonstrated to be effective. Therefore, the samples were treated in several steps with an SDS 10 % solution (24 h, 50 °C) and a hydrogen peroxide 30 % solution (24 h, 65 °C) to remove organic matter, and the enzyme cellulase (several incubations, 24 h, 40 °C), to remove cellulose from toilet paper.

Occurrence of MPs in WWTPs

Different polymers were identified in water and sludge line. The most abundant polymers determined were polypropylene, polyethylene and polystyrene. MPs ranging from 500 µm to 1 mm were easier to determine and were more abundant, which can be explained by the sampling methodology used.

The methodology applied was more effective for sludge samples, with 1.2 * 10^3 MPs/kg_{dw} for mixed sludge in the larger WWTP. This is consistent with literature since sedimentation processes are reported as the main cause of removal of MPs from the water line. The presence of large number of plastics in sludge can be potentially harmful, due to its use as fertilizer (El Hayany et al., 2022). The bibliography regarding water line is less consistent, but MPs presence in effluents implies a risk for the environment and reuse methodologies (Liu et al., 2021).

Abstract

Regenerated water will be highly used in water scarcity regions such as Catalonia (Spain). Currently, disinfectants aimed at the selective inactivation of pathogenic or undesirable organisms generate disinfection by-products (DBPs) when they react with organic matter. Unfortunately, little information is known about toxic and mutagenic DBPs synergies. This study aimed to compare the toxicity and mutagenesis of a DBP mixture, to the individual species values. The potential mutagenicity was assessed following the Organisation for Economic Co-operation and Development (OECD) guideline 471. Results obtained showed the toxic and mutagenic synergism between trihalomethanes and haloacetic acids present in drinking water when they are at very high concentration levels.

Materials and Methods

Chlorine-disinfected water was obtained from a drinking water distribution system in Catalonia (Spain) in March 2021. DBPs were analyzed by LC-MS/MS for HAA and GC/MS for THMs. Results (Table 1) were used to define the DBPs mix to test for synergism regarding toxicity and mutagenesis.

This study was undertaken following OCDE Guideline 4712, using S. typhimurium TA98, TA100, TA102, TA1535 and TA1537 strains in the presence and absence of metabolic activation (Fig. 1). The principle of this bacterial reverse mutation test is based on the detection of those mutations which revert mutations present in the test strains and restore the functional capacity of the bacteria to synthesize an essential amino acid 3–5. Each condition had a positive control, a negative control and six different concentrations of the sample. All of them were evaluated in triplicate. The toxicity of the sample was assessed from the reversion results.

Results and Discussion

The results are shown in Figure 2. The highest concentration (P1) showed signs of toxicity in most strains with and without metabolic activation since the number of reverted colony-formed units (CFUs) was significantly lower than in the case of the negative control or had a value of zero. Concerning the mutagenicity effects, the only concentration that showed significant differences with the negative control, despite not exceeding the threshold of twice the CFUs with respect to this control, was the P2 concentration for the TA100 strain in the absence of metabolic activation 4,8. Therefore, this concentration should be considered mutagenic for the conditions assessed in the bacterial reverse mutation test.

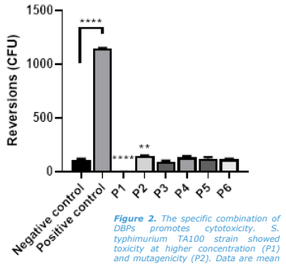

Figure 2. *The specific combination of DBPs promotes cytotoxicity. S. typhimurium TA100 strain showed toxicity at higher concentration (P1) and mutagenicity (P2). Data are mean ± SEM. ** p < 0.01, **** p < 0.0001 vs. negative control. CFU; colony forming unit.*

Conclusions

The potential mutagenicity of the DBP1 test item has been evaluated. The results obtained indicate that the concentration of 5.0 µL/plate is toxic to bacteria. In addition, the concentration of 1.6 µL/plate is the only presenting potential mutagenicity in one condition (TA100 without metabolic activation) which could be considered mutagenic in this test. Therefore, due to this result, the sponsor is recommended to confirm this result in an additional experiment. M2 DBPs' individual concentrations are not supposed to be mutagenic accordingly to their respective EC20 threshold, indicating a possible synergic effect between the mixture DBPs.

Abstract
Wastewater reuse for vegetable crops irrigation is regularly applied all over the world, which might introduce numerous pharmaceutical and personal care products into agro-food systems. Among marketed pharmaceuticals, over 50% are chiral. Despite their identical physicochemical properties, pharmaceutical stereoisomers may have distinct environmental toxicity and fate. In this study, an enantioselective method is being established for the analyses of the chiral venlafaxine and its main metabolite O-desmethylvenlafaxine and applied to study their enantioselectivity in lettuce under laboratory hydroponic conditions; i.e., enantioselective uptake, distribution, and transformation. Comprehensive data about the environmental fate of relevant pharmaceutical compounds such as venlafaxine and O-desmethylvenlafaxine in agro-food systems are needed to assess the feasibility of water reuse for irrigation purposes.

Keywords
Chiral pharmaceutical; enantioselectivity; distribution; bioaccumulation; biotransformation; reclaimed water.

INTRODUCTION

Due to climate change, urbanization, regional drought, and pollution, the issue of water shortage is becoming serious in many countries. Thus, agriculture is increasingly relying on treated wastewater as a vital irrigation source. In order to assess environmental and human impact of such practices, the plant uptake of chemical pollutants present in wastewater such as pharmaceuticals (e.g., antibiotics, non-steroidal anti-inflammatories, sulfonamides, and β-blockers) needs to be evaluated. However, there are no studies focusing on the enantioselective profiling of chiral pharmaceuticals in the agro-food system during irrigation. The different bioactivity, metabolism, and bioaccumulation between stereoisomers may pose distinct environmental risks. Thus, in this study, we focus on the enantiomeric fraction change of venlafaxine (VFX) and O-desmethylvenlafaxine (ODVFX) in lettuces through a laboratory hydroponic system. The aim of this study is to provide a chiral view on contaminants' fate in agri-food system to evaluate the opportunities and potential risks of the use of reclaimed water for irrigation of plants and crops.

MATERIALS AND METHODS

Laboratory hydroponic study

Lettuce seedlings of uniform size were selected, rinsed with Milli-Q water, and transferred to the hydroponic channels filled with half-strength nutrient solutions (Hoagland). The hydroponic channels were placed in a controlled environment, with a daily photoperiod of 14 h at an average light intensity of 2,700 Lux, temperature of 20−22 °C, and humidity of 50%. As shown in Figure 1, two exposure groups were spiked at a nominal individual concentration of 100 μg/L Rac-VNF and Rac-ODVFX. Control experiments without seedlings, and non-spiked seedling control were also set up. The spiked exposure solution was renewed twice per week, to keep the exposure concentration constant. The lettuces and solutions were sampled at time points, 0, 7, 14, 21, 28 d. The lettuce samples were washed with Milli-Q water and divided into two functional groups, including roots and edible parts (stems and leaves). Each part of the tissue was freeze-dried for 48 h in a lyophilizer, weighed, homogenized by grinding into fine powder, and stored at −20 °C.

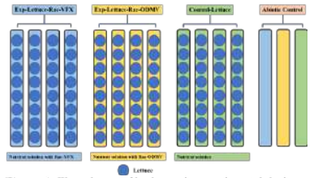

Figure 1. The scheme of hydroponic experimental designs.

Analytical methods

The lettuce roots, edible parts and water samples were collected in the laboratory experiments and analysed by liquid chromatography coupled with a hybrid mass spectrometry detector (UPLC-QqLIT) based on a method from Gros et al. (2012) and Santos et al. (2019). A Chirobiotic V column (250 × 2.1 mm, 5 μm) was applied for chromatographic separation (Liu et al., 2007). 50 mg of freeze-dried lettuce tissues were extracted with 1 mL of citric buffer pH 4: ACN (1:1, v/v) using a mini bead beater. Then samples were centrifuged (8,000 g, 15 min, 4 °C). This extraction procedure was repeated three times. All the supernatants were combined, evaporated until dryness, and reconstituted in 50mL ultrapure water with 0.1% formic acid. A solid phase extraction (SPE) using Oasis HLB (3cc, 60 mg) (Waters) was performed for sample clean-up.

RESULTS AND DISCUSSION

A chiral analytical method for VFX and ODVFX is being established, with acceptable LODs and recoveries in all the matrices. Further, the enantiospecific uptake and distribution in lettuce were found and the difference in bioaccumulation between VFX and ODVFX were obtained. Risk to human health (through dietary exposure) was not evaluated since the spiking concentrations were higher than usual environmental values. A field study is foreseen, where the enantiomeric fraction of VFX and ODVFX will be studied in lettuce grown in agricultural plots irrigated with reclaimed wastewater. More realistic data will thus be obtained, which will be used to evaluate human health risks.

Contactless membrane distillation for effective ammonia recovery from waste sludge

Lei Wen and Xiao-yan Li*

Department of Civil Engineering, The University of Hong Kong, Pokfulam, Hong Kong, China
(E-mail: *wenlei17@connect.hku.hk)*

Abstract
Serious membrane fouling caused by direct contact between the hydrophobic membrane and feed hinders the ammonia (NH_3) recovery from waste fermented sludge via MD. In this study, a contactless MD system was developed by introducing an air gap and subtly solved the problem. Results showed the overall NH_3 transfer coefficient by contactless MD was $(1.49 \pm 0.05) \times 10^{-5}$ m/s, 7 times greater than that of conventional MD ($(0.20 \pm 0.01) \times 10^{-5}$ m/s). In continuous operation with a short retention time of 20 min, a high NH_3 recovery (greater than 80 %) and a clean membrane without foulant attachment were maintained, while the conventional MD system had failed in 12 h due to formation of a thick fouling layer on the membrane surface. This contactless MD can be an innovative technology to treat multiple NH_3-rich waste liquids.

Keywords
Ammonia recovery; mass transfer coefficient; membrane distillation; membrane fouling; sludge

NTRODUCTION

Through fermentation, sewage sludge can release more than 1,000 mg/L of NH_3-N and should be recovered. By means of MD, ammonia is vaporized as NH_3 and passes through the hydrophobic membrane, which rejects water, solutes, and solids in the sludge liquor. The penetrating NH_3 is then absorbed by acid on the other side of the membrane. However, the membrane often suffers from pollution by organic, salt, and solid impurities owing to its direct contact with the sludge. Since gaseous NH_3 is the transport species, ammonia removal and recovery do not require direct contact between the membrane and the NH_3-containing feed solution. Therefore, an air phase may be kept between the feed and membrane to avoid their direct contact. In this study, a contactless MD system with feed-air-membrane-acid compartments was introduced to realize efficient and fouling-free NH_3 recovery from sludge liquor.

MATERIALS AND METHODS

Two different MD modules and open evaporation were tested (Figure 1). In the conventional MD configuration, the MD feed chamber had a depth of 2.2 mm and was fully filled with the feed solution (fermented sludge liquor). The feed solution was in complete contact with the PTFE membrane. Serving as the absorbent of NH_3, 0.5 M H_2SO_4 was circulated at the top; In the contactless MD system introduced in this study, the same MD module was used, except the feed chamber had a depth of 15.0 mm. The air gap avoided the contact between feed solution and membrane; Open evaporation makes the upper free space a large dilution pool, which represents the minimal resistance to NH_3 transport.

The flux of NH_3 transport (J) through the interface of the two phases follows Fick's law of diffusion, i.e., $J = -D\frac{dC}{\delta n}$, where D is the diffusion coefficient of NH_3 molecules and $\frac{dC}{\delta h}$ is the concentration gradient at the interface. For an actual two-phase system such as the feed liquid phase (L) and phase A (referring to air, acid, or absorbent), the flux may be approximated to $J = -K(C_L - C_A)$, where K is the mass transfer coefficient.

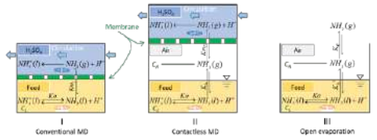

Figure 1. Schematics of ammonia transport in different MD modules and open evaporation.

RESULTS AND DISCUSSION

NH_3 recovery from sludge liquor via different MD modules

NH_3 removal from the fermented sludge liquor by contactless MD reached 95 % after 12 min, close to the open evaporation result, whereas the removal by conventional MD was only 50 % for a fresh membrane (Figure 2A). The calculated overall NH_3 transfer coefficient was $K_I = (0.20 \pm 0.01) \times 10^{-5}$ m/s for conventional MD and $K_{II} = (1.49 \pm 0.05) \times 10^{-5}$ m/s for contactless MD, which was significantly enhanced by more than 7 times. Contactless MD maintained a stable NH_3 recovery of 80 ± 2 % during the 12 h continuous test with a sludge retention time of 20 min, while conventional MD has totally failed after 12 h (Figure 2B).

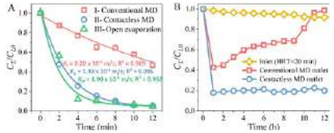

Figure 2. Ammonia removal via different MD modules in the batch (A) and continuous (B) tests.

Membrane fouling in different MD modules

In the contactless MD module, the membranes were kept fresh and maintained their original appearance throughout the 12-h test (Figure 3). Membrane fouling was observed in the conventional MD module. Impurities or foulants continued to adhere to the membrane surface on the feed side during the MD process. The thick fouling layer on the membrane surface significantly increased the resistance to NH_3 transport for the conventional MD.

Gravity-driven Membrane Filtration Primary Wastewater Effluent for Irrigating Soil-plants and Hydroponic-plants

Sif Guðjónsdóttir, Megan Wiegmann, Selina Hube, Bing Wu

Faculty of Civil and Environmental Engineering, University of Iceland, Hjardarhagi 2-6, IS-107, Reykjavik, Iceland; (E-mail: sig108@hi.is; mew@hi.is; seh34@hi.is; wubing@hi.is)

Abstract
In this study, gravity-driven membrane (GDM) systems packed with Icelandic lava stones were employed to treat primary wastewater for water reclamation and nutrient recovery. The results revealed that (1) Compared with non-cleaning condition, periodic physical or chemical-enhanced physical cleaning improved water productivity without compromising water quality. (2) In soil-based systems (tomato and basil), plant growth profiles or non-essential heavy metal contents in soils were comparable (p>0.05) when tap water, commercial fertilizer, and permeate water were used as irrigation water. (3) In hydroponic-based systems (lettuce and basil), insignificant difference of lettuce growth using permeate water and fertilizer solution was noticed (p>0.05), while basil plants could grow better in fertilizer solution. More heavy metals were accumulated in lettuce plants than those in basil plants. However, the hazard quotient indexes of heavy metals in the plants were less than 1, indicating negligible human health risk.

INTRODUCTION

Globally, the recovery of nutrients and water from wastewater is crucially important for achieving circular economy and coping with the challenges of water scarcity and fertilizer shortage. However, the potential presences of pathogens and chemical contaminants in the reclaimed wastewater raise major concerns for its reuse (Hube and Wu, 2021). The recently reported gravity-driven membrane (GDM) filtration process utilizes hydrostatic force and naturally developed biofilm, combined with microfiltration (MF)/ultrafiltration (UF) membrane separation to obtain superior permeate water (Pronk et al., 2019), offering an alternative solution for municipal wastewater reclamation. However, the feasibility of using GDM permeate water as irrigation water to culture plants in soil-based and hydroponic-based systems has not been well investigated.

In this study, we aim to (1) illustrate the effects of biocarrier packing ratio and cleaning protocols on GDM performance, especially water quality; and (2) examine the applicability and feasibility of low-cost, easy-maintenance GDM systems in reclaiming primary wastewater for cultivating vegetables in both soil-based and hydroponic-based systems.

Regeneration of high-quality water for reuse by forward osmosis-reverse osmosis system treating urban wastewater

X. Yang*, I. Fernández* and C. Martínez García*

* CETIM Technological Centre, 15180, Culleredo, A Coruña, Spain
(E-mail: *xyang@cetim.es)*

Abstract
3.5 million people worldwide will face water scarcity by 2025 due to climate change. Wastewater reuse is one of the most important alternatives to traditional water sources to solve the problem of water shortage. Conventional municipal wastewater treatment plants (WWTPs) are ineffective at removing most of the emerging contaminants and pathogens. These pollutants can cause some concerns for the environment and human health, especially if WWTPs effluents are intended to be reused for agricultural irrigation. Osmosis membrane-based technologies are at the forefront of tackling this problem. Treatment of urban wastewater through osmosis membranes can produce high-quality treated water for reuse, because most of the bacteria, viruses, salt, emerging pollutants and refractory organic matter will be intercepted in the filtration unit. Hence, this study aims to investigate the feasibility of reusing the treated water for agricultural irrigation by a Forward Osmosis (FO)-Reverse Osmosis (RO) system according to the upcoming Regulation (EU) 2020/741 on the minimum requirements for the reuse of treated water. The results showed that the FO-RO system had a 100% removal efficiency for pathogens, a high removal rate for COD and TSS, and a removal rate higher than 90% for 92% of related emerging pollutants. Subsequently, values of the treated water regarding to *E. coli*, BOD_5, TSS and turbidity were verified as meeting the criteria for reuse at least in Class B agricultural irrigation according to Regulation (EU) 2020/741.

Keywords (maximum 6 in alphabetical order)
Biomimetic membranes; Forward osmosis; Reverse osmosis; Sustainability; Urban wastewater; Water reuse

INTRODUCTION

The scarcity of water resources is influenced by factors such as population growth, urbanization, per capita consumption, water pollution and climate change (Ungureanu et al., 2020). According to the estimates of the World Resources Institute in water sector, with 2025 as the reference year, about 3.5 million people in the world may face water shortages (World Resources Institute. Water, 2020). In order to overcome this problem, wastewater reuse is one of the most important alternatives. Reuse of treated wastewater for agricultural irrigation is by far the most defined end use of reclaimed water (Rizzo et al., 2020). Growing concerns about wastewater reuse for agricultural irrigation mainly include microbial risks and emerging contaminants such as pesticides, pharmaceuticals, illicit drugs, synthetic and natural hormones, etc. The recent EU Regulation 2020/741 is expected to be effective from June of 2023 on the minimum requirements for the reuse of treated water for agricultural irrigation (EU Regulation 2020/741, 2020).

To meet the criteria for water reuse, osmosis membrane-based technologies are at the forefront of tackling this problem. In recent decades, forward osmosis (FO) has gained attention as a novel membrane process for urban wastewater treatment. Unlike pressure-driven membrane processes, forward osmosis is driven by an osmotic pressure gradient between feed solution (wastewater) and draw solution (DS), which has the advantages of high product water quality, low energy consumption, and low tendency to membrane fouling (Liu et al., 2015). However, FO requires a DS recovery procedure to maintain the osmotic pressure gradient. A followed reverse osmosis (RO) process can re-concentrate the diluted DS while providing a second barrier to ensure the treated water with high quality for agricultural reuse.

Considering the above background, the objective of the present study is to validate the behavior of FO process with biomimetic membranes followed by RO process for DS recovery in treating urban wastewater and to evaluate the feasibility of reusing the treated water in agricultural irrigation.

MATERIALS AND METHODS

The FO-RO pilot system (treatment capacity up to 12 m^3/d) consists of a FO unit as the first barrier for wastewater purification, and a RO unit for the DS re-concentration as well as the second barrier to obtain the high-quality water for reuse. The pilot diagram of the system is shown in Figure 1.

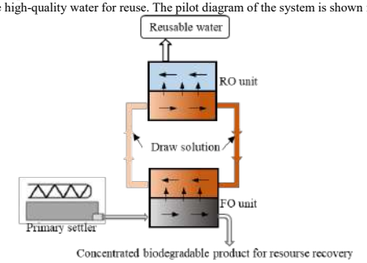

Figure 1. Pilot diagram of the FO-RO system

In this study, the biomimetic hollow fibre membranes (Aquaporin) were selected for the FO unit because of their higher performance. 3.5% NaCl was selected as the DS after testing the permeate flowrate. Toray TM810V RO membranes were considered for the RO unit due to their high salt rejection, which can minimize the DS salinity loss in the permeate (i.e., producing a permeate of higher quality). Water characteristics of influent and effluent were measured periodically following the Standard Methods for the Examination of Water and Wastewater (E.W. Rice et al., 2017).

RESULTS AND DISCUSSION

After 10 months operation of the FO-RO pilot plant at an urban WWTP, the validation of the treating performance is concluded in the following content. The average chemical oxygen demand (COD) and total suspended solids (TSS) removal rate of the system were 88.2% and 97%, respectively. In addition, the system obtained 100% removal of pathogens (*E. coli*, total coliforms and nematodes), and 92% of the relevant emerging pollutants were removed with removal rate higher than 90%.

In order to evaluate the reuse feasibility of the treated water, the upper part of Table 1 shows the value limits established by the upcoming Regulation (EU) 2020/741 on the minimum requirements for the reuse of treated water for agricultural irrigation. In the meanwhile, the last row of Table 1 shows the corresponding values of each parameter of the treated water to determine if they meet the reuse standards.

Table 1 Requirements for water reuse for agricultural irrigation of Regulation (EU) 2020/741and corresponding average values for the treated water

Reclaimed water quality class	***Escherichia Coli***	**BOD_5**	**TSS**	**Turbidity**
A: Raw consumption, contact with water	≤ 10 UFC / 100 ml	≤ 10 mg/l	≤ 10 mg/l	≤ 5 NTU
B: Raw consumption, without contact with reclaimed water	≤ 100 UFC / 100 ml	In accordance with Directive 91/271/EEC	In accordance with Directive 91/271/EEC	-
C: Raw consumption, without contact with reclaimed water. drip irrigation	≤ 1000 UFC / 100 ml			-
D: Destination industry, seed production, energy	≤ 10000 UFC / 100 ml			-
FO-RO treated water	0.04 UFC/100 ml	8 mg/l	3 mg/l	6 NTU

After comparing the standard and values of the treated water regarding to *E. coli*, BOD_5, TSS and turbidity, FO-RO treated water can be reused for Class A agricultural irrigation, except that turbidity was not complaint with the limit. Therefore, in general, the FO-RO system obtained reusable water for Class B agricultural irrigation, with high potential to meet Class A requirements.

Abstract

The olive sector is one of the main sectors of the agri-food system in the Mediterranean basin and other producer countries, due to its economic, social, environmental and public health importance. Olive leaves are one of by-products of the olive oil and olive table products and they are produced in large quantities, although it is underutilised. These by-products can be used for animal feed, but generally without application of industrial interest, but currently olive industry waste is generating a great deal of interest within the framework of biorefineries. From olive by-products high number of added-value compounds can be obtained for energy, pharmaceutical, food and cosmetics use. The present study was undertaken to investigate the effect of different pre-treatment procedures to recover sugars, metals and natural antioxidants from Andalusian olive tree leaves. After the different pre-treatments the bioenergy generation potential will be evaluated and compared to the potential of the untreated leaf.

Keywords
Anaerobic digestion; contaminants; methane production; olive by-products.

INTRODUCTION

The olive sector is one of the main sectors of the agri-food system, due to its economic, social, environmental and public health importance. Olive cultivation is present and its cultivation area exceeds 11.6 million hectares and most of it is located in the countries of the Mediterranean basin (Figure 1).

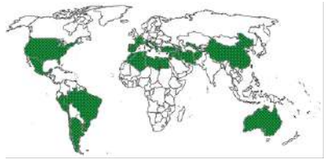

Figure 1. Olive cultivation around the world.

The most important products from the olive sector are the olive oil and olive table industries. Spain is the worldwide largest olive oil producer, reaching a production of more than 1.3 million of tons in the season 2021/2022. This amount corresponds around 65% of the European production (1.97 million) and 42% of the world production (3.1 million) (IOC, 2022). More than 80% of the Spanish production is located in Andalusia. Regarding to the olive table, the average production of table olives in Spain in the last five seasons was 561,100 tons, which represents 19.7% of world production of this product (Ruiz-Barba et al., 2023). Olive leaves are one of by-products of the olive oil and olive table products and they overcomes one million tonnes (Romero-García et al., 2016). Olive leaves occasionally can be used for animal feed, but currently olive industry waste is generating a great deal of interest within the framework of biorefineries. From olive by-products high number of added-value compounds can be obtained for energy, pharmaceutical, food and cosmetics use. As prominent examples as sugar, flavonoids and phenolic compounds can be highlight.

Other important point is because of the use of the extended use of metals, specially, Cu-derived compounds as antifungals in olive tree agricultural, Cu is expected to be detected in high amounts in the olive leaves and this should be removed from the leaves. The first reason for its great interest as a raw material, secondly for its oxidative potential in bioactive compounds and thirdly for its toxic potential in soils when the leaf is used as a soil amendment or soil improver.
As global energy consumption continues to grow and in order to mitigate global warming and he current energy crisis more eco-friendly researches are necessary. For this reason, the bioenergy generation potential is evaluated and compared to the potential of the untreated leaf.

MATERIAL AND METHODS

The leaf samples were collected and manually cleaned of twigs, insects, soil, etc. Once the material not coming from the leaves was removed and in order to reduce the particle size of the sample, the leaves were passed through a Yazicilar shredder, model DIV Line Countertop Cutter-Mixer, L9DIV. The samples were stored refrigerated (4 ºC) while characterisation and extraction tests are carried out. C/N, organic matter, ammonia, metals and bioactive compounds are being determined in both pre-treated and untreated olive leaves. Total polyphenols are being be determined through the Folin-Ciocalteau method, after extraction with an 80% methanol/water solution and the individual phenols concentration will be measured by liquid chromatography using a Hewlett-Packard 1100 HPLC-system using a C-18 column and a diode array detector. Trace elements will be measured using Inductive Coupled Plasma Mass Spectrometry (ICPMS-Agilent-7800.
To investigate the biochemical methane potential of the olive leaves and the effect of different pre-treatment on the methane production potential of PS, BMP tests will be evaluated. The BMP tests will be carried out in 250 mL bottles.

Each BMP test contained an inoculum to olive leave ratio of 2 on a dry VS basis. All the bottles will be closed and maintained in a mesophilic temperature controlled (at 35-37 ºC) regulated with a thermostat, and continuously stirring (300 rpm). Methane production will be measured using 0.5 and 1.0 L gasometers immersed in a solution of NaOH 2 N. Owing to the NaOH property of chemically absorbing the CO_2 present in the biogas, a correct measurement of the methane volume can get by liquid displacement and they will be maintained until biogas production will be totally exhausted, approximately 30 days.

