ECOSTP 2023

6th IWA International Conference on eco-Technologies for Wastewater Treatment

GIRONA- SPAIN
26th-29th June

Following the previous successful IWA ecoSTP conferences (Spain 2012, Italy 2014, UK 2016, Canada 2018, Italy 2021), it is our great pleasure to welcome you to the 6th IWA International Conference on eco-Technologies for Wastewater Treatment to be held from June 26th to 29th, 2023 in Girona.

ecoSTP-23 aims to discuss the latest cutting-edge eco-technologies for a sustainable transition in wastewater treatment, reuse, and resource recovery, at urban and industrial scale, giving special attention to the efficient transfer of knowledge into practice. Building a more resilient future for water management needs a transdisciplinary and multi-domain examination, including socio-economic and governance aspects. ecoSTP23 will include hydro-social aspects and the multiple factors that currently frame water management.

Maite Pijuan and Ignasi Rodriguez-Roda

Co-chairs of ecoSTP23

PROGRAM

PRECONFERENCE ACTIVITIES

PC1-PC2 Room	Sala de Graus	Room R1	Room R3
	Urban Biorefineries for circular economy		
Advanced Course Modelling Resource Recovery			
		Workshop: Water reuse and resource recovery at decentralized level in MED area	
Advanced Course Modelling Resource Recovery	Urban Biorefineries for circular economy		
	Urban Biorefineries for circular economy		**Workshop: IWA TG on modelling of phototrophic systems for water treatment**
		Course: Coliphages, the key viral indicator to transform wastewater into reclaimed water	

Room: Sala Sinfònica

Welcome from the Chairs
Maite Pijuan (ICRA) and Ignasi Rodriguez-Roda (UdG)

Conference opening
Catalan Minister of Universities and Research
Hble. Sr. Joaquim Nadal i Farreras
Vicerectora d'investigació i transferència del coneixement (UdG)/
Vice-chancelor for Research and Knowledge Transfer University of Girona
Mrs. Maria Pla de Solà Morales
Sotsdirector (ICRA)/Deputy director (ICRA)
Mr. Sergi Sabater Cortes

Plenary 1
Prof. Zhiguo Yuan (City University of Hong Kong. China)
"Exploring new opportunities for resource recovery and reuse in wastewater treatment"

Plenary 2
Ms. Eva Martínez Diaz (Isle Utilities. UK)
"Navigating towards an innovative and sustainable water industry"

TECHNICAL SESSIONS

T1. N& P recovery

Chairs: Mathieu Sperandio (INSA-Toulouse) & Juan Baeza (Univ. Autonoma of Barcelona)

1.1. Towards a sustainable biorefinery: integrated treatment of the liquid fraction of digestate from the organic fraction of municipal solid waste scale up from laboratory to pilot-scale. Queralt Farras, Eurecat

1.2. Combined water and nutrient recovery from treated wastewater effluents: a case study from Northern Italy. Matia Mainardis, Univ. of Udine

1.3. Recovery of ammonia and phosphate resources from wastewater using gas-permeable membranes. Matias Vanotti, USDA

1.4. Ammonia Removal and Recovery From Municipal Wastewater, Ana Soares, Cranfield Univ.

1.5. NPHarvest efficient nutrient recovery technology for making clean and safe fertilizers. Ana Mikola, Aalto Univ.

1.6. Applying electrodialysis technology for the concentration of nutrients from an anaerobic membrane reactor effluent: operational problems. Patricia Ruiz Barriga. Univ. Valencia

1.7. Pilot Study for Recovery of Phosphate and Ammonia as Struvite from Semiconductor Wastewater. Jhy-Chern Liu. National Taiwan University of Science and Technology.

.8. Effect of suspended solids content on ammonium recovery from pig slurry liquid fraction by liquid-liquid membrane contactors. Rubén Rodríguez-Alegre, LEITAT

T2. N& P recovery II

Chairs: Ana Soares (Cranfield Univ.) & Francesco Fatone (Univ. Polytechnic Marche)

2.1. Optimization of ammonia recovery from urine and digestate using transmembrane chemical absorption. mathieu Sperandio. INSA-TOULOUSE

2.2. Recovery of K-rich struvite after biological nitrogen removal. Emma Company Masó, LEQUIA-UdG

2.3. Phosphorous recovery from waste aerobic granular sludge. Tommaso Lotti. Univ. of Florence

2.4. Recovering vivianite from manure: opportunities and bottlenecks. Sophie Banke. TU Delft

2.5. Nutrient recovery from source separated human urine as vivianite. Chibambila Simbeye. Univ. of Cape Town

2.6. A Comprehensive Assessment of The Opportunities of Integrating a SSSF Into EBPR Systems in view of P Recovery. Mengqi Cheng. Univ. Autonoma of Barcelona.

2.7. Nutrient recovery from hydrolysed urine by Na-chabazite adsorption integrated with ammonia stripping and (K-)struvite precipitation. Haotian Wu. Univ. Laval

2.8. Development and experimental comparison of a precipitation model for struvite using a low-grade magnesium oxide (industrial by-product) as an alternative magnesium source. Beñat Elduayen-Echave. Ceit-BRTA

2.9. BIOFERES: Advanced Recovery of Nutrients from sewage sludge to obtain value-added products for Agriculture: bio-stimulants and liquid fertilizers. Raquel Tamarit Coronado. FACSA

2.10. Continuous bioelectrochemical nitrogen recovery from high N-loaded wastewaters. Zainab Ul. Univ. Autonoma de Barcelona

T3. Water Reuse

Chairs: Jordi Raich (S::can Iberia) & Matia Mainardis (University of Udine)

3.1. Wall2Water, the NAWAMED pilot of living wall for greywater treatment and reuse in Mediterranean countries. Anacleto Rizzo. IRIDRA Srl

3.2. Feasibility assessment of reclaimed wastewater reuse in agriculture: how we do it. Luca Penserini. Politecnico di Milano

3.3. Fertilizer drawn forward osmosis for greywater treatment and subsequent reuse in hydroponics. Esther Mendoza. ICRA

3.4. LIFE AMIA. An innovative combination of wastewater technologies to promote water reuse and sustainable treatment. RUBEN GARCIA TIRADO. Grupo Gimeno

3.5. Towards water self-sufficiency: pilot operation of an off-grid water cycle based on rainwater harvesting and low-tech, biological greywater treatment in an inhabited demonstration house in Switzerland. Devi Bühler. Univ. Gent.

3.6. Tertiary wastewater treatment and natural pigment recovery by cyanobacteria: fate of organic microcontaminants. Marta Bellver Catalá. Univ. Politecnica de Catalunya.

3.7. Plant growth potential of hotel greywater reuse in hydroponic system. Josephine Vosse. ICRA

3.8. Integration of forward osmosis into a granular anaerobic membrane bioreactor for low energy and high quality water reuse and energy production: potential and challenges. Pere Olives. LEQUIA-UdG

T4. WW treament for water reclamation

Chairs: Wolfgang Gernjak (ICRA) & Javier Marugan (URJC)

4.1. Comparing Efficiency in Solar Water Treatment: Photovoltaic-LED vs. Compound Parabolic Collector Photoreactors. MARIA DOLORES MOLINA RAMIREZ. Univ. Rey Juan Carlos

4.2. Peroxymonosulfate/Solar process for the simultaneous disinfection and decontamination of urban wastewater at pilot plant scale. Ilaria Berruti. CIEMAT-PSA

4.3. Chlorine-free inactivation of E. coli in water with manganese oxide-doped graphene-based electrodes. Anna Segués. ICRA

4.4. LIFE RECYCLO: Recycling wastewater from small and medium sized laundries with advanced oxidation process. Baptiste Mathon. Treewater

4.5. Innovative Dual Membrane System for Integrated Water-energy Recovery from Municipal Wastewater. Conghui He. Tsinghua Univ.

4.6. Application of UV-B and UV-C light-emitting diodes (LEDs) for the removal of diclofenac in drinking water. Cristina Pablos Carro. Univ. Rey Juan Carlos

4.7. Natural based solutions combined with solar processes at pilot scale for urban wastewater reclamation. Alba Hernández Zanoletty. PSA-CIEMAT

4.8. Assessment of the Integration of a Vermifilter and a Zooplankton-Based Reactor for the Removal of Microcontaminants to Produce Reusable Water. Manuela Hidalgo. Univ. Girona

T5. Removal of recalcitrant and emerging pollutants

Chairs: Manuela Antonelli (Univ.Politec. Milano) & Sonia Suarez (USC)

5.1. Improvement in the pharmaceutical removal from hospital wastewater in a full-scale hybrid PAC-MBR. Paola Verlicchi, Univ. Ferrara

5.2. Long-term performance of an anaerobic membrane bioreactor amended with graphene oxide treating municipal wastewater. Oriol Casabella, ICRA

5.3. The Study of a Hybrid System - Moving Bed Biofilm Reactor and Nanofiltration for the Elimination of Micropollutants in Wastewater. Muhammad Mukhlis Eshamuddin, Univ. Toulouse

5.4. Presence of Organic Micropollutants and Antibiotic Resistance Genes in an Anaerobic-MBR integrated system (SIAM) treating urban sewage. Matias Rivadulla, Univ. Santiago de Compostela

5.5. Bioreactors for immobilized fungus: Application to long-term continuous pesticides removal by Trametes versicolor. Montserrat Sarra, Univ. Autonoma de Barcelona

5.6. Effect of HRT and dissolved oxygen on the fate of pharmaceutical compounds and antibiotic resistance genes in a high-rate activated sludge reactor. Lorena Gonzalez, Univ. Vigo

5.7. Combining Thermophilic Aerobic Reactor (TAR) with Mesophilic Anaerobic digestion (MAD) to improve sludge reduction and pharmaceuticals degradation, Yolaine Bessiere, INSA-Toulouse

T6. Removal of recalcitrant and emerging pollutants II

Chairs: Paola Verlichi (Univ. Ferrara) & Jelena Radjenovic (ICRA)

6.1. Electrochemical degradation of per- and polyfluoroalkyl substances in real waste streams using boron- and borophene-doped graphene sponge electrode. Nick Duinslaeger. ICRA

6.2. Assessment of PFAS pathways for environmental contamination during landfill leachate treatment. Nicola Lancioni. Marche Polytechnic University

6.3. PFAS in textile wastewater: an integrated approach to reduce the environmental risk for their mixture. Beatrice Cantoni. Politecnico di Milano

6.4. Integration of electrochemical processes in a landfill leachate treatment system for removal of the recalcitrant organic load. Nabil Mostefaqui. Université Gustave Eiffel.

6.5. Effective micropollutant depuration by a novel sustainable approach: coupling solar photo-Fenton with regenerated activated carbon. Paula Núñez-Tafalla. Univ. of Luxembourg

6.6. Boosting active sites of municipal sludge-based biochar for Fenton-like degradation toward phenolic contaminants from water. Battuya Byambaa. Water Cycle Research Center

6.7. Adsorption on activated carbon for PFAS removal: should we act at the source or before the discharge into the environment? Manuela Antonelli. Politecnico di Milano

6.8. Electrochemical removal of antibiotics and multidrug-resistance bacteria using graphene sponge electrodes. Natalia Ormeño. ICRA

6.9. Emerging contaminants in sludge treatment reed beds: degradation or accumulation? Alba Martinez i Quer. Aarhus University

6.10. Developing innovative eco-efficient process for Contaminants of Emerging Concern removal in wastewater reuse applications. Beatrice Cantoni. University of Western Ontario

T7. Algal systems for WW treatment and RR

Chairs: Ramon Barat (Univ. Polytecnic Valencia) & Rosario Rodero Raya (INRAE-LBE & Univ. Valladolid)

7.1. Microalgae Biorefinery for Sustainable Recovery of Bioproducts and Bioenergy from Wastewater. Evelyn Ruales Dávila. Univ. Politècnica de Catalunya

7.2. The Effect of Light Cycling in the Formation of Algae-Bacteria Aggregated Flocs. Holly Stolberg. The Univ. of Queensland

7.3. Anaerobic and microalgae-based treatments: potential for virus inactivation during secondary treatment of municipal wastewater. Andres Torres-Franco. Univ. of Valladolid

7.4. Pilot Scale Wastewater Remediation Using Algae Bacterial Aggregated Flocs (ABAF). Andrew Ward. The Univ. of Queensland

7.5. Comparison of High Rate Algal Pond mesocosm performance using filamentous algae or microalgae. Rupert Craggs. Nat. Inst. Water and Atmospheric Research NZ.

7.6. Wastewater grown microalgae as biofertilizer: Contaminants of Emerging Concern, heavy metals and pathogens assessment. Ana Álvarez González. Univ. Politècnica de Catalunya.

7.7. Effect of veterinary antibiotics and heavy metals in the composition and valorization of a consortium of microalgae and bacteria. Elena M. Rojo. Univ. of Valladolid

7.8. Valorisation of microalgae grown in food waste digestate as biofertilizer. Ana Álvarez González. Univ. Politècnica de Catalunya

T8. Digitalization

Chairs: Rafael Gimenez (CETAQUA) & Paula Carrera (Univ. Ghent)

8.1. Fault-tolerant Control in WRRFs: A Practical Approach Using Case-Based Reasoning for Fault Identification. Sanaz Mohebali. modelEAU - Université Laval

8.2. The use of a low-cost monitoring dataset for sewer model calibration. Paul Schütz. Kompetenzzentrum Wasser Berlin

8.3. Real-time monitoring of adsorption processes in wastewater by innovative spectroscopic sensors: a pilot-scale study. Cecilia Bruni. Univ. Politecnica delle Marche

8.4. Water reuse on the move: decision support for reclaimed water network design solutions. Joaquim Comas. ICRA

8.5. Energy optimization in water distribution systems: Data mining and quality forecasting approach for reducing pumping costs. David Abert. LEQUIA, UdG.

8.6. Design and Deployment of sewage Monitoring Stations to Mine Information from neighbourhoods. Jordi Raich. s::can Iberia

8.7. Intelligent control of wastewater treatment plants by agent reinforcement learning. Oscar Emilio Aponte Rengifo, University of Salamanca

8.8. Sustainable technologies and real-time monitoring for treating industrial wastewater: the case study of Solvay chemical plant at Rosignano Marittimo. Marco Parlapiano, Polytechnic University of Ancona

T9. Modelling

Chairs: Joaquim Comas (ICRA) & Ruben Garcia (Grupo Gimeno)

9.1. A novel methodology for modelling SUDS using SWMM and Giswater: Case study on Montjuic Girona/Spain. Nicole Arnaud, UdG

9.2. Elucidating the field of application of 0D and 1D biofilm models integrated with the hydrodynamics of aerobic granular sludge reactors. Arianna Catenacci, Univ. Politecnico de Milano

9.3. Successful strategies for improving energy self-sufficiency at Grüneck wastewater treatment plant in Germany by improved aeration and food waste co-digestion, Konrad Koch, Tech. Univ.Munich

9.4. Mass-balance-based approach in planning a measurement campaign for energy factory Tilburg. David Ysebaert. U.Gent

9.5. Development of a hydraulic and biological model for trickling filters. Model-based assessment of the 6.6operational strategy. Kepa Olaciregui Arizmendi, Ceit-BRTA

9.6. Model-based assessment of alternative modes of operation in a full-scale industrial wastewater treatment system. Xavier Flores-Alsina, DTU

9.7. Modelling the Metabolism and Population Dynamics of Fermentation-Enhanced EBPR Processes. Rhys Thomson, The Univ. of Queensland

9.8. Mathematical modeling of the long-term dynamics of a sulfate-reducing UASB bioreactor from methanogenic to sulfidogenic conditions. Eric Valdés, Univ. Autonoma de Barcelona

9.9. Influence of substrate characterization on trace metal dosing to improve biogas yield during anaerobic digestion: a dynamic model-based study. Susan George, Instituto de la Grasa CSIC

9.10. CFD modelling as an emerging digital tool for the design and optimization of WWTPs: Learnings from two case studies. Hossein Norouzi Firouz, InsPyro

T10. Membranes

Chairs: Watsa Khongnakorn (Prince of Songkla Univ.) & Vicky Ruano (Univ. Valencia)

10.1. Produced water treatment by membrane aerated biofilm reactors at elevated oxygen partial pressures. Borja Valverde. DTU

10.2. Biological Processes Modelling for Integrated MBR Systems: A Review of the State-of-the-Art. Giorgio Mannina. Palermo University.

10.3. Modelling the impacts of operational conditions on the performance of a full-scale membrane aerated biofilm reactor. Xavier Flores-Alsina, DTU.

10.4. (short presentation, 15:00-15:05) Granular Anaerobic Membrane Bioreactor for low-energy domestic wastewater treatment. Lucie Sanchez. Univ. de Montpellier

10.5. (short presentation, 15:05-15:10)Low temperature anaerobic membrane bioreactor (AnMBR) demonstrator plant: effects of influent characterisation and site operation. Matthew Palmer, Severn Trent

10.6. (short presentation, 15:10-15:15)New framework for standardized notation in membrane filtration modelling for resource recovery from municipal wastewater. Valeria Sandoval. Univ. de València

10.7. (short presentation, 15:15-15:20) Recycled membranes for treating urban wastewater using gravity-driven force. Bianca Zappulla. LEQUIA-UdG

T11. Recovery of added value chemicals

Chairs: Albert Guisasola (UAB) & Tommaso Lotti (Univ. Florence)

11.1. An electrochemical strategy by Lithium recovery from waste battery and brine desalination. Alberto Maimone. CETIM Technological

11.2. From Waste Streams to Platform Chemicals. Isaac Owusu-Agyeman. KTH-Royal Institute of Technology

11.3. High-rate production of carboxylic acids from carbohydrate-rich wastewaters. Ramon Ganigué. Ghent University

11.4. CO2 bioelectrorecycling to butyric acid and its upgrade to butanol. Meritxell Romans Casas. LEQUIA-UdG

11.5. Innovative cell platforms to transform CO2 into fine chemicals for the pharmaceutical industry. Elisa Huang-Lin. Univ. Valladolid.

11.6. Recovery of Cu and Zn from liquid anaerobic digestates via S. pasteurii induced carbonate precipitation: influence of pH and volatile fatty acids on metals precipitation. Ailén Maria Florencia Soto. Spanish National Research Council

11.7. Inhibition limits by undissociated acids in mixed culture fermentation and strategies to increase process capacity. Tomás Allegue. Khalifa University

11.8. Thermal hydrolysis pre-treatment has no positive influence on VFA production from sewage sludge. Ander Castro. CETAQUA

T12. Recovery of PHA and SCP

Chairs: Maria Reis (UNL) & Zeynep Cetecioglu (KTH)

12.1. Volatile fatty acids yield and profile during sludge and food waste co-fermentation at different temperatures. Noemí Pérez i Esteban. University of Barcelona

12.2. Exploring the ammonia presence effect on PHA production of a phototrophic-chemotrophic consortium operated under Light-Feast/Dark-Aerated-Famine. Juliana Almeida. Institute for Health and Bioeconomy and UCIBIO

12.3. Top-down engineering of natural phototrophic microbiomes into stable and productive consortia for the production of bioplastics. Eva Gonzalez Flo. Universitat Politècnica de Catalunya

12.4. Bioconversion of H2 to Single Cell Protein by Purple Bacteria consortia: Influence of environmental conditions on microbial kinetics. Rosario Rodero Raya (INRAE-LBE & Univ. Valladolid)

12.5. The potential of H2S- and CO-tolerant hydrogen-oxidizing bacteria to convert sewage sludge into microbial protein through aerobic syngas fermentation. Vincenzo Pelagalli. Univ. of Cassino and Southern Lazio

12.6. Integration of heterotrophic microalgae beads bioreactor in microbial electrosynthesis for bioelectro-conversion of carbon dioxide into bio-oil and proteins. Silvia Bolognesi. LEQUIA-UdG

12.7. Co-treatment of urban wastewater and municipal solid waste by mixed phototrophic cultures to generate PHA by varying organic carbon loads. Sandra Chacón. Universidad Rey Juan Carlos de Móstoles.

12.8. Maximising the production of composition-specific polyhydroxyalkanoates from volatile fatty acids. Anuska Mosquera. Univ. de Santiago de Compostela

12.9. Resources from wastewater: employment of an advanced strategy for polyhydroxyalkanoates (PHA) synthesis and recovery. Antonio Mineo. Palermo University

12.10. Acidogenic fermentation of model carbohydrate/protein mixtures: how does substrate organic composition impact? Ana Vázquez-Fernández. Univ. Autònoma de Barcelona

T13. Energy Recovery

Chairs: Frank Rogalla (AQUALIA-FCC) & Francisca Sousa Braga (DTU & Skanderborg Spildevand A/S)

13.1. Energy recovery from wastewater: ammonia and hydrogen production from nitrogen-containing waste streams. Ruben Asiain-Mira. AQUALIA-FCC.

13.2. Anaerobic microbial electrochemical fluidized membrane bioreactor for domestic wastewater treatment and reuse with energy recovery. Hari Ananda Rao. KAUST

13.3. Optimising anaerobic digesters with thermal pre-treatment by understanding sludge composition full-scale and laboratory results on trace elements and enzyme supplementation. Yadira Bajon Fernandez. Cranfield University

13.4. High-rate Activated Sludge at very short SRT: key factors for process Stability and Performance of COD fractions removal. Joan Canals GSInima- Lequia UdG

13.5. An integrated system to produce bio-based volatile fatty acids for the industry and biogas from sewage sludge. Ander Castro. CETAQUA

13.6. Influence of carbon-coated zero-valent iron-based nanoparticle concentration on continuous photosynthetic biogas upgrading. Edwin Gilbert Hoyos. Univ. de Valladolid

13.7. Enhancing bioelectrochemical hydrogen production from industrial wastewater in a 150 L microbial electrolysis cell pilot plant. Oscar Guerrero. Univ. Autònoma de Barcelona

13.8. Organic loading rate and pH as optimization parameters for biohydrogen production via dark fermentation coupled with microbial electrolysis cells. Jose Antonio Magdalena. LBE-INRAE

T14. Aerobic granulation

Chairs: Liu Ye (UQ) & Damián Amador (FCC-AQUALIA)

14.1. Unravelling the alpha factor for aerobic granular sludge reactors. Laurence Strubbe. Ghent University

14.2. Determining the causes of the deterioration of granules in an aerobic granular sludge continuous flow system. Anuska Mosquera Corral. Univ. Santigao de Compostela

14.3. A Pilot-Scale Study on the Impact of Aerobic Granular Sludge on Membrane Filtration Performance. Eirini Tsertou. University of Antwerp

14.4. Combined Aerobic Granular Sludge and Gravity-Driven Membrane System for Energy-Efficient Wastewater Treatment and Reuse. Hari Ananda Rao. KAUST

14.5. Getting the most out of existing infrastructure: Denmark and Spain put MABR and AGS technology to the test. Nerea Uri Carreno. VCS Denmark

14.6. Dynamics of antibiotic-resistant genes in aerobic granular systems in aerobic granular reactors treating real wastewater. David Correa-Galeote. Univ. of Granada

14.7. Carbon and nitrogen removal from wastewater in a continuous upflow aerobic granular sludge blanket reactor. Anna Lanzetta. University of Naples

14.8. Kinetic characterization of Phosphorus Accumulating Organisms (PAO) and Glycogen Accumulating Organisms (GAO) anaerobic metabolism in Aerobic Granular Sludge (AGS). Jan Pietro Czellnik. University of Florence

T15. Partial nitritation & anammox

Chairs: Jesús Colprim (LEQUIA-UdG) & Jan Dries (University of Antwerp)

15.1. Energy-efficient nitrogen removal from sewage: achieving mainstream partial nitritation/anammox via recurrent multi-stressor floc treatments. Michiel Van Tendeloo. University of Antwerp

15.2. Sustainable Mainstream Deammonification by Ion Exchange and Bioregeneration via Partial Nitritation/Anammox. Sheldon Tarre. Technion

15.3. Kinetic and stoichiometric characterization of a new thermophilic anaerobic ammonium oxidation culture. Lin Zeng. Ghent University.

15.4. Mainstream Aerobic Granular Sludge start-up from HRAS effluent targeting partial nitritation. Oriol Carbó. GS-Inima

15.5. Sensitivity of anammox bacteria under mainstream conditions: combined effect of low temperature and pH with inhibitory concentrations of free ammonia/free nitrous acid. Alba Pedrouso. Univ. de Santiago de Compostela

15.6. Nitrogen Removal/Recovery in the mainstream of a WWTP including ultrafiltration after the primary treatment: Partial Nitrification+Anammox vs. Ion Exchange+Hollow fiber membrane contactors. Jesús Godifredo. IIAMA

15.7. Influence of free nitrous acid on nitrifiers to introduce shortcut nitrification in the mainstream of WWTP. Edyta Laskawiec. Silesian University of Technology

15.8. When its worthwhile to include the nitrite pathway in a WWTP with C/N/P removal? Àlex Gaona. Univ. Autònoma de Barcelona.

15.9. A novel wastewater treatment process incorporating acidophilic ammonia oxidation. Min Zheng. The University of Queensland.

15.10. Long-term effect of shortcut biological nitrogen removal as energy saving strategy for liquid waste treatment. Laura Palli. GIDA spa

T16. GHG & Microbial community dynamics

Chairs: Adrian Ohemen (UQ) & Evina Katsou (Brunel Univ.)

16.1. The long-term full-scale monitoring of GHG from an Australian WWTP demonstrated the upstream carbon capture can stimulate downstream emissions. Liu Ye, The Univ. of Queensland

16.2. Real-time monitoring and data-driven management of N2O generation in biological reactors. Laura Flores. CETAQUA

16.3. Unraveling the N2O emissions from thermophilic nitrification reactors. Ramon Ganigué. Ghent Univ.

16.4. A laboratory-scale study to mitigate greenhouse gas emissions from open sludge lagoons. Sarah Aucote. Univ. of Queensland.

16.5. Nitrous oxide production for nitrogen valorisation on side stream of an urban waste water treatment plant. Lluc Olmo. Univ. Autònoma de Barcelona.

16.6. Low nitrous oxide emissions and its mechanisms in a pilot-scale mainstream Partial Nitritation/Anammox process. Haoran Duan. The Univ. of Queensland.

16.7. Characterization of hydrogenotrophic methanogenic cultures through a novel pressurized headspace-free Hydrogen Uptake Rate methodology. Manuel Fachal. Univ. Autònoma de Barcelona

Abstract

A pilot-scale treatment train based on stripping, thermophilic anaerobic membrane bioreactor (tAnMBR) and membrane contactors was operated for more than 260 days to demonstrate the feasibility of the proposed scheme of technologies to recover energy and fertilisers from organic fraction of municipal solid waste (OFMSW) liquid digestate. Studies at bench scale showed that a stripping process working at 55ºC was needed to remove ammonium (68 %) and avoid ammonia inhibition in the tAnMBR. More than 80% of the total chemical oxygen demand (COD) was removed by the tAnMBR operated at 3.1 kgCOD $m^{-3}\cdot d^{-1}$. Membrane contactors recovered close to 100 % of the residual ammonium. At pilot scale, the two-stage stripping unit allowed ammonia removal at a lower extent (39%) due to temperature instabilities, and the tAnMBR, operated at 1.5 KgCOD $m^{-3}\cdot d^{-1}$, removed 84% of the COD.

Keywords

membrane contactors; stripping; thermophilic anaerobic membrane bioreactor (tAnMBR)

INTRODUCTION

The OFMSW represents about 30-40% of the MSW [1],[2] and, therefore, plays an important role in the transformation towards a circular economy. The most preferred treatment for the OFMSW is anaerobic digestion (AD), which produces biogas and digestate. The digestate is usually separated in liquid and solid fractions for a more sustainable management. The liquid fraction is a challenging wastewater, as it is rich in ammonium and recalcitrant organic compounds [3]. This fraction is conventionally treated by aerobic bioprocesses, which are very energy intensive, and are not designed to recover valuable resources contained in this stream. Thermophilic AD is an interesting option to recover the recalcitrant organic matter in the liquid digestate in form of biogas. If this technology is coupled with an ultrafiltration step, a more robust and efficient technology is obtained: thermophilic anaerobic membrane bioreactor (tAnMBR) [4]. NH_4^+ can be recovered in form of ammonium salts. This can be achieved by using a two-stage stripping process coupled to a scrubber [5]. By stripping CO2, the pH of the liquid current can be increased to benefit the efficiency of ammonia stripping, often completely eliminating the need for caustic dosage. NH_4^+ can also be recovered by novel technologies such as membrane contactors [6]. This work aimed to demonstrate at pilot scale an innovative treatment based on (i) tAnMBR and (ii) ammonium recovery by two-stage stripping and/or (iii) membrane contactors, to valorise the liquid fraction of the OFMSW digestate.