RESULTS AND DISCUSSION

We are currently carrying out leaf characterisation and pre-treatments for the extraction of high added value compounds and next week we will set up the BMP tests. The most relevant results will be presented at the ECOSTP conference.

Abstract
The mesophilic (35ºC) and thermophilic (55ºC) biomethanization of poultry, swine and cattle manures were investigated using biochemical methane potential (BMP) tests. Pasteurization pretreatment and post treatment was also investigated in combination with anaerobic treatment at 35 °C. Specific methane production (SMP), 24 pharmaceutical compounds (PhACs) and four antibiotic resistance genes (ARGs) (*qnrS*, *tetW*, *ermB* and *sul1*) were analyzed. The results showed that swine and poultry manure had higher methane productivities in mesophilic range (380 mL CH_4/g VS and 248 mL CH_4/g VS, respectively) than in thermophilic range (356 mL CH_4/g VS and 202 mL CH_4/g VSS, respectively), while for cattle manure an increase from 258 mL CH_4/g VS (mesophilic range) to 273 mL CH_4/g VS (thermophilic range) was observed. Several PhACS were detected in the manures. Most of these compounds were partially degraded. Tylosin was completely removed. Chlortetracycline (at thermophilic) and sulfamethoxazole presented removals higher than 50%. On the contrary, enrofloxacin, sulfadizine, sulfapyridine and flunixin showed poor removals (< 25%) indicating that anaerobic treatment can only partially remove these micropollutants which remain in the solid phase after treatment. The best removals were obtained at high temperatures indicating that thermophilic digestion is better suited for the removal of these compounds. This general trend was contrary to that observed in the study of antibiotic resistance genes, as the relative abundance of most of the genes studied (tetracycline, sulphonamide, fluoroquinolone and macrolide resistance genes) and of the horizontal transfer indicator of resistance genes (*IntI1*) not showed a lower relative abundance after thermophilic treatment. Finally, we studied the presence of potentially pathogenic bacteria and the most abundant genera were Streptococcus, Clostridium, Corynebacterium, Acinetobacter and Pseudomonas. All these genera were reduced after anaerobic treatment, except Clostridium which increased after thermophilic treatment.

Keywords
Anaerobic digestion; Antibiotic resistance genes; Methane production; Veterinary drugs.

INTRODUCTION

Intensive livestock farms are growing worldwide, leading to an increase on the production of different types of manures that, if untreated, can lead to a major environmental problem. Anaerobic digestion (AD) of organic manures offers an opportunity for energy recovery, making their treatment more attractive and economically more favourable. A part of the high content of conventional pollutants, manures are characterized also for containing relatively high concentrations of emerging pollutants such as pharmaceutical compounds (PhACs) and antibiotic resistance genes (ARGs). It is necessary to study the fate of these emerging pollutants in different types of manure as well as the capacity of AD to remove some of them. It is known that mesophilic (MAD) is not sufficient to reduce the content of pathogens, while thermophilic (TAD) present a higher removal efficiency, but it is more unstable and expensive for this type of waste. To overcome this limitation, interest in thermal pre-treatment before mesophilic digestion has increased. Sterilization of pathogenic microorganisms from wastewater can be achieved via a thermal pretreatment (70 °C for 1 h) before AD.

The fate of 24 PhACs, four ARGs (*qnrS, tetW, ermB and sul1*) and the gene *IntI1* were investigated in this study. The biogas production potential of swine, poultry and cattle manure under different anaerobic treatment conditions including the sanitation effect of pasteurization as pre or post treatments was also evaluated, as well as the effect of both temperatures on the degradation of the emerging pollutants.

The three substrates investigated were swine, cattle and poultry manure, which were obtained from a swine, cattle and poultry farms with a capacity of 600 pigs, 400 cows and 12,000 chickens.

RESULTS AND DISCUSSION

Biogas production

Mesophilic BMP tests displayed methane production from the first day with both substrates while the BMP performed under thermophilic temperature showed a delay. This is probably due to the adaptation of the inoculum to 35ºC as it was withdrawn from an anaerobic digester working at this temperature. The exponential increase in the specific methane production under thermophilic conditions was detected after 3-4 days indicating that the inoculum also had microorganisms able to work at 55ºC. The BMP tests conducted with poultry and swine showed significant differences in the average SMP values obtained under both temperatures, with 248 mL CH_4/ g VS and 202 mL CH_4/ g VS and 350 and 380 mL CH_4/g VS at thermophilic and mesophilic conditions, respectively. In the tests conducted with cattle manure (Fig. 1B) higher SMP was obtained at 55ºC.

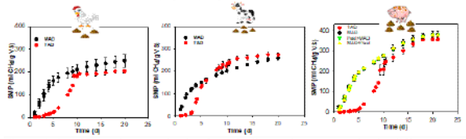

Figure 1. Specific methane production from the livestock manure under the different conditions tested.

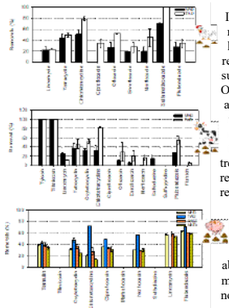
Pharmaceuticals and antibiotic resistance genes



In general, general, all groups of PhACs showed higher removal in TAD as compared to MAD (except for lincomycin) (Figure 2). Tylosin was completely removed. Chlortetracycline (at thermophilic) and sulfamethoxazole presented removals higher than 50%. On the contrary, enrofloxacin, sulfadizine, sulfapyridine and flunixin showed poor removals (< 25%) indicating that anaerobic treatment can only partially remove these micropollutants which remain in the solid phase after treatment. Regarding the effect of pasteurization treatment in combination with AD on PhACs removal, results suggest that this treatment does not influence the removal of PhACs.

Four ARGs (*ermB, qnrS, sul1 and tetW), intI*1 and 16S rRNA genes were quantified in the biomass used as inoculum, in the livestock manures and at the end of the BMP tests. When comparing the relative abundance of ARGs at the end of each treatment, the most significant removal was found for *qnrS* which was not detected after most of the anaerobic treatment.

Figure 2. Removals of PhACs in the BMP tests conducted.

Abstract

The implementation of municipal wastewater treatment technology for phosphorus (P) recovery from marine sediments can be a promising strategy for P resource recovery and eutrophic ecology remediation. Currently, few studies explored the role of ammonia nitrogen (NH_4-N) in affecting P internal release under anaerobic eutrophic environments, although NH_4-N serves as an essential nutrient that can influence the metabolic activity of microorganisms. In our study, acetic acid and glucose, as prevailing carbon sources studied in the biological P removal system, were chosen, and the effects of different carbon/nitrogen on P release from marine sediment were investigated. Results showed that extra NH_4-N loading significantly impeded the decomposition of P ($p<0.05$), during the 24-day anaerobic operation, the maximum P release was 4.07 mg/L and 7.14 mg/L in acetic acid and glucose-fed system without extra NH_4-N addition. When glucose was fed as the carbon source, in addition to P releasing, volatile fatty acids were produced simultaneously.

Keywords
Alkaline phosphatase activity; ammonia loading; anaerobic reactor; marine sediments; microbial community; phosphorus release

INTRODUCTION

Phosphorus (P) present in eutrophic seawater and sediment could probably be a promising source for recovery, which can simultaneously address the burden of excess nutrient loading. The municipal technology for recycling P from waste streams has been well established; for example, the process of P removal/uptake relies on polyphosphate accumulating organisms (PAOs) under alternating anaerobic and aerobic conditions. In anaerobic conditions, PAOs can use organic carbons, hydrolysis of stored poly-P, and subsequently release orthophosphate to the environment (Cakmak et al., 2022). However, the feasibility of applying relevant processes to recover P from marine sediments has not been reported.

Ammonia nitrogen (NH_4-N), an influential bioavailable N in the sediment, however, studies on its role in influencing P internal release in anaerobic eutrophic environments are lacking. In this study, to clarify the overall influence of NH_4-N loading on P decomposition from anoxic sediments and to reach the goal of P recycling simultaneously, we conducted batch experiments using sodium acetate and glucose as external carbon sources under anaerobic conditions with different ratios of C/N (chemical oxygen demand, COD/NH_4-N).

MATERIALS AND METHODS

A serial of batch experiments was conducted in 120-mL serum bottles in triplicate, in acetic acid-fed system, 16 g of fresh sediments were dispensed in 80-mL synthetic seawater prepared with NaCl (6.5 psu) which is the average salinity of the Baltic Sea. Later, acetate (1 g/L acetic acid) and NH_4Cl were added to the serum bottles to provide carbon and nitrogen source, and different C/N loading groups were studied as no NH_4-N addition, COD/N=100, COD/N=5, and COD/N=10. The corresponding NH_4-N concentrations are around 0, 14, 28 and 140 mg/L. The bioreactors were operated for 3, 6, 9, 12, 18 and 24 days with daily manual mixing at 20°C. The experimental bottles were set up under initial pH of 7.2 and sealed with septa and aluminum caps. Each bottle was flushed with nitrogen gas for at least 5 min to provide anaerobic conditions. We repeated the above batch operation for the glucose-fed system using the same initial COD. PO_4-P, NH_4-N, acetic acid/glucose concentrations in the bioreactors, alkaline phosphatase (AP) activity, and microbial community structure of marine sediments were monitored with 24-day bioreactor operation.

RESULTS AND DISCUSSION

(1) Effects of C/N loading on phosphorus release

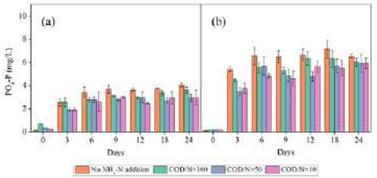

Figure 1. Variations of PO_4-P in two different carbon-fed systems under different C/N loading: (a) acetic acid system; (b) glucose system

The dissolved PO_4-P released from sediments with different NH_4-N loadings is shown in Figure 1. The concentration of PO_4-P increased considerably during the first 6 days, with 3.41 mg/L and 6.55 mg/L of P solubilization in acetic acid- and glucose-fed systems without extra NH_4-N addition. Although an increasing trend was observed in both systems, the maximum P release only increased by 19.35% (4.07 mg/L at day 24) and 8.26% (7.14 mg/L at day 18), respectively. The results exhibited that the release of P was significantly inhibited when more NH_4-N was dosed in the anaerobic system. With the increase of NH_4-N level from low (COD/N=100) to high (COD/N=10), the concentration of PO_4-P in supernatant of acetic acid-fed system decreased from 3.62 mg/L to 2.95 mg/L at the end of 24 days, while in supernatant of glucose-fed system, it decreased from 6.32 mg/L to 5.5 mg/L on the day 18.

(2) Variations of carbon in the acetic acid/glucose-fed system

Acetate consumption under different N loading is shown in Figure 2(a). Acetic acid concentrations remained stable in all groups, while only in no extra NH_4-N and COD/N=100 group exhibited slight consumption of 8.5% and 6.8% of acetate, respectively. However, unlike the acetic acid-fed system, the glucose was rapidly consumed in the glucose-fed system, for instance, over 95% of glucose was consumed in all groups in 6 days. Meanwhile, a large amount of biogas (data not available) and volatile fatty acids (VFA) were produced in the glucose-fed system (seen in Figure 2(c)-(f)), the dominant VFA types were acetic and butyric acids, the maximum VFA production was observed in no extra NH_4-N addition group on day 24 with 795.56 mg/L of total VFA, and 528.82 mg/L of acetic acid, 235.54 mg/L of butyric acid and 31.20 mg/L of propionic acid were generated, respectively.

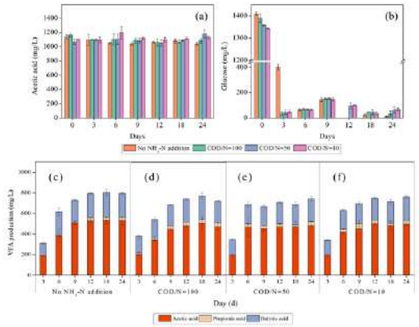

Figure 2. Variations of (a) acetic acid consumption in the acetic acid-fed system, (b) glucose consumption, and (c)-(f) VFA production in the glucose-fed system

(3) Variations of alkaline phosphatase activity

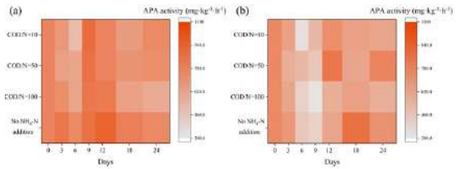

Figure 3. Variations of alkaline phosphatase activity of marine sediment: (a) acetic acid-fed system; (b) glucose-fed system

Ammonia acts as an essential nutrient for the growth of microorganisms; however, it may promote/inhibit the P release from sediment by influencing metabolic processes/activity (Li et al., 2016; Ma et al., 2018). For instance, Xie et al. (2010) investigated the correlation between phosphatase activities and P in activated sludge during the wastewater treatment process, and a negative correlation between phosphatase activities and ortho-phosphate in anaerobic bioreactors was reported. However, the contrary finding has been found by Ma et al. (2018), in the mesocosm experiment, extra NH_4-N loading stimulated AP activity and led to the promotion of lake sediment P release. Therefore, AP of marine sediments as a key enzyme in organic P mineralization, the role of its activity P decomposition under anaerobic conditions should be explored.

In this study, the activity of AP was measured during a 24-day bioreactor operation. As illustrated in Figure 3(a), the activity of AP in the acetic acid-fed system firstly increased then decreased, a maximum of 1046.97 mg/(kg·h) was reached on the day 12 in the group of no NH_4-N addition group. The opposite phenomenon was observed in the glucose-fed system, where the activity of AP was initially decreasing and lowest at day 6, with the AP activity of no NH_4-N addition, COD/N=100, COD/N=50, and COD/N=10 group was 490.67 mg/(kg·h), 447.86 mg/(kg·h), 584.45 mg/(kg·h) and 354.75 mg/(kg·h), respectively. However, the enzyme activity of the no NH_4-N addition group increased up to 967.79 mg/(kg·h) on day 18, the value was higher than that of the initial (day 0, 838.11 mg/(kg·h)).

(4) Analysis of microbial community structure

The analysis of microorganisms can help clarify the mechanism of microbial activity in the P release. The microbial community data will come later and will be presented at the conference.

CONCLUSION

Our study adopted the technology and theory of municipal wastewater treatment and investigated the feasibility of P recycling by anaerobic batch reactors from marine sediments. The influence of NH_4-N dosing on P decomposition was clarified. Our results can provide information for P release and recycling from marine sediments. Based on the findings of anaerobic batch experiments, conclusions are as follows:

(1) Additional NH_4-N loading can significantly inhibit P release from marine sediments.
(2) In terms of promoting P release, the glucose-fed system performed better compared to the acetate-fed system, up to 7.12 mg/L P can be obtained through 18-day anaerobic batch reactors.
(3) Stimulated AP activity derived by different NH_4-N loading could be the underlying reason for sediment P release.

Abstract

In recent years, a large number of researchers believe that electrocoagulation (EC) treatment has a future in wastewater treatment. In this work, we investigate the possibility of applying the EC process for the purification of meat industry wastewater. The experimental removal efficiencies for COD, BOD, total P, total N, and turbidity were 46%, 50%, 95%, 97%, and 99%, for aluminum electrodes and for iron electrodes removal efficiencies were 48%, 52%, 94%, 99%, and 98%, respectively. The next step is to optimize and improve the treatment to obtain water as a product that we can use for irrigating the surrounding agricultural areas or for reuse in the production process, which is very important from the point of view of the circular economy.

Keywords
wastewater, electrocoagulation, water reuse

INTRODUCTION

The meat industry generates wastewater highly loaded with organic matter. According to the United States Environmental Protection Agency (US EPA), this wastewater is one of the most damaging wastewaters for the environment (Štefanac et al., 2021). Application of traditional methods generally requires high investment and operation expenses can be a substantial hurdle to their implementation, particularly in small enterprises or developing nations. Therefore, it is necessary to find a treatment that is both, sustainable and environmentally friendly. In the last few years, electrocoagulation (EC) has attracted increasing attention in wastewater treatment. The main advantages of the EC process are flexibility, efficiency, ease of setup, does not require any chemical additives, lower production of sludge, and no representative copollution (Pinedo-Hernández et al., 2015). During EC treatment due to the application of low-voltage direct electric current and by the action of sacrificial metal electrodes, which are usually made of aluminum or iron, coagulants and metal hydroxides are electrochemically generated, in situ, which causes the destabilization and aggregation of contaminants (Morales-Rivera et al., 2020). In this work, we investigate the possibility of the application EC process for the purification of meat industry wastewater.

MATERIALS AND METHODS

Two sets of the EC experiments have been performed: (1) two aluminum electrodes Al(-)/Al(+)(EC1), (2) two iron electrodes Fe(+)/Fe (-) (EC2). The treatments were done in an EC unit which was made of borosilicate glass with a volume of 600 ml. For treatments aluminum and iron electrodes with the same dimensions of 10 cm x 5 cm x 0.1 cm were used. During the treatments the distance between the electrodes were 3 cm, the current strength were 3.33 mA/cm2, the rotation speed were 280/min, the surface of the immersed electrodes were 30 cm2, with the treatment time were 1 hour, and the volume of treated water was 0.5 l. The raw meat industry wastewater was characterized before and after each EC treatment determined: chemical oxygen demand (COD), biochemical oxygen demand (BOD), total phosphorous (P), total nitrogen (N), pH, and turbidity.

RESULTS AND DISCUSSION

The effects of electrocoagulation on meat industry wastewater were present in Table 1. To assess the effects of EC determining the pH value is the most appropriate step. Based on the obtained results, it is observed that the pH value increased by ~1 pH unit. We can explain this by a significant amount of ion OH− released by the electrochemical reaction of the hydrolysis of water at the cathode. The change in pH during EC was also observed by other researchers (Tahreen et al., 2020). The experimental removal efficiencies for COD, BOD, total P, total N, and turbidity were 46%, 50%, 95%, 97%, and 99%, for aluminum electrodes and for iron electrodes removal efficiencies were 48%, 52%, 94%, 99%, and 98%, respectively. We can explain the reduction of COD, BOD, P, and N in treated water by the adsorption onto the surfaces of hydroxide precipitates, which are released by the electrodes. The high percentage of turbidity reduction is in accordance with the previously mentioned efficiencies of the tested treatments. The presented results show that there is no big difference in the achieved efficiencies between EC1 and EC2, therefore our recommendation is EC2 because Fe electrodes are cheaper.

Table 1. Parameters of wastewater characterization, before and after electrocoagulation

Parameters	E0	EC1	EC2
COD (mg O_2/l)	846	454	443
BOD (mg O_2/l)	433	215	206
Total P (mg/l)	2.26	0.12	0.14
Total N (mg N/l)	64.8	2.13	0.86
pH	6.66	7.93	7.82
Turbidity (NTU)	210	2.85	5.06

Based on the above conclusions, it can be noted that EC holds immense potential to replace conventional wastewater treatment methods. In the future, we will focus on the optimization and improvement of the treatment in order to obtain water as a product that we can use for irrigating the surrounding agricultural areas or for reuse in the production process, which is very important from the point of view of the circular economy.

Abstract
The effect of salinity on aerobic granular sludge treating fish-canning wastewater was evaluated through a one-dimensional biofilm model. Salt inhibition was described by a non-competitive inhibition term, for which the value of the half-saturation coefficient was estimated based on data from literature. The model was calibrated and validated with experimental lab-scale data regarding COD and nitrogen removal from industrial wastewater. Two dynamic operating periods with salinities of 13 and 5 g NaCl L^{-1} were used for calibration and validation, respectively. The presence of salt caused nitrite accumulation, as well as unusually low estimated maximum growth rates of nitrifying bacteria. The addition of a salinity inhibition term to the model accurately described the COD and nitrogen species experimentally measured along the cycles with different salinities.

INTRODUCTION

The Aerobic Granular Sludge (AGS) technology is nowadays regarded as an established way to treat both municipal and industrial wastewater. In addition, there has been an increasing interest to also treat saline wastewater with AGS. This includes municipal wastewater from treatment plants located in coastal areas, as well as from different industrial sectors, such as petrochemical or seafood processing. However, the presence of salt is known to affect the physical properties of the granules and hinder the biological activity of the bacterial populations. In this study, a model was set-up to describe the operation of an AGS reactor treating saline wastewater and evaluate the effect of salinity on reactor performance. The model was calibrated and validated under dynamic (cyclic) reactor operation, treating influent with different salt concentrations. In addition, the need to consider an inhibition term to include the effect of salinity was investigated.

MATERIALS AND METHODS

The operating conditions of a lab-scale AGS reactor (1.7 L) fed with fish-canning wastewater, described by Carrera et al. (2019), were taken as a reference scenario. The cycle length was 4 h, including 5 min of feeding, 227 min of aeration, 1 min of settling and 7 min of effluent withdrawal. During the aeration phase, the dissolved oxygen concentration reached saturation values of 8.6 g O_2 m^{-3}. Two independent datasets corresponding to operational periods with different salinities of 13 g NaCl.L^{-1} (0.61 kg soluble COD.m^{-3}, 73 g NH_4-N.m^{-3}) and 5 g NaCl.L^{-1} (0.90 kg soluble COD.m^{-3}, 106 g NH_4-N.m^{-3}), were used for model calibration and validation, respectively.
A one-dimensional ASM3 model was implemented in AQUASIM. Three modifications were applied to ASM3 for an accurate description of the process: simultaneous growth and storage processes of heterotrophs, two-step nitrification and addition of a non-competitive inhibition term to express the effect of salinity (Table 1). This term was added to all the growth processes of the different bacterial groups. The values of the half-saturation constants were estimated based on activity tests from literature reporting a reduction of the biological activity with the increase of salinity. Simulations were done for constant influent composition, corresponding to the measured average values.

Table 1. Estimated values for the half-saturation constant of the inhibition term

Inhibition term	**$K_{Inh,50}$ (g NaCl/L)**		
$\frac{K_{Inh,50}}{K_{Inh,50} + S_{Inh}}$	Ammonia oxidizing Bacteria	Nitrite oxidizing bacteria	Heterotrophic organisms
	24.8	21.7	44.3

RESULTS AND DISCUSSION

The calibrated kinetic parameters of heterotrophic bacteria ($\mu_{max,H}$ of 6 d^{-1} and storage rate constant (k_{STO}) of 8 d^{-1}) were similar to those from previous research works modelling AGS with ASM3. However, the calibrated values of nitrifying bacteria ($\mu_{max,A}$ of 0.18 and $\mu_{max,N}$ of 0.10 d^{-1} for AOB and NOB, respectively) were lower than the reported ranges of 1.1 – 1.3 and 0.9 – 1.3 d^{-1} for $\mu_{max,A}$ and $\mu_{max,N}$, respectively (Ni et al., 2008; Zhao et al. 2016). This difference was mainly attributed to the presence of salt, combined with other factors such as a high biomass retention in the reactor, which can cause a shift in the community composition towards slow-growing nitrifiers.

The addition of the non-competitive inhibitory term to the model could accurately predict the effluent concentrations of organic matter and nitrogen compounds with different salinities during calibration (13 g NaCl.L^{-1}) and validation (5 g NaCl.L^{-1}) (Figure 1, 2). Regarding the biological activity inhibition, heterotrophic bacteria were the least affected by the presence of salt. The biological activity was reduced with 23 and 10 % under salinity conditions corresponding to calibration and validation, respectively. The activity of both AOB and NOB suffered higher reductions, especially with salt concentrations of 13 g NaCl.L^{-1} (34 and 27% reduction for AOB and NOB, respectively), showing a higher sensitivity to the increase of salinity.

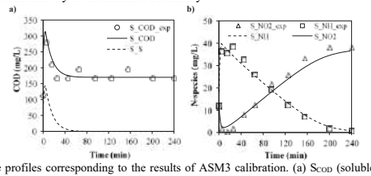

Figure 1. Cycle profiles corresponding to the results of ASM3 calibration. (a) S_{COD} (soluble COD) and S_S (soluble readily biodegradable COD) profiles predicted with ASM3; and S_{COD} profile from experimental data. (b) S_{NH} and S_{NO2} profiles predicted with ASM3; and S_{NH} and S_{NO2} profiles from experimental data.

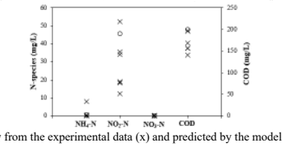

Figure 2. Effluent quality from the experimental data (x) and predicted by the model (○) during validation.

Nevertheless, the model was tested with low- to moderate salinities (< 15 g NaCl.L^{-1}), and further research is needed to validate it with a wider range of salt concentrations (20-40 g NaCl.L^{-1}).

Abstract
Safe water reuse requires the development and implementation of new strategies for microbial risk control in WWTP. Digitalisation and implementation of pathogen sensors are potential tools for WWTP operators to ensure safe water reclamation practices from public health and environmental perspectives. A machine learning model trained by real-time and analytical data has been developed to predict changes in the quality of reclaimed water. Local microbial risk control has been improved through the development of photonic biosensors for *Escherichia coli* and *Cryptosporidium* targets. Removal rates of pathogens in WWTP, including virus, are close to the values requested in the new regulation for safe water reuse in agriculture but further treatment is required for full viral particle removal.

Keywords (maximum 6 in alphabetical order)
digitalisation; machine learning; photonic; reclaimed water; sensors; WWTP.

INTRODUCTION

Water scarcity is among the top of the consequences of climate change and the increase of worldwide population. By 2030 the demand of freshwater will be 2680 km^3 over the available volume for supplying purposes on Earth (WRI, 2020). Also, in some regions such as the Mediterranean a 11% reduction of water resources by 2060 is expected (IPCC, 2022). In Europe, the Regulation on minimum requirements for water reuse will apply from June 26th, 2023, on. Microbial risk control will require measurement of bacteria, virus, and protozoa. Besides, risk management plans are required to protect health and environment. However, current methods for microbial control in WWTP are slow (2-3 days) and data management of reclaimed water quality is still at a low digitalisation level.
Alternative strategies for water reuse management are required. The aim of this work is to develop an innovative digital platform for managing the quality of reclaimed water based on microbiological parameters combining artificial intelligence and new microbial sensors. The novelty of this project relies on (i) the use of photonic technology in combination with immunoassays for high-specificity detection of pathogens in treated water and (ii) the application of artificial intelligence techniques to develop indicators of reclaimed water quality decay for WWTP managers.

MATERIALS AND METHODS

WWTP plant and microbial quality monitoring

The project was carried out in Castelló de la Plana WWTP which treats 45,000 m^3/d of urban wastewater. Five monitoring points were established: (P01) WWTP influent, (P02) Reclaimed water, (P03) UV influent, (P04) UV effluent and (P05) chlorination labyrinth. A probe for indirect measurement of E. coli (Proteus, UK) was installed in P05 for data analysis and machine learning model development. Microbial risks are being evaluated against UNE-EN-ISO 9308-1-2-3; UNE-EN ISO 10705-2; and EPA Method 1622 standards for *E. coli*, bacteriophages, and *Cryptosporidium*, respectively.

Photonic sensor

An IoT-sensor based on photonic technology has been developed for simultaneous detection of specific viable bacteria (*E. coli*) and protozoa (*Cryptosporidium*) in WWTP inlet and outlet samples (Figure 1). The sensor implements photonic readings over Photonic Integrated Circuits (PIC) with fixed antibodies for pathogen targets detection and quantification. The photonic system consists of: (i) a microfluidic cartridge that integrates the biofunctionalized PIC and the microfluidic structures; (ii) a biosensing platform that includes the read-out subsystem, optoelectronics and fluidic elements, the signal processing software and user interface. This system carries out the full measurement procedure automatically without any human intervention and is connected to the data lake for later analysis.

Data treatment and Machine Learning

Along with the analytical data from laboratory or biosensor, 7 years real-time operational data has been collected for the development of predictive analysis using machine learning techniques. Summarizing, 47 variables have been analysed. The stated hypothesis was that combination of real-time and laboratory data could predict changes reclaimed water quality in terms of *E. coli* indirect measurement (turbidity, tryptophan parameters). Retrieved data was filtered and transformed before linear and order correlation analysis. Models such as Ridge, SVM or XGBoost were applied. The resulting prediction was dockerized and implemented in the data lake for data exploitation.

RESULTS AND DISCUSSION

Predictive digital platform for water reuse management

A data model for water reuse management combining real-time from WWTP and analysis data from the photonic sensor and laboratory was established. The geospatial reference of the inputs and data allowed the application of artificial intelligence analysis combining both datasets. Several significant correlations were obtained. Best predictive model for reclaimed water quality in terms of turbidity was based on XGBoost algorithms (R2=0.41) (Figure 2). But predictions were not accurate for *E.coli* (R2=-0.04). It can be concluded that establishing a predictive model is possible but higher accuracy is required for predicting *E. coli*. This would be possible through the increase of *E. coli* measurements in WWTP effluent with the developed photonic sensor. However, high sensitivity of this biosensor for effluent would be required (below 10UFC/100mL).

Microbial risk monitoring and photonic biosensor

Microbial risk control in treated water was performed through log10 removal values as shown in Figure 3 for *E. coli*. Treated water quality meets the legal requirements (*E. coli*<200 UFC/100mL and log10 removal>5). The sensor could detect this pathogen in values with a difference of 1 or 2 log10 values compared to the laboratory measurements. Further training of the sensor is needed and will be performed in the following months to increase accuracy. Also, further work is being carried out to evaluate detection of *Cryptosporidium* oocytes (data not shown).
The extended analysis of virus revealed different levels of coliphages, rotavirus, norovirus (GI and GII) and crAssphage in WWTP effluent (Table 1). Highest removal rates were observed for coliphagues (log10=4) meeting the legal requirements. It should be highlighted that the rest of the virus were analysed using DNA/RNA detection techniques. Thus, infectivity capacity complementary analysis should be carried out to fully evaluate the risk of viral presence in reclaimed water after WWTP treatments.

ACKNOWLEDGEMENTS

This project has been co-financed by the Valencian Innovation Agency (AVI), under file number INNCAD/2021/95-96-101 and the entities of the Valencian Community participate in it: Sociedad de Fomento Agrícola Castellonense S.A. (FACSA), Lumensia Sensors S.L. and Eurofins Iproma and has the collaboration of the Castelló de la Plana City Council. PhD Gloria Sánchez research team from IATA-CSIC (Spain) is fully acknowledged for extended virus analysis in samples. Joan García Esquerdo from Instituto Tecnológico de Informática (ITI) Valencia (Spain) is also acknowledged for data analysis.

Abstract
Nutrient pollution is the most prevalent global water quality issue. Nitrite (NO_2^-) and nitrate (NO_3^-) are considered nutrient pollutants and they play a key role in wastewater treatment. The established approach for the monitoring of these nutrients is manual sampling and laboratory analysis. Up to this point, real-time selective and accurate monitoring data of NO_2^- and NO_3^- in the sector has not been available. Using Aquamonitrix, a novel real-time *in-situ* NO_2^- and NO_3^- monitoring analyser, a new set of data can be obtained from activated sludge (AS) and final effluent from wastewater facilities. The system delivers lab-based analytical performance in the field. In this work, we report real-time *in-situ* nitrite and nitrate data from aeration tanks and final effluents of several wastewater treatment facilities. This level of *in-situ* analysis performance had not been previously available within the wastewater treatment sector. The delivery of this new dataset creates opportunities to control processes in a way that has not been possible before. Using this data there is potential for processes to be optimised to achieve energy savings by improved understanding of the aeration process, to potentially reduce nitrous oxide (N_2O) emissions and to improve management of nutrient pollution from wastewater treatment facilities.

Keywords (maximum 6 in alphabetical order)
Activated Sludge, *In-situ* monitoring, Process Control, Wastewater Treatment

INTRODUCTION

Environmental water quality has been heavily impacted due to growing global population and development of anthropogenic activities and industry. The most prevalent global water quality problem is nutrient pollution [1]. These pollutants are key parameters when considering wastewater treatment and management. At present, their monitoring predominantly consists of manual sample collection which is then transported for laboratory analysis. This method has drawbacks including cost and results are only available typically several days after sampling. This leads to the possibility of pollution events being missed and provides only limited information on the real time status of processes.

In recent years, significant progress has taken place in the field of *in-situ* analysers to improve established approaches. In this work, for the first time, a new set of data which has not been previously available in the sector is provided using Aquamonitrix, a novel technology platform for real-time selective *in-situ* monitoring of NO_2^- and NO_3^-. The system delivers lab-based analytical performance in the field and examples of this performance are reported. The system was deployed in several facilities were it successfully delivered real-time *in-situ* NO_2^- and NO_3^- data from activated sludge (AS) and final effluent.

MATERIALS AND METHODS

Automated *in-situ* nitrite and nitrate analyser

The Aquamonitrix deployable nitrite and nitrate analyser (Figure 1) was utilised in this work. The system employs rapid ion chromatography with a 235 nm LED-based absorbance detector module for selective detection of both nitrite and nitrate [2, 3]. The portable ion chromatography (IC) configuration used an eluent of 120 mM sodium chloride, so the analyser is environmentally friendly and does not use or generate any hazardous materials. The analyser included an internet-of-things (IoT) module to allow for real-time communication of concentration data and remote management of the system. Several systems were deployed within the aeration tank of a wastewater treatment facility in Ireland and within the aeration tank and final effluent of a wastewater treatment facility located in the UK.

Figure 1. Aquamonitrix real-time *in-situ* NO_2^- and NO_3^- analyser. The exterior dimensions of the unit are 60 × 37 × 27 cm and the unit weighs ~ 11 kg.

RESULTS AND DISCUSSION

The *in-situ* analyser has been assessed and verified for application within wastewater treatment facilities through analytical performance trials designed according to ISO 14034:2016 Environmental Technology Verification (ETV) standards. The analyser was deployed within septic tank water for a one-month trial led by the US EPA. The analyser was also deployed within final effluent of a Scottish Water facility for 3 months. An example of the typical analytical performance of the system in wastewater applications is illustrated in Figure 2. The average accuracy achieved by the system is ca.95% and an average precision of ± 5% is typically achieved.

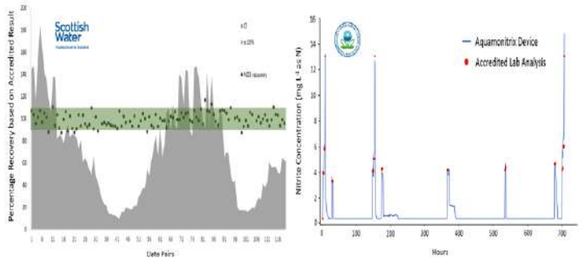

Figure 2. Demonstration of Aquamonitrix accuracy and precision in wastewaters. (Left) Accuracy assessment for Nitrate monitoring in wastewater effluent carried out by Scottish Water. The salinity of the wastewater varied yet accuracy was >90% throughout the 3-month deployment. (Right) Nitrite performance results from one-month verification monitoring within septic tank water performed by the US EPA. An accuracy of >95% for nitrite in septic tank water was obtained for the one-month deployment.

The real-time *in-situ* nitrite and nitrate analyser was deployed in a wastewater treatment plant in Ireland and in the UK for the analysis of AS and final effluent. An example of the real-time data generated is shown in Figure 3. The deployment delivered a level of *in-situ* analytical performance that has not previously been available within the wastewater treatment sector. No other analyser to this point has provided real-time nitrite and nitrate data which can be remotely accessed from ASP. The system provides advantages over the established approach of manual sampling and laboratory analysis, including the use of non-hazardous or toxic solutions; real-time *in-situ* data while delivering laboratory-analytical performance results.

The availability of this new set of data creates opportunities to optimise processes within the sector. The monitoring of final effluents in real time will aid to identify pollution events and mitigate or prevent them by taking immediate action. Aeration consists of a multi-step biological conversion of ammonia to nitrogen gas in which nitrite and nitrate are intermediates. Through real-time nitrite and nitrate data, an improved understanding of the nitrification and denitrification status within the aeration process could be enabled. This could facilitate improved process control towards the mitigation of N_2O emissions from wastewater treatment plants. Also, automation and linkage between aeration and NO_2^- is key to maximise energy savings. Monitoring of these nutrients in real time in ASP could potentially help to optimise the aeration process and save energy costs since up to 50% of energy consumption in wastewater treatment plants is attributed to aeration in ASP, being the single-most energy-intensive operation of the treatment.

Abstract
The search of appropriate predictive methane production models is a high priority to optimize anaerobic co-digestion in wastewater treatment plants. The methodology involved included the comparison between two regression machine learning models (Random Forest and Support Vector) and one metabolic model (Modified Gompertz) applied using pig manure as co-substrate in laboratory scale digesters fed discontinuously. The use of machine learning models allows predicting biogas production in systems with pig manure co-digestion The model with the best fit in this study was the Vector Support Regression model with 77% adjustments.

Keywords (maximum 6 in alphabetical order)
Anaerobic digestion; co-digestion; machine learning; methane prediction; pig manure

INTRODUCTION

In Europe about of 216 million tonnes of pig manure are produced yearly (Foged et al., 2011). This waste is estimated to have a potential methane production rate by anaerobic digestion around 0.25-0.5 Nm^3CH_4 per kg of volatile matter (Steffen et al., 1998), which results in an energy production of 165 GWh that is enough for supplying energy to 30 million people. The digestion of pig manure can be done in wastewater treatment plants (WWTP) as co-substrate in order to make good the existing digesters.

Machine learning (ML) is a data driven method for modelling that considers processes as a black-box models from input and output measurements, thereby facilitating prediction capability based on observations (Rudin, 2019). Thus, the implementation of this type of models is an effective way to predict and determine biogas production (Tufaner and Demirci, 2020) and, therefore, to optimize anaerobic co-digestion process (Jeong et al., 2021) by facilitating the decision-making process (De Clercq et al., 2019). Despite this, automated control strategies have not yet been successful implemented, so ML-based models have emerged as promising tools for prediction and decision-making for anaerobic co-digestion process.

The goal of this study is to develop a model based on ML for the improvement of methane production in the co-digestion of pig manure and sewage sludge in WWTP by the prediction of biogas production. To achieve this, Modified Gompertz, Random Forest (RF) and Support Vector (SVR) regressions were applied to a data set obtaining from discontinuous laboratory scale reactors and compared.

MATERIALS AND METHODS

Raw data collection

Every quarter of hour methane production was collected from six 1 L digesters (35 °C), three inoculated with adapted digestate to pig manure as co-substrate (SA) and three with non-adapted one (SNA). Organic matter (COD and volatile solids) and ammonia concentration were measured twice a week. All digesters were fed three times a week with a mixture of primary and secondary sludge (weekly total of 0.8 $kgVS/m^3$ digester), one SA and another SNA were fed three times a week with pig manure to a weekly total of 0.5 $kgVS/m^3$ digester and one SA and one SNA were fed once a week with pig manure at 0.5 $kgVS/m^3$ digester.

The data set obtained from the instantaneous flow produced in the laboratory digesters was 265 days

Models applied

The study applied both metabolic and regression models to predict methane output. To explore which models could most accurately predict methane production, the parameters of the Gompertz functions were based on empirical data from batch trials and tested. The ML algorithms (RF and SVR) were trained and tested with data recorded continuously and separated in training set and test set. Modified Gompertz assumed that the biogas production kinetics have a correspondence to specific growth rate of methanogens and in this study was evaluated based on root square error (R^2). On the other hand, RF is a non-parametric statistical method that permits regression and classification problems and SVR tries to find a hyperplane in the feature space that divides different categories of observations to the largest separation. Both, RF and SVR, were evaluated using the R^2 correlation coefficient.

RESULTS AND DISCUSSION

The application of the modified Gomperz model had an initial RMSE fit of 0.977, however, this fit decreased over time until 0.542, evidencing the need to recalculate the parameters frequently. The RFR model showed a fit of 0.756 and the fit obtained for the SVR model was 0.776.

Abstract

This abstract introduces the advances to bring a drone-based chemical monitoring system to a more mature technological level within the framework of the SNIFFIRDRONE project. To improve the temporal resolution of our monitoring system we have reduced the chemical sensor chamber to a point of having only 25 mm^3 per single sensor cavity. This will dramatically reduce the air mixing effect of the chamber allowing for a better temporal resolution of the measurements. As a case study, we performed a measurement campaign in Torredembarra wastewater treatment plant. This preliminary results show the locations where the emissions of H_2S and NH_3 are higher.

Keywords
Drone-based monitoring, Chemical sensing, odour mapping, wastewater treatment plant

INTRODUCTION

In this work, we present a drone-based pollution and odour monitoring system for wastewater treatment plants. We will focus on the advances to bringing our current system [Burgués et al., 2022] to a more technologically mature status within the framework of the SNIFFIRDRONE project. The main objectives of the project are three. First, development of a high-performance multi-gas NDIR sensing unit that will allow a faster measurement of relevant chemicals such as H2S and NH3. Second, generation of a map of the environmental chemical emissions of the wastewater plant. Third, generation of a second map of the environmental odour within the plant. We use a machine learning model to predict the odour generated.

Our current system is composed by a Matrice 600 DJI drone equipped with a custom made IOMS with 21 chemical sensors and an air sampling system. The challenges we face to increase the Technology Readiness Level of the system to TRL7 are the following three: (1) Increasing the temporal resolution of measurements, (2) improving the system robustness, and (3) obtaining enough experimental data to train and validate the odour prediction models.

MATERIALS AND METHODS

We must consider two main factors that limit the temporal resolution of the measurements (1): the measuring time of the sensors and the volume of the sensor chamber. The measuring time of the sensors will be reduced with the new NDIR multi-gas sensor unit. On the other hand, the sensor chamber limits the temporal resolution of the measurements due to its air mixing effect. It mixes the air accumulated into the chamber in a certain time period before the measurement. As a result, we are measuring an accumulated concentration during this time period instead of the specific time measurement we are seeking. Considering that the length of this mixing time period is proportional to the volume of the chamber, we vanish this effect by reducing considerably the chamber volume. In Figure 1(b), we can see the design of the new sensor chamber where the volume has been reduced to 25 mm^3 of a single sensor cavity when in the previous chamber [Burgués et al., 2021] was 96 cm^3 for the total sensor chamber. The compact and design of the new chamber that includes all needed electronics attached to it makes the system much more robust (2).

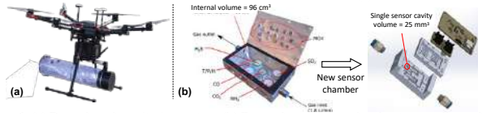

Figure 1. (a) Drone-based monitoring system. (b) From a larger sensor chamber to a smaller and more robust chamber design

RESULTS AND DISCUSSION

To collect enough data (3) within the SNIFFIRDRONE project we have planned 9 campaigns during the summer of 2022, 2023, and 2024. Figure 2 shows results obtained in measurements in Torredembarra WWTP during summer 2022. Overlaid on top of the plant map, we have the measuring path followed to cover the plant extension. The sensor responses show a clear increase on NH_3 and H_2S at $t \cong 1950$ s as we get close to the pre-treatment building (white building bottom left). There is also a lower-level signal, more noticeable in the MOX sensors, at $t \cong 1250$ s as we pass by the bioreactors. These preliminary results show that the concentration levels of H_2S and NH_3 are very low around all the plant except mostly in one location, around the pre-treatment building.

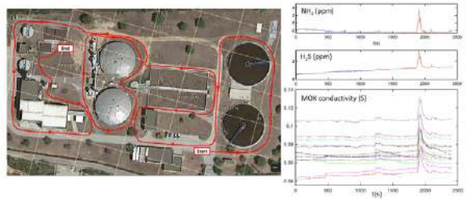

Figure 2. Measuring campaign in Torredembarra wastewater treatment plant

AGREEMENTS

This project has received funding from the European Union's Horizon 2020 research and innovation program under Grant Agreement No. 101004462.

Abstract
The monitoring of the emission of gases from wastewater facilities and their impact is a necessity to have preventive and corrective measures that are best adapted to each focus or nuisance, always seeking the greatest efficiency and sustainability. This study, carried out in the wastewater facilities of Torredembarra, in Catalonia, Spain, aims to predict the H_2S concentration using Artificial Intelligence (AI) and Machine Learning (ML) tools, such as Neural Networks, Linear and Nonlinear Regression.

Keywords
Artificial intelligence; hydrogen sulphide; machine learning; neural networks; prediction; wastewater treatment plant

INTRODUCTION

Wastewater treatment plants (WWTPs) are considered important sources of gaseous emissions, including greenhouse gases (GHG) and odorants (Shaw and Koh, 2018). Malodours causes several negative impacts such as: (i) complaints and discomfort around pumping stations, network sewages and WWTP; (ii) reduction in property and real estate value; (iii) labour risks for operators; (iv) corrosion of exposed equipment and facilities. Hydrogen sulphide (H_2S) is the most important of all odour compounds generated in WWTPs and sewage systems (Vincent y Hobson 1998).

Depuración de Aguas del Mediterráneo (DAM) participates together with BGEO in the analysis of odoriferous gases and how they are influenced by variables such as temperature, retention time, humidity and flow, among others.

The study aims to predict, through Artificial Intelligence (AI) and Machine Learning (ML) tools, the H_2S emissions in a particular section of the wastewater facilities (Zounemat-Kermania et al., 2019), in order to efficiently minimise the release of this pollutant downstream.

MATERIALS AND METHODS

The project will be carried out in the facilities of Torredembarra (Tarragona, Spain) through the following stages:

(i) Research of odoriferous gases, their generation and emission. This will allow finding out the main compounds that cause bad odours and the main gas emission points in the facility. At this stage, an optimal AI algorithm for this real case will be proposed.

(ii) Selection of the case study, variables to monitor and installation of the equipment for data collection (Table 1) and assembly of the database. A database will be generated with, at least, one month of data.

(iii) Design, assembly and train the prediction algorithm.

Table 1. Device and sources used for the study

Device/Source	Parameter	Units	Location

Ijinus LOGAZPRO-200X-H2S-8X	H_2S gas	ppm	EBAR General
National station	Sea level height	m	Tarragona station

RESULTS AND DISCUSSION

Predicting hydrogen sulphide generated in WWTPs and sanitation networks could be a challenge for Machine Learning algorithms, since a wide variety of interfering chemical compounds and other environmental factors are also involved. Currently, three weeks of data is being collected and a recurrent neural network will be used for the prediction of the gas between the last pumping station and the entrance of the WWTP.

At the end of this work, it is expected to achieve predictions of H_2S in liquid or gas at a given point, at least one hour earlier (less than the hydraulic retention time from the start to end point). It will be possible to optimise the actions to minimise the pollutant emissions and anticipate possible odorous impacts in the facility surroundings.

AGREEMENTS

The study described in this paper is part of a research project called atmosphAIr (AEI-010500-2022B-8), coordinated by the Catalan Water Partnership (CWP) and financed by the Ministry of Industry, Trade and Tourism of Spain under the Innovative Business Groups support program (AEI) in the frame of the NextGeneration EU - The Recovery and Resilience Plan.

The entire project seeks to predict and mitigate emissions of both odorous gases and greenhouse gases in sanitation networks and wastewater treatment plants. A consortium made up of the CWP itself, DAM, ACSA, Obras e Infraestructuras, SAU (Sorigué Group), BGEO OPEN GIS S.L, AERIS Tecnologías Ambientales S.L. and SPIN S.A participate in the project.

Abstract
The methane generation rate and the biodegradability index (BI) of agri-food residues and manure in digesters at different temperatures were determined. In this study the biochemical methanogenic potential (BMP) of the residue according to its composition was compared with the empirical BMP determined by batch tests. Subsequently, these empirical tests were modelled with two methodologies: first-order kinetic model to determine the degradation constant of the residue (obtaining kSA of 0.73-0.87 and kSNA of 0.80-2.07d-1) and through the use of sigmoidal model to calculate the lag phase (λ) and the maximum rate of methane production (Rmax), obtaining lag phase values λSA of 0.02-0.08 and λSNA 0.01-0.02d-1.
The results showed that this type of residue can be valorised in WWTP anaerobic digesters prior to acclimatization, obtaining BISA of 75.4-76.7% and that both modelling methodologies enable the simulation of methane production over time.

INTRODUCTION

The energy consumption in wastewater treatment plants (WWTPs) varies depending on volume of water treated, organic load and the type of treatment technology used and it is estimated to entail in typical WWTPs between 25 and 40 % of total operating costs (Panepinto et al., 2016). This value varies between the range of approximately 0.3-2.1 kWh/m3 of treated wastewater (Gandiglio et al., 2017). Albadalejo et al. (2014) concluded that the energy consumption increases in an exponential way while the size of WWTP decreases, from values of 0.286 kWh/m3 of wastewater treated in facilities for the treatment of 200,000 population equivalent (p.e.) to 2.807 kWh/m3 of wastewater treated for the treatment of 250 p.e. In addition to the economic costs for the use of energy, which in the current context are increasing, the use of energy in WWTP, mostly from fossil sources, causes the emission of 27 million tons of CO2 in the EU (Lotti, 2016). On the other hand, Spain produces 22% of all pig heads in the EU (Foged et al., 2011), which implies the need to manage approximately 36,083 miles of tons of manure per year, that have the potential production of 992 million cubic meters of biogas by anaerobic digestion, which represents 1.2% of the annual production of natural gas. This biogas production have to be summarized to the annual energy production from wastewater that it is estimated in 11,062 GWh. In this context, the present work proposes the application of the concepts of the circular economy in the treatment of agri-food waste and pig manure through their co-digestion in WWTP digesters. Thus, a circular solution is proposed for the waste generated while obtaining renewable energy.

The anaerobic digestion process can be carried out in a wide range of temperatures. Within the same system, methane generation rates will depend on the optimum temperature of the microbial population present. Despite the advantages of co-digestion in WWTP, co-digestion of agri-food waste can cause overloads and acidification of the system. On the other hand, the codigestion of manure presents a series of challenges, such as: i) inhibition due to a high concentration of ammonium, ii) high alkalinity content of the pig manure, iii) inhibition due to a high metal content and iv) inhibition of the process by the presence of antibiotics. For this reason, in this work the effect of the digestion temperature of agri-food waste and pig manure in WWTP digesters on the kinetics of methane production has been evaluated.

MATERIALS AND METHODS

Experiments were carried out in batch at laboratory scale in Automatic Methane Potential Test System, AMPTS II (Bioprocess Control, Sweden) using an inocula adapted to manure degradation from WWTP digester. The assays were conducted for the determination of kinetics constants with five replicates at four different concentrations (0.25, 0.5, 1 and 2 kg volatile solids (VS) of pig manure/m3) plus blank at mesophilic conditions (35 °C). The experiments were finished when the instantaneous methane production matched that of the blanks.

The determination of the theoretical methanogenic potential was carried out based on the nutritional composition of the pig manure, and for the determination of the degradation kinetics, first-order kinetics were assumed for hydrolysis and Monod kinetics for the semi-saturation constants. The determination of the lag phase was made using the modified Gompertz model.

The statistical indicators correlation coefficient (R2) and root mean square error (RMSE) were used to assess the mathematical adaptation of applied models and t-student tests were applied to evaluate the fitting of the results obtained for the different organic loads and parameters obtained with the studied models.

Digital Twin, BIM, Monitoring, modelling, sensors, sewers, Combined Sewer Overflow (CSO)

INTRODUCTION

Digital twins are a combination of models and real-time data that provide a digital representation of the behaviour of the water systems or part of its, being the main advantage of the digital twins is to improve the performance of the infrastructures.
The purpose of the project "Digital Twin at Consorci Besòs Tordera (CBT) is to generate a single Centre of Operations of all the facilities that be capable to collect, organize and analyse all the information in a single place through a digital model of the physicals installations for each sanitation system of CBT capable to reproduce simulations, integrations, testing, monitoring and maintenance, etc.
In this work, the develop of the operational decision support is focused to improve the control of combined sewer overflows (CSOs) in a sewer systems and proactive maintenance and process optimisation of a Waste Water Treatment Plant (WWTP).
The Consorci Besòs Tordera (CBT) is a Local Water Authority founded in 1988, with the main objective is to conserve the water quality of the Besòs river to guarantee the fish life on it. Among the activities of the CBT is the management, operation and maintenance of the water sanitation facilities, made up of a set of 27 WWTPs, 300 km of sewer pipes and 52 pumping stations.