MATERIALS AND METHODS

For the tAnMBR, experiments at bench scale were conducted in a glass reactor of 2 L at 55ºC. The reactor was inoculated with thermophilic anaerobic sludge treating OFMSW from the mechanical and biological treatment plant Can Barba (Terrassa, Catalunya, Spain). Once a day, a peristaltic pump fed the reactor with the liquid fraction of the anaerobic digestate from Ecoparc 2 waste management facility (Montcada i Reixac, Catalunya, Spain). The effluent of the reactor was pumped through a tubular ultrafiltration (UF) membrane (Berghof) of 0.03 µm of pore size and 0.012 m^2 of active area. The concentrate from the UF was recirculated to the reactor and the permeate was collected. Biogas production was measured by means of a Ritter's milligascounter. For stripping, a glass reactor (2 L) was operated in batch mode with 2 h of reaction time. Air was fed from the bottom of the reactor at an aeration rate of 0.25 $L\cdot L^{-1}\cdot min^{-1}$. The permeate of the tAnMBR was treated with a hollow fiber membrane contactor module (HFMC) (MiniModule™ 1x5.5, 3M). Experiments were performed by recirculating an acid solution (H_2SO_4, 0.5M, 0.25L) and the waste (0.5L) through the HFMC. The pH of the effluent was adjusted to 12 prior to the treatment with HFMC, to increase the amount of free ammonia. The overall ammonia mass transfer coefficient was determined according to Licon et al. (2016) [7]. The stripping operation at pilot scale was conducted in a 2.5 m^3 reactor and operated in batch mode at 55ºC with 9 h of retention time. Air was fed from the bottom at an approximate aeration rate of 10 $L\cdot L^{-1}\cdot min^{-1}$. The tAnMBR operation was performed in a 50 m^3 reactor at 55ºC. The reactor was inoculated with centrifuge liquid of anaerobic digestion from Ecoparc 2 waste management facility (mesophilic). The reactor was fed once a day with the effluent of the stripping unit. The effluent of the reactor was pumped through a tubular ultrafiltration (UF) membrane (Pentair) of 0.03 µm of pore size and 4 m^2 of membrane area. The concentrate from the UF was recirculated to the reactor and the permeate was collected.

RESULTS AND DISCUSSION

The tAnMBR was operated at bench-scale for 170 days (Figure 1). During the first 14 days, the reactor was operated at an organic loading rate (OLR) of 0.3 kgCOD $m^{-3}\cdot d^{-1}$, treating directly raw waste, composed by 36.90 $gCOD\cdot L^{-1}$ and 3.80 $gN\text{-}H_4^+\text{-}N\cdot L^{-1}$. Progressive accumulation of COD was observed, which could be related to the high ammonia content in the reactor [7]. To reduce ammonia inhibition, stripping technology was applied to the raw waste, and the effect of temperature on ammonium removal was evaluated (see Fig. 2). Considering technical and economic viability issues, 55ºC was selected as an optimal temperature to remove nitrogen. At this temperature, close to 70% of the NH_4^+ in the influent was removed, producing an influent with suitable characteristics for the tAnMBR (24.50 and 0.82 $g\cdot L^{-1}$ of total COD and NH_4^+-N, respectively). On day 36, continuous operation with the tAnMBR was restarted by feeding the effluent of the stripping process (at 55ºC). A stepwise increase of the OLR was performed, from 0.3 until 3.1 kgCOD $m^{-3}\cdot d^{-1}$, resulting in a progressive accumulation of COD inside the reactor (from 2.64 until 13.63 $gCOD\cdot L^{-1}$). However, the obtained permeate remained stable around 3.50 $gCOD\cdot L^{-1}$, achieving a COD removal above 85%. This behaviour can be explained by the accumulation of highly recalcitrant organic matter inside the reactor that was retained by the UF membrane. Average biogas productivity was 0.05-0.10 $m^3\cdot m^{-3}\cdot d$, which is related to the low COD removal inside the reactor (20-50%).

Based on these results, the tAnMBR at pilot scale was operated with stripped raw waste as influent. However, the temperature operation was unstable until an independent heating system was installed for the stripping unit. This instability during the stripping resulted in lower temperatures of operation, which allowed reduced NH_4^+ removal (39%) (Fig. 2), resulting in an effluent with 19.2 and 1.9 g L^{-1} of total COD and NH4+-N, respectively. The higher $NH4^+$-N of this effluent may have impacted the tAnMBR performance, which achieved lower COD removal (84%) compared to the operation at bench scale. However, the biogas productivity was similar (0.06 $m^3\cdot m^{-3}$ d).

On the other hand, residual NH_4^+ in the wastewater (0.80 $NH_4^+\text{-}N\ g\cdot L^{-1}$) from the bench-scale operation was recovered by HFMC technology. The impact of the pH adjustment on membrane fouling and mass transfer due to the precipitation of salts contained in the effluent was assessed by performing experiments with and without filtration pretreatment (Fig. 3). During the first experiments (Exp. 1), 99.8% of the NH_4^+ was recovered after 105 min. Accumulative fouling after only two cycles without any pretreatment in successive experiments (Exp. 2 and 3) decreased the overall mass transfer coefficient by 35%. These results indicate the importance of including an effective pretreatment step prior to the treatment with HFMC. The performance of HFMC at pilot scale still needs to be evaluated.

Abstract

Agriculture is the major water consumer sector. Recurring water shortages due to accelerating climate change, which increases the duration of dry periods, boost the exploitation of unconventional water sources. In this framework, treated effluents from wastewater treatment plants can be a reliable and controlled source of water and nutrients for agriculture. A techno-economic assessment methodology was proposed to ascertain the feasibility of reusing effluents from a selected treatment plant in North-eastern Italy to irrigate typical cultivated crops (soybean, maize, rice, vines). A significant reduction in N supply (>40%) could be obtained, while P supply with treated effluents was limited, due to an unbalanced N/P ratio and a lower P use efficiency. As concerns the economic aspects, water saving had a major impact when compared to fertilizer saving. This methodology can be preliminary used in all situations to assess the feasibility of applying fertigation schemes.

Keywords

Agriculture; Fertigation; Nutrient reuse; Techno-economic assessment; Water reuse

INTRODUCTION

Water shortages are increasing worldwide: population growth, climate change, and water quality deterioration are all factors that push for the exploitation of alternative water sources, especially for water-intensive sectors such as agriculture (Jeong, Bhattarai, et al., 2020). Treated effluents from wastewater treatment plants (WWTPs) can be a valuable and controlled water source of water and nutrients for many end-uses, including irrigation.

Through fertigation schemes (combined water and nutrient recovery) from reclaimed wastewater, it is possible to reduce greenhouse gas (GHG) emissions, when compared to traditional fertilization approaches (Jiménez-Benítez, Ferrer, et al., 2020). The nutrients (N, P, K, micronutrients) embedded in treated effluents, in fact, can be recovered, reducing the need for chemical fertilization, showing positive economic, environmental, and sustainability aspects (Chojnacka, Witek-Krowiak, et al., 2020).

However, worldwide the legislative framework for reclaimed wastewater in agriculture is far from being uniform, even if the new European Union Regulation on Reuse (Directive 2020/741) aims to uniformize the requirements for effluents reuse throughout Europe, boosting reuse practices (Mainardis, Cecconet, et al., 2022). Quantitatively, at present the reuse of treated effluents is still limited, accounting for about 0.5% of total freshwater withdrawals, and 2.4% of treated effluents volume in the EU (Gawlik and Alcade-Sanz, 2014), thus further effort is needed to promote this virtuous practice in a safe and controlled way.

In this work, a methodology to preliminary assess the techno-economic feasibility of fertigation practices is proposed and applied to a relevant case study in North-eastern Italy, comparing water and nutrient requirements through traditional irrigation and fertigation and through advanced fertigation. The typical cultivated crops in the area are considered. This simple methodology can be applied in all situations to assess the best match between effluent and crop characteristics.

MATERIALS AND METHODS

The irrigation volumes to be supplied to selected crops were determined based on monthly water balances; Turc equation was employed to determine the effective rainfall from local meteorological data (Trajkovic and Kolakovic, 2009). The net irrigation requirement (L/s ha) was determined by subtracting the effective rainfall from crop evapotranspiration and dividing by the overall irrigation efficiency (Mainardis, Cecconet, et al., 2022).

N and P were considered in the nutrient analysis, due to lack of data concerning K. The specific nutrient requirements of each considered crop (soybean, maize, rice, vines) were used; for the fertigation scenario, the mass balances were drawn considering the volumes of supplied effluents and the nutrient concentration therein. In case the nutrients supplied through fertigation were higher than crop requirement, a limitation was imposed through the reduction of the applied volumes. Two different scenarios were considered in a fit-for-purpose approach (Capodaglio, 2021): actual effluent characteristics and effluent characteristics equal to the legislation standards.

The reduction in CO_2 emissions was calculated by considering emission factors of 5.79 kg CO_2/kg N and 0.633 kg CO_2/kg P for N and P, respectively (Jiménez-Benítez, Ferrer, et al., 2020). A simplified economic analysis was finally conducted to ascertain the savings that could be obtained through fertigation schemes, by considering the cost of commercial fertilizers and water from agricultural consortia.

RESULTS AND DISCUSSION

The investigated crops significantly differed in terms of nutrient and water requirements: maize, soybean and vineyards required irrigation from April to August, while rice required watering from May to September. The maximum water demand was normally encountered in July. The overall water requirements were highest for rice (9,283 m^3/mo ha), followed by maize (10.6% less than rice), grapes (23.2% less than rice) and soybean (29.0% less than rice).

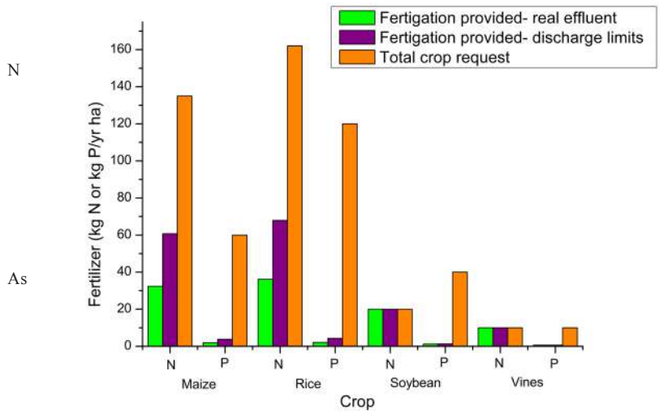

Figure 1. Fertilizers provided by fertigation (kg/ha yr) in comparison with total crop demand.

The amount of nutrients supplied by reclaimed wastewater are shown in Fig. 1. Due to fertigation, a significant reduction in mineral fertilizer dosage could be achieved, while P showed a very limited supply by the effluent. In the second scenario (effluent nutrient concentrations equal to discharge standards), a relevant reduction in mineral N addition (>40%) could be achieved for all crops, while P supply was again extremely low. Soybean and vines, in particular, could be supplied with most of the required N in fertigation schemes. Proper tailoring of wastewater treatment (especially regarding N:P ratio) could lead to improved effluent characteristics for specific crop requirements under a fit-for-purpose approach.

concerns the economic assessment, relevant savings (up to >40%) in mineral fertilizers could be obtained through fertigation. Vines proved to be the most favoured crop, while lower benefits (25%) were calculated for soybean, with maize and rice showing worse performances (respectively 15% and 11% savings). For the two investigated scenarios, the complete results of the economic analysis are summarized in Table 1, while the reduction in nutrients release into the environment and GHG emissions is recapped in Table 2.

Table 1. Water, fertilizers, and total economic savings (€/ha yr) for scenarios 1) and 2).

	Scenario 1 (actual effluent)			Scenario 2 (legislation limits)		
Crop	Water savings (€/ha yr)	Fertilizer savings (€/ha yr)	Total savings (€/ha yr)	Water savings (€/ha yr)	Fertilizer savings (€/ha yr)	Total savings (€/ha yr)
Maize	851	76	927	851	144	995
Rice	952	144	1,096	952	161	1,113
Soybean	526	47	573	281	47	328
Grapevine	263	24	287	140	24	164

Table 2. Saving in fertilizers and GHG emissions for the two analysed scenarios: actual effluent characteristics and legislation limits.

	Scenario 1 (actual effluent)			Scenario 2 (legislation limits)		
Crop	N saving (kg N/ha yr)	P saving (kg P/ha yr)	GHG saving (kg CO_2/ha yr)	N saving (kg N/ha yr)	P saving (kg P/ha yr)	GHG saving (kg CO_2/ha yr)
Maize	32.4	1.9	189	60.7	3.8	354
Rice	36.2	2.1	211	67.9	4.3	396
Soybean	20	1.2	117	20	1.3	117
Grapevine	10	0.6	58	10	0.6	58

Compared to traditional fertilization, fertigation allows a better nutrient use efficiency, improving plant uptake and nutrients availability in the root zone; however, long-term salinity and sodium monitoring is mandatory, due to high sodium adsorption ratio (SAR) levels, sometimes observed in treated effluents.

CONCLUSIONS

The methodological approach developed in the present study can be extremely useful to preliminary ascertain the match between crop water and nutrient requirements and effluent availability and quality in wastewater reuse schemes. The presence/absence of suitable water distribution networks for effluents conveyance to the fields is also an important factor of choice, as well as the availability of appropriate water storage to provide flexibility. The collaboration between stakeholders, from water utilities to agricultural consortia and farmers, is a key point to achieve success. Punctual effluent monitoring and early warning on pollutants and pathogens could reduce the diffused scepticism that still undermines fertigation social acceptance. Further research should involve drawing nutrient balances on monthly bases, considering the different nutrient request throughout plant growing phases, but also considering, besides the positive aspects, the negative factors (such as SAR) that may limit wastewater reuse feasibility.

Abstract

Phosphorus recovery was combined with ammonia recovery using gas-permeable membranes. In the first step, the ammonia and alkalinity were removed from municipal side-stream wastewater using a gas-permeable membrane manifold. In a second step, the phosphorus was removed using magnesium chloride ($MgCl_2$) and reduced amounts of alkali. The side-stream wastewater contained 730 mg N/L, 140 mg P/L, and 2900 mg/L alkalinity. The process recovered approximately 79-93% of the ammonia and 80-100% of the phosphorus. The phosphates produced were very-high grade (42-44% P_2O_5) with a composition like the bio-mineral newberyite. However, lower-grade phosphate products (27-29% P_2O_5) were produced whenever the N recovery step was bypassed, or carbonate alkalinity was added. Therefore, removing ammonia and alkalinity is important in producing high-grade phosphate products.

INTRODUCTION

Conservation and recovery of nitrogen (N) and phosphorus (P) from municipal, industrial and agricultural effluents using anaerobic digesters (AD) is important because of economic and environmental reasons.

A promising new method to recover ammonia (NH_3) from wastewater is using gas-permeable membranes (Vanotti and Szogi, 2015). The gas-permeable membrane manifolds are submerged in the liquid manure, and the gaseous NH_3 is removed from the liquid matrix before it escapes into the atmosphere. The N removal is done with low-rate aeration in the reactors that naturally increases the pH of the liquid and accelerates the rate of passage of NH_3 (>96%) through the submerged gas-permeable membrane manifold and further concentration in an acid stripping solution reservoir (Garcia-Gonzalez et al., 2015; Dube et al., 2016). The effluent after ammonia treatment is low in buffering compounds (ammonia and carbonates). In turn, the unbuffered conditions promote phosphorus precipitation reactions.

This work aimed to develop new technology for simultaneous N and P recovery suitable for digester effluents (Vanotti et al., 2018). It combines a gas-permeable membrane technology (N recovery) with P recovery of solid products by precipitation of phosphates. Phosphorus-precipitating compounds such as magnesium chloride (MgCl2) are added to the system after the N removal. Results obtained with municipal side-stream wastewater presented here are consistent with results obtained with livestock wastewater (Vanotti et al., 2017).

MATERIALS AND METHODS

In this example, two steps are used. Ammonia in wastewater is substantially removed in the first step. In the second step, $MgCl_2$ is added to the N-treated effluent in the phosphorus recovery tank (Figure 1). The wastewater was a side stream collected from James River municipal plant, Hampton Roads Sanitation District, Virginia. The side stream wastewater was a centrate effluent from waste sludge subjected to anaerobic digestion and solids separation and contained about 140 mg/L P and 730 mg N/L. The gas permeable membrane module was connected with a stripping solution reservoir containing diluted acid, as described in Dube et al. (2016) and Garcia-Gonzalez et al. (2015). Low-rate aeration was delivered to the bottom of the tank. The gas-permeable membrane was tubular and made of e-PTFE material. A nitrification inhibitor (22 ppm) was added to ensure nitrification inhibition. Concentrated acid was added to the stripping solution to an end-point pH of 1 when the pH increased above about two due to ammonia capture. In a second step, the treated effluent from the N recovery tank was transferred to the phosphorus separation tank, and mixed with $MgCl_2$ and NaOH to obtain a phosphorus precipitate and an effluent without phosphorus or ammonia. $MgCl_2$ was applied to obtain an Mg:P ratio of 1.2:1. Alkali NaOH was applied to pH 9.2. The chemicals were mixed for about one minute. After about a 0.5-hour gravity sedimentation period, the phosphorus precipitate was dewatered using glass-fiber filters and characterized for total N, P, Mg, Ca, and K and plant available phosphorus.

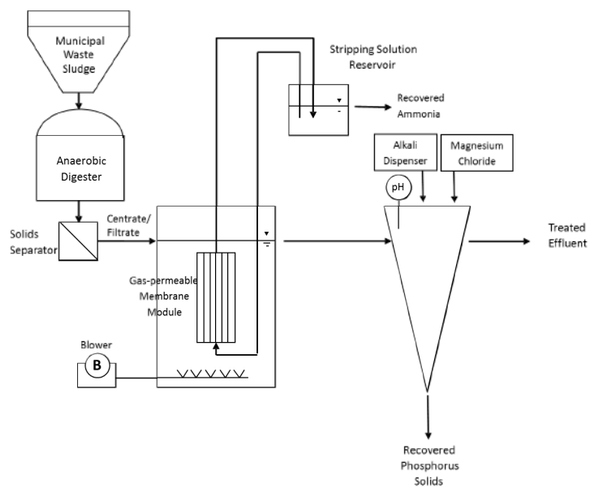

Figure 1. Schematic diagram of nitrogen (N) and phosphorus (P) recovery system using ammonia separation tank and P recovery tank.

RESULTS AND DISCUSSION

Phosphorus recovery of anaerobically digested municipal wastewater via $MgCl_2$ precipitation was enhanced by combining it with the recovery of NH_3 through gas-permeable membranes and low-rate aeration. The low-rate aeration destroyed the natural carbonate alkalinity in the wastewater and increased pH, which accelerated NH_3 uptake in the gas-permeable membrane system (Figure 2). The ammonia capture process substantially reduced carbonate alkalinity, from 2990 mg/L to 90-130 mg/L, and ammonia concentration, from 730 mg N/L to 50 mg/L. These conditions benefited subsequent P recovery. The combined process provided quantitative (ca 100%) P recovery efficiency (Table 1).

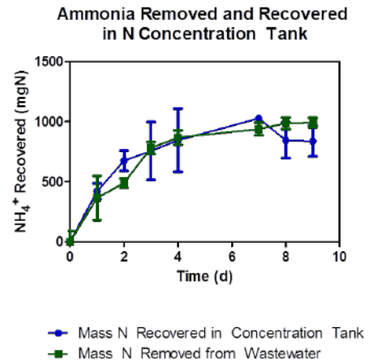

Figure 2. Mass removal and recovery of nitrogen (N) from municipal wastewater using gas-permeable membranes and aeration.

Table 1. Changes in concentration and mass balances for nitrogen (N) and phosphorus (P) using $MgCl_2$ and NaOH. Municipal Wastewater Case 2.

	Influent Concentration	Effluent Concentration	Mass Inflow Initial Manure	Mass Outflow			Total Recovery
				Recovered Solid	Recovered by Membrane	Effluent	
	mg/L			mg (% of initial)			
N	733	60	1100 (100%)	30 (2.73%)	837 (76.09%)	90 (8.18%)	867 (78.82%)
P	133	20	200 (100%)	212 (106.00%)	0 (0%)	30 (15.00%)	212 (106.00%)

With active NH_3 extraction, the magnesium phosphates produced contained higher P_2O_5 grade (42%) with high plant availability (Table 2). The phosphorus product was like the composition of newberyite ($MgHPO_4.3H2O$), a biomineral found in guano deposits, which has approximately 40.8% P_2O_5 and 13.9% Mg composition and a 1:1 P: Mg molar ratio.

Table 2. Composition of recovered solid in the system of Figure 1 using approximately 5.42 mmol/L MgCl2 and about 10 mmol/L NaOH.

N	P (P_2O_5)	Mg	Ca	K	Plant Available P (Citrate soluble)
				%	
2.56	18.30 (42.0)	14.6	1.4	1.9	98.4

However, lower-grade phosphate products (27-29% P_2O_5) were produced whenever the N recovery step was bypassed, or carbonate alkalinity was added (Table 3). Therefore, removing ammonia and alkalinity is essential for making high-grade phosphate products.

Table 3. Effect of ammonia and alkalinity concentration on recovered phosphate minerals.

Conditions before precipitation with $CaCl_2$ (Mg:P = 1.2:1)				NaOH added to pH 9.2 mmol/L	% P recovered by Process	Phosphate mineral composition	
Pre-treatment	NH4-N	Alkalinity	pH			% P_2O_5	% Mg
	mg/L	mg/L					
N recovered	70	90	6.0	8.4	100	42.0	14.6
Added 2 g/L $KHCO_3$, then N recovered	0	1000	8.1	4.4	63	27.4	12.7
None	840	2900	7.6	33.2	99	29.8	10.5

These results showed that it is possible to produce Mg phosphates with high P_2O_5 content by removing the NH_3 from the liquid with the gas-permeable membrane process. This is an important finding because recovered phosphates with high P_2O_5 content are more in line with commercial mineral fertilizers and favored by the fertilizer industry.

Abstract

This study demonstrates the application of ion exchange process to remove and recovery ammonia (NH_4-N) from secondary/anaerobic membrane effluent from a full-scale WWTP. The average NH_4-N concentration fed the IEX was 56.9±9.6 mg N/L at flow if 1 m^3/day, and the IEX process achieved > 90% NH_4-N removal. Four percent NaOH was shown to be the most efficient regenerant for Zeolite-N IEX media used the adsorb the ammonia. The regenerant was used multiple times was able to concentrate ammonia-nitrogen to a high concentration up to 1,750 mg N/L. The ammonia regeneration efficiency peaked at 95.3% and regeneration capacity of 10.0 mg N release/g media. The ammonia was recovered from the regenerant using a hollow fibre membrane contactor (HFMC), and complete recovery of NH_4-N (99.8%) was achieved in the form of ammonium sulphate, which has a potential to be applied as in the production of used for fertilizers, plastics, textile, cleaning products or protein. The obtained data demonstrated that HFMC effectively recovered the ammonia from the regenerant brine establishing the feasibility of IEX-HFMC combined technologies for municipal wastewater treatment, contributing to the circular economy and NET-ZERO targets.

exchange; membrane contactors; ammonia recovery

IINTRODUCTION

Ammonia is an essential nutrient in agriculture, with global fertilizer production increasing at around 1.5% per year. Ammonia production to manufacture fertilizers entails 1.5-2.5% of the global energy consumption via Haber-Bosch process. Eventually, ammonia-based fertilizers enter the food and water cycle, ending in wastewater treatment plants. Once there, ammonia is converted into atmospheric N2 in biological processes generating 14-26% of the overall carbon footprint of the wastewater treatment plants (Yea et al., 2018, Cruz et al., 2019). On the other hand, ammonia is a recoverable resource (Darestani et al., 2017). Therefore, developing an effective removal and recovery technology by combination of economic, environmental and energy considerations, would support a sustainable nitrogen cycle.

Ion-exchange process have been tested for ammonia removal and recovery. Despite the potential advantages of ion exchange such as simple operation, high removal efficiency and fast kinetics, regeneration of exhausted zeolite beds produce high concentrated ammonia-nitrogen streams. The feasibility of the process is dependant on the requirement of frequent regeneration periods (with new regenerant solutions each time) and disposal of loaded regenerant as hazardous waste (Lubensky et al., 2019, Huang et al., 2020, Vecinoa et al., 2019). Several processes have been proposed to recover NH4-N from regenerant brines, such as air stripping, steam stripping, and magnesium ammonium phosphate precipitation (Reiga et al., 2021). Among those, membrane contactors provide an attractive alternative due to their simplicity and ability to produce pure product in the form of ammonium sulphate. Regeneration of loaded ammonium zeolites generates rich ammonia concentrates (2–6 g NH_3/L) in brine solutions (NaCl, KCl, NaOH) that is ideal for the integration of hollow fibre membrane contactors (HFMC) (Sancho et al., 2017). HFMC offers a selective ammonia removal with lower energy inputs and without additional chemicals. In HFMCs, volatile free ammonia in the brine transfers across the micro-porous membrane due to a concentration gradient as a driving force provided by reactive acid phase flowing on the lumen side of the membrane, then forming ammonium sulphate upon instantaneous reaction with sulfuric acid on membrane interface (Darestani et al., 2017). The hydrophobicity of the membrane material prevents either liquid from penetrating into the pores, which remain gas-filled, so that only volatile NH_3 transferred across the membrane.

The possibility to recover ammonia from saturated brine promotes a circular approach of resource utilization by enabling the reuse of brine multiple times which decreases the chemical consumption and the production of high purity end product to be used as a fertilizer. The aim of the study is to demonstrate the benefits of ion exchange concentration of NH_4-N in regenerant brine and subsequent ammonia recovery with HFMC in the form of $(NH_4)_2SO_4$.

MATERIALS AND METHODS

For the demonstration scale plant, the AnMBR effluent was obtained from Spernal wastewater treatment plant, 1 m3 a day. The components of the IEX demonstration plant included a compressed air diaphragm pump, a storage tanks for the regeneration chemical 4% NaOH solution), 1 IEX column with zeolite-N for ammonia removal. The IEX columns were filled with 28 L (30 kg) of Zeolite-N. During normal operation, the AnMBR effluent was fed from the top of the IEX column and regenerations were conducted after treating every 2 m^3 of AnMBR effluent. The regenerant flowed into the IEX column from the bottom to give an upward flow for 2 hours. For regeneration of Zeolite-N media, 10 bed volumes (i.e. 278 L). The recovery of ammonia rich brine was performed using an Liqui-Cel 1.7x5.5 MiniModule hollow fibre membrane contactor to obtain ammonia sulphate crystals (Figure 1). The wastewater was analysed with standard methods.

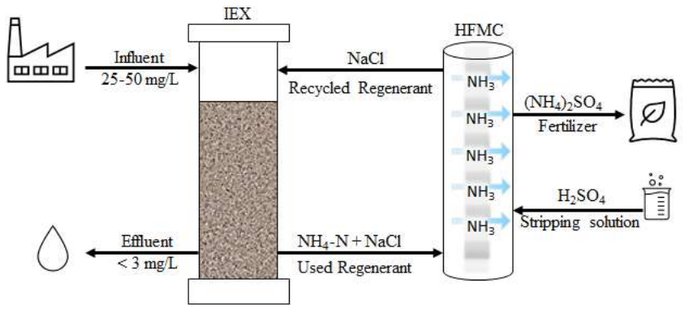

Figure 1 Schematic representation of the IEX and hollow fibre membrane contactor (HFMC) used for ammonia removal and recovery, as ammonium sulphate.

NH_4-N used for fertilizers, plastics, textile, cleaning products or protein production

RESULTS AND DISCUSSION

The influent NH_4-N concentration to the IEX was relatively high at 56.9 ±9.73 mg NH_4-N/L The first 325 bed volumes (BV) operation aimed to reach saturation as far as possible. The effluent NH_4-N concentration increased from 5.3 mg NH_4-N/L and reached 28.6 mg NH_4-N/L, where the peak C/C_0 ratio was 0.6 and the adsorption capacity was 10.6 mg NH_4-N/g media Then the first regeneration was conducted. After the 1st adsorption cycle, the following regenerations were applied after 2 m^3 of AnMBR effluent was treated. Figure 2 shows the IEX influent and effluent NH_4-N concentrations against BV treated from the 2nd to 6th adsorption cycles. Throughout the operation from 1st to 6th adsorption cycles, the average effluent NH_4-N concentration was 1.6 mg NH_4-N/L, with an average removal of 97.3%. When looking at the shape of the curve of the effluent ammonia concentration after regeneration, it is possible to see that concentration took some BV to stabilise, this was likely due to poor rising of the regenerant in between cycles. Nevertheless, the process was efficient and high ammonia removal was achieved.

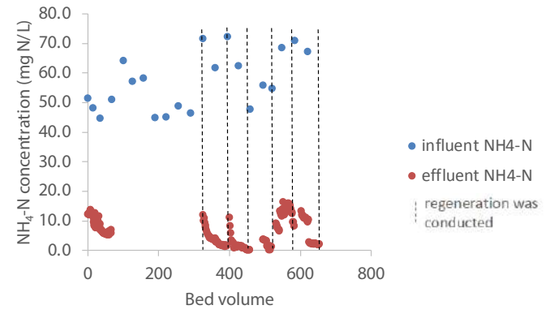

Figure 2 Influent and effluent ammonia concentrations during operation of IEX demonstration plant.