METHODOLOGY

Since 2020, the CBT started the implementation of the Digital Twin, where was proposed a conceptual scheme as shown in the Figure 1, where the methodology was defined accord the process of the water cycle. Furthermore, once the structure of Digital Twin will be possible to optimization the systems, have energy saving, improve the quality of water and inform the citizen.
The implementation of the Digital Model was selected as a pilot case the WWTP located in Caldes de Montbui. The WWTP is designed to cover a population of 30,000 equivalent inhabitants, with a daily flowrate of 6,000 m³ and it collects the wastewater from the municipality of Caldes de Montbui that has 12,10 km long of sewer network.

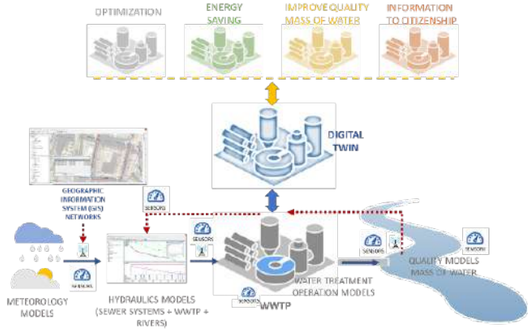

Figure 1. Basic Structure of Digital Twin Application in the ambit of CBT.

The first Digital model developed as BIM model was been the WWTP of Caldes de Montbui as shown in the Figure 2, where this model has a 3D repository of each element. In order to have a BIM model active to navigate, was necessary to generate a protocol of the general approach to combine different software's as asset management, management of sanitary systems, GIS, and SCADA (Riera i Llordella et al., 2022).
The use of 3D models will make it possible to have updated graphic information on the installations, which will include all the modifications/extensions made to the installation throughout its useful life.

Figure 2. Building Information Modelling (BIM) of WWTP of Caldes de Montbui.

In order to avoid using different software to obtain specific data, and to avoid having the same duplicate data in two different databases, the CBT has decided to create a digital twin through a middleware platform that ensures correct integration between the 3D models and management software (Figure 3). The middleware platform generates a central database and collects the information from all the software that is in the solution to feed said database. With this middleware platform, it will be possible to guarantee the bidirectionality of the information.

Figure 4. Relation of software's in the Digital Twin of CBT

The integration between BIM model and platform of Middleware was using the software ecodomus as shown in the Figure 5, with this result is possible to navigate and consult the characteristics and maintenance of each element.

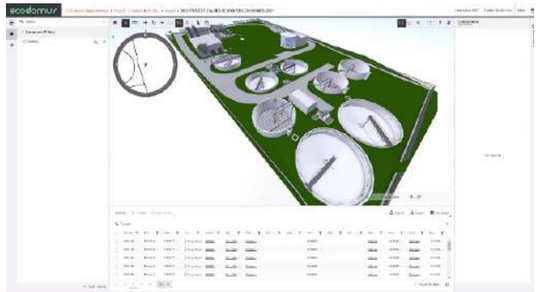

Figure 5. Relation of software's in the Digital Twin of CBT

In parallel, this study presents a methodology for outfalls' monitoring of Combined Sewer Systems (CSS) for the sewer network managed by Consorci Besòs Tordera (CBT), in the framework of the projects MIMER (Intelligent Discharge Monitoring to Receiving Environment using Overflow Sensors) and SewMo (Sewer network Modelling in rain events). The pollution of receiving water bodies resulting from Combined Sewer Overflows (CSO), especially in rain events, is a problem to tackle in the cities' sanitation facilities management, which have a dramatic impact in the environment and hence, the quantification of the spilled volume and water quality during these events, as well as their periodicity, is of paramount importance.
This technical study proposes the analysis of methodologies to determine, estimate, quantify, categorize and minimize the episodes of discharges into the river. The purpose of this study is the reduction of the impacts of these discharges in the framework of the public sanitation systems managed by CBT —about 300 km of sewer network— in order to improve the quality of the receiving water bodies when CSOs during rain events occur (Tellez-Alvarez, et al., 2022).
Spanish Royal Legislative Decree (RD) 1290/2012 (MAAMA, 2012) established that companies and public institutions involved in urban water drainage services are compelled to monitor, detect and quantify direct discharges into the environment (Cosco et al., 2018). For this reason, methodologies such as the one presented here are essential, in order to fulfil the requirements of RD 1290/2012. Hence, for the last years CBT has been installing new sensors for monitoring and modelling the network in its ambit, especially in the outfall points [2], whilst also periodically reporting to the Catalan Water Agency (ACA) about instrumentation of the drainage network using overflows sensors (OS) and level sensors (LS), respectively, for several of the sanitation systems which manage.

RESULTS AND CONCLUSION

The digital twin is a tool for Decision Support for engineers and techniques capable to visualised quickly the effects of the systems, and generate real or future scenarios. Also, is possible to elaborate a comparison between model predictions and measured data which require particular attention by operators and maintenance staff, thus minimising their efforts.
In order to achieve the objective of reducing the impacts of the CSOs of CBT systems to the environment, the technical study presented here has been developed. Specifically, here the behaviour of sewer networks is studied in order to detect criticalities and reduce related additional pollution, thus improving the water bodies in the CBT ambit.
The objective of the Besòs Tordera Consortium is, sooner rather than later, to create the digital twins of all the managed infrastructures and gradually incorporate the other management software used by the organization (LIMS Labware, Eplan, etc.), so that all the information managed by this entity is in one place and is accessible from the digital twins.

Abstract
Quantitative image analysis can be used to predict dewatering related sludge properties such as settling velocities or sludge volume index. Morphological parameters such as particle length and area are common features extracted and used in predictive models such as partial least squares. Here we develop a framework where the particles are analysed by a pretrained convolutional neural network (CNN), reduced with principal component analysis, grouped with K-means clustering and used in a partial least squares or random forest model to predict reject suspended and total solids related to industrial decanters treating inactivated biosolids. The models with CNN features from the CNN model had an improvement of 8% and 15% for predicting SS and TSS respectively compared to clusters built on conventional morphological parameters.

INTRODUCTION

Microscopy techniques have long been used within the field of wastewater analysis for identifying biomass characteristics, viability, and composition. However, often the analysis of the microscopy information is labour intensive and requires a trained expert to distinguish for instance between different morphologies that could cause sludge bulking [1]. To automate the analytical procedure quantitative image analysis (QIA) and tools from the field of chemometrics have been combined. QIA applies a wide set of mathematical tools to segment images and obtain morphological parameters such as the length, area and circumference of particles present in the image which can be used to estimate sludge properties such as the sludge volume index (SVI). In recent years models from the field of deep learning (DL) such as convolutional neural networks (CNN) have excelled at computer vision (CV) tasks such as segmentation and classification. DL models represent end-to-end learning in the sense that they take the raw input image, generate features internally and relate the features to the output of interest [2]. The aim of this paper is to compare traditional morphological features with features obtained from a pretrained DL model in a transfer-learning (TL) approach. The features are compared in terms of their ability to predict reject quality in terms of turbidity which is deemed the best performance indicator of dewatering for the centrifugal decanters investigated here.

MATERIALS AND METHODS

Most of the studies on image characterization of sludge deal with activated sludge from municipal plants. Variations with operational impact are commonly obvious and significant [1]. Here we attempt to characterize inactivated biosolids to construct a semi-automated workflow for process monitoring and performance optimization of decanters from the largest industrial WWTP in Northern Europe located in Kalundborg (Denmark) which treats the wastewater produced at two biotech companies (Novozymes and Novo Nordisk). For a thorough description of the plant layout the reader is referred to our previous works [3-5]. Two measurement campaigns were conducted: A fall campaign from the 21st of September to the 8th of October 2021 and a spring campaign from the 28th of April to the 16th of May 2022. For each batch investigated in the two campaigns one feed sample of the inactivated biosolids was obtained, and three reject samples corresponding to 3 different polymer dosages -25%, mean, +25% where the mean polymer dosage is determined by the operators working a given shift. To obtain images that are not overcrowded a volumetric dilution factor of 20:1 is used. Since the operating pH affects the interaction energies of the particles observed in the image a sodium hydroxide solution is added after dilution so the pH is equal to the pH before dilution. The images were collected and processed off-line using a ParticleTech flow cell system and its corresponding software [6]. The morphological parameters for each particle were then recorded including: area, equivalent circular diameter (ECD), the minimum Feret diameter, the maximum Feret diameter, the mean Feret diameter, the Feret ratio, perimeter length, compactness, and circularity. For generating feature vectors, a pretrained image model such as a convolutional neural network is required. The Xception model is selected as such, optimising the trade-off between a high accuracy and a low computational demand [7]. Some of these features may be redundant – as the Xception model was trained on colourised photos, and these images are black and white. Principal component analysis (PCA) is commonly used for dimensionality reduction and in this case, it can create a more compact representation for our feature vectors by eliminating redundant variables which will speed up the clustering in the next step. Each sample photo has a different number of particles in it, and segmenting each will therefore yield a different number of particles and consequently a different number of feature vectors for each sample. For developing a model to predict reject turbidity a standard data-format is desired with an equivalent number of inputs per sample, and as such a transformation is required to go from a variable number of feature vectors per sample to a set number of feature vectors per sample. Clustering is a technique that groups similar observations into clusters and a cluster participation vector can be formed for each sample where each position in the vector represents the fraction of the total sample belonging to that respective cluster. A large variety of clustering algorithms exist and here we use K-means clustering. To predict the continuous reject solids content a regression tool is required such as partial least squares (PLS) or Random Forest (RF). For sludge characterization PLS is a widely used technique for regression, while RF has not been used thus far to the knowledge of the authors. In comparison to PLS, RF is a non-linear technique which may be able to outperform PLS if non-linear relationships are present in the data. **Figure 1** illustrates the proposed methodology.

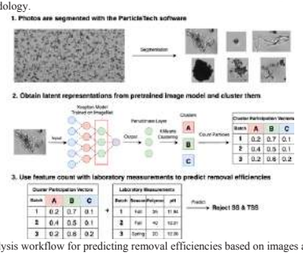

Figure 1. Analysis workflow for predicting removal efficiencies based on images and laboratory measurements.

RESULTS

Figure 2 shows the reject SS (g/kg) content for each polymer dosage for each batch. For each batch, a second order polynomial has been fit to visualize the apparent relationship between the polymer dosage and the reject quality in terms of SS. Theoretically all the response curves between polymer dosage and removal should be convex, since a concave curve implies that a negative SS measurement is possible, however since this is an empirical model with imperfect data that is not the case.

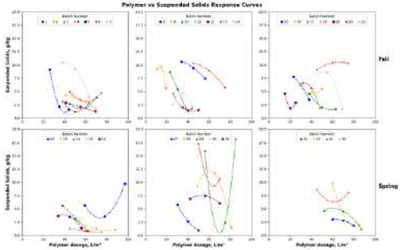

Figure 2. Measured suspended solids (g/kg) in the reject for a given polymer dosage. Each parabola corresponds to a polynomial fit between the three reject samples collected for each batch. The top and bottom plots are for fall and spring sampling campaigns respectively.

10.000 segmented photos randomly sampled from all the batches are fed through the Xception model to obtain a feature vector from the penultimate model layer for each. These feature vectors are reduced into principal components (PCs) by PCA. Before applying PCA the vectors are standardized by subtracting the mean and dividing by the standard deviation, and the variables in the obtained feature vector that are constant are removed reducing the size of the vectors from 2048 to 1731 elements. A threshold is selected where 99% of the variance is retained which corresponds to 1276 principal components, i.e., a dimensionality reduction of approximately 40% from 2048 to 1276. After the threshold of 1276 PCs is found K-means clustering is performed in conjunction with the supervised pipeline where the reject SS and TSS values are predicted. Three sets of independent variables are constructed. (i) the cluster participation vectors based on the Xception feature vectors, (ii) the mean of the morphological parameters for a sample, (iii) a cluster participation vector based on the morphological parameters. All three contain the laboratory measurements of pH of the sample taken, the adjusted pH after dilution, a continuous polymer dosage, a categorical polymer dosage, and a binary variable indicating which campaign the sample is taken from (seasonality). For each dataset a RF and PLS model is created which is trained and validated through leave-one-out cross-validation on a training set consisting of 24 of the 35 batches (covering both fall and spring campaigns) at random. This procedure is repeated 10 times with a different subset of batches each time. The performance is then evaluated in terms of a mean of root mean square errors (RMSE) on the 11 batches not used for training and validation over the 10 repetitions. This workflow is performed for different numbers of clusters to evaluate the best number of clusters for predicting reject SS and TSS. The number of clusters evaluated varies from 1 to 25. Figure 4 shows the RMSE for predicting SS and TSS in the reject as a function of the number of clusters used to characterize the obtained images.

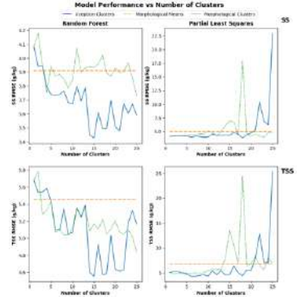

Figure 3. Performance of models as a function of the number of clusters used to characterize the images. Models predicting SS and TSS are depicted in the top and bottom row respectively, and RF and PLS models are depicted in the first and second column respectively.

Table 1. Average RMSE on an independent test set, standard deviation of RMSE, and the number of clusters associated with the given model. For predicting SS and TSS the models built on Xception clusters with RF and PLS are best respectively. The two best models are marked with asterisks.

	SS		TSS	
Reject	**RF**	**PLS**	**RF**	**PLS**
Xception Cluster	3.43 (0.51), 15*	3.82 (1.04), 18	4.55 (1.07), 15	4.33 (0.72), 10*
Morph. Mean	3.91 (0.47), 1	5.04 (1.73), 1	5.46 (1.01), 1	6.73 (3.51), 1
Morph. Cluster	3.73 (0.55), 25	3.98 (0.99), 23	4.83 (1.24), 25	5.08 (1.10), 2

Discussion

Estimating recovery in centrifugal decanters from laboratory measurements is difficult as the operation of the machine has a great influence and is unaccounted for in most methodologies that try to extrapolate from lab scale to full scale dewatering in decanters [8]. We postulate that the setup would see similar if not better results if applied to estimation of settling velocities or capillary suction time instead of reject quality in centrifugal decanters, and the methodology presented here can easily be adapted to other industrial or municipal systems for biomass characterisation and prediction of settling properties.

Conclusion

We present a new framework for utilising the power of DL vision models to extract features and track species in inactivated biosolids and relate said features for predicting reject quality in an industrial setting. The features outperform the conventional approach with morphological parameters, and we postulate that this can generalise to other QIA applications for predicting settling velocities or capillary suction time. An example of generating the utilised features from a sample of the used photos is freely available at the wwtmodels Github repository.

Abstract
The optimization of treatment processes in wastewater treatment plants (WWTP) is crucial to achieve environmental goals and reducing energy and reagents consumptions, while preventing harmful biological events. While Industry 4.0 and proactive control approaches have shown promising potential, there is still a gap between the classical reactive solutions, still common in plants, and state-of-art developments. HADES is a project aiming to this gap with the development of a digital twin as a decision support tool for WWTP operation that includes advanced control features for the optimization in terms efficiency, reliability, and compliance, while preventing events such as foaming, bulking, deflocculation, and greenhouse gases emission. The HADES solution core combines mechanistic, hybrid, and heuristic models to perform as virtual sensor, bench test for optimized control strategies based on model predictive control, and prediction of biological events. In this paper the project HADES and the first findings are presented.

Keywords (maximum 6 in alphabetical order)
Decision support system; knowledge-based models; model predictive control; risk models; wastewater treatment

INTRODUCTION

Wastewater treatment plants (WWTP) are energy-intensive and consume notable amounts of reagents. Plants are also affected by weather conditions and hard to predict and revert biological events that can disrupt operation, such as deflocculation and foaming. Optimizing WWTP operation is crucial to meet environmental goals, lower costs, and maintain the process stability.

Despite the potential benefits of technological advancements and global trends around the digitalization of processes, the literature suggests a slow adoption of Industry 4.0 technologies and solutions with proactive approaches for optimizing WWTP operation. Among them, digital twins (DT), which popularity has exploded in the last few years (Pedersen et al., 2021) due to their wide range of applications and potential to change operational strategies for utilities and the design processes (Torfs et al., 2022), and optimize energy and resource consumption, environmental protection (effective and efficient treatment processes), and societal benefits (IWA 2021a).

Other solutions include the use of advanced control approaches, like model predictive control (MPC), and the use of heuristic models to predict risks of harmful biological phenomena and emissions of greenhouse gases. Classical control solutions, such as PI/PID, which are still the common practice in WWTP, struggle with the dynamic behaviour of influent, process changes and disturbances. Meanwhile, MPC-based solutions have shown to handle these conditions and interactions more effectively while optimizing WWTP operation, with promising results from previous studies (Steffens & Lant, 1999; Shen et al., 2009; Vrečko et al., 2011; Revollar et al., 2015; Zhang & Liu, 2019). The complexity of the microbiology of the activated sludge systems that cause solids separation problems of microbiological origin could be tackled through models integrating numerical models and knowledge-based systems (KBS) combining process and heuristic data (Comas et al., 2008). Despite having shown promising results in the literature (Rodriguez-Roda et al., 2002; Comas et al., 2003), heuristic methods such as KBS and case-based reasoning systems (CBRS) are still relatively uncommon in full scale WWTP. HADES is an ongoing project aiming to the gap between current WWTP control solutions and Industry 4.0 technologies by developing a DT that integrates the initiatives discussed above for decision support in operation.

OBJECTIVE

The objective of this paper is to present the HADES DT and features as a decision support tool for WWTP operators, composed of mechanistic, hybrid and heuristic models and MPC, oriented to optimize the treatment processes in terms of efficiency, reliability, and compliance. The main outcomes expected, once implemented in full scale WWTPs, are a reduction of 50% of effluent quality non-compliance episodes, a reduction of 15% of the energy consumption through advanced control (around 0,02 €/m3), and savings of 92.000 €/d for ACCIONA in chemicals for phosphorus removal and through the improvements of the sludge settleability and dewaterability.

MATERIALS AND METHODS

The HADES DT will be deployed, monitored, and validated at La Almunia WWTP, which serves the municipalities of La Almunia de Doña Godina, Almonacid de la Sierra, Alpartir, Calatorao, and Ricla. The plant has a capacity of 10.500 m3/d and an approximate load of 28.350 p.e. The treatment configuration consists of two oxidation ditches and two clarifiers. Waste sludge is thickened and dewatered before disposal. The plant already has a high level of instrumentation and automation, but additional sensors will be installed for monitoring key parameters for the DT. La Almunia WWTP has previously hosted digitalization-based projects, so the plant management is familiar with digital tools, making it a favourable environment for the HADES deployment. Since the DT will work as a decision support tool for the WWTP operation, it will be the responsibility of the plant manager, as final user, to close the control loop by using the optimized operational strategies suggested.

Figure 1 depicts the main elements of the HADES DT. The integrations of three complementary models, each of them using different approaches, is necessary to effectively address the complex challenges in the optimization of the treatment process and the prediction of harmful events.

The HADES project will develop a plant-wide model using the commercial modelling software GPS-X® which uses the widely known and validated activated sludge models (ASM). One instance of the model will work as a virtual sensor, another will validate operational strategies computed by the HADES control modules, and a third one will be user-dedicated. A CFD model extended with ASM, developed under ANSYS Fluent®, will be combined with other methods in a hybrid model to optimize the energy consumption of bioreactors mechanical equipment. A heuristic module combining KBS and CBRS will monitor the probability of risk of harmful events in real-time, while estimating the risk of using the optimized operation strategies suggested by the DT control modules.

The models will be back fed by a Data Centre that acquires data from external sources (SCADA, lab reports, weather monitoring databases, etc.), which may require validation and reconstruction before use. A Monitoring and Control Centre will also be part of the DT, fulfilling two functions: on one hand, MPC strategies and other control algorithms will be bench tested and validated over the mathematical models, in the other hand, relevant results of the models, and the conclusions derived from the tested control strategies, will be shown through a User Interface (UI), suggesting, if necessary, modifications to improve efficiency, prevent breaches and problematic events. User-dedicated instances for simulation will also be available through the UI.

RESULTS AND DISCUSSION

At the time of writing this document historical data from La Almunia WWTP was already gathered according to the project needs. A preliminary analysis of historical data revealed that due to agricultural activities in the region, irrigation water infiltrates the combined drainage network and arrives at the WWTP, without a clear pattern, mostly between April and November (Figure 2), so two different operational regimes are common in the plant (Figure 3). This is an additional challenge to consider for the development of data validation, reconstruction and prediction systems.

Data was analyzed and reconciled to detect, identify, and isolate outliers. A reconciled dataset was obtained for use in developing models such as statistical, machine learning (ML), or time series models (TSM) for reconstruction, prediction, and data transformation for the DT simulators. Preliminary models were developed on GPS-X® and ANSYS Fluent®. Software for data communication was developed for the inputs of the GPS-X® model, and reactor geometry and meshing were addressed in ANSYS Fluent® (Figure 4). For the MPC module, the Linear Parameter-Varying (LPV) framework was identified as a promising approach, and first steps have been taken with the development of a reduced linearized model with 6 variables, starting from ASM1.

FURTHER WORKS

Additional analytical measurements will be taken on the influent and additional sensors will be installed to monitor key parameters in influent and effluent. Clustering techniques will be applied to the dataset to separate data according to different operational conditions as a previous step to developing preliminary versions of reconstruction and prediction models using statistical models, ML, and TSM. Comparison and validation of reconstruction methods will be performed over different scenarios. Calibration tasks will be carried out for the GPS-X® model as well as the first multiphase simulations in the CFD model to study the overall hydrodynamics of the reactor in steady and transient state, as well as the interaction between the two phases. A state space model of the biological process will be developed as a Python library, reproducing the process dynamics described by ASM1 and will be used as a fundamental part of the MPC algorithm for computing the optimal sequence of set-points for the WWTP actuators. Historical data and event reports will be analyzed as first step in the development of heuristic models based on KBS and CBRS.

Keywords: Sewer management, Digitalization, Resource and energy recovery, Smart sensors,

ABSTRACT:
The management of sewer systems is a critical aspect of urban infrastructure that faces numerous challenges. The 4SM project aims to address four key challenges in sewer management, namely:
(1) promoting the digitalization process of sewer networks,
(2) enhancing the capabilities of current tools,
(3) tapping into resource and energy recovery from sewers, and
(4) developing highly innovative methods for corrosion, toxicity, and odours control.
This poster provides an overview of the 4SM project and highlights the objectives and progress made in each of the six work packages.

Work Package 1 (WP1) focuses on the development of a digital platform for sewer management. The objective is to create an Internet of Things (IoT) based platform that collects, integrates, and visualizes data from the physical world. This platform will enable advanced standards for data analysis and decision-making in sewer management.

In WP2, the project aims to design a sulfide stripping process unit to extract and concentrate sulfide for recovery. Preliminary designs for a pilot plant have been proposed, and experiments are being conducted to determine the desorption velocity between gas and liquid phases. These efforts will contribute to the removal of Hydrogen sulfide from sewer systems.

WP3 explores a ground-breaking method for sulfide control that relies on electrocatalysis and low-cost nanomaterials. The objective is to test the effectiveness of this method in controlling sulfide gas without the use of chemicals. Initial evaluations of electrocatalytic sulfide removal from wastewater have been conducted, and further experiments using low-cost materials are planned.

The primary goal of WP4 is to develop a semi-autonomous drone for data collection and visual assessment in sewer systems. A prototype drone has been created, and initial tests have been conducted in real manholes. This drone will enable automatic data retrieval and inspection, improving the efficiency and accuracy of sewer management.

WP5 focuses on the integration of smart sensors for real-time wastewater quality control. The project aims to test wastewater quality sensors that can be incorporated into CSO (Combined Sewer Overflow) detection equipment. Online water quality sensors for COD (Chemical Oxygen Demand) and TSS (Total Suspended Solids) are being tested in the field, along with mechanisms for sensor protection against clogging and cleaning. Additionally, temperature sensors from the SENVES concept developed at ICRA are being tested in conjunction with a level sensor.

Work Package 6 (WP6) investigates energy recovery from sewers. Various options for energy recovery have been explored, with a focus on Pico-Hydraulic Turbines commonly used for energy recovery in water supply or irrigation tubes. However, the challenge lies in the presence of urban solids and fibers in sewer systems, which can obstruct the hydraulic flow. Efforts are underway to estimate the energy generated and optimize the design of the Pico-Hydraulic Turbine for sewer applications.

The 4SM project aims to revolutionize sewer management by leveraging advanced tools and sustainable approaches. Through digitalization, enhanced sulfide control, autonomous drones, smart sensors, and energy recovery, the project strives to connect the digital and physical worlds of sewer infrastructure. The results and findings from the project will contribute to the development of efficient, sustainable, and environmentally friendly sewer management practices.

Abstract
Membrane bioreactor (MBR) is one of the best solutions for wastewater treatment systems in producing high quality effluent that meets its standard regulations; The MBR has a broader prospect of its applications in wastewater treatment and reuse. However, the problem of membrane fouling restricts the application of MBR to a great extent resulting in pore clogging and reduced membrane permeability. The main objective of this study is to develop an overall SMP model applicable to a Membrane bioreactor (SMBR). A multivariate projection to latent structures (PLS) and artificial neural network (ANN) models are developed and analyzed to establish the Parameters limiting variables for predict SMP and membrane fouling. The proposed models account for the biological contribution of MBR and predict the SMP product. Regression models are subsequently trained to objectively predict the SMP product of submerged membrane bioreactor systems. Furthermore, this paper aimed to analyze biological parameters data in order to explore the most parameters influenced biomass activity and membrane fouling using statistical analysis. To establish the link between the dead mineral matter MOM, the concentration of the active biomass, the operating conditions and the subsequent fouling of the membrane, the heterotrophic and autotrophic bacteria are first quantified using respirometric measurements. The comparison of their evolution with the conditions and the operating parameters is carried out using the statistical analysis, and SRT, which is identified as the parameter having the greatest impact on active biomass concentration. A multivariate statistical analysis of the biomass activity parameters is performed, based on the data points of the MBR process. The parameters examined are: SOUR, SMP, MLVSS, XBH, XBAI, XBAA, COD, TOC and F/M. The methodology for characterization of MBR biomass activity is based on the above data combining the method of multiple linear regressions (MLR), principal component analysis (PCA)and structural equation modeling (SEM) method,

Abstract
Risk management can be supported and optimized using digital tools for assessment, monitoring, control and decision support. However, signals can give outlier data due to sensor faults, installation and maintenance issues or external conditions. When reliable data are not available, modelling can support providing simulated data of malfunction scenarios. In the context of the European H2020 project Digital Water City, an Early Warning System (EWS) has been developed to monitor effluent water quality and support decision making and risk management for water reuse applications. To carry out the development of this system a digital twin of a wastewater treatment plant was developed using a Multi Task neural network and a forecaster to predict the effluent water quality up to 6 hours later, via a Long Short-Term Memory network.