The regenerant accumulated high concentrations of ammonia (Table 1) that could be recovered in the HFMC process. The NH_4-N concentrated in the IEX brine was recovered by HFMC and the recovery efficiency (NaCl 10%, pH 11) reached to 99.8% (complete recovery) after the recirculation of the brine 360 times through the HFMC corresponding to a total operating time of 6.7 hours. In brine with an initial ammonia concentration of 890 mg NH_4^+-N/L was decreased to 25 mg NH_4-N/L after 250 cycles in the HFMC. The dissolved ammonium sulphate that accumulated within the acid side was then recovered as a solid product by evaporation of the acid phase. The chemical characterization of the product recovered from the IEX brine was analysed by energy-dispersive X-ray spectroscopy (EDX) analysis and the elemental composition of ammonium sulphate was identified in atomic percentage which was revealed the purity of the product. The elements comprising ammonium sulphate were solely detected and the proportions were found to be close to the chemical formula of ammonium sulphate (Table 2).

Table 1 Ammonia concentrations in regenerant at the end of each regeneration.

Regeneration cycle	NH_4-N concentration in regenerant (NH_4-N
1st (end)	1,090
2nd (end)	1,540
3rd (end)	1,745
4th (end)	1,750
*5th (end)	334
6th (end)	660

* new regenerant was prepared for the 5th regeneration cycle onwards

Table 2 EDX analysis of the recovered ammonia product.

	Elemental composition (atomic %)		
	N	O	S
Ammonium sulphate (chemical formula)	28.6	57.1	14.2
Ammonium sulphate (recovered product from IEX)	25.5	55.6	18.8

Abstract

Nutrients recovery from wastewaters has become a critical issue for European food security. NPHarvest nutrient recovery technology has been developed to provide a profitable pathway to recover nutrients from different waste streams in clean and safe products. The technology was tested with a field scale pilot in RecoLab (Helsingborg, Sweden) with digested black water originating from nearby living areas. P recovery efficiency was 90+% and ammonia recovery in NPHarvest contactor was 70%. The fertilizer products, P-rich solid containing calcium phosphates and liquid ammonium sulphate were analysed for over 300 pollutants, including wide array of heavy metals, pharmaceuticals, and organic pollutants. Despite the digested black water containing significant concentrations of these pollutants, the pollutant contents in the fertilizer products were considerably lower than legislative limits.

INTRODUCTION

The nutrients N and P are both a problem and a necessity for us. We would not live without these elements, but we have also changed the natural ecosystems greatly with them (Steffen et al., 2015) by discharging the excess. In addition, the recent developments in the geopolitical landscape, culminating in the Russian attack in Ukraine, have highlighted how vulnerable our food systems are. The EU is especially vulnerable since most of the P used in agriculture is imported (El Wali et al., 2019). This vulnerability culminates in food price volatility, as is the case in the EU in 2022 (Carbonaro, 2022). Nitrogen, on the other hand, is plentiful in the atmosphere. It is bound into reactive forms through the Haber-Bosch process, which consumes a significant amount of global energy (Smith et al., 2020). The top four countries, China, Russia, the United States and India, produced 55% of ammonia in 2021 (Statista, 2022). The energy supply of these countries consists of 76–89% of coal, natural gas, and oil in 2019 or 2020 (IEA, 2022). This leads to significant carbon emissions from N fertilizer production.

Nutrient recovery from waste streams is a viable countering force to these issues. However, wastewaters have a wide variety of pollutants that may be captured with the recovered nutrient products. Currently, the uncertainty of the quantities and effects of these pollutants, especially organic pollutants and pharmaceuticals hinders the use of recycled fertilizers. Thus, it is important to develop nutrient recovery technologies that separate nutrients from pollutants. Furthermore, this should be a cost-effective process to allow wide implementation. NPHarvest technology was developed to be a profitable process (Uzkurt Kaljunen et al., 2021). This study embarked on exploring the quality of NPHarvest end products in detail.

Table 1. NPHarvest product quality compared to municipal wastewater sludge from EBPR plant that is used as fertilizer, commercial struvite made from black water and both Finnish and Swedish legislative limits for fertilizers. b.d.l. = below detection limit.

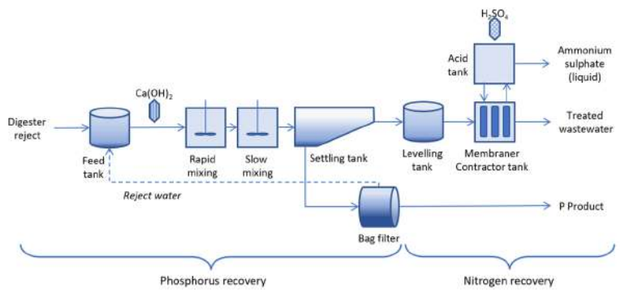

Figure 1. Simplified NPHarvest process schematic.

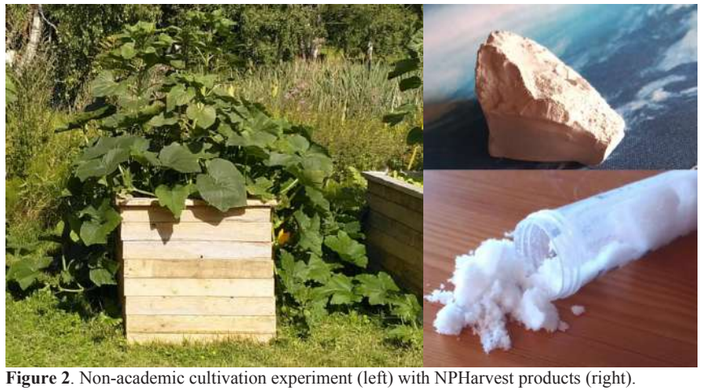

Figure 2. Non-academic cultivation experiment (left) with NPHarvest products (right).

NPHARVEST PROCESS & OPERATIONAL CONDITIONS

Figure 1 presents a simplified process schematic for the NPHarvest process. The process can be divided into two parts: 1) P recovery and pre-treatment and 2) N recovery. In the P recovery phase, the pH of the water is increased to 10+ with Ca(OH)2 which also precipitates P and suspended solids. P-rich sludge is dewatered so that the dry fraction becomes hygienic P fertilizer, and the liquid fraction is returned to the process, so N in the liquid can efficiently be captured. In N

recovery phase the liquid passes through a membrane contactor that has been designed to tolerate relatively high suspended solids concentrations. Hydrophobic membranes passively capture N, in ammonia form, and separate it from the wastewater flow. Ammonia comes in contact with an inorganic acid and reacts forming the N salt products. This product can be crystallized if desired.

The process was continuously operated for two months in Summer 2021 in Recolab, Helsinborg, Sweden. The wastewater was a digested black water collected from nearby apartments. Samples were collected on average 3 times per week from various parts of the process to monitor the process performance. However, detailed pollutant analyses were based on single (but large in mass/volume) samples from influent (digested black water) and recycled products (ammonia salt and P fertilizer).

RESULTS & DISCUSSION

Table 1 summarizes the results of the pollutant analyses, highlighting the most interesting ones out of the over 300 different substances that were analyzed. As can be seen from the first 3 columns, digested black water has noticeable levels of Cu, Ni and Zn. However, the mass concentrations for these metals are not significant in the recycled nutrient products. It is noteworthy that the high Zn concentration in ammonium salt was most likely due to sample contamination. Organic pollutants have also noticeable concentrations in the treated water, but their mass concentrations are below the detection limit for the products. Overall, the product pollutant levels are considerably lower than the legislative limits in Finland or Sweden. Furthermore, they are lower than the fertilizer sludge produced in the same location from municipal wastewater or struvite made from black water (Kern et al., 2008).

During Summer of 2022 we cultivated pumpkin, cauliflower, and sunflower in a non-academic fashion with the produced fertilizers. Inspired by the preliminary results (Figure 2, also showing the fertilizer products), we plan to conduct a proper cultivation test during 2023, focusing on nutrient leaching and growth potential.

CONCLUSIONS

NPHarvest technology has been developed to enhance nutrients recycling possibilities and affordability. The process was operated in a field scale pilot with digested black water and the obtained fertilizer products were thoroughly analyzed. The products, ammonia salt and P-rich solid material have low or non-existent pollutant levels depending on the substance analyzed. Their pollutant levels are lower than competing recycled fertilizers and legislative limits in Sweden and Finland.

Abstract

An electrodialysis process (ED) has been applied to the effluent of an Anaerobic Membrane Reactor (AnMBR) as an ion concentration method for the subsequent ammonium and phosphate recovery. Promising results have been obtained regarding ammonium and phosphate concentration efficiencies. However, in areas with high water hardness, precipitation of calcium compounds during the ED process is a bottleneck that avoids the achievement of greater concentration efficiencies needed to the subsequent nutrient recovery. Thus, the objective of this research is to demonstrate the feasibility of the ED process with wastewater with low concentrations of calcium and to deal with precipitation problems when high loads of calcium are present in wastewater.

Keywords

Electrodialysis, nutrient recovery, precipitation, AnMBR effluent.

INTRODUCTION

Nowadays, there is a growing interest in the recovery of nitrogen and phosphorus for fertilizer production from industrial and urban wastewater (Y. Zhang et al., 2013; W. Tarpeh et al., 2018; A. Ward et al., 2018). Currently, different treatments are being used to fertilizer production as crystallization processes for struvite production (L. Pastor et al., 2008; M. Sena and A. Hicks, 2018) or membrane contactors (G. Noriega-Hevia, et al., 2020; W. Rongwong and K. Goh, 2020) for ammonium sulphate and nitrate sulphate production. Nevertheless, the efficiency of these processes would be increased if a previous concentration step was carried out. For that purpose, electrodialysis is a suitable technology. Electrodialysis has been used as an ion concentration method for more than 50 years, mainly to obtain drinking water from brackish water with industrial applicability (H. Strathmann, 2010). Currently, its use has been extended to the treatment of urban and industrial wastewater. Electrodialysis is an electrochemical membrane process based on the electrical field as the electromotive force to separate and/or concentrate anions and cations alternating anion and cation exchange membranes (H. Strathmann, 2010; M. Xie et al., 2016; T.Yan et al., 2018). On the other hand, scaling is a bottleneck on ED processes when high concentrations are reached since the resistance of the system increase significantly due to filter and membrane clogging, leading to a decrease in concentration efficiencies and other operating problems (M. Turek and P. Dydo, 2003; L. Shi et al., 2019). Thus, the main objective of this research is to establish the optimal operating parameters of the ED process to concentrate the ions coming from the effluent of a pilot-scale anaerobic membrane reactor (AnMBR) and, on the other hand, to obtain a dilute stream that reaches discharge limits established in 91/271/EEC Directive concerning urban wastewater treatment. Related to the first purpose of this work, another objective is also to avoid precipitation problems during the concentration process in the way of achieving optimal concentration values of ammonium and phosphate for a subsequent struvite crystallization step and for ammonium sulphate production in membrane contactors.

MATERIAL AND METHODS

The ED equipment was provided by PCCell GmBH (Germany) and consists of a pumping unit (BED 1-2) and a stack of 100 x 100 mm with a maximum of 10 cell pairs (ED 64-002). A PC-SK membrane (PCCell GmbH, Germany) was used as cation exchange membrane and PC Acid 100 OT as anion exchange membrane (PCCell GmbH, Germany), both with an active membrane surface area of 64 cm^2. The main characteristics of membranes are shown in Table 1. Dilute and concentrate streams were fed with 2 L and 1.5 L, respectively, with the effluent of an AnMBR plant, located in the Conca del Carraixet WWTP near Valencia (Spain). The average concentrations of the AnMBR effluent are presented in Table 2. The electrolyte used was 0.01M sulfuric acid with a total volume of 2L. Galvanostatic mode was chosen as work method at 0.24 A. During experiments, conductivity, pH, current and voltage were recorded. Experiments were performed in batch mode, i.e. one cycle was completed when target condition was reached in dilute and concentrate stream. Target condition was a voltage not exceeding 15 V, as they can cause damage to the membranes. After that, dilute tank was fed with fresh AnMBR effluent to complete a new cycle. Flow rate was 50 L/h for dilute and concentrate streams and the electrolyte flow rate was 150 L/h. At the beginning, middle and end of the cycle, samples of each stream were taken to be analysed by ion chromatography (883 Basic IC Plus, Metrohm, Switzerland).

Figure 1. Filter and concentrate tank with $CaSO_4$.

RESULTS AND DISCUSSION

Short-term experiments were done to establish the optimal operating parameters of the ED process. Once these parameters were determined, long-term assays were carried out to demonstrate the feasibility of the ED process for nutrient concentration. The objective was to concentrate up to values around 80-100 ppm of PO_4-P, optimal value for subsequent recovery as struvite (L. Pastor, 2008). During short-term assays high concentrations of NH_4-N were achieved faster than PO_4-P ones, thus no target values of ammonium concentration were established in concentrate stream. pH of concentrate stream was continuously maintained below 3 to avoid salt precipitation. Feed water concentrations, final dilute and concentrate values are shown in Table 3. After 17 cycles, the assay must be stopped due to the precipitation of calcium sulphate, which clogged the system decreasing the flowrate at concentrate stream to 10 L/h (Figure 1). As it can be seen, phosphate target values were not reached in the concentrate stream despite of the high efficiencies obtained. Besides, in dilute stream, phosphate did not reach discharge limits. However, ammonium efficiencies up to 1500% were achieved in concentrate and discharge limits were reached. In order to avoid calcium phosphate precipitation, calcium has to be reduced from the feed stream. Therefore, feed water with a ratio of AnMBR effluent: water of 1:3 was introduced into the system, diluting not only the calcium concentration but also the remaining ionic concentrations. Hence, ammonium and phosphate concentrations were adjusted until typical AnMBR effluent values (Table 4). Results obtained with this influent are shown in Table 3. In this case, both ammonium and phosphate target values were achieved with concentration efficiencies values two and three times higher, for ammonium and phosphate respectively, than the experiment without diluting feed water. Nevertheless, neither ammonium nor phosphate achieved discharge limits, being this last one greater than the one observed in the non-dilute feed water. This can be associated with a shorter duration of cycles due to a decrease in ion concentration in feed water and in consequence to an increase in the resistance of the system. Hence, optimal values of ammonium and phosphate for crystallization process were achieved with higher concentration efficiencies by removing the excess of calcium from feed water. Thus, feasibility of the ED process as concentration method was demonstrated. However, in high calcium loads areas, as the Mediterranean coast, it is necessary to apply an alternative treatment to remove calcium from concentrate stream. Thus, two different options are being studied: i) a previous treatment for ED by cationic exchange resins application or ii) a 3 chamber ED configuration with selective monovalent cation exchange membranes that allows to separate divalent cationic streams from the remaining ones (ED 64004, PCCell GmbH, Germany). Finally, to reach discharge limits in dilute stream, working with several ED stacks in series will be also evaluated.

Abstract

The pilot-scale study was conducted for converting phosphate (PO_4^{3-})-containing and ammonium (NH_4^+)-containing wastewaters from semiconductor industry to high-purity struvite ($MgNH_4PO_4$). By adding magnesium chloride ($MgCl_2$) at molar ratio of $[PO_4^{-3}]$:$[Mg^{2+}]$:$[NH_4^+]$ of 1:1:1 and pH 9. total of 80-90% of PO_4^{3-} was reacted at initial PO_4^{3-} concentration from 1,000 to 20,000 mg/L. The formation of struvite was confirmed by FESEM, XRD, and wet chemical analysis. Theoretical equilibria were modeled with PHREEQC and compared with experimental results. It was found that initial PO_4^{3-} concentration affected the size and morphology of struvite precipitates. The effluent of the process can be further polished by adding calcium chloride ($CaCl_2$) to induce the formation of hydroxyapatite ($Ca_3(PO_4)_3OH$, HAP). A two-stage process is proposed that ensures resource recovery and meet the effluent standards. The scale-up system was evaluated for potential applications in the factory.

Keywords

Ammonia; phosphate; recovery; semiconductor; struvite; wastewater

INTRODUCTION

Owing to the increasing demand for electronic products worldwide, semiconductor industries have grown rapidly. Semiconductor device fabrication involves a series of complicated processes in which a substantial amount of chemicals, gasses, and ultrapure water are used. It generates significant waste and wastewater (Kuo et al., 2022). Typically, the etching and cleaning processes utilize several chemical compounds, such as ammonium hydroxide (NH_4OH), sulfuric acid (H_2SO_4), phosphoric acid (H_3PO_4), and hydrofluoric acid (HF) (Warmadewanthi and Liu, 2009). Consequently, different streams of wastewater are generated. Among them, the phosphate (PO_4^{-3})-containing wastewater and ammonium (NH_4^+)-containing wastewater received much attention, since the removal of excess PO_4^{-3} is imperative to prevent eutrophication. In this pilot study, we examined the conversion of the two streams of wastewater to struvite ($MgNH_4PO_4$), a valuable fertilizer, by adding magnesium chloride ($MgCl_2$) at molar ratio of $[PO_4^{-3}]$:$[Mg^{2+}]$:$[NH_4^+]$ of 1:1:1, and pH 9.0.

MATERIALS AND METHODS

A semi-batch pilot reactor with diameter of 0.2 m, height of 0.45 m, and total capacity of 12 L was used (**Figure 1**). It is agitated by a multi-impeller composed of anchor and paddles. Three creeping pumps are for the control of $MgCl_2$ dosage, and of pH through a PID controller. Pilot experiments were conducted based on the results of bench-scale experiments using the Jar test apparatus. The PO_4^{-3}-containing wastewater and NH_4^+-containing wastewater were prepared by diluting the concentrated waste H_3PO_4 and NH_4OH from a semiconductor manufacturer. Pilot runs were carried out at molar ratio of $[PO_4^{-3}]$:$[Mg^{2+}]$:$[NH_4^+]$ at 1:1:1, and pH 9.0. Constant flowrate of $MgCl_2$ (Acros) solution was added to induce precipitation. It was stirred at 200 rpm and allowed to react for 5 min, followed by slow mixing at 30 rpm for 30 min. The suspension was sampled and filtered by 0.22 μm PVDF membrane (Advantec) and the filtrate was analysed by ICP-AES (JY 2000) to determine the PO_4^{-3} concentration. The filter cake was dried at 60ºC for at least 48 h and characterized by XRD (G2 Phaser Bruker) and FESEM (JOEL JSM-6500F).

RESULTS AND DISCUSSION

Figure 2 shows that when initial PO_4^{-3} concentration was 1,000, 3,000, 6,000, 12,000, and 20,000 mg/L, the phosphate removal efficiency was 80.1%, 82.5%, 86.8%, 87.1%, and 90.1%, respectively. On the other hand, the ammonium removal efficiency was 80.1%, 82.5%, 86.8%, 87.1%, and 90.1% (Figure not shown), respectively. Compared with the bench-scale system, the removal efficiency was slightly higher since magnesium source of pilot scale system was industrial grade $MgCl_2$. It contained some impurities, which may be beneficial for PO_4^{-3} conversion. It could be proved from wet chemical analysis.

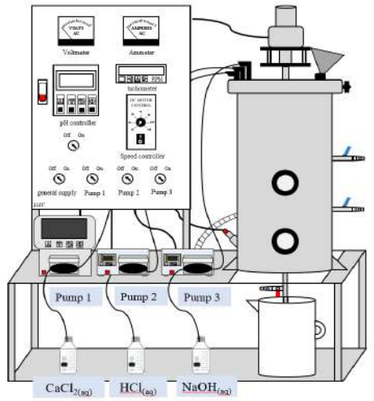

Figure 1 Pilot reactor system

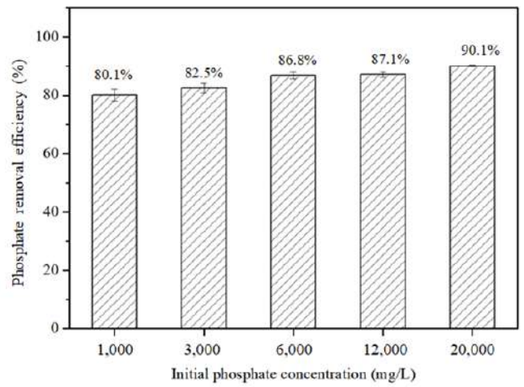

Figure 2 Phosphate conversion as affected by $[PO_4^{-3}]_{initial}$

The preliminary cost analysis was evaluated based on kg P recovered (= kg P_{rec}; = 4.4 kg struvite). The cost of $MgCl_2$ (46.5%) was 3.1 NTD/kg and it needs 12.5kg for kg P_{rec}, while the cost of NaOH was 4.5 NTD/kg and it needs 9.6 kg per kg P_{rec}. For electricity requirement, 5.4 kWh was needed per kg P_{rec}. Total of 38.1 NTD was need for 12.5 kg of $MgCl_2$ per kg P_{rec}, while 43.3 NTD for NaOH. And total electricity was 8.8 NTD per kg P_{rec}. The struvite is priced at 43.7 NTD/kg P recovered as referenced by Berliner Pflanze® and Alibaba. **Table 1** shows the preliminary estimation of profit of 102.1 NTD (ca. 3.3 USD) per kg P_{rec}. The quality the product needs to be further determined, and it is important to carry out more pilot runs and collect related information of the price and specifications of struvite. However, preliminary estimation was positive.

Table 1 Revenue as calculated per kg of P recovered

Resource demand	[NTD/kg P_{rec}]	Energy and water	[NTD/kg P_{rec}]	Product	[NTD/kg P_{rec}]	Revenue (NTD/kg P_{rec})
$MgCl_2$	38.1	Electricity	8.8※	MAP	192.3※※	102.1
NaOH	43.3

Abstract

The increase in food demand and the resulting intensification in agricultural activities make unsustainable the current linear economy. In this context, it is needed a paradigm shift to a circular economy regarding fertilizers production. Stripping using liquid-liquid membrane contactors reported to be a good alternative for NH_4^+ recovery from waste streams. However, the use of membranes has some limitations such is the fouling issue due to solid presence. In this work, the use of different pre-treatments have been assessed to reduce the content of solids, aimed to expand the lifespan of membranes. As main results, 95% of the ammonium was recovered as ammonium sulphate after 90, 120 minutes centrifuged and sieved samples, respectively, whereas only 55% of recovery was achieved after 150 minutes of experiment for raw sample. The obtained mass transfer coefficient were $1.38 \cdot 10^{-6}$, $1.15 \cdot 10^{-6}$ and $3.03 \cdot 10^{-7}$ m s^{-1} for centrifuged, sieved and raw samples respectively.

Keywords Ammonium sulphate, pig slurry, centrifuge, sieve, liquid-liquid membrane contactor, groundwater

INTRODUCTION

Food demand and its subsequent production have been continuously increased since decades ago due to population growth. In this context, Spain is one of the European countries with the largest production of pork products (19% of the EU production), according to data provided by the European Commission. As a result, livestock farming is becoming more intensive, increasing the environmental issues related to manure management. This manure contains in its composition a high amount of nitrogen, mostly in the form of ammonium (NH_4^+), which can be transformed into N_2O once the manure is directly spread on the soil as fertilizer. This compound can lixiviate and contaminate groundwater. Therefore, it is essential to effectively remove and recover NH_4^+ from pig manure obtaining a valuable subproduct while making an approach to the circular economy.

Ammonium sulphate($(NH_4)_2SO_4$) is a well-known fertilizer used worldwide. This compound can be obtained from the ammonium present in manure by stripping. Previous works reported recovery rates of around 87% (Provolo et al., 2017). This efficiency may be raised by using liquid-liquid membrane contactors (LLMC) as it improves the contact surface between the sample and the stripping acid (Mayor et al., 2020; Reig et al., 2022). Nonetheless, the performance of this membranes-based systems are subject to raw manure characteristics, especially solids presence, as they may cause membrane clogging. In order to limit the membrane contactor's efficiency decrease, the selection of a pre-treatment step is essential (Rongwong & Goh, 2020).

The aim of this study is to assess the effect of suspended solids content in pig slurry liquid fraction (SLF) in the ammonia mass transfer coefficient using LLMC. The studied samples were raw sample and pre-treated samples by centrifugation and sieving.

MATERIALS AND METHODS

For solids removal, centrifugation and sieving were assessed as pre-treatment. Centrifugation was performed using a centrifuge Allegra® 25R (BECKMAN COULTER, Spain) at 5100 rpm and 5ºC for 30 min. Sieving was carried out using a stainless-steel mesh with a mesh light of 106 µm (FILTRA VIBRACIÓN, Spain).

The LLMC for ammonia recovery was performed by using a hollow fibre contactor (MM-1.7x5.5 3M™ Liqui-Cel™, Denmark). Specifications of the device can be found in Table 1.

TABLE 1

Feed and stripping acid were passed respectively through the shell and lumen in countercurrent mode. During experiments, the pH of the stripping acid solution was maintained at 1 by adding sulphuric acid 98% while the feed's pH is maintained at 10 by adding sodium hydroxide 17M, if needed. Both solutions were prepared with reagents from Scharlab (Spain). Acid and feed were used in recirculation with flow rates fixed at 0.5 L min^{-1} at room temperature.

The mass transfer coefficient (K_m) in m s^{-1}, was determined following equation 1 suggested by Licon Bernal et al. (2016) and Hasanoğlu (2013):

$$ln\left(\frac{C_{0(NH_3)f}}{C_{t(NH_3)f}}\right) = \frac{K_{m(NH_3)}\,A_m}{V_f} \cdot t \qquad \text{Equation 1}$$

Where V_f is the total volume of treated feed (L), A_m is the membrane area on the contactor (m^2), $C_{0(NH3)f}$ and $C_{t(NH3)f}$ are the ammonia concentration at the beginning and at the time "t".

The performance of NH_4^+ extraction experiments was carried out in batch mode using the same experimental conditions of pH and temperature. A one-way ANOVA was used to assess whether the effect of these pre-treatments in ammonia extraction is significant.

The chemical composition of the different real samples was measured using colourimetric methods by a spectrophotometer (HACH, Spain), through the analysis of nitrogen in the form of ammonium ($N\text{-}NH_4^+$) based on the Indophenol blue method. pH was determined by using a multimeter coupled with a pH sensor (HACH, Spain) based on standard methods 4500-H+. Finally, the dry matter contents were determined by using method 1684 related to sample evaporation, detailed elsewhere.

RESULTS AND DISCUSSION

In this work, different pre-treatments for total solids removal from SLF and heir effect in the ammonium recovery rate was assessed. Pre-treatments suggested for total solids removal yielded successful results in solids content reduction, obtaining a dry matter reduction of 55,66% in the case of centrifugation and 13.49% in the case of the sieving (Table 2).

TABLE 2

The results obtained from the LLMC experiments are shown in Figure 1 and summarized in Table 3. With an initial NH_4^+ concentration of around 2700 mg L^{-1}, recovery rates of 95% were achieved in 90 and 120 min for centrifuged and sieved samples respectively. On the contrary, in the case of raw SLF, after 150 minutes of experiment, the content of ammonium on the sample remained higher than 1000 mg L^{-1}, which corresponds to a 55% of recovery rate. The difference in experimental times may be explained by the higher solid reduction in the centrifugation step in front of the sieving pre-treatment as when the solid content is higher, the membrane pores are more easily clogged, reducing its mass transfer coefficient. After mass transfer coefficient calculations it was obtained values of $1.38 \cdot 10^{-6}$ m s^{-1} (R^2=0.986), $1.15 \cdot 10^{-6}$ m s^{-1} (R^2=0.972) and $3.03 \cdot 10^{-7}$ m s^{-1} (R^2=0.981) for centrifuged, sieved and raw SLF, respectively. In addition, one-way ANOVA results reported no significant differences between the mass transfer coefficient between centrifuged and sieved samples (p-value = 0.776) while showing significant differences between pre-treated samples and raw SLF as it was reported p-value of 0.009 and 0.022 compared with centrifuged and sieves samples, respectively.

FIGURE 1 | TABLE 3

CONCLUSIONS

This work has studied the effect of total solids removal in the efficiency of ammonium stripping through LLMC after two different pre-treatments: centrifugation and sieving. The obtained results demonstrate the importance of solids removal for improving the performance of LLMC. In addition, obtained results showed the better performance of centrifugation as pre-treatment in front of sieving in terms of total solid removal. However, no significant differences were observed between both pre-treatments in terms of mass transfer coefficient in stripping process.

Abstract

Nitrogen recycling is one of the major challenges for wastewater management in the future. In this work the optimal conditions for ammonia recovery with gas-permeable membrane absorption are scrutinized. Experiments and modelling works demonstrate the effect of TAN/IC ratio for determining the pH and temperature setpoints, the pretreatment to be applied for minimizing the energy demand.

Keywords

Nitrogen recovery; digestate; urine; wastewater treatment; membrane;

INTRODUCTION

Nitrogen recycling is one of the major challenges for our society. However, nitrogen recovery technologies like stripping, adsorption or reverse osmosis, are still poorly implemented in the water sector, due to capital and operational costs as well as maintenance needs. Biological deammonification (nitrogen conversion into dinitrogen gas through partial nitritation and anammox) is considered as the most cost-effective technology for sidestream systems in treatment plants (…). Besides the scenarios of decentralised management of high strength effluent as urine or liquid digestate encourage nitrogen recovery techniques. Transmembrane chemical absorption process (also called membrane stripping or gas-membrane absorption) is a promising technology to recover ammonia. It consists in transferring ammonia through gas-permeable membrane and capturing it in acid solution. It can be applied on high strength wastewater to produce a liquid fertilizer for agriculture (Richter et al., 2020; Uzkurt Kaljunen et al., 2021; Molinuevo-Salces et al., 2020; Ulbricht et al., 2013). A critical review (Gonzalez-Salgado et al., 2022) has shown the recent progress and pointed out remaining questions regarding this technology and its scale-up: elucidate the effect of ionic strength, reducing the water vapour transport through hydrophobic membranes, optimizing the operating conditions for pre-treatment as well as energy minimization. In this study, transmembrane chemical absorption (TMCS) was applied on digestate, urine, and synthetic wastewater at different scales (lab and industrial pilot). The objective was to support a model describing physical-chemical mechanisms which was used for comparing different scenarios and operational options with a specific focus on energy efficiency.

MATERIAL AND METHODS

The pilot was composed of membrane module (polypropylene, 53 m^2) with pre-treatment processes including aeration, NaOH addition, settling, heat exchanger, and prefiltration (Figure 1). Ammonia was absorbed in sulfuric acid to obtain an ammonium sulphate solution. Ammonia recovery efficiency (ARE) and water vapour transfer were determined through mass balance. A model was developed on Matlab for solving the chemical equilibriums (electroneutrality and thermodynamic constants) and predicting pH variations, mass transfer of ammonia, energy and chemical needs. The primary energy demand of the overall process was calculated using the primary energy factors (PEF) from Ecoinvent database v3.8. Energy saving for producing an equivalent kilogram of nitrogen by Haber-Bosch process was also considered (12.5 kWh kgN^{-1}, Van der Hoek et al., 2018). The ammonia transfer coefficient of the model was determined with experimental results using synthetic wastewater (NH_4Cl) and real effluents (urine, digestate). The influent flow rate varies from 25 to 100 L h^{-1} and influent total ammonium (TAN) concentration ranged from 1 to 4 gN L^{-1}.

RESULTS

Effect of pH, temperature and wastewater composition on performances and energy needs

Ammonia recovery efficiency (ARE) was measured for different hydraulic conditions and varied from 64% to 98%. Results were not significantly different for synthetic wastewater, urine and digestate, despite a small effect of ionic strength. Similar performances (ARE) can be obtained with different couples of pH and temperature in the TMCS process, due to their respective effect on NH_3/NH_4^+ ratios and Henry's law constants of NH_3. Working at lower pH can be compensated by higher temperature. Our results showed that the Nitrogen to Inorganic Carbon ratio (TAN/IC) of the wastewater has a key role in the energy needs for pre-treatments depending on the chosen operational pH for effluent (Figure 2). Aeration (stripping of CO_2) allows to reduce the NaOH consumption for pH rising. The total primary energy requirements per kilogram of nitrogen recovered and the gain in energy saving is more important when the ratio of TAN/IC decreased. The stripping process reduced by 11-23% the use of NaOH and by 8-19% the primary energy. Simulations showed that it is preferable to work at high pH for high TAN/IC (i.e. low IC) whereas it is energetically more efficient to work at lower pH at low TAN/IC (i.e. high IC). The TAN/IC ratio of stored urine ranged from 1.78 to 3.16 whereas a lower TAN/IC was observed for digestate (0.71 to 1.83). Hence different optimal conditions could be chosen for these two types of wastewaters.

Global optimization of primary energy needs

For similar recovery efficiency (ARE=90%) the global primary energy required is also sensitive to the heating source. When TMCS is implemented after anaerobic digestion, methane can be used for heating. In that case the optimal operating condition was found at pH 10 and 35°C whereas the operating conditions of pH 10.5 and 25°C were more suitable for heating with natural fossil gas boiler (Figure 3). When the process operates at ambient temperature, a lower influent flow rate can be applied to increases the ARE and reduce the primary energy requirements (Figure 4). ARE increases from 80% to 92% and up to 98% by dividing the flowrate by 2 and 4 respectively. This would need a higher membrane surface to treat the same effluent flow, but as a consequence the primary energy needs can decrease to less than 15 $kWh_{primary}\ kgN_{recovered}^{-1}$. In that case, considering the energy saving by substituting conventional nitrogen fertilizer from Haber Bosch process (12.5 kWh kgN^{-1}) the energetic needs become lower than partial nitritation – anammox process.

CONCLUSION

TMCS is a mature technology for nitrogen recovery from high strength wastewater. Energy consumption is much lower than conventional stripping. The complete modelling approach shows the influence of TAN/IC ratio on the optimal conditions (pH, T) and associated pre-treatments. This should be taken into consideration for application on urine or digestate. Several choices of temperature and pH, allowed obtaining the same ammonia removal efficiency but the optimization also depends on the heating source (biogas of fossil gas). Working at ambient temperature was the best option for minimising energy needs.

Abstract

Swine manure offers mining opportunities for nutrient recovery and subsequent reuse as renewable fertilizer. This research aimed to integrate conventional biological nitrogen removal (BNR) with P and K recovery as K-struvite ($MgKPO_4 \cdot 6H_2O$). The denitrified effluent has an unbalanced Mg/K/P molar ratio of 1.4/9.5/1, so external P and Mg sources should be considered to recover all the K. Waste sludge from the BNR reactor presented a rich and balanced composition (0.7/1.2/1). An acid pre-treatment release PO_4^{3-} and K^+ from the sludge but also Ca^{2+}, which has to be trapped to prevent the formation of calcium phosphates instead of K-struvite. This downstream process allowed for the production of a multi-nutrient fertilizer with 0-1% N, 10-17% P and up to 8% K.

INTRODUCTION

Agricultural crop production requires macronutrients such as nitrogen (N), phosphorus (P) and potassium (K) which can be supplied in the form of recovered bio-based fertilizers.

The recovery of P is particularly relevant in the EU framework since P and phosphate rock have been identified as two of 27 critical raw materials (Cordell et al., 2009). Similarly, K is mostly obtained from potash ores, but it is not commonly recovered from wastewater or other similar sources. Thus, there is a need to identify new sources of K (Manning, 2015).

Concerning N, nitrification-denitrification (NDN) is typically applied as a Best Available Technique (BAT) for effective on site biological N removal (BNR) (Giner-Santonja et al., 2017) and the fulfilment of legal criteria in pig production. Under the circular economy framework, after the biological step, innovative procedures for the recovery of P and K as K-struvite (MPP, $MgKPO_4 \cdot 6H_2O$) are of high interest. In the EU, on the basis of the fertilising products regulation (EU) 2019/1009, a legal framework for struvite has already been developed (Huygens et al., 2019).

The waste sludge from the NDN bioreactor (Figure 1) has higher concentration of P than the denitrified liquid effluent, which can be mobilised by acidification. Unfortunately, calcium (Ca^{2+}) will be also mobilised. The crystallisation of K-struvite is disfavoured by high levels of Ca^{2+} due to the formation of calcium phosphates (Ca-P), and thus, the development of new procedures for preventing the interference of Ca during K-struvite formation are needed (Srinivasan et al., 2014).

This study aims to investigate the recovery of K-rich struvite from the denitrified eddluent and the waste sludge of a NDN bioreactor treating pig slurry. Different methods to avoid Ca interference have already tested.

MATERIAL AND METHODS

Samples of denitrified effluent and waste sludge were taken from a NDN treatment plant located in a pig farm from Osona (Spain) and follows the process layout shown in Figure 1.

The denitrified effluent had as soluble Mg/K/P molar ratio 1.4/9.5/1 (136 ±8 mg P/L) whereas the waste sludge had a total Mg/K/P molar ratio of 0.7/1.2/1 (1292 ±8 mg P/L).

When using the denitrified effluent and considering P as the limiting element, magnesium oxide (MgO) and magnesium chloride ($MgCl_2 \cdot 6H_2O$) were dosed as Mg external sources. When considering K as the limiting element, the simultaneous addition of Mg and P was performed with own-synthetized newberyite particles (NP, $MgHPO_4 \cdot 3H_2O$), following Astals et al. (2021). The NP were synthesised with 2.4 g H_3PO_4/g MgO and dried at room temperature.

When using the waste sludge, H_2SO_4, ethylenediaminetetraacetic acid (EDTA) and oxalic acid solutions were used as acidifying agents. All the tests were performed in 1-L glass beakers using a flocculator (mod. JLT6, Velp Scientifica, Italy). NaOH was used to increase the pH. Soluble ionic forms were analysed by ion chromatography. The composition and structure of the precipitate were analysed with inductively coupled plasma (ICP) and X-ray diffraction (XRD), respectively.

RESULTS AND DISCUSSION

Denitrified effluent: As shown in Figure 2A, by considering P as the limiting element, low K recovery efficiencies (KRE) (between 3% and 10%) were reached under different values of pH (from 10 to 12) after 2h mixing. Moreover, the molar removal ratio between Mg and P ($MRR_{Mg:P}$) was slightly above 1 suggesting the co-formation of the magnesium phosphate known as cattiite ($Mg_3(PO_4)_2 \cdot 22H_2O$) (Zhang et al., 2018). By considering K as the limiting element, stable IRE_K were reached after 2 h of reaction (Figure 2B). The higher the dose of NP applied (8-14 g NP/L) the higher K removal efficiency reached, so best results were obtained with the addition of 14 g NP/$L_{effluent}$ (KRE reaching 90%).

Waste sludge: As shown in Figure 3, by adding the acidic agent (H_2SO_4, EDTA or oxalic acid) according to a targeted pH (values from 6 to 4), significant amounts of PO_4^{3-}, Mg^{2+} and, Ca^{2+} were released. In each test, the lower the pH considered, the higher the solubilisation achieved. The concentration of K^+ remained almost invariable during the acidification test because this element was already soluble. The solubilisation efficiencies reached using H_2SO_4, EDTA and oxalic acid at pH 4 were 78%, 70% and 75% for PO_4^{3-} and, 91%, 79% and 83% for Mg^{2+}, respectively. As it was previously reported by Srinivasan et al. (2014), at this pH, the dosage of EDTA and oxalic acid resulted in similar solubilisation efficiencies than H_2SO_4. By adding oxalic acid, any increase in the concentration of Ca^{2+} was observed (Figure 3) due to the formation of calcium oxalate (insoluble). Contrarily, by adding EDTA, an increase in Ca^{2+} concentration was observed (Figure 3) because the interaction between the EDTA and Ca^{2+} ions result in the formation of the complex Ca-EDTA (soluble). Following acidification pre-treatment and solids separation by centrifugation, the pH of the centrate was increased with the addition of NaOH. As shown in Table 1, low calcium removal efficiencies (CaRE) were obtained using EDTA and oxalic acid (i.e., 12% and 0%, respectively) demonstrating the good performance of both as Ca blocking agents. The best KRE (44%) were obtained when using oxalic acid as the acidifying agent.

The analysis of the precipitates formed after raising the pH of the denitrified effluent considering K as the limiting element (using NP) and from the waste sludge using oxalic confirmed in both cases the presence of K_2Na-struvite ($Mg_2KNa(PO_4)_2 \cdot 14H_2O$) with a composition between 10% and 17% for P and 7% to 8% for K (Figure 4).

CONCLUSIONS

This work has proved as feasible the simultaneous recovery of P and K from the denitrified effluent and waste sludge produced in a BNR system treating pig slurry. Concerning the denitrified effluent, limited K recovery was attained y only raising the pH (3-10%). The addition of NP allowed increasing significantly the KRE, reaching 90%. Regarding the waste sludge, an acidifying pre-treatment increased ion availability in the liquid phase, but the use of a Ca-sequestring agent is necessary to prevent the formation of Ca-P compounds. A multi-nutrient valuable product was recovered. Nevertheless, further work is needed to reduce the presence of Na^+ in the recovered precipitate.

Abstract

This study aims to investigate phosphorus recovery from waste aerobic granular sludge (WAGS). Phosphorus is an essential element for the growth of all living organisms, but it is a limited and non-renewable resource. It is mainly used as nutrient in the agronomic sector to produce mineral fertilizers and it is included in the list of Critical Raw Materials by the European Commission. Domestic wastewater are streams containing phosphorus that can be recovered from waste activated sludge (WAS) where it is accumulated. Aerobic Granular Sludge (AGS) is a pseudo-spherical biofilm, made of self-aggregated bacteria enriched in slow-growing organisms including phosphorous accumulating organisms (PAOs), applied for biological wastewater treatment. Batch tests have been performed by varying the pH. WAGS was withdrawn from a Granular Sequencing Batch Reactor (GSBR) performing a bioP-removal efficiency of 99%. WAGS was characterized by a VSS/TSS of 84% and a total phosphorus (TP) of 48.8 mgP/gTS, higher than conventional WAS (TP≈14-17 mgP/gTS). The fractionation of TP in WAGS revealed that the 88.6 %wt was inorganic phosphorus (IP), and the 11.4 %wt was organic phosphorus (OP). Preliminary results highlighted a TP-recovery efficiency up to 92% at pH 4 after 12 days. Salts with high P-content, that comply with the EU regulation (2019/1009) on fertilizers, were chemically precipitated from bulk at the end of the tests. These salts could be reused for agronomic applications. Considering an almost complete bioP-removal in a GSBR, the obtained results show the potentials of an attractive side-stream treatment chain with a P-recovery efficiency > 90% of TP contained in raw wastewater.

Keywords (maximum 6 in alphabetical order)

Aerobic granular sludge; phosphorus; resource recovery; wastewater resource recovery facilities

INTRODUCTION

Phosphorus (P) is an essential element for the growth of all living organisms, but it is a limited and non-renewable resource. It is obtained mainly from rocks located in few regions of the world (e.g. about 75% of world's P reserves are in Morocco (Cordell and White, 2015)farmer livelihoods, agricultural productivity and global food security. Yet there is a lack of research and effective governance at global or national scales designed to ensure the future availability and accessibility of this global resource. The world's main source of phosphorus, phosphate rock, is a finite resource that is becoming increasingly scarce, expensive and subject to geopolitical tensions as one country, Morocco, controls three-quarters of the world's remaining high-grade reserves. Given the criticality of phosphorus and the vulnerability of the world's food systems to phosphorus scarcity, there is a strong need to stimulate appropriate sustainable phosphorus practices and technologies, and simultaneously, to initiate effective international governance mechanisms, including policy/research coordination and accountability. Sustainability indicators are increasingly being used as tools to facilitate accountability, implementation, evaluation and communication for global sustainability challenges. This paper presents the first comprehensive set of phosphorus vulnerability and security indicators at global and national scales. Global indicators include: phosphate price, market concentration and supply risk, relative physical phosphorus scarcity and eutrophication potential. National indicators include: farmer phosphorus vulnerability, national phosphorus vulnerability, national phosphorus equity and soil phosphorus legacy. Monitoring and tracking such indicators at the national and global levels can ultimately provide evidence of key phosphorus vulnerabilities or 'hotspots' in the food system, support effective phosphorus governance to stimulate targeted and effective action, raise awareness of this food security challenge, and evaluate the effectiveness and performance of global or national sustainable phosphorus projects.",",author":[{"dropping-particle":"","family":"Cordell","given":"Dana","non-dropping-particle":"","parse-names":false,"suffix":""},{"dropping-particle":"","family":"White","given":"Stuart","non-dropping-particle":"","parse-names":false,"suffix":""}],"container-title":"Food Security","id":"ITEM-1","issued":{"date-parts":[["2015"]]},"title":"Tracking phosphorus security: indicators of phosphorus vulnerability in the global food system","type":"article-journal"},"uris":["http://www.mendeley.com/documents/?uuid=339cdc4e-ad60-4751-9d7f-d35d011b510a"]}],"mendeley":{"formattedCitation":"(Cordell and White, 2015). P is mainly used as nutrient in the agronomic sector to produce mineral fertilizers and it is included in the list of Critical Raw Materials by the European Commission from 2014 (Bobba et al., 2020). Domestic wastewater are alternative sources of P. It was estimated that the total P excreted by humans could meet 22% of global P demand (Mihelcic et al., 2011), and therefore it would be worthwhile to recover it. In this context, a paradigm shift from wastewater treatment plants (WTTPs) to water resource recovery facilities (WRRFs) has taken place over the last few years (Chrispim et al., 2019). P can be mainly recovered from waste activated sludge (WAS) where it is accumulated or precipitated as P-mineral (Chrispim et al., 2019). A novel and promising wastewater treatment technology, named Aerobic Granular Sludge (AGS), is based on pseudo-spherical biofilm made of self-aggregated bacteria enriched in slow-growing organisms including phosphorous accumulating organisms (PAOs) (Pronk et al., 2015) aerobic granular sludge technology has been scaled-up and implemented for industrial and municipal wastewater treatment under the trade name Nereda??. With full-scale references for industrial treatment application since 2006 and domestic sewage since 2009 only limited operating data have been presented in scientific literature so far. In this study performance, granulation and design considerations of an aerobic granular sludge plant on domestic wastewater at the WWTP Garmerwolde, the Netherlands were analysed. After a start-up period of approximately 5 months, a robust and stable granule bed (>8gL-1. The metabolism of PAOs consisted of two phases: in anaerobic conditions, PAOs store volatile fatty acids (VFAs) as polyhydroxyalkanoates (PHAs) inside their cells. The energy that is required to take up VFAs is provided by the hydrolysis of the internally stored glycogen and poly-P thus resulting in PO_4-P release in the bulk. In aerobic/anoxic conditions, PAOs take up the released PO_4-P, thus refilling the internal poly-P pool, using the intracellular PHAs they stored in anaerobic conditions as carbon source and electron donor (Smolders et al., 1995) considering also components like adenosine triphosphate (ATP. Therefore AGS is considerable as an unconventional reservoir of P that is present as poly-P in PAOs and as minerals precipitated on the bacterial surfaces. The aim of this study is to investigate the feasibility of P-recovery from waste aerobic granular sludge (WAGS).

MATERIALS AND METHODS

Anaerobic batch tests were performed by varying the pH of WAGS bulk liquid. pH was regulated by dosing a 1M HCl solution. Throughout all the batch tests duration the following parameters have been monitored: P released (LCK 350 HACH®), heavy metals (ICP-OES), anions/cations (Dionex1100®), total organic carbon (TOC analyser), chemical oxygen demand (COD LCK 614 HACK®), pH. Total Solids (TS) and Volatile Solids (VS) have been analyzed according to standard methods (APHA/AWWA/WEF, 2017)cis-9, cis-12. P fractionation of WAGS was performed according to a protocol named Standards Measurements and Testing (SMT) harmonized procedure (González Medeiros et al., 2005), in order to determine the total P (TP), the inorganic P (IP), as sum of non-apatite-inorganic-P (NAIP, i.e. the forms associated with oxides and hydroxides of Al, Fe, and Mn) and apatite P (AP, i.e. the forms associated with Ca), the organic P (OP, i.e. the P biologically stored inside PAOs cells as poly-P).

RESULTS AND DISCUSSION

WAGS was collected from a Granular Sequencing Batch Reactor (GSBR) performing a bioP-removal efficiency of 99%. WAGS was characterized by a VSS/TSS of 84% and a total phosphorus (TP) of 48.8 mgP/gTS, higher than conventional WAS (TP≈14-17 mgP/gTS) (Cordell et al., 2011; Pokhrel et al., 2018)means phosphorus will also need to be recovered for productive reuse as a fertilizer in food production to replace increasingly scarce and more expensive phosphate rock. Through an integrated and systems framework, this paper examines the full spectrum of sustainable phosphorus recovery and reuse options (from small-scale low-cost to large-scale high-tech. This confirms the high potential of P-recovery from WAGS, at least three times higher than WAS. The fractionation of TP in WAGS revealed that the 88.6 %wt was IP (NAIP+AP) and the 11.4 %wt was OP. These values were comparable with those of WAS that resulted: IP=84.4 %wt, OP=15.6 %wt (Pokhrel et al., 2018) and IP=88.7 %wt, OP=11.3 %wt (González Medeiros et al., 2005). Despite this similar repartition between IP and OP for WAGS and WAS, looking at the IP fractionation some differences are evident. The NAIP fraction for WAGS was considerable higher than WAS (79,6 %wt versus 44.8-48.0 %wt), as visible in Figure 1. This suggested that, due to the biofilm structure of WAGS, in the inner layers of granular sludge the local pH may have favoured the NAIP over the AP precipitation. NAIP fraction is considered the most labile P form, therefore more simple operational conditions are needed to recover it (e.g. pH close to 5-6). Conversely, more severe operational conditions are requested in order to recover AP fraction (e.g. pH close to 4) (Pokhrel et al., 2018). Therefore, a sludge high in NAIP fraction, such as WAGS, will be more promising and less expensive for P-recovery.

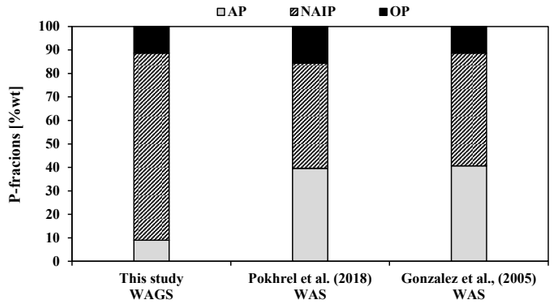

Figure 1: P-fractionation for WAGS (this study) and WAS (reference studies).

Looking at the P-recovery kinetics (Figure 2), it was observed that after 12 days a maximum P concentration of 45.2 mgP/gTS and 37.5 mgP/gTS (92.6 %wt and 76.9 %wt of TP) was reached for pH = 4 and pH = 5 batch tests, respectively. These data suggest that at pH = 4, also a part of AP can be recovered against greater operational complexity, as observed by Pokhrel et al. (2018). However, given the higher NAIP fraction, WAGS permits a significant P-recovery (close to 77% of TP) that would not be obtainable with a WAS under the same operational conditions. Therefore, by its nature, WAGS is in an advantaged position compared to WAS regarding the P-recovery.

Observing the kinetic of the batch test operated without pH control, a dramatic slowdown in P-recovery was registered reaching the maximum concentration of 31.6 mgP/gTS (64.7 %wt of TP) only after 31 days. Therefore, pH control is a key driver in order to maximize the P-recovery in the shortest time, which implies full-scale recovery reactors with smaller volumes. Since all the batch tests were conducted in strictly anaerobic conditions, it is assumed that in all the experiments there was a similar OP recovery.

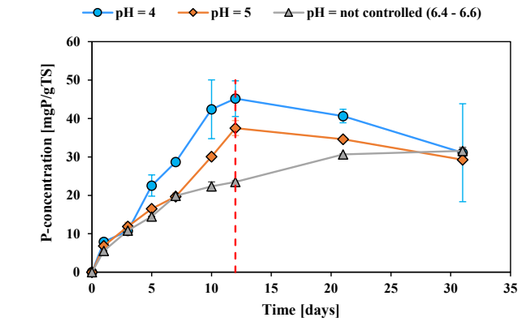

Figure 2: P-recovery kinetics at different pH conditions (fixed WAGS concentration: 2.1 gTS/L).

Salts with high P-content, that comply with the EU regulation (2019/1009) on fertilizers (EC, 2019), were chemically precipitated from bulk at the end of the tests. These salts could be reused for agronomic applications.

In summary, an innovative solution for P-recovery from WAGS is reported in Figure 3.

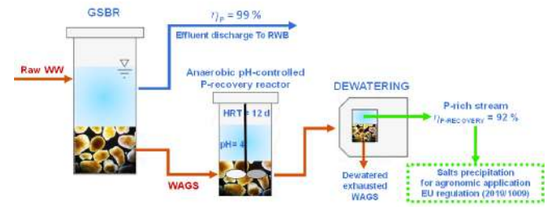

Figure 3: Hypothetical layout of P recovery-chain from WAGS.

Considering that 99% of TP contained in raw wastewater will be removed/accumulated in aerobic granular sludge and hypothesizing to maintain WAGS in anaerobic condition at pH=4, the results obtained in this study highlight that more than 90% of TP contained wastewater can be recovered. This finding places the AGS technology not only as one of the most efficient and promising biofilm technologies for wastewater treatment, but also as a precious mine for resource recovery.

CONCLUSIONS

This study reports on P-recovery from waste aerobic granular sludge. WAGS has higher NAIP fraction then WAS, therefore it offers an easier P-recovery. WAGS was collected from a GSBR performing an almost complete bioP-removal. The maximum P-recovery was achieved after 12 days at pH=4 (92.6% of TP). The obtained results show the potentials of an attractive side-stream treatment chain with a P-recovery efficiency > 90% of TP contained in raw wastewater. P-rich salts, after chemical precipitation from bulk, could be reused for agronomic applications.

Abstract

When dosing iron (Fe) to digested sewage sludge, phosphorus (P) can be magnetically recovered from in form of the paramagnetic mineral vivianite ($Fe_3(PO_4)_2$*8 H_2O). In this presentation we discuss the potential to use a similar approach for recovery of phosphate in manure. The low solubility of vivianite holds perspective to recrystallise other mineral phosphate forms into one recoverable mineral phase. However, while vivianite forms quite efficiently at a Fe/P ratio of 1.5 in sewage sludge, we observed that in pig manure a significant higher Fe dosing of up to Fe/P 4.5 was necessary to form vivianite. Organic matter is known to hinder vivianite formation in lake sediment by complexing Fe. Our first results show although organic ligands can influence vivianite formation and dissolution, the organics found in diluted manure do not have a significant influence. This highlights the necessity of more research on vivianite formation in different environments.

Iron complexation, manure organic matter, organic ligands, phosphorus recovery, vivianite

INTRODUCTION

In manure, P is often bound to magnesium (struvite) and calcium phosphates (Pagliari 2012). This makes targeted P recovery difficult because these minerals cannot be retrieved easily. A possible approach to recover P is solubilisation via acidification followed by a solid liquid precipitation and precipitation using alkaline magnesium or calcium salts. This implicates a high use of chemicals, and a more complicated extraction procedure (Tao 2016, Szögi 2015, Schoumans 2014). Therefore, it would be beneficial to have an easier transformation of the phosphorus precipitates in manure to one mineral. Vivianite ($Fe_3(PO_4)_2$*8 H_2O) is a promising mineral for phosphorus (P) recovery from municipal wastewater (Prot et al., 2019). Thanks to its paramagnetic properties it can be recovered magnetically, which has been shown at pilot scale (Wijdeveld et al., 2022). It forms over any other P and Fe-mineral in anaerobic digested sludge, after Fe has bound to sulfur (S). To maximize the transformation of P to vivianite, the stoichiometric dose of Fe/P 1.5 has to be increased depending on the S content of the sludge.(Prot et al., 2020). Vivianite can also be found in lake sediments. Due to similar conditions in sewage sludge and lake sediment, vivianite should also be the most stable mineral P form, which would make it easy to recover.

MATERIALS AND METHODS

Vivianite formation from phosphorus precipitates in manure

One litre of undigested sieved pig manure (< 200 µm) was poured into a sealed Duran bottle of 1.5 L. The bottle with pig manure received iron in three quantities. The quantities were calculated based on the pig manure composition. For the 4 g/L dose the total precipitation of FeS and then 5060 % of the

phosphorus as vivianite; for the 11 g/L, the total precipitation of FeS, then the binding of iron to 25 % of the organic carbon and the precipitation of all phosphorus as vivianite; for the 52 g/L dose a significant excess to maximize the quantity of phosphorus present as vivianite. The iron was added as $FeCl_2$*4 H_2O solution.

Establishing scales of known organic ligands competing with Fe-P bond in vivianite

Vivianite dissolution and formation with commercially available ligands

For vivianite dissolution experiments, vivianite was added to solutions of organic ligands (bipyridine (bipy), citrate, and humate) at a total organic carbon (TOC) content of 330 mg/L. The amount of Fe and P in solution was tracked via ICP-OES over the course of 3 weeks. For the vivianite formation experiment, $FeCl_2$*4 H_2O in solution was added to a solution containing K_2HPO_4 and the above-mentioned organic ligands at the same TOC. Fe and P that did not precipitate after 1 h were determined via ICPOES. The different organic ligands were classified on a scale according to their potential to keep Fe in solution per organic carbon for the dissolution and formation experiment respectively.

Diluted cow manure

Undigested sieved cow manure (< 200 µm) **was diluted to a TOC around 500 mg/L (table 1). Vivianite dissolution and formation experiments were performed according to the procedures described above replacing the organic ligands by the diluted manure. Then the results were compared with the help of the established scales.**

RESULTS AND DISCUSSION

Phosphorus precipitates in manure are transformed to vivianite at higher Fe dosing

For the 4 g/L dose, no vivianite was detected with Mössbauer spectroscopy (figure 1). When dosing 11 g/L a partial transformation of struvite P to vivianite could be seen under the stereoscope, amounting to 80 % of the total P based on calculations from the Mössbauer spectrum. Only in the excess Fe dosing of 52 g/L the complete P transformation to vivianite could be observed. Based on these results, it was estimated that a molar ratio of Fe/P 4.5 would be necessary to transform most of the phosphate into vivianite. This means a lot of Fe in manure stays in the organic material after vivianite recovery, implicating a loss of Fe salt, and making the quality of the organic material questionable for reuse as organic amendment in agriculture (figure 2).