Keywords (maximum 6 in alphabetical order)
Artificial Neural Network; Digital tool; Early Warning System; risk management; soft sensor; water reuse.

INTRODUCTION

The transformation of the wastewater treatment sector to smart water treatment and reuse facilities is boosted by the process of digitalization of the wastewater treatment plants (WWTPS), improving process performance and reducing malfunctions. Digital technologies have the potential to develop predictive maintenance, extending the life of the infrastructure; to increase the efficiency in capital and operational management; to foster greater speed in decision-making due to the rapidity in data processing; and to detect malfunctions and anomalies in the WWTPs operation. Furthermore, digital tools can improve notably the management of water infrastructures, the quality of service provided to citizens and the levels of awareness and collaboration between utilities, authorities and citizens. However, the transition to a digital management of wastewater sector is often hammered by the low level of maturity and diffusion of innovative digital solutions; the commonly high investment needed to acquire digital tools, the efforts required to train the personnel and to keep digitals systems updated, other than a static regulatory landscape. Technological development, awareness on the benefits of digital tools as well as economic and political support to water utilities are thus expected to implement this digital transition in the water sector, which is essential to implement water reuse practices. In the framework of the European project Digital Water City, which aimed to boost digitalization in the water sector, an Early Warning System (EWS) has been developed in Peschiera Borromeo WWTP for safe wastewater reuse for agricultural purposes. The EWS provides warnings if in the plant are detected conditions where quality requirements for water reuse cannot be satisfied. The EWS represents a tool to support risk management, since it can receive real time information about effluent water quality WWTPs. In this way, decision making about water reuse can be supported and risk minimized allowing rapid reactions in case the occurrence of a hazardous event is detected by the EWS.

MATERIALS AND METHODS

Peschiera Borromeo WWTP

Peschiera Borromeo WWTP is located in the periurban area of Milan, in Italy. It has a treatment capacity of 500,000 P.E. and is divided in two treatment lines, of which the one selected to deliver reclaimed water is composed by pre-treatments, lamellar settler, biologic treatment combined with filtration and tertiary UV disinfection unit. The WWTP is equipped with a series of sensors for continuous monitoring of water quality, including ammonia, nitrates, pH, phosphates and suspended solids.

Development of an EWS for safe water reuse

The Early Warning System has been developed at Peschiera Borromeo WWTP to forecast water quality depending on sensors measurements and soft-sensing techniques. The EWS architecture includes the generation of warning and alarms related to measurements obtained by on-line sensors and from machine learning algorithms (i.e., soft sensors). Artificial Neural Networks (ANN) were developed for real-time and time-series prediction of parameters related to wastewater quality.
In particular, two neural networks have been developed. The first one is a MultiTask (MLT) neural Network that has to estimate the effluent Biochemical Oxygen Demand (BOD), the effluent Chemical Oxygen Demand (COD) and the effluent Total Suspend Solids (TSS), having as input influent flowrate, influent pH, temperature in the anoxic reactor, dissolved oxygen (DO) concentration in aerated reactor, effluent flowrate and effluent pH, which corresponded to the available sensors installed in the WWTP. MLT represents an implicit data augmentation strategy which allows to avoid model overfitting (Ruder, 2017).
Since microbial risk was highlighted as one of the most significant risks during wastewater reuse, particular attention has been addressed to TSS predict since solid particles may be vehicle of pathogens. With this aim, a Long Short-Term Memory network capable of predicting the behavior of TSS up to 6 hours later was developed. Predictive models require an affordable and large set of data to be trained and validated, including both periods of normal operation and periods with malfunctions occurrence, which are rarely available (Newhart et al., 2019). Hence, a model representing typical operational conditions of Peschiera Borromeo WWTP was created using a simulation software, also because sensor data were not always reliable and included outliers. Once the ANN models were generated, a procedure was elaborated to adapt its configuration using a real data set, made up by sensors data and lab measurements. The domain adaptation procedure allowed to fit the developed ANN to real data. Indeed, for the training procedure only 1000 data points were available. On the contrary, for ANN development using simulated data 6912 measurements were used for training, which represent the 80% of the simulated dataset.

RESULTS AND DISCUSSION

According to the WWTP operational conditions, the soft-sensing algorithms were able to forecast the quantitative values of target parameters and compare them with threshold limits for water reuse. Considering the first development using input data generated by model simulations, good performances of the ANN model were observed as shown in table 1.

A deviation was observed in correspondence of the simulated malfunction scenarios even if the network would still detect the presence of the malfunction as shown in Figure 1 in the case of the TSS (Figure 1).

Table 1. Statistical parameters calculated to evaluate the performance of the developed ANN model during the testing phase.

Predicted Parameter	CC	RMSE	SI	BIAS	Mean Absolute Percentage Differences (APD)	Std APD
Effluent BOD	0.963	1.235	0.228	-0.006	8.460	10.480
Effluent COD	0.961	2.388	0.147	-0.050	6.671	8.521
Effluent TSS	0.856	1.419	0.217	-0.105	5.630	11.966

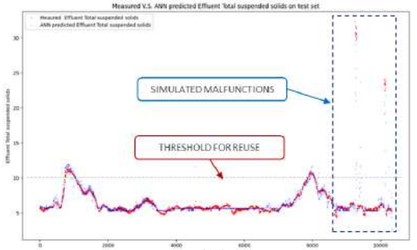

Figure 1. ANN predictions of effluent TSS using simulated data.

The second model was also able to forecast TSS with very high accuracy for the three different time offsets considered in this study, as reported in Table 2.

Table 2. Average of statistical parameters calculated to evaluate the performance of the forecasting models for TSS prediction.

Forecasting model	RMSE	SI	BIAS	Mean Absolute Percentage Differences (APD)	Std APD
1 h	0.224	0.025	-0.087	1.682	1.763
3 h	0.229442	0.0264834	-0.045	1.792	1.844
6 h	0.234	0.027	-0.099	1.855	1.661

Unlikely, results obtained during the test phase of the domain adaptation with the real sensors dataset were not consistent and the model was not able to produce stable outputs obtained for all the three target parameters. However, according to the scientific literature, in the case of real sensors installed on-line, acceptable errors in terms of APD values are assumed to be < 20% (Cecconi et al., 2019). In the case of the developed soft sensor in this work, the calculated mean APD was about 26 %for BOD, 22 for COD, and 19% for TSS, meaning that further steps are required to reach the convergence below the acceptable level. Nonetheless, it is expected that with the progressive increase of the dataset of sensors data, coupled with a deeper focus on maintenance and specific procedures designed to remove sensors outliers, the domain adaptation will be able to provide more affordable results.
The developed EWS follows a dynamic risk management approach and allows monitoring and control on health risks associated with the reuse of treated water, reducing the likelihood of the occurrence of hazardous outcomes and supporting risk minimisation.

Lowering of groundwater levels and their effect on Water, Sanitation and Hygiene services in the Savelugu District, Northern Region of Ghana

Albert Acheampong, PE-GhIE, MGhIG, MIAH, MASCE
PhD Candidate, KNUST, World Vision Ghana, acheampongalbert@gmail.com

ABSTRACT

Of all the natural resources available to humankind, water holds a prominent place, particularly because of its importance for human livelihood. Savelugu district in northern Ghana is characterized by unpredictable rainfall patterns with periodic and perennial water shortages. The distance people travel to fetch water and the person-hours spent in search for water affect productivity, economic livelihood, and health and education benefits. Provision of potable water supply to these communities is expected to bring not only health, education benefits but also increase in sanitation and hygiene practices. Static water levels (SWLs) of 19 wells in the study area were collected, analyzed and compared to the initial SWLs measured when the wells were immediately drilled and constructed. The SWL data was subjected to paired samples T-test (with $\alpha = 0.05$). From the results, there was significant difference in the SWL immediately after drilling and construction ($\mu = 12.15$, $\sigma = 7.50$) and SWL after at least 10 years ($\mu = 17.81$, $\sigma = 10.29$); $t(18) = -3.7$, $P = 0.002$. Lowered groundwater levels were recorded in all wells measured. This can lead to drying up of some of the wells whose difference between the current SWL and well depth is close. There must be strong advocacy, development and implementation of IWRM plans to help address the problem of inadequate WASH in the study area.

INTRODUCTION

The provision of water through drilling of wells or boreholes helps to increase access to water. The availability of adequate water or increased water coverage promotes increased sanitation and good hygiene practices thereby reducing and preventing the myriad problems associated with inadequate water and sanitation infrastructure, and hygiene practices (WHO/UNICEF JMP progress report, 2018). The link between inadequate access to safe and affordable water and public health problems, cannot be over-emphasized. Water scarcity represents the single greatest threat to food security, human health, education and the natural ecosystem (WHO/UNICEF JMP progress report, 2017).

As high as 89.3 % of households in the Savelugu district are engaged in agriculture, 97.0 % out of this are involved in crop farming (Ghana Statistical Service, 2010). Savelugu district/AP is characterized by unpredictable rainfall patterns with periodic and perennial water shortages (Ghana Meteorological Agency, 2018), this serves as serious constraints to meeting the challenges to provide adequate water to all rural residents in the district. Wells were drilled by World Vision Ghana in Savelugu AP/district in the Northern region of Ghana to help provide adequate water and sanitation infrastructure and hygiene practices (Savelugu Nanton District Assembly, 2006). Some of these wells are drying up or have dried up over time, making them low yielding and even some non-functional/operational probably due to the lowering of the groundwater table with time and some environmental issues.

The study seeks to look at and address the possible causes of the drying up of these wells at Savelugu district and its associated cross cutting issues to Water, Sanitation and hygiene. Since WASH affects many other development sectors such as health and healthcare facilities, education, environment, agriculture and livelihood, etc. (WHO Guidelines on Sanitation and Health, 2018), the general wellbeing effect that arises out due to inadequate water and sanitation infrastructure, and hygiene practices needs to be looked at critically.

MATERIALS AND METHODS

Review of the works of one or two water committees, interviews, questionnaires and focus groups discussions – government officials, stakeholders/schools/clinics/CHPS and area mechanics were conducted. Static water levels (SWLs) of 19 wells in the study area as shown in Figure 1 were collected, analyzed and compared to the initial SWLs measured when the wells were immediately drilled and constructed. The SWL data was subjected to paired samples T-test (with $\alpha = 0.05$).

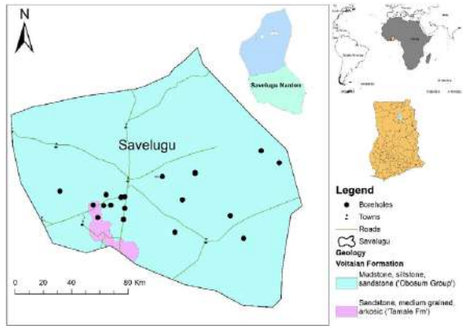

Figure 1. Map of study area showing drilled wells/communities

In addition, rainfall data were collected and analyzed. Also considered were land use information, river flows, geology within the area to determine the actual cause of lowering of the water table. Socio-economic parameters leading to the drying up of the wells and impact on WASH were analyzed to draw valid conclusions.

RESULTS AND DISCUSSION

The district is found in a region of the country with unfavourable natural environmental conditions. There is little tree-cover and it experiences harsh harmattan seasons, which results in many bush-fires caused by farmers clearing their lands and hunters searching for game (Yiran et al., 2016). The serious threat however, is the rate at which the tree vegetation is being cut down for fuel wood. The less tree-cover, harsh harmattan and rampant tree vegetation removal leads to desertification, increase surface runoffs, less percolation to recharge the underground waters after rainfall. This is mostly supplemented by hand-dug wells which dried up in the dry season. since most of the limited received rainfall would be trapped in the vadose zone, thereby impacting greatly on the water cycle of the district.

Lowered groundwater levels were observed and recorded in all the wells visited/measured with change in static water levels (SWL) range between 0.2 m to 26 m with an average of 6 m as shown in Table 1 and Figure 2. It is to be noted that, all current SWL measurements were taken in second (2nd) week of November, just after the main raining season. This point to the possible increase in the numbers/margins if taken in the dry season, potential increased lowered groundwater levels would be recorded. This can lead to drying up of some of the wells with time like Afayili, Tigu, Chehayili, etc where the difference between the current SWL and well depth is close (Figure 2). Longer and intense dry season period might compound the problem and enhance the chances of the drying up of these wells.

The SWL data was subjected to paired samples T-test (with $\alpha = 0.05$). From the results in Table 2, there was significant difference in the SWL immediately after drilling and construction ($\mu = 12.15$, $\sigma = 7.50$) and SWL after at least 10 years ($\mu = 17.81$, $\sigma = 10.29$); $t(18) = -3.7$, $P = 0.002$. Lowered groundwater levels were recorded in all wells measured. This can lead to drying up of some of the wells whose difference between the current SWL and well depth is close. The lowering of SWLs could be attributed to reducing tree-cover, the harsh harmattan and rampant vegetation removal, which contributes to desertification, increase surface runoffs, less percolation to recharge the underground waters after rainfall in the area.

However, limited and unreliable access to water for domestic, industrial and irrigation use due to dried up wells and surface waters, affect time spent in accessing water, school attendance/enrolment and guinea worm eradication. The provision of potable water supply to these communities is expected to bring not only health and nutrition, education benefits but also a significant improvement in agricultural productivity, sanitation and hygiene practices. Hence a combination of decreased water availability and increased level of water use greatly imparts negatively on WASH. WASH is instrumental in achieving goals in: Poverty, food security, education, gender equality, health (child mortality, maternal mortality, and major diseases), environmental sustainability (loss of environmental resources, improving lives of slum dwellers) (WHO/UNICEF JMP progress report, 2019).

CONCLUSIONS AND RECOMMENDATIONS

Conclusions

The district experiences increased stream flow with high evaporation and transpiration due to high temperatures, low rainfall and landscape dominated by the savannah grasslands and less vegetation cover. The area experiences less base flow into the groundwater as a result of less percolation, since most of the limited received rainfall would be trapped in the vadose zone.

Lowered groundwater levels were observed and recorded in all the wells measured with change in static water levels (SWL) range between 0.2m to 26m with an average of 6m. This can lead to drying up of some of the wells whose difference between the current SWL and well depth is close.

The provision of potable water supply to these communities is expected to bring not only health, education benefits but also a significant improvement in agricultural productivity/economic empowerment, increase sanitation coverage and hygiene practices, and ecosystem sustenance.

Recommendations

There should be strong advocacy, development and implementation of IWRM and water efficiency strategies, plans, and programs at the study area to help address the problem of inadequate WASH in these communities in order to improve health and wellbeing in the study area.

Effective and efficient integrated land and water management needs to be instituted to prevent farming along river courses, reduce runoffs, increase water absorption and crust at the soil surface.

There is the need to replace or add up to existing wells that showed greater potential of drying up with time as disclosed by the results/findings from this study in the Savelugu Nanton district to address WASH in the district.

Abstract
The Balearic Islands, like many areas of the Mediterranean, are highly dependent on the tourism industry and environmental issues related to over tourism are widely reported. Natural groundwater bodies, for example, present severe problems of quality, due to wastewater contamination and marine intrusion. High efforts need to be done on water protection, and to find new water sources and water recycling systems. New water technologies and solutions are demanded to achieve a more sustainable level. The methodology designed and provided by UNIVPM in the context of the H2020 EU HYDROUSA project was applied to theoretically evaluate the feasibility of several wastewater, and rainwater harvesting nature-based solutions in the context of three islands of the Balearics: Mallorca, Cabrera, and Formentera.

Keywords
Rainwater, tourism; wastewater; water reuse; water scarcity.

INTRODUCTION

The Balearic Islands are highly dependent on the tourism industry (Pons, 2014). In 2019 they received 16.4 million tourists (54% in terms of GPD in 2019; AETIB, 2019). This high number reflects a heavy consumption of natural resources, especially water and energy, as well as waste production. Environmental issues related to over tourism are widely reported. The available drinking water supply sources for domestic uses are groundwater (71%), natural springs (9.6 %), water dams (5.6 %), and desalination (13.4 %; PHIB, 2019). Natural groundwater bodies present severe problems of quality, due to marine intrusion or wastewater contamination. High efforts need to be done on water protection, and to find new water sources and water recycling systems.

Regarding wastewater treatment, in all the archipelago there are 79 wastewater treatment plants (WWTPs) operating and treating 93 hm^3/year. These plants are designed for at least 400 PE and the public company responsible for the treatment has no or preliminary experience with small treatment systems. Scattered urbanizations and touristic urbanizations are an environmental issue/opportunity to deal with in the Balearic Islands, with a lack of sanitation system in some of these sites. It is estimated, in fact, that 55,000 houses in Mallorca are using only septic tanks or black wells (PHIB, 2019). Sewage sludge is another big problem on the islands. Each of the islands has different characteristics, and requirements, and the applicable solutions need to be carefully tailored. On the island of Cabrera, moreover, there is a lack of a proper wastewater treatment system, and the island is a National Park with specific legal binding and environmental requirements.

New water technologies and solutions are demanded to achieve a more sustainable level. The so-called HYDRO solutions of the H2020 EU HYDROUSA project improve the circular management of water, energy, and resources/waste. One advantage about living on an island is that when a new technology or operation strategy is implemented it becomes easily replicable, because on an island it is easy to create a connected network of innovators. Nonetheless, integrated water resources management is still largely in the theoretical body in the Balearic Islands, and there is not much experience right now. Different nature-based solutions were theoretically applied (in terms of wastewater treatment and irrigation, as well as to rainwater harvesting) to the island of Mallorca, Cabrera, and Formentera in the Balearic archipelago (Spain).

MATERIALS AND METHODS

The chosen nature-based solutions were the so-called HYDRO1 (wastewater) and HYDRO2 (irrigation) for the case of Mallorca Island; HYDRO1, HYDRO2, and HYDRO4 (rainwater harvesting) for the case of Cabrera Island; and HYDRO6 (small, decentralized tourist facility) for Formentera Island. The islands were theoretically analysed regarding social, legal, technical, and economic perspectives. In each of these areas, a group of theoretical feasibility criteria were defined that should be scored to obtain the feasibility of the feasibility study in that area (e.g., 80/100). The overall score of the project was calculated by giving a ponderation factor to 4 areas, that correspond to 30%, 30%, 20%, and 20%, to social, legal, technical, and economic areas, respectively. The methodology was completely designed and provided by UNIVPM (www.univpm.it).

RESULTS AND DISCUSSION

The three islands (Mallorca, Cabrera, Formentera) were theoretically evaluated in terms of potential applicability of the corresponding solutions (Table 1). The policy analyses considered European, National, and local (e.g., Cabrera National Park) legislation. Similarly, was done for the social analyses to highlight stakeholders that would act in favour or against the application of the chosen demonstration solutions. In terms of technical and economic feasibility, a preliminary design was drafted, as well as the CAPEX, OPEX, and payback periods were evaluated and compared for the installation of the wastewater reclamation and rainwater harvesting solutions.

Table 1. Theoretical feasibility results for Mallorca, Cabrera, and Formentera islands.

	Mallorca HYDRO 1, 2	Cabrera HYDRO 1,2,4	Formentera HYDRO6
Social Feasibility (30%)	77	69	74
Legal Feasibility (30%)	81	76	68
Technical Feasibility (20%)	76	43	40
Economic Feasibility (20%)	77	50	60
OVERALL FEASIBILITY	78/100	62/100	63/100

Confidence can be provided to the decision makers and lower the fears in front of new technologies and innovations. The proposed solutions can create a system that can close the loop on water and nutrients, reasons have been found under the laws related to agriculture, water, and waste treatment. The need for these decentralized systems is, in fact, high. Decentralized small towns and scattered facilities "off grid" do not have any wastewater treatment or water reuse system. When a first system is implemented and working in every island, the rest of the actors can learn and reply easily, and the public administration can adapt the procedures to allow and promote these systems.

Abstract
Critical validation of N_2O emission factor values is key to analyse the carbon footprint of WWT technologies. Current efforts to report N_2O emissions rely on approaches for NH_4^+, NO_3^-, or COD. However, the variability and uncertainty of N_2O production in WWT is significantly higher. Average values do not capture the intrinsic variability and propagated uncertainty associated to N_2O emissions. Here we analyse the error associated to all the measurements and model fitting efforts during a N_2O monitoring campaign and propagate them to the calculated Emission Factor. Gaussian distributions (average ± standard deviation) are not adequate and alternative probability distributions are necessary.

Keywords (maximum 6 in alphabetical order)
GHG; Nitrous oxide; Uncertainty; Nitrogen removal; Net-zero;

INTRODUCTION

Nitrous oxide emissions during biological nitrogen removal in wastewater treatment operations can compromise the environmental impact of the process. The carbon footprint of a WWTP is highly sensitive to N_2O emissions. However, reports of N_2O emissions focus on average emission factors (EF, N_2O emitted / TN removed), instead of accounting for the large uncertainty associated to N_2O emissions which depends on: technology, operational strategy, influent characteristics, spatial heterogeneity within reactors, etc. Hence, as the number of N_2O monitoring campaigns increases worldwide, accurate comparison between reports and technologies is necessary. In this study we:

- Propagate the uncertainty of every experimental value associated to N_2O EFs.
- Investigate more accurate methods compared to Gaussian distributions to report N_2O EFs.

MATERIALS AND METHODS

Experimental campaign: WWTP and N_2O monitoring: The Gummerup WWTP uses a Bio-Denitro technology with conventional activated sludge process for BNR and operates on alternating phases in the same reactor (Nitrification / Denitrification), with twin reactors interconnected. N_2O emissions were monitored for 110 days during spring and summer with 3 liquid sensors in one reactor and 1 in the twin reactor. Brush aerators at constant depth supply oxygen and operate in ON/OFF basis with varying aeration durations. The mass transfer coefficient for N_2O was estimated from a 2D-map of air flow measurements across the surface and linked to the oxygen mass transfer coefficient. The campaign accounts for daily variations but not for seasonal/yearly variations known to affect N_2O emission profiles (Gruber, Villez, et al., 2020) (**Figure 1**).

Data analysis: uncertainty propagation in N_2O emission factors: The experimental dataset considered to calculate the N_2O emission factor included measurement errors. The uncertainty of all the measurements was propagated via MC simulations assuming normal distributions in the parameter estimates maintaining correlation. The number of measurements for TN was significantly lower than for N_2O. The uncertainty associated to the calculation of emission factors was propagated throughout the study (**Figure 2**).

RESULTS AND DISCUSSION

Nitrous oxide emissions: Online measurements of N_2O emissions (gN/d) showed intrinsic variations due to diurnal, influent, and seasonal variations (Daelman, De Baets, et al., 2013) and were fitted to probability distributions. The distribution of daily or monthly N_2O emissions do not follow normal distributions and are highly skewed, with very few points being responsible for a large fraction of the total emissions. Still, in literature, the analysis of GHG from technologies relies mainly on average values. The calculated emission factor shows a large variability ($\sigma/\mu > 1$) and highlights the need for non-Gaussian distribution models for N_2O emissions. N_2O values differ from other WWT variables such as NH_4^+, NO_3^-, COD, whose dynamics are significantly lower compared to N_2O.

Abstract: Industrial water treatment facilities often treat multiple influents resulting from the different upstream production schemes. These streams may differ in quantity and quality, which will strongly affect the way they need to be managed. In this publication, a set of mathematical tools are used to assess the quality and quantity of industrial streams and re-think the way are handled. A full-scale site treating eight streams generated during leather processing is selected as case study. Reconciliation methods are applied to historical data to close mass and volumetric balances. Process simulation reproduces occurrence, transformation, recovery, and fate of organic (COD) and nitrogen (N) compounds (average deviation = 10 %). Hence, both data and model predictions reveal that 41 % of the incoming COD is converted into methane in the two anaerobic reactors (granular sludge and conventional). 16 % and 46 % of COD and N are biologically converted in the activated sludge reactor and 49 % and 36 % accumulated in the bio-solids (= cake). A scenario analysis suggests that it is possible to substantially increase the quantity of generated electricity (+82 %) and heat (+ 83 %) and reduce the quantity of sludge for disposal (-30 %) by modifying 1) upstream practices, and 2) carbon refluxing.

INTRODUCION

The use of digital tools has revolutionized the way we design, operate and optimize industrial wastewater treatment plants (Müller-Czygan *et al.*, 2021). Digital tools provide engineers and operators with powerful assets to predict the behaviour of wastewater treatment processes, identify potential problems, and optimize the performance of the plant. One of the most widely used digital tools for predicting the behaviour of wastewater treatment plants is process simulation software (PSS) (Henze *et al.*, 2000, Batstone *et al.*, 2002). PSS allows engineers to create a digital model of the treatment process, which can be used to simulate the performance of the plant under different operating conditions. By simulating the treatment process, engineers can identify potential problems and optimize the performance of the plant to achieve better treatment efficiency.

The main objective of this paper is to show how mathematical modelling tools implemented in PSS can be used to re-think flow-diagrams treating industrial wastewater. An industrial site treating multiple streams coming from the leather processing industry is used as case study. The paper shows how to close mass balances in a data scarce environment, reproduce plant performance using process simulation, generate different re-design scenarios and assess the feasibility of these new proposals with the help of energy consumption / resource recovery criteria.

PLANT CONFIGURATION, MODELS, DATA & EVALUATED OPTIONS

The plant mainly treats effluents from the beam-house, which corresponds to the processing of raw hides into semi-finished leather (also called wet blue). The different transformation processes result in the following process wastewater streams (In): *In-S* soaking (1), *In-L* (2) liming (2) and deliming (4) water, *In-F* includes fleshings (3), In-*PC* includes pickling (6) and chrome water (7), *In-B* includes enzymatic treatment of the

hides (bating) (5). In addition, there are two additional streams containing rain water and polymer preparation (*In-RP*) and re-tanning, finishing water and R&D (*In-RD*). More info about tannery wastewater can be found in Jain et al., 2011.

The plant treats the previously described Process Waste Streams (*In*). The process layout consists of three buffer tanks (BFF1-3), 2 thickeners (THK, BT), 1 anaerobic granular sludge reactor (AnGSR), 1 biogas desulfurization tower (BDST), 1 tri-canter (TRI), 1 anaerobic digester (AD), 1 belt filter press (BF), 1 chrome treatment unit (CT), 1 activated sludge reactor (ASR), 1 secondary clarifier (SEC) and 1 belt thickener (BT). A schematic representation of the flow diagram can be found in **Figure 1**

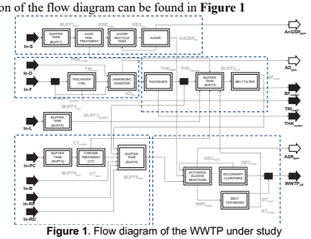

Figure 1. Flow diagram of the WWTP under study

Plant data used in this study comprises one year of measurements between January and December 2022 (1 to 3 measurements per week). Samples were taken from 7 locations: 1) BFF1 output, 2-3) AnGSR input & output, 4) AD2 output, 5) BFF2 output, 6) BFF3 output, 7) SEC output. There are some occasional measurements at *In-F*, *In-B*, *In-RF* and *In-RD*. Analytics involved the determination of: pH, total suspended solids (TSS), volatile suspended solids (VSS), chemical oxygen demand (COD) & total nitrogen (TN). These analyses were complemented with filtered (0.45 µm) samples for quantifying ammonium / ammonia (NH_x), nitrate/nitrite (NO_x) & sulfate/sulfite (SO_x) in selected points. Flow rate, COD & N (total concentrations) were balanced and adjusted using the approach proposed by Monje *et al.* (2022) where: 1) an identity matrix was defined, 2) data were cleansed and curated, 3) missing fluxes were estimated, 4) optimal flows were calculated and 5) the new data set was verified.

MATHEMATICAL MODELLING APPROACH

A full description of the plant-wide model used in this case study can be found in Monje et al., 2022a and b. In a few words, AnGSR and AD are approximated using the IWA Anaerobic digestion Model No 1 (Batstone *et al*, 2002). The syntrophic acetate oxidation pathway had to be included to correctly account for the absence of inhibition expected at these high ammonia concentrations on COD and N removal in the AD. The ASR is based on the ASM1 (Henze *et al.*, 2000), pH and liquid-gas transfer are modelled using the General Physicochemical Modelling (PCM) approach (Batstone and Flores-Alsina, 2022). Both interfaces (ADM-ADM and ADM-ASM) ensure COD and elemental (C, N) continuity. All separation units are modelled as ideal splitters. An empirical approach is used before belt and thickening filter in order to assume coagulation/flocculation. More info about the model can be found in Monje *et al.*, 2022a,b.

RESULTS

From the initial volumetric balance calculations, one may conclude that *In-L* (lime water) (25 %) is the main contributor, closely followed by *In-S* (Soaking) (19 %), *In-B* (Bating) (15 %) and *In-RP* (rain water + polymer preparation) (15%). With respect to COD and N loads, 32 + 30 % and 31 + 29 % comes with *In-L* (lime water) and *In-F* (fleshings) due to the high content of proteins and fats resulting from removal of hair and other keratinous material. When it comes to the outputs, the effluent (=overflow of the secondary clarifier) (SEC_{over}) carries most of the hydraulic load (98 %). The remaining 2 % is linked to bio-solids for post-digestion (THK_{under}) and/or disposal (BF_{under}). Around 31% of the incoming COD is transformed into methane and potentially recovered ($AnGSR_{gas}$ + AD_{gas}). The remaining COD is removed aerobically/anoxically (16%) in the activated sludge reactor (ASR_{gas}), ends up in bio-solids (49%) (BF_{under} + THK_{under}) or part of the effluent (> 1 %) (SEC_{over}). Regarding N, 46 % is biologically removed (ASR_{gas}). The second largest N outflow is in the biosolids (36%) (BF_{under} + THK_{under}) while another fraction leaves with the effluent (11%) (SEC_{over}). Detailed calculations can be found in **Figure 2**.

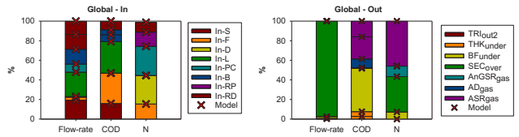

Figure 2. Relative contribution of flowrate, COD and N at the input (left) and output (right). Red crosses represent model predictions

All eight Influents (*In*) were fractionated using the principles described in Monje *et al.*, 2022a,b. Computer simulations reveal that the mathematical approach proposed in this study is capable of reproducing flow, mass and the main transformations (average deviation 10%) within the multiple units comprising the flow diagram (see **Figure 1**). In general, the model predicts the quantity of COD that, potentially, can be recovered in form of methane (AnGSR + AD), the COD and N that is biologically removed in the activated sludge reactors (ASR), the particulate material purged from dewatering units (THK + BF) and the energy demand (ED) in the aeration basin. More specifically, to better describe data: 1) the AnGSR model is assumed to function at less than half capacity, 2) Acetate oxidizers in the AD model had higher tolerance to ammonia inhibition than acetate degraders, 3) an empirical model assuming coagulation/flocculation was added at BF and BT in order to match under and overflow data (and mimic the effect of polymer addition), 4) a combined power and heat generator (CHP) assuming 40 and 42 % efficiency for electricity (EP) and heat (HP) production was assumed for both AnGSR and AD gas streams and 5) a factor of 1.4 kgO_2/kWh was used to estimate energy consumption (diffuser aerators) in the ASR. *More details about the model specific arrangement will be discussed in case the paper is selected for platform presentation*.

SCENARIOS & OUTLOOK

Two additional scenarios are simulated using the adjusted model. S1: *In-L* is redirected from ASR to AnGSR after Ca removal. This will remove the risk of intra-granule precipitation (Feldman *et al.*, 2017). In S2, *In-S*, *In-B* and *In-F* will be sent to a dissolved air flotation (DAF) unit. The underflow will be sent to the ASR. Two coagulation/flocculation efficiencies are assumed. The AnGSR will be decommissioned. Plant data, baseline simulation and the results of the two scenarios are summarized in **Table 1**. For a comprehensive description of operational cost indices quantification the reader is referred to Monje *et al.*, 2022a,b.

Table 1. Plant data and simulation results (Baseline, scenarios)

		Plant data	Baseline	S1	S2 (a)	S2 (b)
Biogas Production (BP)[1]	m^3/d	420 / 1700	450 / 1720	2028 / 1720	0 / 2000	0 /2600
Heat Demand (HD)[1]	kWh/d	2383 / 474	2383 / 474	5248 / 474	0 / 834	0 / 934
Heat Production (HP)[1]	kWh/d	-	2505 / 4465	8288 / 4465	0 / 5542	0 / 7079
Electricity Prod. (EP) [1]	kWh/d	-	2369 / 4228	7838 / 4228	0 / 5240	0 / 6694
Electricity Demand (ED)	kWh/d	1815	1837	2200	3998	3212
Disposed Sludge 1 (DS1)[2]	ton/d	4.7	4.7	4.7	8.6	11.8
Disposed Sludge 2 (DS2)[2]	ton/d	18.1	19.0	13.3	6.1	5.26

[1] The first value correponds to the AnGSR and the second value is the AD, [2] DS produced in THK. 3 DS produced in the BF

Model-based evaluation results (S1) show that diverting *In-L* to AnGSR (S1) substantially increases the quantity of COD recovered. This is reflected in 1) BP and 2) EP. Since *In-L* is treated anaerobically, sludge production (DS2) is also reduced. However, a comparatively higher COD (with respect to Baseline) leaving the AnGSR overloads the ASR and increases the energy needed for aeration (see ED values). These simulations were conducted assuming that :1) the AnGSR was operating at full capacity and 2) nitrification efficiency in the ASR was maintained. With respect to S2, the model suggests a substantial reduction in (total) BP and EP. In addition, a substantial increase of the EC. However, the higher the DAF capacity to capture more of the colloidal material part of CODs (= better coagulation/ flocculation), the lower the EC. However, DS1 is increased as trade-off (see S2b). These simulations are conducted assuming a DAF with 97 % TSS removal efficiency and 14 % TSS in the overflow.

The study has offered the preliminary results of a research study involving industry and academia. Additional information will be provided including more scenarios, accounting for water reclamation options and the use of chemicals for coagulation/flocculation (not added at this stage). Also better OPEX estimates (revenues versus costs). The mass balance analysis of the origin/transformations/fate of the different compounds gives a better picture of plant drawbacks and foresees potential optimization solutions. The possibility to generate and assess alternative retrofitting scenarios with the proposed plant-wide model will allow the scientist/process engineering to evaluate the feasibility of a new operational procedure/technology beforehand and only implement the solution with the highest chance of success.

Abstract
Microplastic (MP) contamination in the river system has attracted widespread attention, whereas the abundance, characteristic and risk of microplastics in River remain poorly understood. Thereby, we develop a systematic assess framework to M. And the Yangtze River is taken for example. It is compiled a microplastic dataset, including 194 samples sites along the Yangtze River. It is found that MP abundance is from 2263.60±4231.77 particles/m³. According to MPs abundance and characteristic with a comprehensive risk assessment considering with all of these methods, the environmental risks of microplastics were partitioned into four classes, and Upstream and Midstream of Yangtze River were identified as potential high risk distinct. MPs risk assessment method and standard suggested that a unified standard is essential to further enhance our knowledge on the risk of microplastics in the river system.

Keywords
microplastics, Yangtze River, surface water, risk assessment

INTRODUCTION

There are of global concerns on plastic debris, and especially microplastics (MPs), in the aquatic environment over years. MPs are defined as plastic particles less than 5 mm in diameter, which can be derived from the breakdown of larger plastic items or deliberately manufactured for plastics productions (Xu, Chan, et al., 2021). MP has been considered as an emerging contaminant due to its recalcitrance, ubiquity and potentially adverse effects on the environment and human health (L. Zhang et al., 2020). Recent studies have reported that MPs are discovered in the digestive tract of aquatic organisms and accumulated in various plants (Biginagwa et al., 2016; Mercogliano et al., 2020; Mazurais et al., 2015), thus showing potential harmful impacts on ecosystems and agricultural sustainability (Ibrahim et al., 2021; Sun et al., 2020). MPs can be also exposed to humans through inhalation or ingestion (Biginagwa, Mayorna, et al., 2016; Takebira, Mondal, et al., 2021; Vethaak and Legler, 2021), and contained in the tissues and organs of the human body, which could cause specific toxicity by such as enhancing oxidative stress or further inducing inflammation and diseases (Liu et al., 2021; Noventa et al., 2021). After entering organisms, MPs are able to be transferred via the food web, leading to their widespread occurrence in the ecosystems.

Thus, it is urgent to build a systematic risk assessment framework for MP, in order to prophylaxis environmental pollution and human diseases better. Nowadays, there are PLI(Xu, Peng, et al., 2018), H(Xu, Peng, et al., 2018), SSD(Jung et al., 2021; Liu et al., 2022), ESI Rangel-Buitrago et al. (2021), and other risk assessment methods for the ecologic risk assessment of microplastics in rivers from a single characteristic of microplastics, but no method can comprehensively assess the environmental risk of microplastics in the river system. Therefore, we constructed a more comprehensive and convincing assessment method for the environmental risks of microplastics in the river system based on the Beta coefficient, a risk index commonly used for risk assessment in economics. And BetaMP coefficient, which is similar to Beta coefficient, was used for quantitative evaluation in the risk assessment of microplastics.

MATERIALS AND METHODS

The method what we called BetaMP that based on β, is firstly applied to the risk assessment of microplastics in the environmental field The BetaMP coefficient (BMPC) constructed by us calculated the comprehensive risk index of MPs in river system based on the formal risks index of PLI, H, SSD and ESI. In order to distinguish the influence factors of different risk assessment methods on the same region as well as comprehensively evaluate the risk of MPs in a region, we further subdivide BMPC into BMPC $_{method}$ and BMPC$_{distinct}$ Among them, BMPC $_{method}$ is used to evaluate the influence weight of different MP characteristics in a certain region on the regional risk index, so as to determine which MP characteristics in this region have a greater impact on the environmental risk of MPs. BMPC$_{distinct}$ is used to evaluate the environmental risk of MPs in different region in a wide range, so as to determine the harm of MPs in different regions to the environment. The calculation formula is as follows:

$$BMPC_{method} = \frac{\sum_{i=1}^{n} x_{ij} - x_{0j}}{\sum_{i=1}^{1-m,1-n} x_{ij} - \sum_{j=1}^{n} x_{0j}} \quad (1)$$

$$BMPC_{distinct} = \frac{\sum_{j=1}^{n} x_{ij} - x_{0j}}{\sum_{i=1}^{1-m,1-n} x_{ij} - \sum_{j=1}^{n} x_{0j}} \times \alpha \quad (2)$$

Where *i* presents MPs region (Source, Upstream, Midstream, Downstream, Estuary), that is, m=5, *j* presents the MP risk assessment method (PLI, H, SSD, ESI), that is, n=4, x_{0i} is risk-free value of a risk assessment index in each region after normalization, x_{0j} is the risk-free value of a normalized risk assessment index, x_i is the normalized actual risk value of a risk assessment index, x the normalized actual risk value of a region.

It is worth noting that in our analysis and assessment process, the risk assessment index ranges of existing risk assessment indexes PLI, H, ESI, and SSD are different, which brings great inconvenience to the comprehensive environmental risk assessment of microplastics in the river system. Therefore, we normalized each risk index before the comprehensive assessment. Differently from the formal risk assessment method, the normalization process first needs the support of experimental data.

RESULTS AND DISCUSSION

In order to verify the new risk assess framework for MP in the river system, MP pollution and exposure risk in different areas in the Yangtze River is analysed, calculated and compared. Based on the concentrations of MPs at the 147 sampling sites (Figure1).

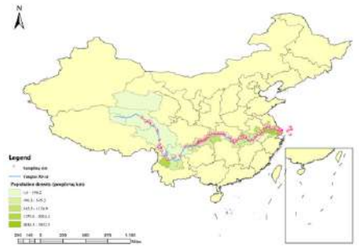

Figure 1. Sampling sites collected and screened from the relevant published articles. The colours represent the population density in the river basin in a range of 1.6-3922.5 people/km².

The risk index of PLI was firstly determined. The obtained results showed that 84.4% of sampling sites were with a risk level of V, suggesting that the entire watershed (from the source to the estuary) was at high risk of MP pollution (Figure 2). The values of PLI for the upstream, midstream and downstream were even significantly higher than those for the source and estuary, which was in consistent with the abundance distribution of MP in the basin. As known, the estuary area is affected by e.g., tides that may dilute the concentration of MPs in the surface water, making its abundance much lower than in other areas(Malli, Corella-Puertas, et al., 2022). Even if that, the PLI results suggested that the estuary area was still at an MP risk level of as high as VI, indicating that the risk of MP pollution in this area is high enough to pay more attention. For example, the PLI for Chongming, an island located in the estuary, was as high as 161.2, showing Chongming was at a risk level of V. Compared with the nearby downstream areas, e.g., Shanghai and Nanjing, Chongming in the estuary area has fewer human activities and industrial production there, so the amount of primary MPs discharging from the island is relatively small. Thus, it can be speculated that the high abundance of MPs occurred is likely to attribute to the effect of MPs emitted from surrounding areas (Liu, Lu, et al., 2018; Zhao, Zhu, et al., 2014).

For example, MPs discharge into the river from industrials area of the Yangtze River Delta via mainstream hydrological processes.(Luo, Su, et al., 2019).

Compared to the results of PLI-based risk assessment, the assessment based on ESI, H score and SSD index, were quite various (Figure 2). For example, the ESI-based assessment evaluated the source as "Unsatisfactory", while the other four areas were only at the level of "Mediocre". It suggested that the source was at relatively high risk of MP exposure from the perspective of the morphology, which was not consistent with the results of PLI-based. This may be explained by the high proportion of particle-shaped MPs in the surface water of the area of the source due to atmospheric deposition being the major source of MPs there. Furthermore, the downstream was assessed as an area with the same high-level MP exposure risk as the upstream and midstream based on the PLI assessment, while it was suggested to be a lower risk area by H-based assessment. This was supported by the fact that the uneven polymer types distribution of MPs in the Yangtze River, and the polymer types of MPs with high hazardous-score, e.g., PVC, were less contained in the downstream than in the upstream and midstream. Also, the midstream and downstream that were considered to have the highest level (level V) risk of MPs exposure based on the PLI assessment were viewed to have no toxic risk to the ecosystem in the assessment of the SSD approach. Therefore, the above confirms our hypothesis that evaluating the ecological risk of MPs exposure in the Yangtze River by single either the abundance or the characteristics and composition of MPs tends to make an underestimation or overestimation.

Notably, the upstream, which has ever been widely regarded as an area with low pollution risk (Zhang, Xu, et al., 2022) is surprisedly suggested as a high-level risk area of MPs exposure in the Yangtze River by not only PLI-based assessment but also H- and SSD-based assessment. Due to various driving factors, including the WWTPs discharging and the locations of dams on the river, causing the appearance of MP 'hotspot' in the region of upstream of the Yangtze River, in fact, it is reasonable to consider the risk of MPs exposure is at a high level in this region. Additionally, it is speculated that the 'hotspot' can be related to not only the high MPs concentration but also the high toxic effect of MPs.

Unlike other individual risk assessment method, BetaMP is to provide a quantitative recommendation on the risk level of different areas of the Yangtze River from an overall perspective. According to the results of BetaMP shown in Figure 2, the comprehensive risk of the different areas of the Yangtze River was in order as: Upstream (BMPC=0.34) > Midstream (BMPC=0.28) > Downstream (BMPC=0.19) > Estuary (BMPC=0.12) > Source (BMPC=0.07). Noteworthy, the obtained results show that the risk level of MP pollution in the areas of upstream and midstream is more serious than the average risk level (BMPC=0.2) of the entire river. It suggested that, for the Yangtze River, the upstream and midstream where are previously thought to be less polluted by MPs, should receive more attention on the MPs pollution than before. Furthermore, by means of BetaMP method, the influence of each individual MP risk assessment method on the comprehensive MP risk assessment is also able to be determined. As shown Table S7 in Supplementary Material 1, risk coefficients of each individual MP risk assessment method are in order as: H (0.77) > ESI (0.16) > PLI (0.05) > SSD (0.02). These obtained results indicate that the method of H index cause the highest effect on the result of the risk assessment, suggesting that polymer type may have the highest impact to MPs environmental risk in the Yangtze River. Although MP abundance is typically viewed as the most important impact factor on its risk in the river systems, abundance related indexes, i.e., PLI and SSD, show a relatively low impact on the final risk assessment results in this case. Therefore, it can be reasonably deduced that due to the differences of characteristics of MP pollution between different rivers or different areas of the river, the main factors that cause risk could be variable. However, given the MPs in the Yangtze River have only received attention in the past decade and related research is in its infancy, our analysis is certainly not fully representative. Nonetheless and to the best of our knowledge, it represents the most comprehensive study of spatial distribution and risk assessment of MPs in the riverine system, so far.

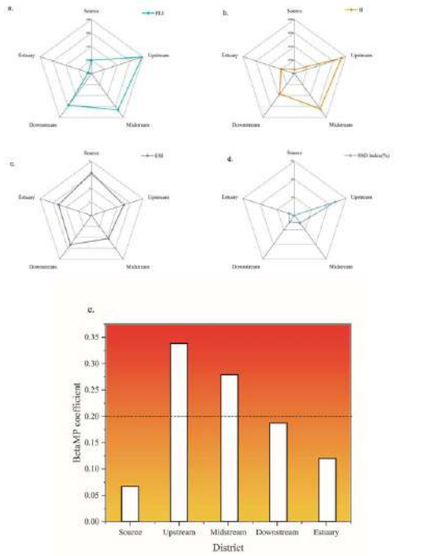

Figure 2. Comparisons of risk of MPs exposure in the different areas of the Yangtze River according to multiple evaluation methods, including assessment based on the (a).PLI, (b).H score, (c).ESI, and (d).SSD index of MPs presented in the five different regions, as well as the results of BetaMP method. (e).Dashed (BetaMP coefficient=0.2) in the figure presents the average BetaMP coefficient (0.2) of the Yangtze River.

This processing method can well avoid the differences caused by different data processing methods, and give a more convincing result for the research. To BetaMP coefficient (BMPC) coefficient as the evaluation index of the microplastic basin environmental risk comprehensive evaluation method not only can be flexible to change with different features of the microplastic evaluation method of risk assessment, species and amount can be compared to these evaluation methods compared, find out what kind of a greater role in the risk of micro plastic characteristics in this basin. In addition, the comprehensive environmental risk assessment method of microplastic watershed can also accurately assess the environmental risk values of microplastic in different regions of the whole watershed.

In conclusion, the microplastic watershed environmental risk comprehensive assessment method is a more comprehensive risk assessment method that integrates the existing microplastic risk assessment methods, and is suitable for the modified microplastic risk assessment articles in the Yangtze River system.

Case Study of Climate Change Countermeasures (Jeju Island in South Korea)

J. K. Kim*

* Department of Environmental Engineering, Jeju National University, 102 Jejudaehak-ro, Jeju-si, Jeju-do, Republic of Korea
(E-mail: *kjinkeun@jejunu.ac.kr)*

Abstract
Climate change adaptation strategies for 8 wastewater treatment plants(WWTPs) in Jeju, South Korea were investigated. Based on survey of 54 workers and risk assessment, climate change adaptation measures for heavy rains, strong winds, heat waves were proposed. Installation of equalization tank was proposed for heavy rain countermeasure to minimize impact of inflow surge. Dual power supply and flood prevention measures were proposed for strong wind. In the case of heat waves, it was suggested to improve responsiveness to toxic gases and reduce water use. This adaptation plan is a five-year plan, and the required budget is also calculated.

Keywords (maximum 6 in alphabetical order)
Abstract; adaption strategy; climate change; wastewater treatment plants

Climate change adaptation strategies for 8 wastewater treatment plants(WWTPs) in Jeju, South Korea were investigated following General process steps for adaptation planning (**Figure 1**.).

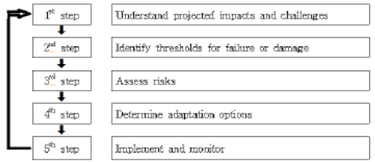

Figure 1. General process steps for adaptation planning

The climate change factors were evaluated on a 5-point scale (5 point means the negative impact is the largest) for 54 workers. Climate factors that negatively affect sewerage facilities are heavy rain (4.79), strong wind (3.46), heat wave (3.12), heavy snow (3.10), cold wave (2.67), and drought (2.12). If it is larger than 3.0 in the survey, it is a case where the negative impact on climate change is large. Therefore, this study established detailed climate change adaptation measures for heavy rains, strong winds, heat waves. Due to the warm climate of Jeju island, snow melts in a short period of time (e.g., less than 2 days), so the increase in sewage inflow becomes a problem, which is actually linked to heavy rain countermeasures. Therefore, in this study, adaptation measures were established by focusing on heavy rains (including heavy snow), strong winds, and heat waves.
Risk assessment for each climate change factor is calculated by calculating the probability of occurrence of climate impact factors (A) and the magnitude of impact (B) for climate impact vulnerable facilities when climate impact factors occur, and multiplying them (A×B).
In the event of heavy rain, a temporary increase in sewage inflow is expected in the case of combined sewer areas, and it is difficult to completely exclude the effect of precipitation even in separate sewer areas, so heavy rain can lead to an increase in sewage inflow. As an adaptation measure, installation of equalization tank was proposed.
In the case of strong wind, the risk of falling facilities increases. There is also a high risk of power outages. The risk of flooding due to waves increases in coastal pumping stations. Dual power supply and flood prevention measures were proposed as an adaptation measure
In the case of heat waves, the amount of tap water used increases, resulting in an increase in the amount of sewage generated. Increased sewage inflow in warm season may increase toxic gas generation in enclosed spaces and odor concentration in WWTPs, and eutrophication in discharged water areas are expected. As an adaptation measure, it was suggested to improve responsiveness to toxic gases and reduce water use.
This adaptation plan is a five-year plan, and the required budget is also calculated.

Social footprint evaluated within Chilean rural wastewater treatment plants.

Gatica[1] and C. A. Villamar-Ayala[1*]

[1]Facultad de Ingeniería, Departamento de Ingeniería Civil en Obras Civiles, Universidad de Santiago de Chile (USACH), Santiago, Chile (*email: cristina.villamar@usach.cl*)

Abstract
Wastewater treatment plants (WWTPs) correct operation can condition the public health risk of the surrounding population, generating strong resistance from nearby communities. The aim of this study was to measure the social footprint of five Chilean rural WWTPs over their social stakeholders, being these the workers and local community. The study included interviews to 8 operators and 4 administrators, as well as a total of 98 surveys to the local community. An Analytic Hierarchy Process (AHP) was used. Results demonstrated that natural-based WWTPs were un-valuated due to security and operational problems for worker and local community, respectively. Community engagement (0.56) and health and safety (0.27) were the best valuated subcategories for workers and local community, respectively. Better community engagement strategies and training could improve the performance of Chilean rural WWTPs.

Keywords
Activated sludge, local community, nature-based technologies, operation problems, workers.

INTRODUCTION

According to the 2019 Sustainable Development Goals Report (United Nations United, 2019), around 4 billion people in the world are affected by water scarcity, which represents more than 40% of the world population. It is so that water and sanitation are part of the Sustainable Development Goals as part of the 2030 Agenda. In relation to wastewater treatment, there are large gaps between developed and developing countries with percentages that average 75.6 and 18.5%, respectively (Malik et al., 2015). Rural areas tend to increase these gaps, with respect to urban zones, so Chile has sanitary urban coverage close to 100%, but in rural zones it does not reach 20% (Villamar et al., 2018). Moreover, the health risk in these sectors is increased by some factors, such as: frequent operational problems, little knowledge of workers and proximity of the population to WWTPs. There are few studies that evaluate the performance of WWTPs from the social footprint. Padilla-Rivera et al. (2016) compared rural and urban Mexican WWTPs considering 25 indicators, where urban WWTP was better evaluated than rural one, due to that urban population had not close WWTP. These precedents reveal the importance of measuring the social footprint in preventive and corrective decision-making inside WWTPs.

MATERIALS AND METHODS

Aim and scope of the study.