This high surplus of Fe needed cannot be explained by the S content alone. Further explanations could be found in research on vivianite formation in lake sediments. Here, significant losses in vivianite yield have been attributed to 25 % of Fe equivalents binding to sedimentary organic carbon (Kleeberg et al., 2013). Therefore, we hypothesize, that Fe is sequestered by manure organic matter, and hence unavailable for vivianite formation. Therefore, we will study the influence of manure organic matter and compare this with a scale of known organic compounds.

Organics influence vivianite formation and dissolution

Vivianite dissolution (table 1) was observed for citrate, bipy and humate in decreasing intensity. Vivianite formation (table 1) was inhibited by citrate to the biggest extent lesser extent by bipy and humate. The stoichiometric ratio of Fe in solution to the TOC of the organic ligand was plotted on a scale for vivianite dissolution (Figure 3a) and formation (Figure 3b). Based on the hypothesis, manure organics were expected to dissolve vivianite and inhibit its formation to a greater extent. However, this was not the case here. Several factors could explain this unexpected result: low TOC content, the type of animal manure, and kinetic hindrance of the recrystallization from struvite to vivianite. The experiments related to these hypotheses will be performed from February on and the results will be available by June to be presented at the ecoSTP.

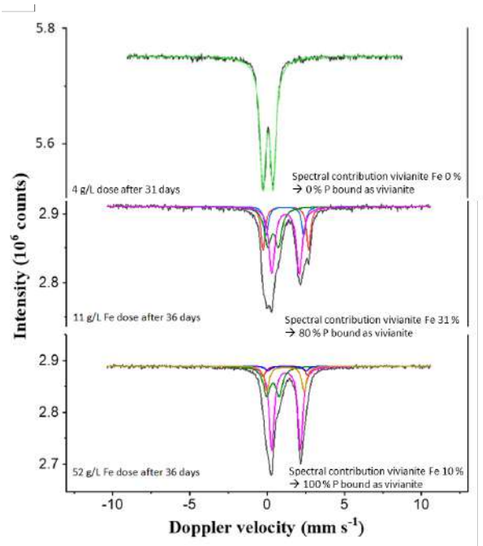

Figure 1. Mössbauer spectra for the samples measured at 300 K with the corresponding amount of P bound as vivianite calculated based on the spectral contribution of vivianite Fe, total amount of Fe, and P. The colors used correspond to, Black: sum of all the contributions, Blue: Vivianite site A, Red: Vivianite site B, Pink: $FeCO_3$, Green: Fe^{3+}/Fe^{II} standing for Fe(III) compounds, and low-spin Fe(II) compounds like pyrite, Yellow: $FeCl_2$*2H_2O.

Abstract

Urine contributes up to 70% of the phosphorus load in domestic wastewater, and decentralized sanitation systems and source separation provide an opportunity to recover this phosphorus. In this study, we assessed the feasibility of recovering phosphorus as vivianite from human urine, using thermodynamically modeled and experimentally determined data. We found that type of iron salt used, and also reaction temperature, did not affect yield and purity of vivianite. However, urine pH affected the solubility of vivianite and other co-precipitates, with the highest yield (93 ± 2%) and purity (79 ± 3%) of vivianite obtained at pH 6.0. Yield and purity of vivianite were both maximized when Fe:P molar ratio was greater than 1.5:1, but less than 2.2:1. This molar ratio provided sufficient iron to react with all available phosphorus, while exerting a competitive effect that suppressed formation of other precipitates. Vivianite produced from fresh urine was less pure than vivianite produced from synthetic urine, because of the presence of organics in real urine, but washing the solids with deionized water improved the purity by 15.5% at pH 6.0. Overall, this novel work adds to the growing body of literature on phosphorus recovery as vivianite from wastewater.

INTRODUCTION

Excess phosphorus (P) in the environment is harmful, as it can cause hypoxia and eutrophication in natural water bodies (Preisner et al., 2020). Domestic wastewater is a major contributor to the global flux of P. Considering that 80% of wastewater produced globally receives no treatment (Connor et al., 2017), it is unsurprising that eutrophication remains a problem worldwide (Hendriks and Langeveld, 2017). This has led to the implementation of stricter effluent standards across the world on discharge of treated wastewater to the environment. However, treatment that only removes P from wastewater is not sufficient and the focus must be shifted to recovering P, as it is a finite resource (Priambodo et al., 2017).

Human urine is rich in P which could be recovered as a valuable solid such as vivianite, which is more valuable than other P-compounds. In freshly excreted human urine, most of the nitrogen present is in the form of urea (Kabdaşlı et al., 2006), which hydrolyses and promotes struvite precipitation. If magnesium does not limit formation of struvite, then all the P in urine is precipitated as struvite (Simha et al., 2022) and no vivianite can form.

In freshly excreted urine not subjected to urea hydrolysis or stabilization treatment, recovery of P as vivianite is likely to be high, as the pH is near-neutral and all phosphate is in solution. In this study, we investigated the feasibility of recovering P in the form of vivianite from source-separated fresh human urine for the first time. We also examined the effects of various process parameters, such as pH, temperature, composition of human urine, and type and dose of iron salts, on precipitation of vivianite. We then compared the yield and purity of vivianite precipitated from synthetic and real urine under different conditions, by combining empirical data with thermodynamic modeling of urine chemistry. This study provides a new eco-friendly and decentralized treatment strategy for P recovery from source separated urine, especially if waste sources of iron are used.

MATERIALS AND METHODS

Both synthetic and real urine were used in this study. Fresh urine was collected from fertilizer-producing urinal developed by Flanagan and Randall (2018).

Thermodynamic modeling was conducted using the Mixed Solvent Electrolyte (MSE) model in OLI Stream Analyzer (OLI System Inc., 2021. The model was used to investigate the effects of type of iron salt used, operating temperature, dose molar ratio (Fe:P), and pH on precipitation and on the yield and purity of vivianite that could be recovered from urine.

All experiments were conducted using 500 mL of urine, which was added to a jacketed crystallizer (GlassChem, Cape Town, South Africa) that was temperature-controlled by water circulation at 25 °C using a chiller (M1907-0156, PolyScience, Illinois, United States). The pH, temperature, and composition of the urine were analyzed before and after iron dosing. A pH probe (HANNA Instrument, Rhodes Island, United States) was used to determine the pH of urine before and after iron dosing, and also during the reaction. Solution pH was controlled by an automated pH controller and logger (GlassChem Instrument, Cape Town, South Africa). A magnetic stirrer (M520, LabCon, California, United States) was set to 150 rpm to keep the solution homogeneous during the experiment. Sodium hydroxide (NaOH, 1 mol L^{-1}) and hydrochloric acid (HCl, 0.5 mol L^{-1}) were used to regulate the pH, at a dosage rate of 51 µL per event. Once the urine solution was dosed with iron salt, the experiments were run for 15 min. All experiments were conducted in triplicate.

RESULTS AND DISCUSSION

Ideal operating conditions for producing vivianite

The iron dose (Fe:P molar ratio) and operating pH were found to have differing effects on the yield and purity of vivianite (Figure 1). It was observed that regardless of iron dose, operation outside the pH range 5.0 - 8.0 adversely impacted the yield of vivianite (Figure 1A). In jar-tests on different wastewaters, (Wu et al., 2019) also found that vivianite formation is generally possible in the pH range 5.0-8.5, although much lower yields have been reported at the extremes of this range (Liu et al., 2018). Reaction pH directly affects the solubility of compounds present in urine.

Iron dose had a direct effect on the amount of vivianite formed at a particular pH, and the concentration of Fe^{2+} in solution also influenced the type and concentration of co-precipitates. It was found that excess Fe^{2+} competed with Ca^{2+} and Mg^{2+} cations for P, hence preventing formation of compounds containing these cations (e.g., hydroxyapatite (HAP), bobierrite), resulting in higher yield and purity of vivianite. In the pH range 5.5-8.5, the highest vivianite yields were achieved when the iron dose was equal to or greater than a Fe:P molar ratio of 1.5. The highest purity was obtained from pH 4.0 (when the solid began to form) to pH 7.0-8.0, depending on the Fe:P dosage ratio. This agrees with findings in the literature that the optimal pH range to maximize the yield and purity of vivianite extraction from wastewater is pH 6.0-8.0 (Wu et al., 2019).

The P in urine can form precipitates of calcium, magnesium, or iron, depending on their concentration and the pH of the urine. Hydroxyapatite begins to form at pH 6.5 and increases in concentration as the pH increases. The solubility of HAP declines as the pH increases, resulting in Ca^{2+} competing with Fe^{2+} for P. The amount of HAP that formed when the urine was underdosed with iron (Figure 1B) was significantly greater than that formed when the Fe:P dosage ratio was 1.5 (Figure 1C) or when iron was overdosed (Figure 1D), in increasing order. Struvite formation was only observed when urine was underdosed with iron (Figure 1B). Excess Fe^{2+} was found to inhibit the formation of calcium and magnesium precipitates at pH values below 8.3.

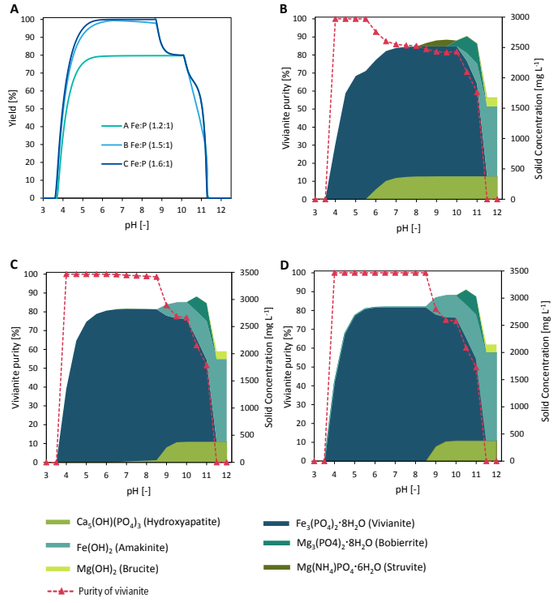

Figure 1. (A) Effect at different pH levels of iron sulfate ($FeSO_4$) dose on yield of vivianite, and effect of pH on vivianite purity and solids concentration when $FeSO_4$ was (B) underdosed [Fe:P ratio 1.2], (C) dosed in the exact molar ratio [Fe:P ratio 1.5], and (D) overdosed [Fe:P ratio 1.6].

Generally, operating in a pH range of 4.0 to 5.5 always produced the highest purity of vivianite, but at the expense of reduced yield due to the relatively higher solubility of vivianite in this pH range (Table 1). Yield of vivianite was maximized between pH 6.0 and 8.3, while the purity depended on the Fe:P ratio. Higher dosages of Fe^{2+} favored formation of vivianite over other precipitates of calcium and magnesium within the pH range 6.0 to 8.3. Within the pH range 4.0 to 8.5, when urine was overdosed with iron (Figure 1D), vivianite was produced in its purest form as the only solid. Above pH 8.5, $Fe(OH)_2$ began to precipitate, consuming Fe^{2+} and reducing the Fe^{2+} concentration in the solution, thus limiting the amount of Fe^{2+} available to form vivianite. This allowed Ca^{2+} and Mg^{2+} ions to form precipitates with the P, resulting in low yield and purity of vivianite (Figure 1D).

This work demonstrated that vivianite can be chemically precipitated from human urine through addition of iron salt, with maximum yield of 93 ± 2 % and maximum purity of 79 ± 3 % obtained at an optimal pH of 6.0.

Type of iron salt used did not affect the yield and purity of the solid fraction obtained, so choice of salt was only influenced by the amount of solid formed and the operating costs. Iron sulfate ($FeSO_4 \cdot 7H_2O$) was found to be the most economical option and is suggested as the preferred iron salt when dosing for vivianite formation from human urine.

Solution pH was found to affect the solubility of vivianite and other co-precipitates of Mg and Ca, and also affected the rate of oxidation of Fe^{2+} when exposed to oxygen in the air. A Fe:P ratio of between 1.5:1 to 2.2:1 was found to maximize yield and purity of vivianite extracted from urine. Overdosing with iron salt provided sufficient Fe^{2+} to react with all P and had a competitive effect that suppressed formation of other co-precipitates of Ca and Mg. Additionally, a small fraction of the Fe^{2+} present oxidized to Fe^{3+}, so excess Fe^{2+} was critical to maximize the yield and purity of vivianite.

Operating temperature had little to no effect on yield and purity of vivianite, and only affected the solubility of Ca and Mg precipitates at pH values above 8.0, which is outside the ideal pH range for vivianite recovery.

The solid fraction obtained from fresh urine contained about 15% organics by mass, regardless of operating pH. Washing this fraction with deionized water improved vivianite purity from 63.1% to 78.6% by mass.

Abstract

Chemical precipitation as struvite enables phosphorus (P) recovery in wastewater treatment plants (WWTPs). Struvite is generally precipitated using the anaerobic digestion supernatant profiting from its high P concentration. This study shows how the integration of a side-stream sludge fermenter (SSSF), which has been identified as a possible solution to improve the performance of enhanced biological phosphorus removal (EBPR) systems when treating low COD wastewater, opens a pathway for P recovery. The full presentation will detail how, for the first time, incorporating a SSSF into an anaerobic/anoxic/aerobic (A2O) configuration (side-stream EBPR, S2EBPR) can boost P recovery in a 150L pilot plant operated for more than one year. SSSF integration provides a novel location for P-recovery since P concentration in the SSSF can reach values higher than 100 mgP/L, while maintaining excellent P-removal. The S2EBPR performance will also be presented when the SSSF reactor outlet is connected to the anaerobic, anoxic, or aerobic reactor, with the best results obtained for the first case. Moreover, the potential P-recovery opportunities for each of the effluents of the plant under the different scenarios, evaluated using MINTEQ-based simulations, will be presented. These simulations complement the experimental pilot-plant work and will comprehensively show the real possibilities of P-recovery with a S2EBPR configuration.

Keywords

Enhanced biological phosphorus removal (EBPR); P recovery; Side-stream sludge fermenter

INTRODUCTION

Phosphorus (P) is vital to biological processes, but its over-enrichment in water bodies, known as eutrophication, can have detrimental effects on aquatic ecosystems (Suresh Kumar, et al., 2018). Moreover, the demand for P grows yearly with its different applications and depletion. Along with a large amount of P going to WWTPs, P removal and recovery from wastewater become critical, not only for eutrophication control and water reuse initiatives (Nie, Wu, et al., 2019), but also it has been estimated as a suitable solution to meet 15-20% of the global P demand (Venkiteshwaran, et al., 2018).

The anaerobic/anoxic/aerobic (A2O) process is the most accepted EBPR configuration, providing nutrient and organic matter removal, but also high phosphate levels from anaerobic liquors, which is a potential way to implement P recovery (Zhang, et al., 2022). Innovative EBPR configurations are required to move forward from P removal to P recovery. Among them, the integration of a SSSF into a conventional EBPR process (also known as S2EBPR) has recently gained a lot of interest (Onnis-Hayden, et al., 2020). S2EBPR (Figure 1) can overcome the possible bad performance caused by low COD/P ratio input, or excess nitrite returned to the anaerobic reactor (Gu, et al., 2008). There are an increasing number of full-scale applications of S2EBPR facilities worldwide (Tooker, Li, et al., 2017), which have improved P removal performance and stability (Wang, et al., 2019). The possible reasons for the PAO activity increase in S2EBPR are: (1) the biomass fermentation products are mostly VFA, a preferred electron donor for PAO (Wang, et al., 2019); (2) the extended anaerobic phase gives a competitive advantage for PAO with respect to GAO and other heterotrophic organisms (Barnard, et al., 2017) and (3) besides VFA, the SSSF effluent can contain extra readily biodegradable material which could be further fermented to VFA by PAO fermenters such as *Tetrasphaera* (Nielsen, et al., 2019).

The existing knowledge gap in understanding the underlying mechanisms in S2EBPR hampers its further application for P recovery. This work will show the novel results of nearly one-year operation of a 150L S2EBPR pilot plant under different operational conditions. The original idea for S2EBPR was to produce a VFA-rich effluent in the SSSF to improve the whole plant performance. However, PAO activity was so high that all the VFA produced in the SSSF was consumed *in-situ* leading to high levels of P-release and to a high P-concentration effluent. The SSSF P levels (>100 mgP/L, Figure 2) were much higher than those in the anaerobic reactor (>50 mgP/L), opening new scenarios for P recovery.

This observation had two implications that will be fully discussed in the full presentation.

1) The P load to the plant was increased (up to 20%) and, under certain conditions, full P-uptake could be hindered.
2) The high P concentration in the SSSF opened the possibility of recovering P from the SSSF if the purge was located there (more than 25% of the entering P could be recovered). This idea has been experimentally evaluated for the first time under different scenarios of SSSF HRT (0.5 to 2 days) and varied integrated strategies between SSSF and A2O.

We will comprehensively evaluate, for the first time, the opportunities of the S2EBPR system to go beyond P removal and move to P recovery in the full oral presentation. In addition to the one-year experimental measurements, diverse scenarios are simulated using VISUAL MINTEQ (see examples in Figure 3 & 4). For a given scenario, the possibilities of recovering P as struvite from the different effluents of the plant will be shown. Moreover, we will also examine the possibility of subjecting the purge to an extra anaerobic fermentation process to increase the P-levels and, thus, to promote struvite formation and P-recovery. For instance, Figure 3 shows the proportion of different compounds (hydroxyapatite, struvite and $Mg_3(PO_4)_2$) could be precipitated during period I when the purge was subjected to anaerobic digestion with $P\text{-}PO_4^{3-}$, $N\text{-}NH_4^+$ and Mg^{2+} content of 108, 40.3 and 22 mg/L, respectively. It suggests that Ca^{2+} presence limits the P recovery as struvite, as the first option for PO_4^{3-} precipitation is hydroxyapatite (HAP), without being affected by pH. Magnesium will combine with phosphate to produce $Mg_3(PO_4)_2$ at more alkaline pH (>10.4), competing with struvite. With the certain $P\text{-}PO_4^{3-}$, $N\text{-}NH_4^+$ and Mg^{2+} content from conventional EBPR of period I, the purpose of recovering P would be less effective especially in the means of struvite. What we could expect from S2EBPR will be a stronger possibility to recover more P as struvite according to the current data obtained. To better improve the P recovery process with additional dosages, further mathematical simulations have been done. Figure 4 shows that Mg^{2+} addition has a significant effect on P recovery as struvite and correlates closely with the pH. When providing enough NH_4^+ concentration, the struvite formation will be less dependent on the Mg^{2+} supply but on the pH. In this case, adjusting proper pH will be more economical than adding more Mg^{2+}, since its dosage could contribute up to 75% of the total operational cost in some process as reported. More details of different scenarios will be further explained in the presentation.

Abstract

This study investigated the recovery of K^+ along with NH_4^+-N and PO_4^{3-}-P from hydrolyzed urine by technical integration. The K adsorption capacities of biochar, clinoptilolite, artificial zeolite and chabazite were firstly compared. Due to the high K recovery efficiency and additional P recovery capacity, Na-chabazite was selected as the adsorbent in this study. Its kinetics and isotherm analysis indicated that the high molarity of NH_4^+-N seriously hindered the K adsorption onto Na-chabazite in synthetic hydrolyzed urine (SHU). However, this competition between NH_4^+ and K^+ got diminished when their molarity is the same, i.e. in the SHU after ammonia stripping (ASSHU). Based on this key finding, Na-chabazite adsorption was integrated with ammonia stripping and struvite precipitation under different configurations. Simultaneous ammonia stripping was inadequate to diminish the competitive effect of NH_4^+ on K^+ adsorption. Depending on the demand for fertilizer, two sequential configurations were recommended, respectively.

Keywords (maximum 6 in alphabetical order)

Hydrolysed urine; K recovery; K-struvite; Na-chabazite; stripping

INTRODUCTION

Urine has been reconsidered as a renewable resource in the past two decades (Jagtap and Boyer, 2018; Kavvada et al., 2017; Patel et al., 2020). So far, it is typical to hydrolyze urine till 90% of total nitrogen transfers from urea to NH_3/NH_4^+, and then to apply different technologies for nutrient recovery, like struvite precipitation, stripping and adsorption. Currently, most of research focus on nitrogen and phosphate recovery, while potassium (K) recovery is out of main scope despite its huge economic value. Technically, the competitiveness between NH_4^+ and K^+ exists in some nutrient recovery technologies, such as (K-)struvite precipitation. To the best of authors' knowledge, few studies have achieved the efficient recovery of these three macronutrients from hydrolyzed urine. As a result, the current study was undertaken to fill this knowledge gap by selecting a practical adsorbent and integrating it with ammonia stripping and (K-)struvite precipitation.

MATERIALS AND METHODS

K^+ adsorbent selection

In the selection of an appropriate K adsorbent, the tested materials included: 1) sewage sludge derived biochar (1.4 mm); 2) maple biochar (>2 mm); 3) Canada natural clinoptilolite (1 mm); 4) Iran natural clinoptilolite (1.4 mm); 5) Cuba natural clinoptilolite (<0.25 mm); 6) Zeolite 4A China (fine powder); 7) Zeolite 4A Sigma (fine powder); 8) Na-Chabazite (1.4×0.3 mm); 9) Ca/Na-Chabazite (<0.3 mm). These nine candidate adsorbents were added in the KCl solution (1563.92 mg/L) at a dosage of 50 g/L and then shaken at 200 rpm and 25□ for 2h. The supernatant liquid was sampled and filtered through a 0.45 µm membrane before the $[K^+]$ and $[PO_4^{3-}$-P] measurement.

Na-Chabazite (Anhydrous sodium aluminosilicate, natural herschelite-sodium chabazite) was selected as the K adsorbent used in the below sections on Kinetics & isotherm analysis and Technical integration. It was obtained from St. Cloud Mining, USA.

Kinetics and isotherm analysis

In addition to the abovementioned KCl solution, synthetic hydrolyzed urine (SHU) and after-stripping synthetic hydrolyzed urine (ASSHU) were also applied for kinetics and isotherm analysis.

In kinetics analysis, 50 g/L Na-Chabazite was added into SHU, ASSHU and KCl solution and agitated for 8 hours to ensure the equilibrium was reached. The liquid samples were extracted at appropriate time intervals using 0.45 µm syringe filters to detect the change of $[K^+]$ with time. All batch experiments were carried out in triplicate.

For isotherm analysis, SHU, ASSHU and KCl solution were diluted with deionized water to provide a varying initial concentration of K^+. 50 g/L Na-Chabazite was added into diluted batches. The experimental process is consistent with kinetics analysis. All isotherm experiments were also triplicated.

Technical integration

A series of batch experiments was performed to evaluate the nutrient recovery efficiency in different configurations, including:

I) "Stripping + Struvite precipitation + K adsorption";

II) "Stripping → Struvite precipitation + K adsorption";

III) "Stripping → Struvite precipitation → K adsorption".

RESULTS AND DISCUSSION

Selection of K^+ adsorbent

As shown in Figure 1, both natural zeolites, including clinoptilolite and chabazite, and artificial zeolites were able to adsorb K^+ from KCl solution with removal efficiency from 37.3% (Canada natural clinoptilolite) to 93.2% (artificial zeolite 4A Sigma). Sample 7 and 8, namely Sigma artificial zeolite 4A and Na-chabazite, showed an adsorption capacity significantly higher than the other zeolites. On the contrary, maple biochar and sludge biochar desorbed K^+ into KCl solution, improving $[K^+]$ by 1.8% and 4.4%, respectively.

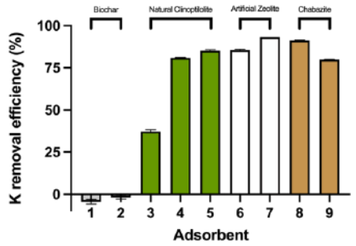

Figure 1. K removal efficiency of different adsorbents in KCl solution

After dropping Na_2HPO_4 solution into their supernatants, precipitation was observed in all batches of natural zeolites, which was not observed in the ones of biochar and artificial zeolites. It indicates that some cations on clinoptilolites and chabazites that could precipitate with PO_4^{3-} got desorbed into supernatant during K^+ adsorption.

Its SEM-EDS spectra indicated that after Na-chabazite adsorption in KCl solution, the content of Na^+, Mg^{2+} and Ca^{2+} decreased from 6.78%, 1.08% and 1.69% to 4.23%, 0.74% and 1.08%, respectively. It suggests that Na^+ was the dominant exchanging cation on Na-Chabazite, and Mg^{2+}/Ca^{2+} also exchanged with K^+, which is consistent with the previous research (Regmi and Boyer, 2021). As to artificial zeolite, in spite of its highest adsorption capacity, sodium was the only exchanging cation, which cannot contribute to PO_4^{3-} recovery (Wang, 2020).

Kinetics analysis

The adsorption of K^+ on Na-chabazite in SHU, ASSHU and KCl solution are presented in Figure 2. As seen, Na-chabazite showed a lower K adsorption capacity in SHU (13.77±0.19 mg/g), compared to the corresponding values in ASSHU and KCl, i.e. 27.11±0.17 mg/g and 27.64±0.17 mg/g, respectively. It suggested that there is a competition between NH_4^+ and K^+ in hydrolyzed urine. Ammonia stripping prior to K adsorption can reduce the competitive effect of NH_4^+ and promote Na-chabazite to adsorb more K^+ from hydrolyzed urine, 5.01 wt% (ASSHU) > 2.88% (SHU). Despite the existence of Na^+ in the effluent of stripping, i.e. 0.108 mol Na^+/L > 0.04 mol K^+/L, it did not cause an obvious decrease to the K adsorption capacity of chabazite, indicating that K^+ has a higher priority to the active sites on chabazite than Na^+.

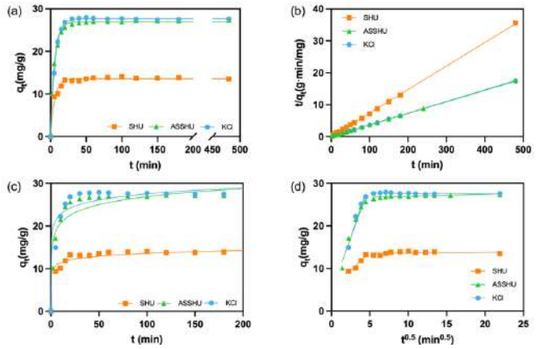

Figure 2. The K^+ adsorption on Na-chabazite in synthetic hydrolyzed urine (SHU), after-stripping synthetic hydrolyzed urine (ASSHU) and KCl solution and their simulation to Pseudo-1st-order (a), Pseudo-2nd-order (b), Elovich (c), and Weber-Morris intra-particle diffusion (d) kinetic models

The regression coefficients of the Pseudo-2nd-order kinetic model revealed to be the best in representing potassium adsorption onto chabazite (>0.99 for all sorts of solution). This could indicate various physical meanings based on different previous research (Esfandiari et al., 2020; Jing et al., 2019; Lalley et al., 2016; Li et al., 2017; Xia et al., 2016; Xiao et al., 2020; Xu et al., 2018). A two-section Weber-Morris IPD kinetics models was observed in Figure 2 (d). It could be stated that the K adsorption on chabazite started with an instant external diffusion followed by intra-particle diffusion, which was the rate-determining step until the equilibrium (Baek et al., 2018; Wu et al., 2009; Zhu et al., 2016).

Isotherm analysis

Figure 3 shows the adsorption behaviour of K^+ by Na-chabazite in SHU (a), ASSHU (b) and KCl (c), when it reached the equilibrium at 25ºC. As the concentration of NH_4^+-N increased from 0 mg/L in KCl solution to 522 mg/L in ASSHU and 6720.5 mg/L in SHU, the maximum quantity adsorbed decreased accordingly, as illustrated in Figure 3(d). The experimental data were well fitted to Langmuir isotherm model, with a coefficient of 0.98 (SHU), 0.93 (ASSHU) and 0.96 (KCl). The value of its parameter, q_m (mg/g), is an indicator of maximum adsorption capacity, which decreased from 75.65 mg/g in KCl to 40.37 mg/g in ASSHU and 11.31 mg/g in SHU. It suggested that the high concentration of NH_4^+-N could restrain the K adsorption capacity of Na-Chabazite in SHU. When it decreased to the same molarity as K^+ in ASSHU by stripping, the adsorption capacity of Na-Chabazite for K^+ got increased.

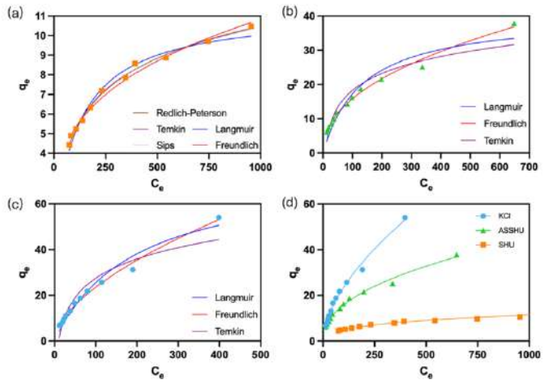

Figure 3. K adsorption onto Na-chabazite at equilibrium in SHU (a), ASSHU (b) and KCl (c) and summary for experimental data and the best-fitting isotherm models (d)

Despite the good fitness to Langmuir isotherm model, those empirical models, i.e. Freundlich model and Langmuir-Freundlich hybrid models, showed a slightly higher correlation coefficient, which is different from the previous research (Leyva-Ramos et al., 2010; Seliman and Borai, 2011). As such, K adsorption on Na-chabazite is supposed to be a heterogeneous process controlled by multiple mechanisms, consistent with the results of kinetics analysis concluded in section 3.2 (Xu et al., 2018).

Comparison of the different configurations of technical integration

To diminish the competitive impact of NH_4^+ on K^+ adsorption and recover all three macronutrients, three different configurations were investigated, and their comparison was shown in Figure 4. As shown, 23.93±2.66% K^+ was removed by simultaneous configuration, significantly lower than the sequential configurations. It indicated that simultaneous stripping has a limited effect on diminishing the competition between NH_4^+ and K^+ for exchanging with Na^+ on Na-Chabazite. As to the reasons behind this observation, the current study infers that despite NH_4^+-N removal through stripping and struvite precipitation, its molarity was still higher than that of K^+ especially at the beginning of the process, hence the competitive effect of NH_4^+-N on K^+ adsorption was not eliminated.

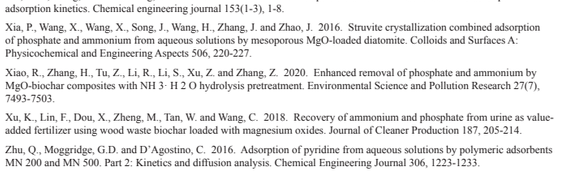

Figure 4. The comparison on nutrient removal efficiency among the different configurations of stripping, K adsorption and struvite precipitation

Both sequential configurations achieved similar recovery efficiency. If pure (K-)struvite is a preferrable end-product, "Stripping → K adsorption → Struvite precipitation" is recommended. In its second step, along with 78.63% K^+, 21.84% PO_4^{3-}-P got recovered in this step even without any addition of Mg source. The ability of both K and P recovery makes Na-chabazite more practical than pristine and surface-modified biochar (Liu et al., 2020).

Abstract

In this contribution the development of a precipitation model for struvite precipitation is explained. The main objective of this work is to implement this technology in a real WWTP located in Tudela, Spain. For that reason, a simulation tool is developed in order to help in the definition of the operational strategy. The model replicates how Mg and Ca are dissolved differently depending on the water composition and how it affects the struvite precipitation. The following steps will consist of validating the precipitation model using experiments in several fluidized bed reactors.

Keywords

Low-grade magnesium oxide; Precipitation model; Struvite

INTRODUCTION

Struvite is a salt formed by equimolar quantities of magnesium (Mg), nitrogen (N) and phosphorus (P) which can be used as a slow release fertilizer. Waterways are rich in N and P, but Mg needs to be added externally. Usually, a commercial reactant ($MgCl_2 \cdot 6H_2O$) is used as Mg source, increasing the operational costs of the process. For this reason, magnesium oxide industrial by-products, low-grade magnesium oxide (LG-MgO), obtained from the calcination process of natural magnesite have been suggested as an optimum alternative (Romero-Güiza et al., 2015).

Many factors affect the overall precipitation process, such as reactants concentration, pH or hydrodynamics (Le Corre et al., 2009). Some authors have developed mathematical models where thermodynamic equilibrium or kinetics are studied (Elduayen-Echave et al., 2019) , but to the authors' best knowledge, implications of using LG-MgO have not been modelled.

In this contribution, a new model is developed and calibrated with different experiments. This model includes the effects of using LG-MgO. This precipitation model is a promising tool that may help in the definition of the operation strategy of the process.

MATERIALS AND METHODS

Precipitation model

This model is developed in WEST-DHI simulation platform. The LG-MgO used as a Mg source is a heterogeneous by-product consisting of different compounds, which release Mg^{2+}, Ca^{2+}, CO_3^{2-} and OH^- to the medium. In the model, nine different solid compounds are considered: LG-MgO, struvite, amorphous calcium phosphate (ACP), $Mg(OH)_2$, $MgCO_3$, $Ca(OH)_2$, $CaMg(CO_3)_2$, $CaCO_3$, struvite coating over LG-MgO and ACP coating over LG-MgO. Table 1 includes some of the different transformations considered. Moreover, in the liquid phase: NH_4^+, NH_3, PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^-$, H_3PO_4, $MgPO_4^+$, $MgHPO_4$, $MgH_2PO_4^+$, $MgOH^+$, Mg^{2+}, $CaPO_4^-$, $CaHPO_4$, $CaH_2PO_4^+$, $CaOH^+$ and Ca^{2+} are considered.

The thermodynamic equilibrium is calculated based on the approach by (Ohlinger, Young and Schroeder, 1998). The thermodynamics equations used in the precipitation model can be found in Table 1, whereas the transformations considered in the model are included in Table 2. Only one dissolution process is included in the table. The stoichiometry of the process is defined by a Gujer matrix, see Table 3, as it is often done in wastewater treatment modelling (Lizarralde et al., 2015). The model incorporates saturation index (SI) calculations for each solid compound in each time step, which are the driving force of the precipitation and kinetics, including nucleation and growth.

Experimentation

In order to validate the model, different experimental set-ups have been defined. The main objective of these configurations is to gradually scale up the technology, with the final purpose of applying it in a real plant. Firstly, batch experiments are done, followed by experiments in a pilot fluidized bed reactor of 5 L, a semi-industrial fluidized bed reactor of 80 L and finally, in an industrial reactor located in the WWTP of Tudela, Spain. For an initial validation two different 0.5 L batch experiments are considered. In the first one, the solubility of the LG-MgO is studied for different molar ratios in deionised water. In the second one, struvite precipitation is achieved by adding different concentrations of LG-MgO to a real effluent from a wastewater treatment plant.

RESULTS AND DISCUSSION

From both cases of experiments performed, one of each type has been selected to demonstrate the utility of the model. By now, the model has been heuristically calibrated for each experiment. In the future a more rigorous calibration should be performed. For this purpose, the use of Bayesian Inference techniques is being considered.

In the LG-MgO dissolution experiment considered (209.6 mg/L of LG-MgO, Mg:P molar ratio of 1:1), the pH increased from 6.5 until 10.5 in 30 minutes. After this fast increase, its value remains almost constant during the whole experiment. This pH increase is related to the release of OH^- to the medium. Once pH stabilises, Ca reaches a plateau, no more Ca is released to the deionised water, whereas Mg concentration continues increasing, but at a lower rate. This difference is possibly because of the saturation concentration of Ca is reached, whereas the Mg saturation concentrations is not reached yet. These phenomena are well reproduced by the model, as displayed in Figure 1.

Figure 1. LG-MgO release of Mg and Ca in deionised water.

The precipitation experiments showed a different behaviour. The initial pH is almost the optimum for struvite precipitation (8.5), avoiding the previous effect of a fast release of ions to the medium. For 209.6 mg/L of LG-MgO, the consumption of both species is compensated by the release of Ca and Mg from the LG-MgO. P and N are consumed in the same molar proportion, leading to struvite precipitation. In general, the model is able to predict the release of Mg and Ca ions from the solid and to predict the precipitation of struvite and ACP, Figure 2.

Figure 2. Species behaviour in struvite precipitation using real effluent from WWTP.

CONCLUSIONS AND FUTURE PERSPECTIVES

The simulation results show that the developed precipitation model is able to reproduce correctly the data obtained in the laboratory experiments. Verifying that a useful tool to know if struvite or other compounds will precipitate in real WWTP, with an alternative Mg source, has been developed. However, a standard calibration method should be applied. For that purpose, different experiments are considered in the scaling up process of the technology. The next step is to validate the model using the results obtained from the use of a pilot fluidized bed reactor. Then, this precipitation model could be used to optimize the operation of the process directly and even feed other types of models (CFD or compartmental models) for the design of new reactors.

Abstract

The BIOFERES project proposes a new process for advanced nutrient recovery and sewage sludge transformation into high added value products. This new biorefinery concept will bring the wastewater management model closer to the principles of sustainability and circular economy. The project combines the following technologies: (1) Two Phase Anaerobic digestion (TPAD) with co-substrates dosage to increase biogas production and nutrients content in digestate, (2) Production of liquid biofertilizers through advanced nutrient recovery processes using double-stage membrane technologies (ultrafiltration and membrane contactors) and (3) Biostimulant production from the solid fraction of the digested sludge through a solid-state fermentation (SSF) process with bioaugmentation using specific bacterial strains. Results have shown that it is possible to maximize the nutrient content in sludge digestate, reaching values of 5-8 times above the initial ones in the case of P and K, and recovering more than 80% of the nitrogen contained in the liquid fraction.

Keywords

Anaerobic digestion; Biofertilizers; Bioestimulants; Membranes; Sludge.

INTRODUCTION

Traditionally, the sludge from the Wastewater Treatment Plants (WWTP) has been considered the residue produced from the water purification process, so efforts have been mainly focused the reduction of its volume with the objective of reducing management costs from the WWTP to its final disposal.

BIOFERES project has developed and validated a new sewage sludge treatment and valorisation process (Figure 1) that combines different technologies to obtain agronomic products (biofertilizers and bioestimulants), reducing the consumption of raw materials and the carbon footprint, defining a new wastewater management model based on the principles of sustainability and circular economy. The project is led by the company FACSA, together with BIOVIC and INDEREN, and with the participation of the AINIA technology centre and ISIRYM-UPV institute.

MATERIALS AND METHODS

The new process has been studied at lab scale and is currently being validated at pilot scale (Figure 2) in Alcoi WWTP (Alacant, Spain).

Anaerobic co-digestion in double temperature stage and double biological phase (TPAD)

TPAD combines two consecutive reactors for the performance of the hydrolytic-acidogenic and methanogenic steps, respectively, of anaerobic digestion. This allows not only sewage sludge stabilization but also biogas production maximization and nutrients enrichment (including N, P and K) thanks to different organic agrifood wastes used as co-substrates attending to different feeding strategies or diets. Biomethanation potential has been studied at lab scale using BMP tests and TPAD performance and stability has been evaluated using two pilot digesters of 1 and 2,7 m3 that has been operated for several months at thermophilic (55ºC) and mesophilic (35ºC) conditions, respectively, with an organic loading rate ranging from 14,2 to 24,6 gCOD/L·day (Figure 3). Final digestate has been dewatered using an endless screw so solid fraction is taken to SSF and liquid fraction with high nutrients content is derived to the membranes treatment.

Production of liquid biofertilizers through advanced nutrient recovery processes using double-stage membrane technologies

The liquid fraction from digestate dewatering is characterized by containing most of the dissolved nutrient's (N, P and K) and humic and fulvic acids. This fraction is treated using ultrafiltration (UF) to remove solids and pathogens and finally introduced into a membrane contactors stage for N recovery as $(NH_4)_2SO_4$ and remaining a P and K rich liquid biofertilizer. Both UF and membranes contactors has been studied in different lab experiments where different membranes materials (PVDF, PES, PTFE and ePTFE) and operation conditions (TMP (1, 1.5 and 2 bars), pH, time, and acid concentration) has been tested, and finally validated in a pilot prototype treating 110 L/d.

Bio-stimulant production from the solid fraction of the sludge through a solid-state fermentation process and bioaugmentation with specific bacterial strains.

Most of the stabilized organic matter and part of the nutrients, are concentrated in the solid fraction after digestate dewatering. This solid fraction is treated using a SSF process bioaugmented with a specific bacterial strain with biostimulant properties, such as improving nutrients bioavailability and assimilation by crops, so a sludge-based biostimulant is produced. This stage has been studied first using a small solid-state fermenter for sludge-strain compatibility tests and operational conditions definition and is currently being validated in a pilot fermenter of 60L of reacting volume.

RESULTS

Results from BMP of 5 different co-substrates (Co-S) used in the study are summarized in Table 1, where high biogas production potential up to 967±123 NL CH4/kg SV can be observed. During TPAD pilot operation, correct stabilization of both acidogenic and methanogenic reactors have been achieved, reaching more than 11 g/L of Volatile Fatty Acid (VFA) and biogas production with a methane concentration of more than 69% (Figure 4). Moreover, a nutrients concentration increase in P and K of 5-8 times above the initial value has been observed, while N remains constant.

Regarding liquid fraction treatment, best results were obtained with a previous prefiltration (60 microns) and a UF stage with PVDF membrane of 0.03 micron pore size operated at 1 bar. With this membrane, organic matter (COD) and solids removal around 60% and 95%, respectively, has been achieved, but rejection of N, K and P increases above 30%, which could indicate struvite precipitation (Table 2). Membrane contactor selected configuration and conditions were submerged expanded Teflon tubes where 0.1M sulfuric acid was circulated inside the tubes (immersed in the centrifuge drain) and liquid influent pH is adjusted up to 9-10. More than 80% nitrogen recovery was obtained from the liquid fraction (Figure 5).

After the biostimulant strain selection, continuous tests were started to analyse bacterial growth over real dewatered digestate from Alcoi WWTP. After several tests, it was observed that the best strategy was to operate the reactor at 35-37ºC, 16-18%ST concentration, HRT of 5 days and re-inoculate the reactor every 15 days (3 HRT), which allows maintain a strain concentration in the system of the order of 10^6 CFU/ml (Figure 6).

DISCUSSION

With the results obtained so far at lab and pilot scale in BIOFERES project, it has been observed that it is possible to valorise sewage sludge to transform them into biofertilizer and bio-stimulant products that have agricultural applications.

Abstract

Microbial electrolysis cells (MECs) enable ammonium recovery from wastewater with low energy requirements. Electric current drives ammonium ion transfer through a cation exchange membrane (CEM) in these systems. Nitrogen can be energy efficiently recovered from the concentrated nitrogen-rich stream by using a hydrophobic membrane. Novel tailor-made cells (0.8 L) were designed to maximize ammonium recovery by reducing dead volumes and improving mass transfer limitations. This work aims to determine the inhibitory effects of ammonium in the range of 0.5 to 2.5 g N-NH_4^+ /L on the performance of current generation and active ammonia recovery from synthetic wastewater. When the ammonium concentration in the feed was increased from 0.5 to 1.5 g N-NH_4^+ /L maximum current density increased to 3.9 A/m^2, but further increase in the concentration had a remarkable effect on the biofilm activity, decreasing the current density to 0.5 A/m^2 at 2.5 g N-NH_4^+/L. The maximum ammonium removal and recovery efficiencies were 67 % and 33 % at 0.5 g N-NH_4^+ /L, respectively. This is the first study of high-purity ammonium recovery using a hydrophobic membrane in a continuously fed MEC with different cathode materials. This in-situ bioelectrochemical ammonium recovery is benchmarked with other current ammonium recovery techniques as leading-edge technology in the current state of the art.

Hydrophobic membrane; Microbial electrolysis cells; Nitrogen recovery; Nickel foam; Stainless steel.

INTRODUCTION

In the last decade, much focus has been shifted to channelling energy and nutrients contained in waste streams and reducing the burden and costs of wastewater treatment (Puyol et al. 2017)changing the focus from residues treatment, such as wastewater treatment, toward resource recovery. Biotechnological processes offer an economic and versatile way to concentrate and transform resources from waste/wastewater into valuable products, which is a prerequisite for the technological development of a cradle-to-cradle biobased economy. This review identifies emerging technologies that enable resource recovery across the wastewater treatment cycle. As such, bioenergy in the form of biohydrogen (by photo and dark fermentation processes. Ammonium nitrogen in wastewater has emerged as an appealing compound from the resource recovery point of view. Industrially, ammonia is produced by nitrogen fixation (Haber-Bosch process) (Nancharaiah, et al. 2016) nitrogen removal is practiced through energy intensive biological nitrification and denitrification entailing a major cost in wastewater treatment. Recent innovations in nitrogen removal aim at reducing energy requirements and recovering ammonium nitrogen. Bioelectrochemical systems (BES, which is highly energy intensive and dependent on fossil fuels (Wang et al. 2021). In a conventional wastewater treatment plant, ammonium and nitrate are transformed into nitrogen gas (M. Rodríguez Arredondo et al. 2015), and therefore, they are removed to reduce the risk of eutrophication of receiving water bodies (Georg et al. 2021) but not recovered as valuable products. In contrast, a vast amount of nitrogen-based fertilizers are produced for agriculture (Erisman et al. 2008). Ammonia recovery from wastewater using a bioelectrochemical system (BES) holds promise as a suitable alternative in the circular economy framework.

At the anode of BESs, anode-respiring bacteria oxidize organic matter to carbon dioxide and protons and use a solid anode as a terminal electron acceptor (Kondaveeti et al. 2014). The electrons then flow from the anode to the cathode through an external circuit generating an electric current. At the cathode, the electrons combine with an electron acceptor to form the target product. Ammonium ions can diffuse from the anode chamber into the cathode chamber through a cation exchange membrane (CEM) via diffusion or current-driven migration (Yang and Qin 2021). Diffusion of ammonium ions is induced by the concentration gradient across the CEM, while the aim to achieve electroneutrality after electrons flow from the anode to the cathode also drives the migration of ammonium ions. As a result, ammonium ions are concentrated in the cathode chamber. The ammonium ions have an acid-dissociation constant (pKa value) of 9.25 (at 25ºC) (Wu and Modin 2013). Hence, once the catholyte pH exceeds 9.25 due to e.g., electrochemical hydrogen production, ammonium ions dissociate predominantly as free volatile ammonia (NH_3), which can then be recovered. Dissolved ammonia gas in the catholyte can traverse the pores of the hydrophobic membrane and react with the acidic solution placed on the other side (Kuntke et al. 2016)\n \n The application of a gas-permeable hydrophobic tubular membrane in bio-electrochemical systems enables efficient recovery of ammonia (NH\n 3\n . A high concentration of ammonium in the wastewater can affect the performance of BES because it can inhibit the activity of anode-respiring bacteria. This study assesses the inhibition effects of ammonium on current generation and ammonium recovery in continuously operated microbial electrolysis cells (MECs).We also calculated ammonium and organic removal efficiencies and ammonium recovery rates to compare the performance of different conditions and cells quantitively.

MATERIALS AND METHODS

Each of the two flat plate MECs (0.8 L) used had one anode chamber (400 mL), one cathode chamber (200 mL) separated from the anode chamber by CEM, and one recovery chamber (200 mL) separated from the cathode chamber by a hydrophobic membrane (Figure 1). Anolyte was continuously pumped at 0.5 mL/min through the anode chamber using a peristaltic pump. Two carbon brushes (75 mm length x 50 mm diameter, 7.2 µm fiber diameter, Millrose Co., USA) inoculated with anaerobic sludge were used as the anode. Tyvek was used as hydrophobic membrane (100 cm^2). Two types of cathodes were tested:nickel foam (NF) (purity >99.99%, 600/500 mm width, porosity ≥ 95%; Recemat Ni4753.016) and stainless steel (SS) mesh (304, Feval filtros, Spain). The anolyte was a synthetic medium that contained 111 mg/L CH_3COONa, 104 mg/L Na_2HPO_4, 52 mg/L C_2H_5COONa, 274 mg/L $KHCO_3$, 500 mg/L NH_4HCO_3 152 mg/L $CaCO_3$ and 231 mg/L $MgCl_2 \cdot 6H_2O$. The tested ammonium concentration in the influent ranged from 0.5 to 2.5 g N-NH_4^+ g/L. The catholyte solution was sodium chloride 4 g/L, and the recovery solution was 1% sulphuric acid.

RESULTS AND DISCUSSION

MECs were operated continuously to evaluate the microbial adaptation to high ammonium concentration in the feed. Figure 2 presents the current density obtained at each ammonium concentration for different cathode materials. The current density indicates the amount of electric current flowing through a unit cross-sectional area. Since the area remains the same, the current density reflects the biofilm's ability to generate electrons and, thus, enable ammonium molecules to transfer from the anode chamber to the cathode chamber. To maintain electroneutrality, one cation is transported from the anode chamber to the cathode chamber for each electron passing through the external circuit (Liu et al. 2016)while the generated electrical current through the system tends to acidify (or basify. Therefore, current density correlates with the anodic ammonium removal, indicating the maximum migration rate.

Increasing the ammonium concentration in the influent from 0.5 to 1 g N-NH_4^+ /L led to a slight increase in current density. The maximum current density increased from 2.8 to 3.4 A/m^2 and 3.2 to 3.4 A/m^2 for MEC with NF and SS, respectively. A further increase to 1.5 g N-NH_4^+ /L led to a current density plateau. The highest current density obtained was 3.9 A/m^2 at 2 g N-NH_4^+ /L for the SS cathode. Upon increasing ammonium concentration in the influent to 2.5 g N-NH_4^+ /L, the current density significantly decreased to 0.5 A/m^2. The feed's highest ammonium removal and recovery efficiencies were 66% and 33% obtained with 0.5 g N-NH_4^+ /L, respectively. The maximum ammonium flux from the anode to the cathode was 0.65 g N-NH_4^+ /L/d which led to a maximum recovery flux of 0.41 g N-NH_4^+/L/d (normalized to reactor volume) for 1.5 g N-NH_4^+ /L. The highest final ammonium concentration in the recovery solution obtained was 3.9 g/L.

Recently it was proposed that the ratio between the current density and ammonium loading rates, i.e. the ammonium load ratio (L_n), is vital in determining ammonium recovery and energy input (Rodríguez Arredondo et al. 2017). A L_n below 1 indicates that the current density was insufficient to remove all ammonium from the feed and a L_n above 1 means an excess current concerning the ammonium loading rate. In this study, the L_n was 1.1 for 0.5 g N-NH_4^+ g/L in the feed and decreased to 0.5 for 1.5 g N-NH_4^+ g/L. The decrease in L_n with higher concentrations suggests that the current density was the factor limiting the ammonium recovery.

From a practical point of view of MECs for ammonia recovery, these experimental data demonstrate that wastewaters with high ammonium concentrations can be applied to a continuously fed MEC. The threshold recommendation for maximum ammonium in the wastewater should be around 2 g N-NH_4^+/L or less. The whole presentation will detail the operation of two MECs under different ammonium concentrations in the feed. Electrochemical techniques showed that the decline in the anode performance induced the reduction of the current generation.

Abstract

The growing interest towards wastewater (WW) reuse as alternative irrigation source is raised by the worldwide concern on water shortages and enhanced by the new European Directive on water reuse minimum requirements. In this perspective, water utilities and decision makers would benefit from a methodology to evaluate and encourage safe and efficient agricultural WW reuse practices. In this work, we propose a novel approach to identify criteria for assessing and prioritizing WW treatment plants (WWTPs) suitability for WW reuse practices implementation. The developed methodology, coupling WWTPs' characteristics (i.e., flowrate and effluent quality) and features of the local territory (i.e., cultivated crops and climate), is able to quantify the economic savings, in terms of water and nutrients, and avoided environmental impacts, that could be fulfilled from WW reuse, and which WWTPs and territories to prioritize in its implementation.

Keywords (maximum 6 in alphabetical order)

Economic savings; Fertigation; Greenhouse Gas emission; Holistic framework; Nutrients; Sustainability; Wastewater reuse.

INTRODUCTION

The scarcity of fresh water is one of the major challenges faced by humankind today. In this context, agriculture is the sector with the major water demand, accounting for about 70% of global freshwater withdrawals. Water for crops irrigation is typically extracted from natural sources, reducing the freshwater availability and exposing the agricultural sector to a great impact from water shortages (López-Serrano et al., 2020). On the other hand, the reuse of reclaimed municipal wastewater (WW) provides a reliable water source, with continuous and stable production throughout the year. In addition, it is a source of water and nutrients, as nitrogen (N) and phosphorus (P), also contributing to the reduction of green-house gases (GHGs) emissions compared to traditional management approaches, avoiding WW overtreatment and mineral fertilisers addition.

More stringent regulations are continuously proposed on WW quality aimed at direct reuse for irrigation in agriculture, as for the European Union, where the new Directive establishes limits and minimum requirements for reclaimed WW reuse in agriculture (EU Commission, 2020)and in particular Article 192(1. In this perspective, water utilities, often managing hundreds of wastewater treatment plants (WWTPs) of extremely different sizes and characteristics, would benefit from a prioritization methodology, currently missing, that might help them in selecting the most appropriate WWTPs for reuse implementation. This approach should couple both WWTP (i.e., flowrate and effluent quality) and territory (i.e., crops and climate) characteristics. Mainardis et al. (2022) therefore alternatives to use of conventional sources need to be investigated. This paper critically reviews the application of treated wastewater for agricultural fertigation (i.e., water and nutrient recovery proposed a methodological approach to preliminarily assess the techno-economic sustainability and feasibility of WW reuse that was applied to a single case-study.

In this work, the model proposed by Mainardis et al. (2022)therefore alternatives to use of conventional sources need to be investigated. This paper critically reviews the application of treated wastewater for agricultural fertigation (i.e., water and nutrient recovery was upgraded in an holistic framework, including water and nutrients mass balance, economic and environmental impacts assessment. This framework was applied to several Italian WWTPs to: (i) quantify the amount of water and nutrients needed by the crops that could be fulfilled by WW; (ii) evaluate fertigation sustainability over traditional practices; (iii) rank WWTPs and local territory characteristics improving WW reuse feasibility; (iv) determine prioritization criteria for WW reuse practices implementation.

MATERIALS AND METHODS

Irrigation water volumes to be delivered to satisfy crops requirements were estimated based on monthly water balances during the irrigation season (May to September). In the adopted approach, specific crops' evapotranspiration (ET, L s^{-1} ha^{-1}) was considered equal to their water requirement (Mainardis et al., 2022) therefore alternatives to use of conventional sources need to be investigated. This paper critically reviews the application of treated wastewater for agricultural fertigation (i.e., water and nutrient recovery. Thus, the net irrigation requirement (I, L s^{-1} ha^{-1}), which is the necessary fertigation water volume to be provided to the crops, was obtained as reported in Eq. (1):

$$I=(ET-R)/E \quad (1)$$

where R (L s^{-1} ha^{-1}) is the effective rainfall, determined from metereological data through Turc's equation, while E is the overall irrigation efficiency, calculated multiplying (i) irrigation system efficiency, (ii) water distribution efficiency from source to fields, and (iii) application efficiency.

Regarding nutrients, N and P were considered being the ones reported by current reuse regulations. Mass balances were drawn comparing monthly crop nutrient requirements (kg $month^{-1}$ ha^{-1}) and nutrients concentrations of the applied WW volumes, accounting for fertilizer use efficiency. When fertigation-supplied nutrients do not meet crop requirements, mineral fertilizers should be added; in the opposite case, fertigation limitation occurs, resulting in a reduction in the water applied, which should be supplemented with other sources.

Once the amounts of water and nutrients deliverable from the WWTP were calculated, two different outputs were obtained. Firstly, an economic evaluation was performed to quantify water and mineral fertilisers savings. Agricultural water supply cost was considered for water saving estimation. The cost of mineral fertilizers (ammonium nitrate for N, triple super phosphate for P), with their use efficiency were considered. Secondly, the GHGs emission savings due to the reduction of applied mineral fertilisers has been estimated by applying a GHG conversion factor (5.79 kg_{CO2EQ} kg_N^{-1} for N and 0.63 kg_{CO2EQ} kg_P^{-1} for P) (Jiménez-Benítez et al., 2020)by reusing the water and nutrients embedded in the effluent in agriculture (fertigation).

The developed model was applied to 95 municipal WWTPs in two major areas in northern Italy, with a served population equivalent (PE) higher than 2,000 inhab for each WWTP, and close to suitable crop fields. These WWTPs were grouped in different clusters with similar characteristics based on three clusterization parameters: (i) WWTPs size, divided into small (S, PE=2,000-10,000 inhab), medium (M, PE=10,000-70,000 inhab) and large (L, PE>70,000 inhab) WWTPs, (ii) WWTPs nutrient removal, divided into absence of nutrients removal (NO), only N removal (N) and combined N and P removal (NP), and (iii) main crops cultivated nearby the WWTP, divided into seed crops (SEED, maize or soybean) and fruits and vegetables crops (F/V, carrot or vines). The latter parameter was considered due to the significant difference in terms of water required from these two types of crops. One or more representative WWTPs were selected for each cluster, based on the availability and reliability of effluent quality data. For the selected WWTPs, data about median monthly flowrate and N and P concentrations in the effluent, together with the monthly cumulated rainfall and the type of crops nearby the WWTP, were collected.

RESULTS AND DISCUSSION

Ten clusters were determined based on the adopted clusterization parameters, from which the cluster's ID code was derived. Table 1 reports the clusters' characteristics.

For S-WWTPs and M-WWTPs, the evaluation of a single WWTP was sufficient to give a realistic representation of the whole cluster, since the collected data did not show significant differences. Instead, for L-WWTPs' clusters, more than one WWTPs were considered for model application, given the significant variability of the treatment trains; thus, 14 WWTPs were considered in total in the following analysis.

Table 1. Summary of clusters' characteristics: number of available and selected WWTPs, WWTPs flowrate, N and P concentrations, indicated as average and range in brackets.