This study studied five Chilean rural WWTPs based on nature-based and conventional technologies, such, vermifilter (33°0'30.09"S 70°53'21.91"O), constructed wetland (33°10'5.68"S 70°53'13.90"O), aeration lagoon (33°44'43.42"S 70°52'17.32"O), activated sludge (33°49'59.63"S 70°38'50.28"O), and activated sludge + bio-discs (32°50'41.53"S 70°56'18.40"O), considering workers (operators and administrators) and local community. Moreover, only the operation phase was considered. Surveys in the local community considered a range between 15 and 2o interviews per WWTP within a radius of 500 metres.

Inventory analysis

The impact subcategories were defined based on the guidelines proposed by UNEP/SETAC (2019). Local communities considered subcategories, such as: safe and healthy living conditions, local comfort, community engagement, feedback mechanisms. Meanwhile, workers considered: fair wage, hours worked, equal opportunities and treatment, health, and security, working conditions and comfort, and child labour.

Impact assessment

Each stakeholder (workers, local community) was evaluated using Analysis Hierarchical Procedure (AHP) to obtain reference matrices, correlating it with multicriteria analysis between subcategories. This analysis considered Saaty-Gómez (2008) scale comparison using 5 levels (1, 3, 5, 7, and 9). The data obtained were considered valid if the consistency index ratio (CIR) is less than 0.1.

RESULTS AND DISCUSSION

Table 1 shows the AHP results per stakeholder and treatment technology for local community and workers. Local community mentioned that WWTPs using nature-based solutions (vermifilter and constructed wetland) had the worst performance in all subcategories. While that, conventional WWTPs (activated sludge) had the best behaviour. The best evaluated subcategory was safe and healthy living conditions (0.56) and the worst evaluated one was community engagement (0.06). In short, although there were differences between nature-based vs. conventional solutions, these were not related to the type of WWTP, but rather to the operation. WWTP who have ongoing dialogue with the community tend to have better perceptions than those who don't.

On the other hand, workers reported that WWTPs using nature-based solutions (vermifilter and constructed wetland) had the worst performance; while that, conventional WWTPs (activated sludge + bio-discs) showed the best behaviour. The best evaluated subcategory by workers was health and security (0,28) and the worst evaluated subcategory was opportunities equal opportunities and treatment (0.13). In conclusion, workers in rural WWTP often perceive negative aspects, when their safety and health are not prioritised. While salary was an important issue for them, it was only relevant when they had odd or part-time jobs. Working conditions are also reflected in less training, which could influence a better functioning of WWTPs.

Table 1. AHP results per stakeholder and technology (WWTP).

	Local community			Workers		
WWTP	Score (%)	Preference	Position	Score (%)	Preference	Position
Vermifilter	12	9.3	5th	6	6.0	5th
Constructed wetland	15	19.3	4th	8	11.8	4th
Aeration lagoon	17	23.6	2sd - 3th	13	28.5	
Activated sludge	17	23.6	2sd - 3th	17	40.8	1st
Activated sludge + bio-disks	17	23.4	1st	9	12.9	3th

Abstract

Social acceptance is an important factor in terms of the success and feasibility of the technologies' implementation in relation to water and nutrient reuse systems. To implement these systems successfully, it is necessary not only to design this technology, but also to have social support and willingness among citizens to use it. In this study, after having conducted a social network analysis, we analyse the acceptance profiles for nutrient reuse technologies of the key stakeholders in four demo-sites in Europe. The demo-sites are located in Ghent (Belgium), Vigo (Spain), Helsingborg (Sweden), and Sneek (The Netherlands).
A qualitative approach for empirical data collection was used to analyse the acceptance profiles grounding in a thematic analysis of the focus groups conducted to different type of target groups: users's of technology, technology developers, farmers, fertiliser companies, environmental associations among others. According to the analysed data relating to the acceptance profiles, we addressed how perceived advantages and disadvantages from the stakeholders varies depending on the strength level of engagement to the systems development. Therefore, information about the technologies, needs to be used in a way that is most adapted to the audience so that relevant type of audiences are able to understand the added value of these technologies.This requires the development of communications that are part of a defined strategy and that are implemented with a two-way process of information integrating the behaviour and opinion of the users periodically gathered. Thus, we observed that the level of acceptance of the technologies and willingness to use the products from nutrient reuse is favourable around these four pilot decentralised systems.

Monitoring of odorous emissions in WWTPs: proposal for a simple procedure

L. Palli*, D. Fibbi* and E. Coppini*

* G.I.D.A. Spa, Via di Baciacavallo 36, Prato, IT
(E-mail: l.palli@gida-spa.it; d.fibbi@gida-spa.it; e.coppini@gida-spa.it)

Abstract
The most commonly used technique worldwide to determine odor concentration is the dynamic dilution olfactometry, while in this paper we propose a simple and low-cost procedure for the monitoring of the evolution of odor emissions. The procedure consists in a sensory surveys based on the olfactory perception of odors by a selected group of people. A list of points in which to carry out the odor monitoring is decided. During the inspections, the subjects evaluate, at each point, the intensity, the hedonic tone and the nature of the odor. The collected intensity and hedonic tone data are multiplied (IxHT) and then the matrix of IxHT values is mapped, where the most odorous points are easily and immediately visualized. The proposed technique allowed to detect modifications in the nature and in the intensity of the odors, as well as seasonal changes. Furthermore, the simplicity and low cost of the procedure make it applicable to any system and with very high frequencies.

Keywords
Hedonic tone; Intensity of the odor; Nature of the odor; Sensory survey; Simple procedure; WWTP.

INTRODUCTION

Wastewater treatment plants (WWTPs) are considered to be one of the main causes of unpleasant odors noticed by the exposed population (Zarra et al., 2008). Odor emissions from WWTPs are characterized by the presence of a large number of volatile odorants (mainly sulfur and organic compounds) at trace level concentrations, which usually render them harmless from a toxicological point of view (Lebrero et al., 2011). However, monitoring odor emissions from WWTPs over time is important, especially if the plant is located near residential areas. The most commonly used technique worldwide to determine odor concentration is the dynamic dilution olfactometry, based on the concept of the detection threshold and the use of a set of human sensors (panelists) (Sneath, 2001). This technique, despite being the most reliable and reproducible for this type of measurement, is complex and very expensive and for this reason it cannot be performed very frequently. In this paper we propose a simple and low-cost procedure for the monitoring of the evolution of odor emissions from WWTPs which has been performed for over 5 years in two large WWTPs in Italy.

MATERIALS AND METHODS

The procedure consists in a sensory surveys based on the olfactory perception of odors by a selected group of people. The suitable subjects to carry out the inspections were selected excluding that any habits (e.g. cigarette smoke) or pathologies of the respiratory system could make their judgment unsuitable or ineffective. The surveys are carried out four times per year, in the months of March, June, September and December to cover any seasonal differences. A list of points in which to carry out the odor monitoring has been decided, both internally and externally to the plant, choosing internally the most odorous points (emission points) and externally sensitive points (e.g. presence of houses). During the inspections, the subjects evaluate, at each point, the following characteristics of the perceived odor: a) Intensity of the odor, expressed with a number ranging from 0 (perceptive threshold), up to 6 (irritation threshold); b) Hedonic tone of the odor, or unpleasantness (its acceptability), evaluated on scales from 0 to 6; c) Nature of the odor: represents the type and characteristics of the perceived odor. The collected intensity and hedonic tone data are then multiplied to calculate the average product intensity per hedonic tone (IxHT) for each season and each point, thus obtaining a matrix containing the values of the IxHT product. The implant surface was then divided into pertinent areas associated with each monitoring point using the Thiessen polygon method and finally the matrix of IxHT values was mapped, assigning a different color for different IxHT product ranges.

RESULTS AND DISCUSSION

An example of results is presented in figure 1. As can be seen, the most odorous points are easily and immediately visualized with darker colors and, in this example, are located near to the sewage inflows and to the septic tank sludge discharge point. Outside of the plant the odor is generally ten times lower and close to the perception threshold. As far as the nature of the odor is concerned, internally most odors are due to the existing treatment processes (such as sewage or ozone), while in the external monitoring, no odors whose nature can be traced back to the system were perceived.

Figure 1. Examples of mapping of the product IxHE (left) and nature of the odor (right).

CONCLUSIONS

The proposed technique has been performed for over 5 years in two large WWTPs in Italy managed by GIDA spa and it allowed to detect modifications in the nature and in the intensity of the odors, as well as seasonal changes. Furthermore, the simplicity and low cost of the procedure make it applicable to any system and with very high frequencies.

The effect of liquid wastes on a full-scale WWTP nitrogen removal performance

L. Palli*, E. Bacarelli*, F.F. Borchi* and D. Daddi*

* G.I.D.A. Spa, Via di Baciacavallo 36, Prato, IT

Abstract
In some regions most homes are equipped with septic tanks that remove most of the solids and organic matter from domestic wastewater. This habit drastically removes the organic matter content in the receiving system. Having a very low COD leads to a low COD/N ratio which negatively affect the removal of nitrogen. In this study we took as a case study a large plant (190·000 PE) treating municipal wastewater and liquid wastes and we evaluated the impact of septic tank sludge on nitrogen removal. In order to understand the effect of liquid waste on the efficiency of TN removal we evaluated the COD/N ratio of the actual influent of the WWTP and we compared to the COD/N ratio of the the influent of the plant in the absence of liquid wastes. This could be compared with the stoichiometric ratio which is generally considered equal to 4.2 gCOD/gN. However, this ratio is almost never sufficient in real conditions, and the critical COD/N ratio is considered to be about 7.6 gCOD/gN. In case of sewage only, out of 149 determinations, 32 have a ratio of less than 4.2 (21%) and 60 have a ratio of less than 7.6 (40%). We then calculate, day by day, the theoretical percentage of denitrification in the absence of liquid waste, assuming it equal to the real one when the COD/N ratio is greater than 7.6 and reducing it proportionally when the ratio is lower. We found out that the addition of liquid waste in the treatment helped increase the COD/N ratio and consequently increased the removal of nitrogen. We have estimated that without liquid wastes the TN discharged in the environment would be, on average, 18% higher than the real one leading to, considering the total volume of water discharged, almost 17 ton of N released in the environment. We can therefore conclude that, for the present case, the presence of liquid waste, in particular septic tank sludge is of crucial importance for the process of nitrogen removal.

INTRODUCTION

Municipal Wastewater Treatment Plants (WWTP) are designed to treat municipal wastewater and primarily remove solids, organic matter and nutrients such as nitrogen. In some regions, such as Tuscany (Italy), most homes are equipped with septic tanks that remove most of the solids and organic matter from domestic wastewater. This habit reduces the risks of odors and sediments in the sewage system, and reduce the risks linked to the combined sewer overflows, but also drastically removes the organic matter content in the receiving system (Bounds 1997). Consequently, most of the plants in the region receive low COD sewage (often below 125 mg/L which is the discharge limit into surface waters in Italy) (Campo et al., 2020). Having a very low COD leads to a low COD/N ratio which negatively affect the removal of nitrogen, therefore returning this COD to the plants could be useful for nitrogen removal. Some plants, in addition to sewage, also jointly treat liquid waste such as sludge from septic tanks. In this study we took as a case study a large plant (190 000 PE) treating municipal wastewater and liquid wastes and we evaluated the impact of septic tank sludge on nitrogen removal.

MATERIALS AND METHODS

The studied WWTP is located in Tuscany and treats urban wastewater and liquid wastes jointly. The wastewater treatment train is composed of bar screen, grit removal, primary sedimentation, equalization, denitrification, oxidation-nitrification, secondary sedimentation, clariflocculation and final ozonation. Liquid wastes are mainly composed by septic tanks sludge (about 100 000-115 000 ton per year) and landfill leachates (about 150·000-180·000 ton per year), while total sewage is about 9-11 millions of m^3 per year. Septic tank sludge (STS) is pre-treated in a separate line with screening and grit removal and then is pumped in the plant before grit removal, while landfill leachates (LFL) are pre-treated in an MBR plant and then pumped prior to primary sedimentation. In this study we collected for over a year daily samples of sewage, STS, LFL, primary influent (which is the actual mix of the above three components) and plant effluent. In these samples we evaluated COD, total nitrogen (TN) and the inorganic forms ($N\text{-}NH_4^+$, $N\text{-}NO_2^-$, $N\text{-}NO_3^-$) in order to evaluate the COD/N ratio and the removal efficiency of nitrogen in the plant.

RESULTS AND DISCUSSION

Table 1 depicts average values of COD and TN in the sampling points and clearly shows that sewage influent has a much lower COD content that the primary influent, which is enriched by the organic matter coming mainly from STS. The performance of the plant made it possible to comply with the TN discharge limit (which is 10 mg/L on the average value) with a total removal efficiency of 78%.

Table 1. Average values of COD and TN in all the sampling points.

Sampling point	Average COD value (mg/L)	Average TN value (mg/L)
Sewage	317	32
Septic tank sludge	20044	580
Pretreated LFL	1820	403
Primary influent	889	43
Plant effluent	70	9,7

In order to understand the effect of liquid waste on the efficiency of TN removal we evaluated the COD/N ratio of the primary influent (which is the actual influent of the WWTP) and we compared to the COD/N ratio of the sewage only, which would be the influent of the plant in the absence of liquid wastes. In order to understand if the sewage COD/N was sufficient for effective denitrification, this could be compared with the stoichiometric ratio which is generally considered equal to 4.2 gCOD/gN (inter alia Carrera et al, 2004). However, several experimental studies have shown that this ratio is almost never sufficient in real conditions, since it depends on the degree of reduction of the substrate. In fact, when the carbon source is not an easily degradable substance such as methanol or acetate normally used in laboratory experiments, the critical COD/N ratio is considered to be about 7.6 gCOD/gN (Carrera et al., 2004; Sobieszuk and Szewczyk 2006). Results, calculated for a year, are presented in figure 1.

As can be seen, actual plant influent is always well above both the stoichiometric and the experimental ratios, which means that the denitrification efficiency is always possible at its maximum rate. In case of sewage only, out of 149 determinations, 32 have a ratio of less than 4.2 (21%) and 60 have a ratio of less than 7.6 (40%). Taking these data info consideration, it can be stated that, when the ratio is lower than the minimum required, the denitrification can be affected. In particular, Carrera et al found out the denitrification percentage decrease linearly with the decrease in the COD/N ratio. Using this model, it is possible to calculate, day by day, the theoretical percentage of denitrification in the absence of liquid waste, assuming it equal to the real one (78%) when the COD/N ratio is greater than 7.6 and reducing it proportionally when the ratio is lower. Results are presented in Figure 2 and Table 2.

As can be seen, in the absence of liquid waste, the mean TN removal would decrease of about 17% and, even though the TN in the influent would be lower, the TN in the effluent would be higher and, in this case, would not allow the compliance of the discharge limit.

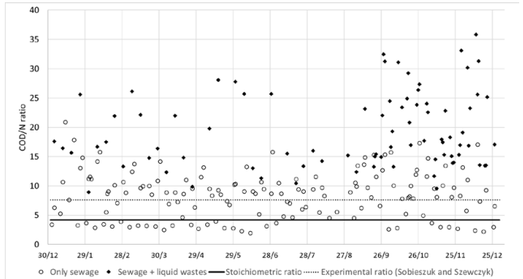

Figure 1. COD/N ratio of sewage and actual plant influent (sewage + liquid wastes) compared to stoichiometric ratio and experimental ratio.

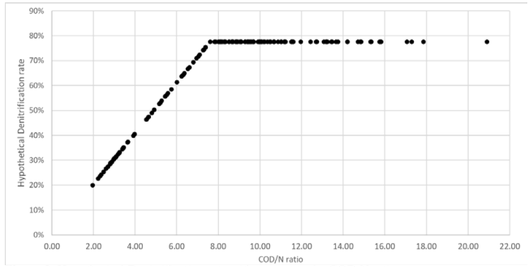

Figure 2. Hypothetical Denitrification rate with respect to the COD/N ratio

Table 2. TN in the influent and in the effluent in real condition and without liquid waste

	Real conditions	Without liquid waste
TN influent (mg/L)	43,1	32,2
Mean TN removal (%)	78%	64%
TN effluent (mg/L)	9,7	11,5

CONCLUSIONS

This study allowed to evaluate the effect of joint treatment of liquid waste such as septic tank sludge and urban wastewater in the removal of nitrogen. We found out that the addition of liquid waste in the treatment helped increase the COD/N ratio and consequently increased the removal of nitrogen. We have estimated that without liquid wastes the TN discharged in the environment would be, on average, 18% higher than the real one leading to, considering the total volume of water discharged, almost 17 ton of N released in the environment. We can therefore conclude that, for the present case, the presence of liquid waste, in particular septic tank sludge is of crucial importance for the process of nitrogen removal.

Abstract
Cities around the world face a number of challenges, including climate change and ecosystem degradation. Nature-based solutions (NbS) can help protect us from the impacts of climate change while also ensuring ecosystem services. However, NbS still face implementation barriers, mainly in developing countries. In order to identify and compare the state of NbS implementation and the main challenges to be addressed in European and Latin American cities, we reviewed and analyzed different case studies and projects published in peer-reviewed articles and gray literature. It was reported that NbS are still evolving as a concept and are not widely implemented in Latin America, mainly due to limited availability of financial resources. There is a marked imbalance in the distribution of studies, with most cases concentrated in the global north, although southern global countries are generally most vulnerable to the impacts of climate change. In Europe, the concept is more integrated into urban planning, however, there are also barriers such as limited understanding of the benefits of NbS by society. The main challenges that Latin American cities aim to address with NbS are agrobiodiversity and improved water management. On the other hand, in Europe, there is a priority to increase urban green infrastructure, as it plays an important role in carbon storage and mitigating the impacts of greenhouse gas emissions in cities.

Keywords
Climate change, Europe, Latin America, Nature-based solutions, Social challenges

INTRODUCTION

Nature-based solutions (NbS) are a concept that is currently gaining ground to address urban challenges. NbS mainly address 7 social challenges including climate change adaptation and mitigation, reduction of natural disaster risk, reversing ecosystem degradation and loss of biodiversity, human health, socio-economic development, food security and water security (IUCN, 2020). In regions with different economic and social realities than developed countries, nature-based solutions are a foreign concept, whose enforcement presents many challenges and limitations. This study aims to describe the state of implementation and challenges that NbS seek to address in Europe and Latin America through a comparative analysis.

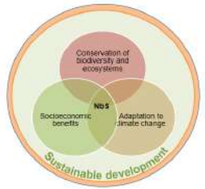

Figure 1. Challenges addressed by NbS

MATERIALS AND METHODS

This work involved a structured search of scientific and grey literature related to Nature-based Solutions (NbS) projects or studies in Europe and Latin America. The obtained literature was analyzed based on the review of the evolution of the NbS topic, its implementation level and the social and environmental challenges to be addressed in these two regions. In addition, limitations, knowledge gaps and opportunities for the implementation of NbS were identified by comparing the literature available in the north and south global. This qualitative method serves as an exploratory tool to achieve a clear picture of the development trajectory of NbS implementation.

RESULTS AND DISCUSSION

The EU has positioned itself as a world leader in NbS research and innovation. Increasingly, European cities are adopting NbS in their public policies, urban plans and programs and their implementation. On the other hand, Latin America society, in general, still does not perceive the importance and benefits of NbS. In this way, public works of another nature associated with the traditional infrastructure are prioritized. Thus, a large part of the projects that are being implemented are still in the phase of preparation and search for financing. One of the main limitations in both Europe and Latin America is the lack of information and data necessary to measure the potential benefits. However, since 2012 the EU has funded multisectoral projects with case studies in Europe and Latin America, which has boosted NbS research in this region as well (Davies et al., 2021). In general, most government objectives for NbS are focused on forests, therefore funding is currently channeled mainly towards tree planting (Seddon et al., 2021). However, this perception is different in Europe and Latin America. The low access of people to green areas is the main challenge in European cities. In Latin America, projects combining conservation and agriculture and solutions focused on improving water management, such as controlling runoff, floods, and rainwater, predominate (Ozment et al., 2021). In general, the social and environmental challenges that NbS are intended to address are different in the two regions. This depends on the local contexts in the environmental, political, economic and social spheres; therefore, more research is needed in terms of cost/benefit analysis and implementation opportunities.

Abstract
Sludge treatment reed beds (STRBs) are an interesting approach to dewater and mineralize sewage sludge. While these nature-based solutions are robust and efficient to dewater and stabilize activated sludge, they are also promising in providing as final product biosolids that can be used as fertilizer – if legislation allows for it. For this, the quality of the treated sludge is important from two angles: 1) the agricultural use potential based on dry content and nutrients composition, and 2) the content of harmful substances is below threshold limits. One of the critical steps to optimise STRBs performance, and therefore the quality of the final biosolid, is the operation regime which ensures proper sludge dewatering and mineralization. A larger study was carried to compare the performance and efficiency of three types of operation mode: passive aeration, draft aeration or forced aeration). The results herein focus on the different dynamics of degradation and/or accumulation of biocides and pharmaceuticals observed in one of the experiments carried out in Slovenia.

INTRODUCTION

Sludge treatment reed beds (STRBs) are an established technology for the management of sludge produced by wastewater treatment plants (Nielsen & Bruun 2015; Brix 2017). Reed beds were used for the first time in Denmark in 1988, when the first sludge processing system was introduced (Nielsen 2003). These systems are now a widespread and common sludge treatment practice in northern Europe, especially in Denmark, and are being used increasingly worldwide. Primary or secondary liquid sludge is loaded on the surface of the reed bed over several years, where long-term (10-12 years) sludge reduction takes place, partly due to dewatering and partly due to decomposition of the organic matter in the sludge (Matamoros et al. 2012).

It is known that the use of sewage sludge or biosolids as agricultural amendments can pose environmental and human health risks related to pathogens and/or antibiotic resistance. A study under Mediterranean climatic conditions demonstrated that the presence of ampicillin-resistant bacteria increased in amended soils 4 months after urban sludge application (Gondim-Porto et al. 2016). The long-term application of sewage sludge and chicken manure significantly increases the abundance and diversity of ARGs in soil (Chen et al. 2016).

In spite of the long-term of mineralization period (10-12 years), STRB operational procedures indicate that the ultimate load should be dewatered and stabilized for 6 months before sludge can be disposed as a biosolid for agriculture (Nielsen & Willoughby 2005). It is uncertain if this time period is enough to ensure the decay of antibiotics and other micropollutants to the environment.

The current project aims to evaluate for the first time the fate of micropollutants, including antibiotics, in STRBs.

MATERIAL AND METHODS

A pilot system was set up at Dragomer, Slovenia (Figure 1) and operated for several experiments until 2022. The pilot contains 9 basins in triplicates for the three of operation mode: passive aeration, draft aeration or forced aeration.

Experimental setup and sampling

Several bags containing the "initial" loading sludge of the beds were wrapped up with a permeable material to replicate natural conditions of water and micropollutant exchange. The bags were left while different sludge loading campaigns were performed onto the STRBs. After each loading campaign, three bags of each bed were pulled off and air dried. The air-dried sludge was used for organic micropollutant quantification.

Analysis

Sludge/biosolids samples were extracted by a two-step process, first water, second methanol, using an ultrasonic bath. The extracts were analysed by LC-MS/MS using two multi-compound methods, one targeting 13 biocides the other 36 pharmaceuticals (Thomsen et al. 2020). Concentrations are reported as dry weight of sludge.

Figure 1. Photo of the pilot at Dragomer, Slovenia in September 2019. The pilot contains 9 basins in triplicates for the three of operation mode: passive aeration, draft aeration or forced aeration.

RESULTS AND DISCUSSION

The biocides irgarol, pyraclostrobin and pirimicarb were detected in the initial sludge, while terbutryn (7 ± 1 ng/g) and the benzalkonium chloride 12-BAC (861 ± 83 ng/g), 14-BAC (210 ± 16 ng/g) and 16-BAC (28 ± 4 ng/g) were quantified. In terms of pharmaceuticals the occurrence was higher than for biocides. The pharmaceuticals tramadol, olmesartan and gabapentin were only detected in the initial sludge, while Azithromycin (75 ± 20 ng/g), Claritromycin (18 ± 4 ng/g), Ciprofloxacin (992 ± 151 ng/g), Propanolol (17 ± 3 ng/g), Carbamazepin (14 ± 1 ng/g), Citalopram (103 ± 13 ng/g), Diclofenac (38 ± 4 ng/g), Phenazone (2 ± 0.2 ng/g), Venlafaxine (21 ± 4 ng/g), Losartan (18 ± 1 ng/g) and Benzotriazole (274 ± 138 ng/g) were quantified.

In terms of fate, we observed three main behaviours of the compounds in time, decrease, no changes and increase in concentration, depending on the compounds (Figure 2). The pesticide terbutryin was stable, 12-BAC and 14-BAC shown a decrease trend, while 16-BAC concentration tended to increase. However, these variations were not significant. For the pharmaceuticals, several compounds showed decrease in concentration such as azithromycin ($p < 0.05$), propranolol, diclofenac ($p < 0.05$), venlafaxine ($p < 0.05$). Carbamazepine, citalopram, and losartan concentration did not change. An increase in concentration was observed for clarithromycin, ciprofloxacin, phenazone ($p < 0.05$) and benzotriazole ($p < 0.05$).

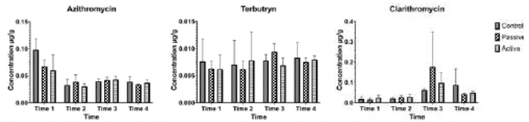

Figure 2. Selected results from representative organic micropollutants showing decrease, no changes and increase in concentration over time.

Statistical tests showed that time was the major variable affecting the micropollutants concentration, while operation mode did not provide any marked difference. It should be noted that the sludge samples in the bags were exposed to x new loadings, thus the increase in concentration. This also implies that a decrease in concentration implies not only biodegradation of the original sorbed compound, but potentially of new amounts that were inserted in the pilots. The experimental setup was considered interesting for understanding removal and accumulation rates in time, but does not allow to perform a mass balance, as the dynamics of a new load implies adding a liquid and a solid fraction and the potential percolation of compounds across de system. Nevertheless, the current results show that emerging contaminants have the potential to be both degraded and accumulated in STRBs in time. This means that it is very important in the future to characterize the stabilization of such systems during the last 6 months of operation without new loads.