Cluster ID	#available WWTPs	#considered WWTPs	Flowrate (m^3 day^{-1})	N concentration (mg L^{-1})	P concentration (mg L^{-1})
S-NO-SEED	5	1	1,454 (652 – 9,005)	18.24 (6.8 – 29.2)	1.49 (0.4 – 3.1)
S-NO-F/V	2	1	243 (212 – 249)	11.25 (3.3 – 22.6)	1.57 (0.4 – 2.5)
S-N-SEED	39	1	2,098 (1,337 – 4,144)	9.29 (4.9 – 23.2)	0.68 (0.3 – 1.7)
S-N-F/V	24	1	675 (249 – 1,663)	12.47 (6.1 – 26.2)	2.70 (0.7 – 4.3)
S-NP-SEED	4	1	397 (344 – 442)	6.67 (2.0 – 13.6)	1.19 (0.2 – 2.4)
S-NP-F/V	5	1	323 (137 – 342)	5.97 (1.5 – 17.8)	1.33 (0.1 – 2.7)
M-NP-SEED	6	1	4,176 (1,800 – 11,026)	4.51 (0.3 – 12.9)	0.31 (0.1 – 1.3)
M-NP-F/V	4	1	7,352 (3,647 – 14,465)	9.44 (2.4 – 20.0)	0.68 (0.3 – 2.7)
L-NP-SEED	4	4	19,519 (8,097 – 38,439)	7.40 (1.5 – 16.1)	0.62 (0.1 – 3.3)
L-NP-F/V	2	2	102,229 (7,879 – 176,662)	6.71 (3.4 – 11.0)	0.70 (0.3 – 1.6)

Based on the developed methodology, three outputs were estimated to assess the suitability of the implementation of WW reuse practices: total (i) water and (ii) fertiliser cost savings, and (iii) avoided GHGs emission on the considered period (April to September). For every WWTP, the model was run twice for both types of crops: in SEED for maize and soybean, in F/V for carrots and vines, since they are both present in the WWTPs proximity. As for water, fertilisers and GHG emission savings as a function of different clusters' characteristics (Figure 1), it is evident that different categories of the clusterization parameters affect the distribution of the single clusters' output.

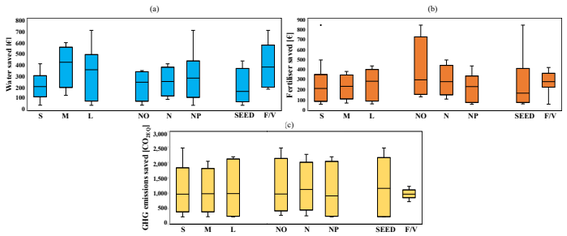

Figure 1. Estimated savings of (a) water, (b) fertilisers and (c) GHG emission differentiated per clusterization parameters.

Regarding the WWTP size, being the size directly proportional to the quantity of treated flowrate (and, thus, of the WW available for reuse), the most affected output is the water cost saving, being on average half for S-WWTPs compared to M- and L-WWTPs. However, conversely to what was expected, L-WWTPs and M-WWTPs water cost savings are not significantly different, due to the limitation in crops nutrients' requirement, which caps the amount of WW deliverable to the crops. For the WWTP's nutrient removal treatment, passing from NO-WWTPs to NP-WWTPs, a slight reduction of the median fertiliser cost savings is observed, and only NO-WWTPs show fertilizers saving over 500 €. This confirms that a lower extent of nutrient removal implies a lower supply of mineral fertilisers to the crops and, thus, a higher saving in fertilisers' cost. Finally, for all the considered outputs, the crop type emerged as the most relevant clusterization parameter. In fact, for each output, the results' distributions vary significantly between SEED-WWTPs and F/V-WWTPs, both in terms of median values and variabilities, meaning that the crops surrounding the WWTP are a fundamental characteristic to consider when a WW reuse practice is evaluated.

The economic savings (given by both water and fertilizers savings) and avoided GHG emissions were plotted in a Pareto chart in Figure 2, for all case studies (14 WWTPs for 2 types of crops), differentiated by cluster. Three distinct groups of WWTPs are evident for GHGs emission savings, which are located on three different horizontal levels. These groups vary only for the specific type of crops, in particular, within SEED-WWTPs, maize-based crops give the best emission savings (mean value of 2,200 kg_{CO2EQ}), but, on the other side, soybean-based crops give the worst ones (mean value of 230 kg_{CO2EQ}). This confirmed the high variability associated with SEED-WWTPs' boxplots in Figure 1b,c. Instead, for F/V-WWTPs, both carrot- and vines-based crops lay on the same horizontal line (mean value of 1,000 kg_{CO2EQ}). Once again, it is confirmed the oustanding relevance of the specific type of crop that is present close to the WWTP in determining WW reuse sustainability. On the other hand, the influence of WWTPs characteristic on economic savings depends on the crop type.

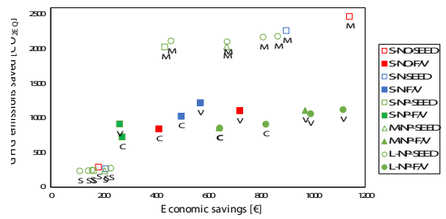

Figure 2. Pareto diagram of all the estimated outputs. The letters refer to the specific crop analysed: M=maize, S=soybean, C=carrots and V=vines.

To conclude, this work highlighted the potential of the developed methodology to rank the characteristics of WWTPs' and their nearby territory for determining useful criteria for the prioritization of WW reuse practices implementation. Further research is needed to validate these results considering other WWTPs, in order to obtain an adaptive methodology that might be applied to a few WWTPs aiming at extending the results to a broader sample of WWTPs.

Abstract

Synthetic greywater with 24 organic micropollutants (OMP) was extracted with forward osmosis (FO) technology, using concentrated fertilizers as draw solution (KNO_3 and $(NH_4)_2HPO_4$). Membrane rejection of OMP was high in all cases (>75%, avg. 91%), with negatively charged compounds at the highest rejection rates. Reverse salt fluxes were moderate for monovalent ions and very low for phosphate. The diluted draw solution, which reached similar nutrient concentrations as commercial fertilizing solutions, was applied in hydroponic systems with lettuces. After four weeks of experiment, lettuces grew less than the control plants, presumably due to lack of some nutrients and the presence of sodium coming from the GW in the draw solution but had a healthy appearance. The positive results obtained in these experiments show the potential of FO technology to treat GW and its further application in hydroponic systems, reducing the demand of freshwater for irrigation.

Keywords: forward osmosis, hydroponics systems, lettuce, organic micropollutants, osmotic dilution, water reuse

INTRODUCTION

Forward osmosis (FO) is a membrane technology in which a highly saline solution (draw solution: DS) is diluted by a less saline solution (feed solution: FS), due to their differences in osmotic pressure, which is the driving force of the process (van der Bruggen & Luis, 2015). FO dense membranes have shown good performance regarding pollutant rejection and have low fouling tendency (Achilli et al., 2009), becoming good candidates for the treatment and reuse of wastewater streams. A good example of FO application is fertilizer drawn forward osmosis (FDFO), which uses concentrated fertilizer solutions as draw, and the resulting diluted solution can be applied for irrigation without the need of DS recovery (Chekli et al., 2017; Majeed et al., 2015). An excellent candidate for FS is greywater (GW), as it represents up to 75% of the domestic wastewater and has low levels of pathogens and solids (Sangare et al., 2021). However, it may contain organic micropollutants (OMP: pharmaceuticals, endocrine disruptors, etc.), with reported concentrations sometimes higher than in wastewater (Hernández et al., 2010), which can pose risk for humans and the environment.

Hydroponic systems (soilless culture) can be installed anywhere and could benefit from the diluted DS as a nutritive solution for the growth of the plants. However, plants in hydroponics can take up contaminants that could be present in the solution (Wu et al., 2013).

The aim of this study was to evaluate the treatment of GW with FDFO, focused on OMP rejection, and the application of the diluted fertilizing DS in hydroponic systems with edibles (*i.e.,* lettuces).

MATERIALS AND METHODS

Forward osmosis experiment

Commercial FO hollow fibre modules (HFFO2, Aquaporin A/S, Nikbakht Fini et al., 2020) were used in this study. Synthetic GW (adapted from Hourlier et al., 2010) was used as FS, with the addition of 24 different OMP, spiked at 20 µg/L each. KNO_3 (0.2 M) and $(NH_4)_2HPO_4$ (0.025 M) (common fertilizers) were used as DS.

The test was performed in batch mode, with constant FS (60L as initial volume) and DS (2L as initial volume) recirculation, in counter current, up to 50% of FS recovery (30 L going from FS to DS). The diluted DS was stored in a cold chamber (5ºC) until its application in the hydroponic system (starting the day after the FO test). The water flux crossing the membrane (J_w, from feed to draw) was determined by mass increase of the DS, using a balance connected to a Programmable Logic Controller (PLC).

Hydroponic experiment

Lettuces *(Lactuca sativa)* with 8 to 10 leaves were planted into a controlled hydroponic lab-scale system, divided into two modules (1 per tested condition) of 4 perforated PVC canals, each of which fits 6 plants (adding up to 24 plants per condition). One module was filled with the diluted DS while the other was filled with a commercial nutrient solution (CNS: KNO_3, $Ca(NO_3)_2$, $MgSO_4$, $NH_4H_2PO_4$, and micronutrients) dissolved in deionized water (biotic control). The hydroponic solutions were changed once per week and the experiment lasted 4 weeks.

Sampling and analyses

During the FO tests, samples of FS and DS were taken at the beginning and end of the test to analyse ions and TOC. Samples at the beginning, after 10 and 60 minutes, and at the end of the test were directly analysed for OMP concentrations by UHPLC-MS/MS (Gorga et al., 2013; Gros et al., 2012) without solid-phase extraction (SPE).

For the hydroponic experiment, weekly samples of influent and effluent were used to measure ions, TOC and OMP. As to OMP, 50 ml of sample (25 ml for influent water) were filtered with 0.45 µm PVDF filters, added with 0.1M Na_2EDTA solution, extracted by SPE with Oasis HLB (3 ml, 60 cc.) cartridges, and analysed by the methods cited above.

To assess plant health and growth, the number of leaves were registered weekly. At the end of the experiment, two representative plants of each condition were rinsed with DI water, separated into roots, stems, and leaves, and weighted to determine their fresh mass.

RESULTS AND DISCUSSION

Forward osmosis: water and nutrient fluxes, and fertilizer dilution

The highest recorded water flux of 4.7 L/m²h, was lower than that of other studies using similar modules but is explained by the lower difference in osmotic pressure between FS and DS, caused by the 10x lower DS concentration compared to previous studies (Mirshekar et al., 2021; Ren & McCutcheon, 2018). However, this configuration achieved a DS dilution, in which the final concentrations of the nutrients were similar to those found in the CNS (**Figure 1**). Higher initial DS concentrations would have increased the water flux (Mendoza et al., 2022) but would have required higher water volumes to achieve the desired dilution.

Table 1. Reverse salt fluxes (J_s) and ion migration from DS to FS

ion	J_s mg/(m²h)	ion migration %
$N\text{-}NO_3^-$	16.5	28.1
$P\text{-}PO_4^{3-}$	0.2	1.5
$N\text{-}NH_4^+$	5.6	34.7
K^+	64.1	37.5

Reverse salt fluxes (J_s, from DS to FS) varied between the different ions (**Table 1**), with the highest for K. This is because K is a monovalent ion and positively charged, so it is attracted by the negatively charged membrane (Lotfi et al., 2015; Minier-Matar et al., 2016) and diffused through it to the FS.

Forward osmosis: greywater treatment and membrane rejection

The rejection of the main GW constituents was very high for sulphate (97%) and TOC (83%), while medium for Na (40%), which diffused easily to the DS due to its size and monovalent positive charge (Roy et al., 2016). Na presence in the DS is an issue in case of application in hydroponic systems, as it is toxic for the plants at high concentrations.

Regarding OMP, all of them were well rejected, with almost complete rejection, at 10 and 60 mins, and slightly lower at the end of the experiment (**Figure 2**), with average rejection 100, 99.8 and 91.3 respectively. Higher rejections were found for most of the negatively charged compounds due to their repulsion by the FO membrane (electrostatic interactions). In general, the rejection is driven solely by steric exclusion, *i.e.*, higher rejection for higher MW (**Figure 2**) as previously reported (Sauchelli et al., 2018). Thus, charge and then MW determined the OMP rejection by the membrane in most cases. In any case, the rejection was higher than 75% for all the compounds, with an average 91% OMP rejection at the end of the experiment.

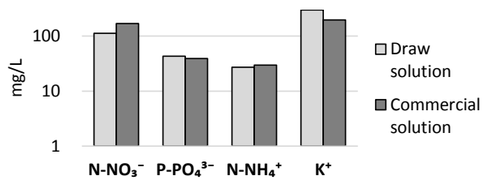

Figure 1. Concentrations of the diluted DS and commercial nutrient solution for their application in hydroponics

Although NH_4 is monovalent, positively charged, and similar to K in size, its J_s was lower because its initial concentration in the DS was around 10x lower than that of K. Thus, initial concentration, charge, and size were responsible for the solute fluxes. The J_s of NO_3 was lower than that of K because it was better repulsed by the membrane. Finally, the J_s of PO_4, due to its nature, was almost negligible. These fluxes led to ion migration from DS to FS, which resulted in nutrient losses, around 30% for monovalent ions and 1.5% for phosphate (**Table 1**).

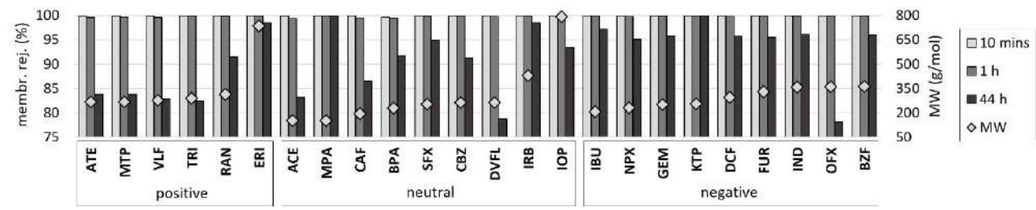

Figure 2. OMP rejection in time periods. OMP: atenolol (ATE), methylparaben (MTP), venlafaxine (VLF), trimethoprim (TRI), ranitidine (RAN), erythromycin (ERI), acetaminophen (ACE), methylparaben (MPA), caffeine (CAF), bisphenol A (BPA), sulfamethoxazole (SFX), carbamazepine (CBZ), desvenlafaxine (DVLF), irbesartan (IRB), Iopromide (IOP); ibuprofen (IBU), naproxen (NPX), gemfibrozil (GEM), ketoprofen (KTP), diclofenac (DCF), furosemide (FUR), indomethacin (IND), ofloxacin (OFX), and bezafibrate (BZF).

Hydroponic system: lettuces grown in the diluted draw solution

The harvested lettuces (4 weeks) growing in DS were slightly darker and had thicker roots than the control ones (**Figure 3**) but looked healthy. Both conditions developed a similar number of leaves along the first three weeks, but the control lettuces had a noticeable higher number of leaves at the end of the experiment (**Figure 4**). Lower leaf and stems fresh mass were measured for DS lettuces, although root mass was similar for both conditions (**Table 1**). This could be explained by the lack of some nutrients in the DS condition (*i.e.,* sulphate, calcium, magnesium, and micronutrients) as well as by the presence of sodium. However, the leaves of the DS lettuces properly grew, suggesting that diluted DS is an appropriate solution to grow lettuces, although nutrients should be balanced.

Figure 3. Lettuces at the end of the experiment, growing in DS (left) and commercial solution (right).

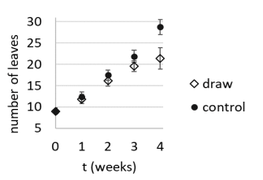

Figure 4. Number of lea-ves along the experiment

Table 2. Fresh mass (g) of the different parts of the lettuces after 4 weeks.

		Lettuces in DS	Control lettuces
Roots	2.2	2.5	
Stems	0.3	1.2	
Leaves	5.7	24.8	

Because of the high rejection in FO, very low OMP concentrations were found in the diluted DS applied in the hydroponic experiment, which ranged from 0.5 to 2.6 µg/L (average 1.4 µg/L). Therefore, the estimated OMP uptake by the lettuces was also very low.

CONCLUSIONS

Forward osmosis technology showed promising results for GW treatment in relation to the rejection of OMP and multivalent ions. Nevertheless, monovalent ion fluxes were medium to high, indicating, on the one hand, loss of nutrients from DS to FS, and on the other hand, sodium fluxes from FS to DS, compromising the quality of the diluted DS.

The lettuces grown in the diluted DS showed a healthy appearance, but grew less than the control, probably due to lack of some nutrients and the presence of sodium in the solution. OMP concentrations in the diluted DS were very low, as well as the estimated OMP uptake by the lettuces. Further studies should focus on decreasing monovalent ion fluxes in FO and optimizing plant growth.

Abstract

The water scarcity crisis has led to an increased focus on water reuse and low-energy consumption processes for wastewater treatment. Current technologies for municipal sewage treatment must be transformed to truly shift towards more sustainable approaches. The LIFE AMIA project validates a new concept for Wastewater Treatment Plants that combines a compact Anaerobic-Aerobic treatment, a High-Rate Algal Pond and an Advanced Oxidation Adsorption Process. The aim is to produce high-quality water effluent for reuse in agriculture following the new EU directive. This project achieves obtaining reclaimed water with energy production via biogas production (65±8% CH4) and nutrient recovery of 27.93 g N/m3 and 12.63 g P/m3 treated water. The sludge and microalgae biomass obtained in the treatment process was used as a biofertilizer for degraded soils with positive results. Emerging pollutants removal rates were higher than in conventional WWTP treatment, highlighting the removal of venlafaxine or diclofenac.

Keywords (maximum 6 in alphabetical order)

Advanced Oxidation Process; anaerobic-aerobic treatment; microalgae treatment, nutrients recovery; water reuse; water scarcity

INTRODUCTION

As environmental policies continue to promote high-quality treated and regenerated wastewater, energy efficiency and resource recovery, traditional purification and regeneration technologies based on activated sludge and chlorination or UV are no longer sufficient for meeting these needs, particularly for small and medium populations. In response, the LIFE AMIA project is developing a new combination of technologies that can regenerate municipal wastewater with minimal energy consumption and in accordance with the principles of the circular economy. The results of demonstration plant located in Alhama WWTP treating 12m^3/d are here presented.

MATERIALS AND METHODS

LIFE AMIA pilot plant

The proposed treatment process begins with a compact system that combines a 375L anaerobic stage in the bottom with a 332L aerobic stage at the top in a vertically stacked reactor. The water is introduced into the lower part of the anaerobic chamber, which uses granular biomass in an EGSB-type upflow reactor to produce biogas. After a three-phase separation system, the water is directed to the upper chamber where it is treated with a moving bed technology (MBBR). Figure 2 shows the A2C reactor, anaerobic granular biomass and the carriers holding the aerobic biomass.

After the anaerobic-aerobic compact treatment, the water is introduced into two 28 m^3 microalgae reactors (high-rate algae pond reactors, HRAP) with an HRT in the range of 3-6 days, where photosynthetic autotrophic microorganisms use sunlight to fix dissolved CO2 and assimilate nutrients present in the wastewater, mainly N and P. The system uses a pH regulation system with a CO_2 dosage to maintain pH in the range 7-8. After leaving the HRAP reactor, the microalgae are harvested from the liquid using a dissolved air flotation (DAF) system, obtaining the biomass that can be used as fertilizer due to their high nutrient content. Figure 3 shows the HRAP reactors and the microalgae-bacteria mixed culture.

As the last stage of LIFE AMIA treatment, the purified water undergoes tertiary treatment for regeneration through an adsorption and advanced electro-oxidation process (AOP) powered by solar energy. This novel process uses a 1.6 m^3 NYEX® particles bed to adsorb organic molecules, which are then oxidized to CO2 through the application of a small electrical current (5-15A) that also regenerates the particles. The use of solar power as the main energy source improves sustainability towards the treatment. As a result of this last stage, emerging pollutants removal and disinfection are achieved according to the upcoming EU water reuse directive. Figure 1 presents the LIFE AMIA treatment plant.

Emerging pollutants, pathogens and biofertilizer assessment

In order to assess the emerging pollutants removal in the process, the following species were analysed throughout the process: sulfamethoxazole, venlafaxine, 4-aminoantipyrine, acetaminophen, ketoprofen, diclofenac, trimethoprim and I-V cypermethrin.

A selection of target pathogens was considered in the study as well: F-specific RNA bacteriophages, somatic coliphages, *Clostridium perfringens* spores, total bacteriophages, *Escherichia Coli* and *Salmonella* sp.

Besides, the biomass obtained, including both sludge and microalgae, has been thoroughly tested and assessed for its potential use as a biofertilizer on degraded soils in agriculture. The total organic carbon (TOC) of the potential biofertilizers was studied.

RESULTS AND DISCUSSION

The results of the validation phase are shown follows. Figure 4 shows the evolution of COD removal performance over time in the A^{2}C stage. The anaerobic-aerobic reactor has been in operation for over 700 days, during which time it has maintained stable COD removal yields (74±16%) and has successfully handled COD peaks of up to 1,500 mg/L without significantly affecting the effluent. Figure 5 shows that once stationary conditions were reached, methane production was maintained at an average of 65±8%., resulting in a significant reduction in energy consumption and potential energy recovery.

The HRAP reactors were stabilized with a HRT of 4.5 days and 404 mg TS/L (87% SSV), resulting in COD values below 100 mg/L (75% removal). The average N and P content in the algal biomass was 6.7% N and 3.1% P in dry matter, respectively, and the amount of nutrients recovered from the wastewater in the form of algal biofertilizer was 335.2 gN/d and 156.1 gP/d.

In terms of emerging pollutants, the two compounds with the highest concentration (acetaminophen and 4-aminoantipyrine) were completely eliminated by the LIFE AMIA treatment. The removal of emerging pollutants was greater in the LIFE AMIA treatment compared to conventional activated sludge treatment, ranging from 45.24% to 99.8% after the AOP stage. The most difficult compounds to eliminate were Diclofenac and Venlafaxine, with a better performance compared to conventional treatment. In the pathogens case, the removal was between 94,6-100% for all the samples of the LIFE AMIA treated water. Figure 6 shows the comparison of the micropollutant removal performance between LIFE AMIA and conventional WWTP treatment.

The results of total organic carbon (TOC) of the sludge indicate a 28.1±1.9 and a 27.9±1.6% higher TOC values compared to the control test mineral material used in the study.

ACKNOWLEDGEMENTS

LIFE AMIA project is funded by the LIFE Programme of the European Union under Grant Agreement LIFE18/ENV/ES/000170. The consortium includes 6 partners: FACSA, ESAMUR, EUROFINS-IPROMA, ARVIA, CEBAS-CSIC and ATLANTIS.

Abstract

With the aim to address water scarcity and support the sustainable use and treatment of (waste-) water, this study examines a self-sufficient, off-grid water system in the inhabited demonstration house "KREIS-Haus". The water system is based on rainwater harvesting and greywater treatment with a low-tech treatment implementing submerged, attached biofilm growth. Treated rainwater is used as drinking water and treated greywater is used for the washing machine and irrigation of the rooftop garden. In an experimental period of 17 weeks, several abiotic and biotic parameters were analyzed once per week before and after the rainwater and greywater treatment. Comparing the results to Swiss/EU regulation and literature, the treated greywater is suitable for irrigation and laundry. However, the treated rainwater did not always meet required microbial limit values, indicating insufficient performance of the LED-UV lamp. The greywater treatment unit achieved removal rates of 92% for COD and 98% for turbidity, and no accumulation of substances was observed in the treated greywater. Water self-sufficiency was at 100% over the whole experimental period, and excess water pumped out of the system met the standard for discharge into a water body. While these first results indicate a promising approach to the water concept, more long-term monitoring and testing with higher occupancy is needed.

Keywords

Biological wastewater treatment; greywater treatment, rainwater harvesting, self-sufficiency, wastewater reuse

INTRODUCTION

Freshwater is becoming an increasingly scarce resource due to global trends such as urbanization, climate change and population growth (UNESCO, 2017). Therefore, the 2017 United Nations Global Water Report (2017) highlights the importance of wastewater reuse as a strategy to address water scarcity. A number of studies have examined local greywater treatment and its reuse potential for non-potable applications such as toilet flushing or irrigation (Chrispim & Nolasco, 2017; Masi et al., 2016; Radingoana et al., 2020; Yoonus & Al-Ghamdi, 2020). With the aim to develop fully water self-sufficient systems, greywater treatment and reuse can be combined with rainwater harvesting for drinking water supply. By doing so, no centralized infrastructure for (waste-) water is needed. The inhabited demonstration house "KREIS-Haus" (German for Klima- und Ressourcen-effizientes Suffizienz Haus, English: climate and resource efficient sufficiency house), located in Feldbach Switzerland, implements completely closed resource cycles on building level on approx. 40m^2. The house is built in three parts: the tempered living unit, the adjacent conservatory with rooftop garden, and the technology room. Beside a range of sustainable building materials and an energy system based on solar energy, the house implements an off-grid water system. The aim of this study was to examine the water cycle in KREIS-Haus in terms of treatment performance, output water quality and compliance with legal standards, and degree of water self-sufficiency

MATERIALS AND METHODS

Water supply and management of the examined "KREIS-Haus" is based on rainwater collection and greywater treatment and reuse. Rainwater from the 77m^2 roof is collected in a 3m^3 tank and processed into drinking water by a series of filtration and treatment steps including a particle filter, activated carbon and UV-LED (Figure 1). Thanks to the dry separating toilet, no wastewater is produced from the toilet. All faucets and the shower are highly water efficient. The lightly polluted greywater from the bathroom (sink, shower), washing machine and kitchen is collected in a 1.5m^3 tank. From there, the greywater is pumped once per day into the in-house treatment unit (own development) in the form of a mobile box of 210 x 70 x 150cm (LxWxH). The treatment technology is based on submerged, aerobic, attached biofilm growth in a low-tech process with the aim to require minimal maintenance, energy, as well as investment and running costs. The technology is a further development based on the findings of the previous study of Buehler et al. (2021). The treated greywater is reused in the house for the washing machine and irrigation of the rooftop garden. Not used treated greywater flows back into the greywater tank. When the greywater tank is full, the water flows into the overflow tank (1.5m^3), which needs to be manually emptied. All tanks are located in the ground under the house. Prior to the sampling period of this study, the house was intermittently inhabited, and the treatment system was operational for 9 months. The sampling period was carried from 22 July 2022 to 14 November 2022 (17 weeks). The house was inhabited by changing visitors staying between 2 to 12 days. On average, the house was occupied by 2 people on 3 days per week. Eco-friendly detergents and body care products were provided but their use was not enforced. The abiotic water quality parameters in Table 1 and the microbial parameters in Table 2 were analyzed once per week before and after the rainwater and greywater treatment.

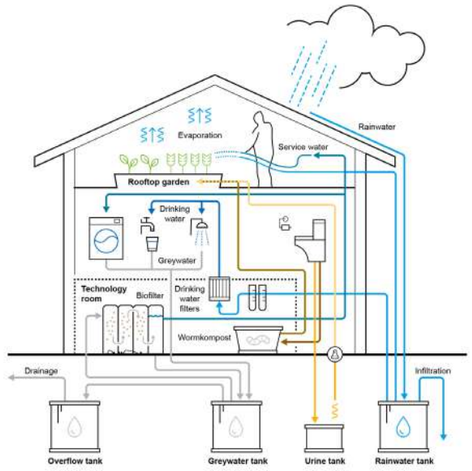

Figure 1. Off-grid water cycle in the KREIS-Haus based on rainwater collection and greywater treatment and reuse

RESULTS AND DISCUSSION

According to the EU regulation 2020/741 for water reuse (European Commission, 2020), the treated greywater is suitable for agricultural irrigation of quality class A in terms of the measured mean values (Table 1, Table 2) for turbidity, BOD$_5$, *E.coli* and Legionella. The treated greywater is also suitable for laundry according to literature values (Ciabatti et al., 2009; Gross et al., 2015; Hoinkis & Panten, 2008) in terms of turbidity, COD, pH and EC. The greywater treatment unit achieved removal rates (92% for COD, 87% for BOD$_5$ and 98% for turbidity) comparable to other well performing attached growth systems (Khalil & Liu, 2021). BOD/COD ratio was before and after the greywater treatment at 0.3, indicating that both biological and physical processes took place. However, biological activity would need to be verified by other methods such as FDA. Figure 1 shows that the pollution loads in greywater fluctuate with the occupancy of the house. Since the values for 'Greywater' do not reflect raw greywater but mixed raw and treated greywater, it is unclear to what extent the treatment system was fed with higher polluted greywater between the sampling times. For an increased stress test, the house should be inhabited permanently over a longer period. Over the experimental period, none of the parameters in the treated greywater showed a trend towards accumulation, one example being COD in Figure 2. This is in contrast to a previous study of the authors on a closed-loop laundry pilot facility with similar technology (Buehler et al., 2021), showing accumulation of COD, TOC and turbidity over time. Even if the two system are not directly comparable, accumulations in the KREIS-Haus should be further observed over a longer period, and if apparent, adequately managed. Assessment of the treated rainwater (drinking water) shows that the values for *E.coli* and Enterococci (Table 2) were at times above the limit values of the Swiss regulation for drinking water (TBDV, 2016) which requires these microbials to be not detectable. This indicates that the UV-LED lamp did not perform sufficiently and needs to be replaced. Over the experimental period, the house was operated 100% water self-sufficiently meaning that no external water supply other than rainwater was used. The overflow tank was emptied twice and contained an average of 52.8 mg/L COD. According to Swiss regulation, the water could have been discharged into a water body (limit value 60mg/L COD) (GSchV, 1998). However, it is unclear if compliance with regulation can be ensured with higher occupancy of the house. These first results indicate that the water concept in KREIS-Haus is a promising approach, but parts as the UV-LED lamp need to be replaced and the greywater treatment needs to be monitored over a longer period with higher occupancy.