Abstract
This study aimed to elucidate the effects of environmental and social factors on eutrophication in Tonle Sap Lake and to propose effective countermeasures against lake eutrophication. The impact of environmental and social factors on eutrophication was analyzed based on Primary Production model sensitivity and scenario analysis. The results showed that the reduction or increase of dissolved inorganic phosphorus concentration in tributaries had highly influential on the percentage of their eutrophication area compared to the baseline eutrophication during 2016–2019 (*%EE*) more than the reduction or increase of particulate inorganic phosphorus and suspended solid concentration in tributaries. For the scenario of the population in 2080, *%EE* could increase by 6.5% in October. In the scenario of wind, Max. wind in 2000 had the highest impact on *%EE*. The countermeasures against eutrophication in less than 10 years are required to reduce phosphorus loading from bed sediment and external loading.

Keywords
Eutrophication, environmental and social factors, Tonle Sap Lake

INTRODUCTION

Tonle Sap Lake (TSL) is the largest tropical lake-floodplain system in Cambodia, being influenced by the seasonal flood pulse of Mekong River. TSL and its ecosystems are seriously threatened by anthropogenic activities such as the development of water infrastructure, population growth, and wastewater pollution, while they are poorly understood in most aspects. Thus, it is important to understand the impact of these environmental and social factors on eutrophication in this lake. Therefore, the objectives of this study are to elucidate the effects of environmental and social factors on eutrophication in TSL and to propose effective countermeasures against lake eutrophication for its short-term (i.e., shorter than 10 years) environmental management.

METHODOLOGY

The impacts of environmental and social factors including suspended solid (SS), dissolved inorganic phosphorus (DIP), and particulate inorganic phosphorus (PIP) concentration in the tributaries, population growth, and wind speed on eutrophication, were analyzed using Primary Production (PP) model of Theng et al. (2023) as illustrated in **Table 1**. Each condition was analyzed by comparing it to the baseline condition (**Table 1**). The indicator of this study was in terms of the percentage of eutrophication in each condition compared to the baseline eutrophication (*%EE*).

RESULTS AND DISCUSSIONS

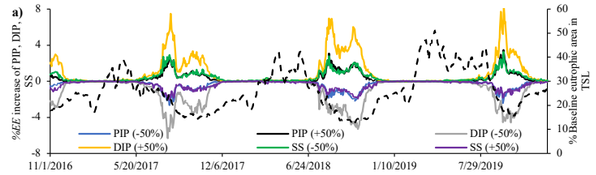
The application of the PP model showed the reduction or increase of DIP concentration in tributaries by 50% from the baseline concentration had a higher influence on *%EE* than the reduction or increase of PIP and SS concentration in tributaries (**Fig. 1a**). Phytoplankton directly uptakes DIP for their growth. Thus, the increment and reduction of DIP concentration in the water directly impact phytoplankton growth. In the scenario of population growth, the *%EE* would be higher than the baseline by 0.7% – 1.8% for the scenario of Pop_2040, 1.5% – 3.9% for Pop_2060, and 2.4% – 6.5% for Pop_2080 (**Fig. 1b**). In the scenario of wind, Max. wind in 2000 had the highest wind speed in 1981 – 2019 and its impact on monthly *%EE* was 0.6% – 15.0% as it could increase sediment carrying capacity through wind-induced surface shear stress and net resuspension which directly increase SS and PIP concentration. According to spatial sensitivity analysis, the effective countermeasures against eutrophication in TSL in a short-term period (i.e., less than 10 years) are to reduce phosphorus internal loading, especially focusing on diffusion from bed sediments, in addition to the reduction of the external loadings from tributaries and villages (unshown figure).

CONCLUSION

The application of the PP model showed the reduction or increase of DIP concentration in tributaries had a higher influence on *%EE* than the reduction or increase of PIP and SS concentration in tributaries. In the scenario of population growth, the *%EE* would be higher than the baseline by 2.4% – 6.5% for Pop_2080. The wind data affect eutrophication as it could increase sediment carrying capacity. The effective countermeasures against eutrophication in TSL in a short-term period are to reduce phosphorus internal and external loadings.

Table 1. Conditions of environmental and social factors impacted eutrophication in TSL

Factors	Condition		
Baseline condition	Simulation of eutrophication and input data during 2016–2019 using PP model		
SS, DIP, PIP concentration in tributaries	-50%	+50%	
Population growth	2040 (Pop_2040)	2060 (Pop_2060)	2080 (Pop_2080)
Wind speed and direction	1981 (Average wind)	2000 (Max. wind)	2010 (Min. wind)



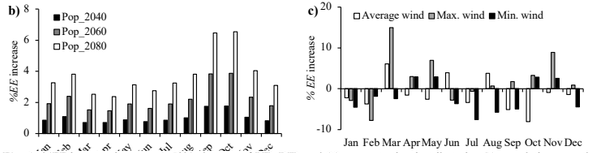


Fig. 1. *%EE* increase in case: **a)** 50% changes of PIP, DIP, and SS concentration in tributaries, **b)** population growth, and **c)** wind speed in 1981, 2000, and 2010 which is the average, maximum, and minimum wind speed during 1981–2019, respectively.

Abstract
The objective of this study is to analyse the removal of certain metals (Pb, Cd, Ni, Zn, Cu, Sn, Ba, B, Cr tot, and Sb) from a large wastewater treatment plant (WWTP) located in the Italian textile district of Prato. For this purpose, two monitoring campaigns were organized, collecting wastewater and sludge samples in some selected sections of the WWTP. It was found a good removal efficiency for Zn, Cu, Ba, Cr, and Sb. These metals are mainly present in a particulate form and leave the plant via the sludge stream. Finally, the good correlation between the influent load and the removed contaminant load demonstrates that the removal efficiency of the plant is not affected by the increasing influent load.

Keywords
Heavy metals; mass balance; metals removal mechanism; sustainability; textile wastewater

INTRODUCTION

Prato (Central Italy) is one of the biggest textile districts in Italy and the most relevant textile centre in Europe. It was the first textile district to create a centralized wastewater treatment plant (WWTP), managed by the company GIDA S.p.A., which treats both domestic and industrial wastewater (mainly originated by textile industries). According to Italian Law, textile industries must have an Integrated Environmental Authorization released upon the Best Available Techniques (BAT). It was necessary to verify the removal capacity of the WWTP for some chemical substances because of the new emission levels provided in the BAT conclusions recently published on the website of the European IPPC Bureau (European Union, 2023). The objective of this study is to analyse the behaviour of some specified metals mainly originating from industrial processes. For this purpose, two monitoring campaigns were organized to study the behaviour of the following metals: Pb, Cd, Ni, Zn, Cu, Sn, Ba, B, Cr tot, and Sb. The final goal is to verify that the removal of these contaminants is due to an effective treatment process and not just to a dilution effect with domestic wastewater.

MATERIALS AND METHODS

The Baciacavallo WWTP (designed for 900'000 PE) treats domestic and industrial wastewater with an average inflow of about 100'000 m^3/d. Industrial wastewater represents approximately 70% of the total influent flow (Muoio et al., 2019) and is partly collected by a separate sewer system. The treatment process (Figure 1) includes screening, grit removal, primary sedimentation, equalization, biological oxidation/nitrification, clariflocculation, and final ozonation. The final effluent is partly discharged into a surface water body and partly sent to the refining section for water recycling in the textile district. The secondary and tertiary sludges are recycled in primary sedimentation and removed together with the primary sludge. The sludge treatment consists of gravity thickeners, centrifuges, and final incineration. Thickener overflow and centrate are recycled into the primary sedimentation unit.

Wastewater sampling was carried out from October 2021 to October 2022. Samples were taken once a week and collected in the same sections of the plant. In this campaign, the composite samples of wastewater were taken simultaneously from the separate sewer system, the influent of the plant, the influent of the biological treatment, the effluent of the tertiary treatment, and the effluent of the plant (Figure 1), without considering the residence time of the WWTP (about 24 h). A further intensive monitoring campaign was carried out in May 2022. Wastewater samples were collected over eight consecutive days, including Saturday and Sunday, in the same sections mentioned above. 24-hour composite samples upstream of the biological treatment (sampling points A, B, C) were taken simultaneously, while those downstream of the tertiary treatment (sampling points D, E) were collected simultaneously but with a delay of 24 h. This sampling rate allowed enough correspondence between influent and effluent samples, a prerequisite for mass balance calculations. The total and dissolved concentrations of heavy metals were determined. In addition, grab samples of sludge were collected from the primary, secondary, and tertiary sludge, while grab samples of the final dewatered sludge were collected one day later, which is the retention time of the thickeners.

RESULTS AND DISCUSSION

Pb, Cd, Ni, and Sn concentrations were always under the Limit of Detection (LOD) both in the separate sewer system and in the total influent of the plant. For this reason, they are not worthy of further evaluations. Regarding the other species, the average removal efficiency of the mass load is higher than 50% for Ba, Cr, and Sb (Table 1). The intensive monitoring campaign confirms these results and shows average removal efficiencies of Zn, Cu, Ba and Sb different from the one obtained previously. Since these species are characterized by high concentration variability, results demonstrate the importance of the sampling procedure. Metal removal efficiencies in WWTPs are mainly related to metal partitioning between the liquid and the solid phase (Cantinho et al., 2016). As shown in Figure 2, most of the species are bound to the particulate matter (Zn, Cu, Cr, and Sb), Ba shows a half and a half distribution, and B is present in a soluble form (this could explain its low removal). The principal mechanism usually considered for metal removal is sorption. Thus, assuming no biodegradation, the total heavy metal load of untreated wastewater will end up in the sludge or remain in the treated effluent. For most metals, release via sludge is expected to be more relevant than via the treated effluent (Karvelas et al., 2003). In this study, the relative importance of the two release processes was calculated daily and mean values are reported in Figure 3. The amount of metal released from the WWTP via the sludge stream varies from 70% for Ba and Sb up to 84% for Cr. Regarding B, since it is mainly present in a soluble form, it is almost entirely released with the final effluent stream.

Finally, a linear correlation between the metal load removal and the metal load in the influent of the WWTP was found (Figure 4). Results demonstrate that the removal efficiency of the WWTP is not affected by the increasing influent load. It means that, at these observed contaminant loads, the sludge cannot achieve its saturation point, and it is still able to remove metals from the water.

CONCLUSIONS

A detailed characterization of the metal's influent on the Baciacavallo WWTP (Central Italy) was carried out. Pb, Cd, Ni, and Sn concentrations are almost always below the LOD. The most significant species are Zn, Cu, Ba, Cr tot, and Sb because they are typically associated with textile wastewater. The monitoring campaigns have demonstrated that the WWTP can remove these contaminants through an effective treatment process since Zn, Cu, Ba, Cr, and Sb are mainly present in a particulate form and thus released from the WWTP via the sludge stream. B is in a dissolved phase and almost entirely delivered with the final effluent stream. Finally, it was found that the removal efficiency of the plant is not affected by the increasing influent load.

Table 1. Removal efficiency (%) of metals' concentrations and mass load calculated for the one-year monitoring campaign and for the intensive one-week monitoring campaign (mean ± STD).

Removal efficiency	One-year monitoring campaign		One-week monitoring campaign	
	Concentration	Mass load	Concentration	Mass load
	Mean±STD	Mean±STD	Mean±STD	Mean±STD
Zn	37±19	39±18	76±12	75±19
Cu	39±20	42±20	57±8	63±11
Ba	58±3	62±5	63±3	68±9
B	19±17	25±15	13±6	27±10
Cr tot	81±6	81±7	78±11	80±11
Sb	68±15	71±13	58±21	61±28

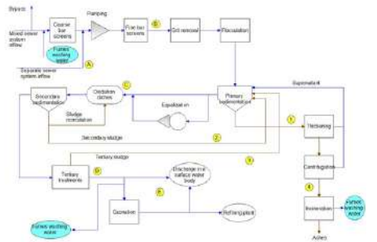

Figure 1. Flowchart of Baciacavallo WWTP. The yellow labels show the sampling points: A: separate sewer system inflow; B: influent of the WWTP; C: influent of the biological treatment; D: effluent of the tertiary treatment; E: effluent of the plant; 1: primary sludge; 2: secondary sludge; 3: tertiary sludge; 4: dewatered sludge.

Abstract
Water security can contribute positively to Sustainable Development Goals implementation and synergies. Indigenous perspective can complement to the original definition of water security with the incorporation of concepts such as indigenous culture and traditional knowledge. In this work, we describe the challenges of indigenous perspective on water security in the Amazon region: environmental threats, environmental biodiversity, water resources, drinking water, adaptation, spiritual and cultural, governance and institutional.

Keywords
Amazon, challenges; indigenous perspective; water security

INTRODUCTION

Water availability is of humanity interest given its character of essential resource for human activities, ecosystems, and life on the planet. Water security may be compromised due to climate crisis. The impacts of climate change could be manifested mainly through water, in particular by changes in extreme weather events, resulting in droughts, floods, and pollution. Given this, the 2030 Global Agenda has set Sustainable Development Goals (SDGs) for both water (SDG 6) and climate change (SDG 13), with strong linkages between the targets associated with these goals, emphasizing the climate change-water nexus (Babel et al., 2020). Improving water security with focus on vulnerable population can contribute to respond to the water-related challenges of climate change. However, there is still a long way to go to achieve SDGs.

Improving water security can contribute positively to SDGs implementation and synergies (Taka et al., 2021). Water security has been a relevant object of study for researchers in the world in the last decade (Chiluwe & Claassen, 2020), with multiple definitions (Zeitoun et al., 2016). For example, Grey & Sadoff (2007) define water security as "the availability of an acceptable quantity and quality of water for health, livelihoods, ecosystems, and production, coupled with an acceptable level of water-related risks to people, environments and economies". Few studies have focused on water security from an indigenous perspective, which could constitute a complement to the western science definition as mentioned by Grey & Sadoff (2007). The indigenous perspective enriches and diversifies water security discourse through the incorporation of concepts such as indigenous culture and traditional knowledge (Awume et al., 2020).

METHODS

This work aims to review the literature on the challenges of the indigenous perspective on water security in the Amazon region. We identified the most relevant scientific literature in Web of Science using the key words "water security", "indigenous perspective" and "Amazon", supplemented with an online search of the Amazon context.

RESULTS AND DISCUSSION

The indigenous communities from the Amazon have a combination of different environmental threats such as deforestation and water pollution by economic and urban activities, and also fires, floods, and droughts by extreme weather events (Esquivel-Muelbert et al., 2019; Rorato et al., 2021). It is a challenge to access affordable drinking water with good quality and quantity due to institutional policies that have been implemented without the Amazonian geographic, biodiversity, spiritual and cultural, social, governance, and economic context. Despite this, the indigenous communities in the Amazon have long adapted to the many water challenges by using indigenous culture and traditional knowledge. But, as the years go by, the adaptation will have to take greater efforts, and thus strengthening of water systems will become more and more necessary. Therefore, the challenges of indigenous perspective on water security in the Amazon region are environmental threats, environmental biodiversity, water resources, drinking water, adaptation, spiritual and cultural, governance and institutional (see Figure 1).

Abstract
Fatty waste and wastewaters have been proved to be suitable for bioplastics production, but the development of the technology is still on its earlier stages. The national funded project ECOPOLYVER aims at taking the valorisation process to pilot scale as well as to develop the information required to include the bioplastics end-of-life (EoL) stage when evaluating the environmental performance of the complete value chain. In fact, EoL is normally excluded with the excuse of the bioplastics´ biodegradability and the lack of the required data for the inventory and impact assessment phases. Therefore, the main objective of this work is to obtain experimental data on accelerated degradation of bioplastics with the aim of filling such gap on the EoL of bioplastics.

characterization factor; fatty waste valorisation; life cycle assessment; marine litter; PHA; polyhydroxyalkanoates.

INTRODUCTION

The fish and seafood sector generates large volumes of wastewater rich in lipids. At the moment, several strategies are under development to valorise these fatty residual streams into value-added products such as bioplastics, i.e. polyhydroxyalkanoates (PHA) (Roibás-Rozas et al., 2020). PHA are biodegradable polymers that can substitute oil-based plastics, which are materials consumed by the companies that generate this waste. By doing so, the fish and seafood sector would be able to implement real circular economy strategies and reduce dependence on conventional plastic.

The national funded project ECOPOLYVER (https://biogroup.usc.es/ecopolyver) aims at developing and evaluating a robust biological system capable of transforming fatty residual streams into PHA, using mixed microbial cultures. Besides being technically feasible, the system should prove a better environmental performance and the main challenge there is the inclusion of the end-of-life (EoL) stage. Only by including it, the full picture that is required to validate the expected better environmental performance on any circular economy strategy will be achieved (Peña et al., 2021). According to Bremer (2022) approximately 22% of produced plastics are mismanaged, i.e. they reach the environment without going through any waste collection and management system, and it is generally assumed that oceans are the final environmental compartment where plastic waste will end up, regardless of where they were originally deposited (Wu & Su, 2020). How to include marine litter impact in the Life Cycle Assessment (LCA) framework is the aim of MarILCA (https://marilca.org/), where the models and methodologies under development require a significant amount of data on plastic degradation which, for bioplastics, is not yet available. The main objective of this work is then to generate that data to make the implementation of the EoL models possible for PHA-based bioplastics.

MATERIALS & METHODS

Degradation data are required to calculate the characterization factors which include the Fate Factor (FF), the Effect Factor (EE) and the Exposure Factor (XF). The FF (expressed in days) is associated to the plastic transport and its fragmentation and degradation, it represents the residence time of the plastic in the environmental compartments; the EF (expressed in Potentially Affected Fraction of species (PAF)·m^3·kg^{-1}) deals with the sensitivity of the species to the released pollutant; and the XF (dimensionless) measures the availability of the released plastic in the environmental compartment. The accelerated degradation data are related to bioplastics fragmentation and degradation under controlled conditions, so will feed the FF estimation. Besides, accelerated degradation experiments will also provide information on the dynamics of additives release.

Real samples of bioplastics manufactured from PHA and other additives will be used, and two different experiments are planned:

- Sun degradation with UV light cameras under controlled conditions of temperature and humidity (Sadi et al., 2010).
- Biodegradability in water (Romero et al., 2022) by means of a Rolling Biofilm Bioreactor (RBB), originally designed for biofilm selective growth for bacteria culture, for biodegradation of bioplastics present in water.
-

By combining both methods, the biodegradation study of bioplastics will cover different environmental compartments. Real samples of bioplastics will be placed in the RBB and their biodegradability will be studied in contact with bacteria; under controlled temperature conditions and with the type of water previously chosen (salt or fresh) to simulate the different aquatic compartments. Jointly analysing the results of the RBB experiment with those of sun degradation experiment will be key to covering the different degradation environmental compartments of bioplastics.

To evaluate the bioplastics bio- and photodegradation, measurements of its properties (i. e. molecular weight, functional groups, mass losses, …) will be carried out. Chemical techniques will be used to assess changes in functional groups [Proton nuclear magnetic resonance (^{1}H-NMR)], thermal properties [Differential scanning calorimetry (DSC) and Thermogravimetric analysis (TGA)] and molecular weight [Size exclusion chromatography (SEC)] (Sadi et al., 2010).

RESULTS & DISCUSSION

Data on the two accelerated degradation methods for two packaging materials will be presented (i.e. film and tray). The estimation of FF will be possible and the correspondent characterization factor calculated. This information together with the bioplastic leakages estimations will make possible the inclusion of the EoL on the environmental analysis of the bioplastic value chains.

Abstract
Climate change and environmental degradation increasingly represent a threat to the entire world, and therefore the safe recovery of resources is crucial in order to encourage the use of what is now considered as waste as a real resource. In this context, risk analysis is the main element to ensure the safe reuse of wastewater and grey water. For this purpose, a semi-quantitative approach was followed for risk assessment in wastewater reuse, while a QMRA calculation tool was developed for a quick assessment of the risk of re-use to support stakeholders in making decisions about possible restrictions.

Keywords (maximum 6 in alphabetical order)
FMEA; QMRA; risk assessment; run-off; stormwater management; water reuse.

INTRODUCTION

Water scarcity and water stress are issues of growing concern at international and European level (Delli Compagni et al., 2020). Freshwater availability is getting scarcer due to effects related to climate change issues, like heatwaves or drought periods. Apart from limiting water resources for human consumption, water scarcity implies some environmental impacts such as increasing contaminants concentration and water pollution. Potential contamination sources include also diffuse inputs, such as urban and agricultural run-offs, which may occur during precipitation and flooding events. Extreme rainfall events may impact on sewer overflows and thus on surface water quality, since they may increase bacterial loads and concur in environmental contamination, affecting both human health and ecosystem. Reclaimed wastewater and greywater can contribute to compensate water needs, providing regular supply (Deviller et al., 2020), reducing the exploitation of natural water resources and alleviating the pressures of wastewater treatment plants (WWTP) discharges into sensitive areas. In this context, risk assessment represents a crucial task to ensure health and environmental protection for water reuse applications. Regulatory frameworks are including this aspect, even if detailed procedures are still lacking, especially for alternative sources, such as greywater. The work carried out aimed to face risk assessment, both for wastewater and for run-off water reuse.
Considering wastewater reuse, a semi-quantitative risk assessment has been developed and detailed for a full-scale water reuse system in Italy. Moreover, a specific methodology has been developed for safe stormwater management and reuse of greywater, during the European project WATERUN.

MATERIALS AND METHODS

Risk assessment has been developed according to existing international guidelines, such as Australian Guidelines and WHO Manuals (QMRA 2016).

Table 1. QMRA methodology.

Step	Description	Formulas
1	**Dose-response relationship** (dose of pathogens with which the exposed group enter in contact)	*d = pathogen concentration × log reduction × exposure* *Exposure/event = volume (mL) with which people enter in contact in a single event of exposure during a certain activity*
2	**Probability of infection** (Pinf) related to each event of exposure to the target pathogen	$P_{inf} = 1 - (1-d/\beta)^{(-\alpha)}$ *Beta Poisson model* α,β = dose response constants
3	**Total probability of infection in one year** (of each pathogen)	$P_{inf\,(year)} = 1-(1-P_{inf})^{N}$ 1 activity N=number of exposures/year
4	**Probability of illness** (Pill) in one year	$P_{illness\,(year)} = P_{inf\,(year)}$ × ratio of illness to infection
5	**Disability-adjusted life years (DALYs)**	DALY/year = $P_{illness\,(year)}$ × DALY per case × susceptibility fraction

Risk assessment includes uncertainties, due to not reliable data or lack of information, which might lead to errors in the overall result (WHO, 2016). Data analysis may support the development of a robust dataset, which allows to increase the numerosity but also to include extreme events characterised by lower probability of occurrence, which are more difficult to detect by standard measures. Literature research may also be useful to define typical ranges of concentration and characteristic ratios between parameters, in case local measures are not available, not sufficient or not trustable. Models and analysis, such as multi-criteria decision analysis, fuzzy and stochastic analysis or Monte Carlo based models can help to deal with uncertainty, but their application requires specific skills. Simpler models, such as Failure Mode and Effects Analysis (FMEA) can also be used to assess water systems. FMEA analysis allows to identify the critical parameters that may have an impact on water quality, by comparing the 95th percentile with intervals defined between the lab detection limits and quality standards (ISS, 2019). The approach and the level of detail are strictly dependant from the site-specific characteristics, the available information and the required results. The methodology for risk assessment should thus be flexible and reshaped to be fitted with the specific application in exam.

Wastewater reuse

The water utility ACEA manages the territorial district of ATO2 in Lazio, Italy, and Fregene WWTP was selected to provide safe reclaimed water for irrigation purposes, since the surrounding area is voted to horticultural cultivation. The WWTP is characterised by pre-treatment, biologic CAS process, secondary sedimentation, sand filtration and UV disinfection. Data from the routinary lab analysis for the characterisation of influent and effluent wastewater were acquired, together with information on the design and operative parameters of each unit.

Run-off reuse

In order to support risk assessment for run-off water reuse, an innovative tool for stormwater management, based on a risk-based approach, is being implemented, in the context of the EU project WATERUN. Hence, a python tool (β -version) for QMRA calculation has been developed, which is able to calculate the microbiological risk for specific reuse scenarios (e.g., garden irrigation, toilet flushing) and for three different pathogens (Campylobacter, Rotavirus, Cryptosporidium). Furthermore, a preliminary version of a graphical user interface (GUI) has been created to allow the communication of a stormwater management model (SWMM) outputs with the phyton tool.

RESULTS AND DISCUSSION

Proposed methodology for risk assessment

A detailed and specific methodology for risk assessment has been developed to be implemented in water reuse applications.
The steps detailed for safe wastewater reuse (Figure 1) included a preliminary phase of system description and asset management, where the design and operative parameters of each operative unit were verified and compared with the literature working ranges, in order to define indicators for the resilience of the treatment layout. Then, a phase of data analytics was performed, in order to detect anomalies or critical conditions occurred in the plant. Once all the information was elaborated, risk assessment must be performed. A first semi-qualitative approach has been carried out, with the definition of a risk matrix that included all the hazardous events identified for each unit, according to the evaluations of the previous data analysis. A quantitative approach could be furtherly performed, in case from the previous phase a deeper analysis would be required. In that case, QMRA and QCRA could be performed to evaluate microbial and chemical risks, respectively. After that, control measures and digital support tools could be applied and implemented in the monitoring. Finally, communication and emergency procedures should be implemented.

Figure 1. Proposed methodology for risk assessment.

The presented approach has been followed to perform the risk assessment of Fregene water reuse system. Data from the WWTP has been analysed and the possible hazardous events have been identified. The FMEA has been then implemented, in order to evaluate effluent quality and identify the most critical parameters. A semi-quantitative approach was followed and a risk matrix has been developed. Scores have been attributed to the probability and the severity of each identified hazardous event, according to the results of data analysis, expertise judgement and considering the control measures applied in the plant.

A more detailed approach has been followed to assess the risks for run-off reuse. In order to provide a more quantitative information on the health outcomes from run-off water reuse and since information on pathogens in urban stormwater were available from literature, a quantitative assessment has been developed and implemented into a tool that could support users to perform a QMRA. More in detail, the developed tool allowed to perform QMRA for each pathogen and for each rainfall event that generate overflow (DWA A-118 (2006) guidelines), implementing Monte Carlo analysis for statistical reliability. This tool will provide information about water quality, indication for safe reuse practices and thus restrictions needed in the districts of the urban catchment for reuse or recreational activities after the simulated storm water event. Moreover, this risk-based tool will allow to evaluate the reduction of the health-risk after the implementation of different preventive measures through the application of different log removals.
This tool will enable stakeholders to quickly assess the risk for different activities following weather events and thus make decisions on possible reuse.