Abstract

One of the main challenges for wastewater treatment coupled to bioproducts recovery from cyanobacteria is maintaining a stable culture and bioproduct content over time. The aim of the present study was to assess the recovery of bioproducts (natural pigments and biogas) using cyanobacteria as tertiary treatment in a biorefinery approach. Secondary effluent from a municipal wastewater treatment plant was treated with wastewater-borne cyanobacteria (*Synechococcus* sp. and *Synechocystis* sp.) in lab (3 L) and pilot scale (30 L) photobioreactors. Biomass was periodically harvested and pigments (phycobiliproteins) were extracted and quantified over time. Residual biomass was then used to produce biogas. For the first time, the presence of contaminants of emerging concern was analysed in secondary effluent, biomass and pigment extracts. Results showed how both cyanobacteria were able to remove up to 83% of N-NH_4^+ and 97% of P-PO_4^{3-} from secondary effluent. The phycobiliprotein content was up to 214 mg gDW^{-1} for *Synechococcus* sp., while up to 222 NL CH_4 $kgVS^{-1}$ were yielded from residual biomass. For *Synechocystis* sp., a steady phycobiliprotein content around 70 mg gDW^{-1} was maintained over a period of 45 days at pilot scale (30 L). Only 3 out of the 20 contaminants of emerging concern detected in secondary effluent were found in pigment extracts. In conclusion, this research highlights tertiary wastewater treatment with cyanobacteria as a promising strategy for improving the quality of secondary effluents while obtaining bioproducts.

Keywords

Bioproducts; circular economy; cyanobacteria; nutrient recovery; wastewater reuse

INTRODUCTION

The increasing word population, together with climate change and the over-exploitation of freshwater sources, makes it urgent to develop sustainable alternatives for water reuse and everyday goods production. Cyanobacteria are microorganisms capable of accumulating several bioproducts, such as bioplastics, natural pigments and lipids (Senatore et al., 2023), by using sunlight and fixing CO_2. Furthermore, their production may be coupled to wastewater treatment, and their biomass extracted in a biorefinery approach to maximize the profitability of the process. However, the implementation of a wastewater-based cyanobacterial biorefinery is still challenging, as strain stability and bioproduct productivity maintenance over time are difficult to achieve. Thus, the use of strains with environmental plasticity, together with the development long-term experiments are needed. In addition, due to the fact that the social acceptation of wastewater-derived bioproducts is still limited, the tracking of organic microcontaminants in the final product is needed so as to develop realistic applications. This presentation will show a compilation of experiments using wastewater-borne cyanobacteria for tertiary wastewater treatment coupled to the recovery of bioproducts (pigments and biogas) in lab and pilot scale photobioreactors. For the first time, the presence of contaminants of emerging concern (CECs) was tracked over the process.

MATERIALS AND METHODS

Two wastewater-borne cyanobacteria strains (*Synechocystis* sp. and *Synechococcus* sp.) were used for tertiary wastewater treatment and recovery of bioproducts. Firstly, lab scale (3 L) tubular photobioreactors of polymethyl methacrylate were fed with secondary effluent from an activated sludge wastewater treatment plant (WWTP) in semi-continuous mode. Biomass was periodically harvested for pigments extraction and quantification by spectrophotometry following Arashiro et al. (2020). Furthermore, the residual biomass of *Synechococcus* sp. was used in Biochemical Methane Potential (BMP) tests under mesophilic conditions (Table 1). Serum bottles with a total volume of 160 mL and a working volume of 50 mL, were inoculated with 5 g Volatile Solids (VS) L^{-1} of substrate ($VS_{substrate}$), and a $VS_{substrate}$:$VS_{inoculum}$ of 0.5 (Arashiro et al. 2020). Following, as *Synechocystis* sp. showed a more stable phycobiliprotein content over time, it was further scaled-up to a pilot (30 L) tubular photobioreactor. Tubular photobioreactors were mixed either with a magnetic stirrer (200 rpm, 3 L) or paddle (90 rpm, 30 L), and pH was maintained at 7.5-9 by CO_2 injection (HI 8711, HANNA instruments, Italy). Light was provided by cool-white LED lamps. Nutrients (P-PO_4^{3-}, N-NH_4^+, N-NO_3^- and N-NO_2^-) removal and biomass growth (measured as volatile suspended solids, VSS) were monitored following Standard Methods (APHA-AWWA-WPCF, 2017). Finally, the presence of CECs was analysed in the secondary effluent, biomass, and phycobiliprotein extracts as described by Matamoros et al. (2015). Schematic diagrams of the scientific questions and experimental steps are shown in Figure 1 and 2.

RESULTS AND DISCUSSION

Promising cyanobacteria strains for domestic wastewater treatment must have tolerance to high N-NH_4^+ concentration, and this study showed that both wastewater-borne cyanobacteria (*Synechococcus* sp. and *Synechocystis* sp.) were able to treat secondary effluent with an average concentration of 42 mg L^{-1} of N-NH_4^+. Indeed, both of them efficiently removed up to 83% of N-NH_4^+ and 97% of P-PO_4^{3-} (Table 2), reaching stable biomass concentrations around 515 and 494 mg $VSS\ L^{-1}$, respectively. In terms of phycobiliprotein recovery, although *Synechococcus* sp. presented a very high pigment production potential (up to 214 mg gDW^{-1}), phycobiliprotein loss was evidenced over time; whereas in the case of *Synechocystis* sp. it was steadily maintained at concentrations close to 70 mg gDW^{-1} (Figure 3 A, B). Given that N was completely depleted, and under N exhaustion conditions phycobiliproteins are degraded as a cellular N source (chlorosis), it seems that *Synechococcus* sp. is more sensitive to N depletion than *Synechocystis* sp. Thus, when *Synechocystis* sp. was scaled-up to a 30 L photobioreactor, the phycobiliprotein content was maintained over a period of 45 days, reaching up to 74 mg gDW^{-1} (Figure 3 D). Following, the methane production from *Synechococcus* sp. residual biomass after phycobiliproteins extraction by the freeze-thaw methodology was quantified (Table 1). The methane yield reached 222 NL CH_4 $kgVS^{-1}$ (Figure 3 C), which is similar or even higher than the values reported (159-199 mL CH_4 $kgVS^{-1}$) by Arashiro et al. (2020). Regarding CECs, only 3 out of 20 detected in secondary effluent were found in pigment extracts.

In conclusion, this study shows the potential of wastewater-borne cyanobacteria as tertiary wastewater treatment coupled to high-value bioproducts (phycobiliproteins) recovery. Moreover, it highlights the circularity of the process by reusing the residual biomass to recover bioenergy (biogas) in a biorefinery approach. Finally, it evidences the stability of the process at pilot scale (30 L) in the long-term, which is one of the main challenges of nutrient recovery from wastewater coupled to cyanobacterial biomass and derived bioproducts obtention.

Abstract
The potential growth of lettuce (*Lactuca sativa*) and mint (*Mentha Sativa*) in a hydroponic system fed with light greywater, collected from bathroom sinks and showers in Hotel Samba in Lloret de Mar (Spain), was studied. Both types of plants were able to sustain and grow in the channels fed with greywater. However, compared to control plants grown in commercial hydroponic solution, the growth was noticeably smaller. Channels fed with greywater supplemented with the same nutrients on the other hand, produced bigger lettuces as well as mint plants of similar size as the control, showing greywater as a good medium to grow edibles in hydroponics. The present study is part of a more extensive research activity aiming to assess the feasibility of reusing different greywater sources to produce food crops and aromatic herbs.

INTRODUCTION

Water reuse has long since been acknowledged to be a necessary measure to counter water scarcity, especially in the Mediterranean region, where touristic activities put additional pressure on decreasing natural freshwater resources. Here decentralised nature-based water treatment and reuse applications (e.g., in hydroponic systems) have been found to be a suitable solution to decrease the fresh water demand in tourist facilities (Estelrich et al., 2021). The agricultural sector has been identified to have the highest potential for water reuse applications (Regulation (EU) 2020/741). An interest to quantify the circularity of water reuse regarding more resources than just the water, by looking into the potential benefit of recovered nutrients from wastewater for plant growth, is rising. Hereby is source separated greywater (GW) an interesting source, as it contains less microbiological contamination than wastewater (Sangare et al., 2021). There is little literature assessing the sufficiency of nutrients in different greywater sources to grow crops. Sangare et al. (2021) found more dry weight production in dishwasher GW irrigated lettuces compared to fresh well water. Conversely, Sawadogo et al. (2014) found that GW constitutes like washing detergent at concentrations <1g/l may negatively affect plant growth. Da Silva Cuba Carvalho et al. (2018) found that treated wastewater only grows plants of comparable size to conventionally grown hydroponic lettuces, if supplemented with nutrients. Similarly due to the lack of essential nutrients, especially nitrogen, for plant growth in treated GW, Eregno et al. (2017) increased their hydroponic lettuce production by using source-separated urine as nutrient solution. This study aims to assess the suitability of hotel light GW (i.e., from bathroom sinks/showers) to grow lettuce and mint plants of marketable size in a hydroponic system. The plant growth assessment is hereby the focus of this abstract.

MATERIALS AND METHODS

The hydroponic system consisted of 15 individual hydroponic PVC channels under controlled environmental conditions (21ºC; 68% relative humidity; 14 light hours, LED lamps). Duplicate channels with either six lettuces or mint plants per channel, were tested per water type. Each channel was fed with 1.5L of either GW, GW plus commercial hydroponic nutrients (GW+), or commercial hydroponic nutrient solution (purchased from groho.es; prepared with deionized water) as control condition (CTRL). Hotel GW was collected weekly and stored at 4ºC in a cold chamber. All water types were renewed twice per week in the system during 4 weeks of experiment. For the plant growth assessment, a minimum of two plants of average representative size (measured by number of leaves and visual appearance) were selected, cleaned with DI water, and separated into functional groups (roots, stems, leaves). The leaf area per plant was measured using the "Easy Leaf Area Free" mobile phone application (last updated 31.07.2015) developed by Hsien Ming Easlon & Arnold J. Bloom. The individual plants parts were dried at 70ºC for 48 hours to calculate average dry weights. The compared plant growth parameters include, next to number of leaves, leaf area and whole plant and leaf dry weight, five traditional plant growth assessment parameters that have been found in guidance literature (Pérez-Harguindeguy et al., 2013; Pandey et al., 2017; van Holsteijn, 1980; Hunt et al., 2002):

$$RGR = \frac{lnW_2 - lnW_1}{t_2 - t_1} \quad (1)$$

Relative growth rate (RGR; g/g/day): Average daily increase in dry matter per unit dry matter per time. Indicates proportionate growth of the plant independent of its size.

$$NAR = \frac{(W_2 - W_1) * (lnLA_2 - lnLA_1)}{(t_2 - t_1) * (LA_2 - LA_1)} \quad (2)$$

Net assimilation rate (NAR; g/cm^2/day) or unit leaf rate (ULR): Increase of plant material per unit of assimilatory material (unit LA) per unit of time. Indicates the daily rate of photosynthesis per unit LA.

$$LWR = \frac{(LW_2/W_2) - (LW_1/W_1)}{2} \quad (3)$$

Leaf weight ratio (LWR; g/g): Ratio of the leaf dry weight (LW) to total plant material dry weight (leaves, stems & roots; W). Indicates the proportion of leaves to the whole plant (i.e., dry weight involved in assimilation).

$$LAR = \frac{(LA_2/W_2) - (LA_1/W_1)}{2} \quad (4)$$

Leaf area ratio (LAR; cm^2/g W): Ratio of leaf area (LA) to total plant dry weight (W). Indicates leafiness of plants (higher LAR indicates more efficient use of dry mass for photosynthesis and respiration).

$$SLA = \frac{(LA_2/LW_2) - (LA_1/LW_1)}{2} \quad (5)$$

Specific leaf area (SLA; cm^2/g LW): Ratio of the leaf area to leave dry weight (LW). A higher SLA indicates less thick and/or dense leaves.

With: W: dry weight of total plant material, LW: dry weight of leaves & LA: total leaf area at t1 & t2: day of planting & harvest of plants each.

RESULTS AND DISCUSSION

GW with and without additional nutrients facilitated plant growth of varying degree (Figure 1).

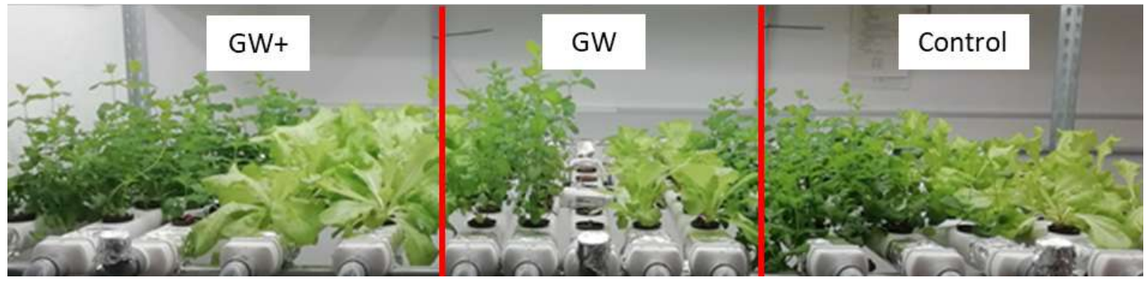

Figure 1. Hydroponic system with mint and lettuce grown in greywater plus nutrients (GW+), greywater (GW) and hydroponic nutrient solution (Control), after week 4 of the experiment.

Comparing the average total nitrogen and total phosphorus influent concentrations (TN (mg/L): 195; 7.7; 199 & TP (mg/L): 35; 0.9; 43) in CTRL, GW, and GW+ respectively, shows that the GW is lacking essential nutrients for plant growth. In the final weeks of the experiment TN & TP concentrations in the GW effluent were depleted below 1 & 0.5 mg/L. The resulting inaccessibility to essential nutrients by the plant explains the limited growth of plants grown in the GW condition.

Figure 2 a & b. Plant growth parameters for lettuce (a) & mint (b); number of leaves, leaf area, and leaf dry weight are provided as additional values produced since the day of planting (t0; initial values indicated as ●).

a. Lettuce. Plant growth parameters in figure 2a show that the control plants grew the same number of leaves as the GW+ condition, which received the same nutrients, but the CTRL leaves were smaller in area and weight. Therefore, while CTRL produced bigger looking plants (higher number and bigger leaves) than GW, plants of both conditions had similarly low RGR (dry weight production). This is because the GW plants grew smaller but thicker leaves indicated by the lower leaf area and SLA, which is a morphological change that has been repeatedly found in GW conditions tested in previous experiments. So, while GW+ and control plants used their dry matter more efficiently for photosynthesis and respiration (higher LAR), GW plants maximized photosynthesis in a smaller area (high NAR). Another typical morphological adaptation to a nutrient scarce environment (Eregno et al., 2017) is the higher ratio of roots to leaves, indicated by the lower LWR. Overall, however, GW+ produced 3 more leaves, 4 times as much leaf area and 3 times as much leaf dry weight as the GW condition. And GW+ was the only condition producing crops of marketable size and form. The control plants did not reach the growth expected, at least as good as GW+. However, this is likely due to their placement in the experimental system, which received the lowest light intensity.

b. Mint. Plant growth parameters in figure 2b show that GW+ and CTRL condition performed similarly well, by multiplying the initial number of leaves by four, the initial leaf area by nine and the initial leaf dry weight by five. While the GW condition only managed to double the number of leaves and triple the leaf area and dry weight compared to t0. Here too the lower LA (SLA) for GW indicates smaller but thicker leaves, to maximize the productivity of the available dry mass (high NAR). While the two other conditions (GW+ and CTRL) used their dry mass more efficiently for photosynthesis and respiration (higher LAR). The lower LWR hints at the adaptation to nutrient scarce environments, through higher root mass, making up 27% of the total GW plant dry weight compared to 14% that it makes up for in control plants. The GW plus additional nutrients, on the other hand, showed growth parameters very similar to the control conditions.

CONCLUSION

The light GW with additional nutrients can be expected to perform similarly well as a conventional nutrient solution prepared with DI water. GW alone did facilitate plant growth, and did not cause visible plant diseases, despite being a raw GW. However, there were noticeable changes in the plant's morphology, and the produced leaf area and dry mass was well below that of the conventional nutrient solution. Therefore, this light greywater source can substitute freshwater in a hydroponic system, however it cannot by itself provide all the necessary nutrients for optimum plant growth.

Abstract

Anaerobic membrane bioreactor (AnMBR) is gaining attention for domestic wastewater treatment thanks to the production of high quality permeate and biogas production towards energy positive treatment. Granular sludge based anaerobic membrane bioreactor (G-AnMBR) has gained emphasis in the last decade since granular biotechnology boosts the biomass activity and reduces membrane fouling simultaneously. With the aim to produce higher quality effluent for water reuse applications and improve system efficiency, forward osmosis (FO) system was integrated to a G-AnMBR. Kubota microfiltration modules were step by step replaced by Submerged FO plate and frame modules. Process stability, impact of salinity on biomass, produced water quality and organic matter removal efficiency were assessed and compared for system working in 100% MF, 70%MF/30%FO, 30%MF/70%FO and 10%MF/90%FO respectively. A 15L reactor fed with synthetic wastewater was operated at 25ºC with neither scouring nor relaxation at around 5 L/m2/h permeation flux during at least 10 days. Above 90% COD degradation was observed for all configurations and with a remaining COD content below 50mg/L and below detection limit for MF and FO permeates respectively. Positively, FO membranes proved to be less prone to fouling and increased COD degradation was observed when operating with FO. However, increasing FO share in the reactor, led to salinity increase and to enhanced fouling propensity probably due to salinity shock on the active biomass, releasing extra polymeric substance in the mixed liquor.

Water reuse; anaerobic membrane bioreactor; water reuse; fouling

INTRODUCTION

Anaerobic membrane bioreactor (AnMBR) is rising attention for domestic wastewater treatment thanks to the production of high quality permeate and biogas production towards energy positive treatment[1]. Granular sludge based anaerobic membrane bioreactor (G-AnMBR) has gained emphasis in the last decade since granular biotechnology boosts the biomass activity and reduces membrane fouling simultaneously[2,3]during anaerobic digestion of domestic wastewater combined with a submerged ultrafiltration membrane with no gas-sparging. A one-stage submerged granular anaerobic membrane bioreactor (G-AnMBR. A very recent study proved that G-AnMBR applied for domestic wastewater at psychrophilic temperature could achieve high organic matter removal rates, increasing effluent quality, while producing a net energy balance due to the biogas production, derived from the organic matter conversion to methane [2]. In parallel, Forward osmosis (FO) gained some interest since it relies on osmotic gradient, using dense membranes and demonstrated to have lower fouling propensity. Unlike MF and UF membranes, FO retains salts, pesticides, pharmaceutical compounds [4]osmotic membrane systems, such as forward osmosis (FO. Operating AnMBR only with FO membrane (Anaerobic osmotic MBR, AnOMBR) led to high rejection rates, moderate fouling but severe salinity build-up overtime when only a FO membrane is used[5]. Combining FO and MF membrane into the AnOMBR reactor avoided severe salinity build-up while assuring production of high water quality (through the FO membrane), production of biogas and concentration of nutrients (phosphorous in the MF permeate) to facilitate its downstream recovery or reuse[6]ability to efficiently process low ionic strength wastewater and high effluent quality. However, salt accumulation remains a main obstacle for causing severe water flux decline, fouling aggravation and inhibitory on the microbial activity. Here, we report a novel microfiltration (MF. Combining G-AnMBR and AnOMBR may represents some synergy by combining the benefits of both technologies allowing for low fouling propensity, low energy requirements, production of biogas and increasing permeate quality thanks to the high rejection of FO membranes. In this study, we evaluated the progressive substitution of MF membranes by FO membranes in a G-AnMBR to evaluate the concept of Granular Anaerobic Osmotic MBR (G-AnOMBR).

MATERIALS AND METHODS

The G-AnMBR pilot featured a rectangular parallelepiped reactor (282 × 100 × 900 mm) with a working volume of 17L (Figure 1). The reactor was seeded with anaerobic granular sludge obtained from a paper mill factory. Synthetic wastewater was fed to the reactor with COD concentration of 500±200 mg.L^{-1}.The hydraulic retention time (HRT) was set at 10 hours aiming to achieve an optimal organic matter removal of 90%. All experiments were conducted at a temperature of 25°C. The biomass level filled up the bottom part of the reactor up until the bottom part of the membrane modules. A recirculation pump set at 40L.h^{-1} was used to assure a good contact in-between the WW and the biomass and a slight microbial granules fluidization. 3 flat sheet membrane modules (MF and/or FO) with a filtration surface area of 0.1 m^2 each where placed in the reactor. MF and FO modules were operated under negative pumping pressure using 323S peristaltic pumps (Watson-Marlow, UK) without relaxation nor gas sparging. Permeate flows (MF and FO) were monitored by the increase of mass in permeate and draw tanks using Kern EWJ balances. Unless specific conditions, the average targeted permeation flux was of 5 ± 1 L·m^{-2}·h^{-1}. MF permeate flux was controlled by the pump velocity; FO permeation flux was obtained by maintaining constant draw conductivity at 23ms.cm^{-1} (15g.L^{-1} NaCl). The pilot was fully monitored and controlled by a homemade Arduino system. Oxidation-reduction potential, conductivity, temperature, and pH sensors were placed in the G-AnOMBR reactor supernatant.

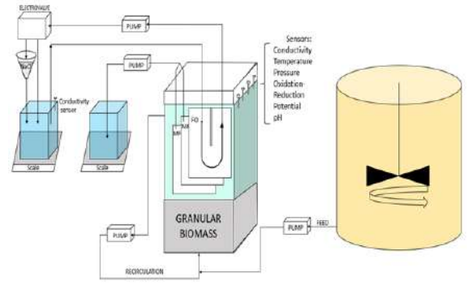

Figure 1. Experimental setup of the G-AnOMBR pilot.

The step-by-step substitution of MF by FO modules led to different hybrid configurations (100%MF, 70%MF, 40-60% MF, 10-20%MF) which were maintained for at least 10 days for each tested conditions. Salinity increase, membrane fouling, organic matter removal, hydraulic retention time, flows were assessed for each operating conditions. MF was operated at constant flux and therefore fouling occurrence was assessed through transmembrane pressure (TMP) increase. MF membranes were cleaned before changing the MF/FO ratio as well as whenever the TMP increased above 300 mbar. FO membrane fouling was assessed through permeation flux reduction; once 30% flux was lost, membranes were cleaned by (1) flushing with 0.5L of DI water followed by osmotic backwashing. For both FO and MF membranes, biofilms removed with the 0.5 L DI flushing of each cleaning were kept for further characterization

RESULTS AND DISCUSSION

Overall, the G-AnOMBR with MF and FO was operated for more than 50 days and with 4 successive steps corresponding to different MF/FO extraction ratio, i.e. 100%MF, 70%MF, 40-60%MF, and 10-20%MF. Hereafter we discuss how this ratio impacts organic matter degradation, salinity and fouling behaviour.

In the initial phase, with 100% MF and 0% FO, COD average removal was of 82.3% (Figure 2). The substitution of MF modules by FO ones into the rector led to an improvement of the overall COD removal well above 90%; leading to average values of 95.9% for 70%MF; 95.0% for 40-60%MF; and 97.2% for 10-20%MF. As such, it indicates first that the integration of FO modules led to an increase of the efficiency of the biological process. Higher COD removal obtained when operating with FO membranes can be explained by the higher retention time of the COD fraction in the reactor; COD rich fraction been extracted only through the MF permeate (fully rejected by FO membrane). As already observed in other studies, FO integration allow for a full dissociation of HRT and SRT, increasing the overall COD fraction degradation.

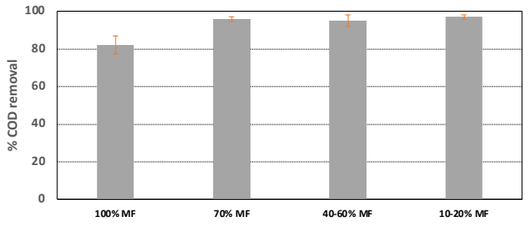

Figure 2. Average % COD removal over 10 days in 100%MF and hybrid MF/FO operation

The integration of FO membranes in the G-AnMBR led to a salinity increase in the reactor (Figure 3a). Conductivity increase was monitored during the study. Initial conductivity operating with 100% MF modules remained around 1.25 mS.cm^{-1} and increased successively up to 2.6, 6.5 and 9 mS.cm^{-1} when increasing the FO extraction rate and consequently decreasing the MF% to 70%, 40-60% and 10-20% MF respectively. Salinity increase was the consequence of (1) high feed solution salt rejection by FO membranes leading to salt accumulation in the reactor and (2) reverse salt diffusion (RSD) from the FO draw solution due to its imperfect salt rejection. Based on conductivity measurement (and theoretical increase due to concentration effect only), it was estimated that RSD was responsible for about half of the salinity increase in the reactor. Developing membranes with higher selectivity and the use of draw solution with lower diffusivity or easily biodegradable organic based draw solutions may help to mitigate this effect.

TMP for MF and permeation flux for FO confirmed the more complicated operation of membrane systems when operation with higher rate of FO membrane. This conclusion was reinforced by the membrane cleaning frequency, which was reduced from 10 days to 7 days, 4-6 days, and 3 days for 100, 70%, 40-60% ad 10-20% MF ratio steps. Interestingly, in 40-60% ratio, FO fouling appeared to less penalizing and MF and FO modules could be operated for a longer time (Figure 3b). Based on biofilm samples collected and dry solids weighted after each cleaning and for each MF/FO ratio, at 70% MF operation, collected amount of biofilm was lower than at 100%, confirming 70% MF as acceptable operating conditions. At higher FO ratio, increased biomass was collected both on FO and MF membranes confirming the higher fouling propensity probably induced by the raised salinity in the reactor which can promote the release of extra polymeric substances (EPS)

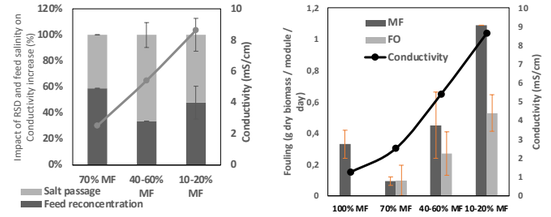

Figure 3. (a) Impact of RSD and concentration effect on salinity increase and (b) total solid (TS) fouling rate (g TS/module/day) attached to the membrane surface for MF and FO modules for various MF/FO operating ratio

Abstract

Seven different solar processes (CPC, PV-UVA LED, PV-UVC LED, CPC+TiO_2, CPC+H_2O_2, PV-UVA LED+TiO_2 and PV–UVC LED+H_2O_2) were investigated, both for the oxidations of chemicals and the inactivation of bacteria. The results showed that, for the oxidation of chemicals, the best photochemical yield (in terms of the use of photons) is achieved by the PV-UVC LED+H_2O_2 process. However, despite being the most effective, the low electrical efficiency of current UVC LED sources makes the CPC+TiO_2 process the most efficient in the use of solar light. In contrast, for bacterial inactivation, the significantly higher effectiveness of the UVC spectral range in damaging DNA makes the PV-UVC LED+H_2O_2 the most efficient in the use of sunlight. When costs are considered, the PV-UVA LED+TiO_2 may be the most efficient process for chemical oxidation, while the PV-UVC LED+H_2O_2 process could be the most efficient for bacterial inactivation.

Keywords (maximum 6 in alphabetical order)

Bacterial inactivation; Chemical pollutant oxidation; Solar CPC photoreactor; Solar PV panel; UVA LED; UVC LED.

INTRODUCTION

Water is a limited resource essential for life and health. In July 2010, the General Assembly of the United Nations recognised through resolution 64/292 the right to drinking water as a fundamental human right (United Nations General Assembly, 2010). However, the availability of water is only legally guaranteed by a few countries. According to a World Health Organization (WHO) report, 29% of the world's population does not have access to drinking water at home. Every year millions of people get diseases such as diarrhoea, cholera, dysentery, typhoid fever, and polio because of the intake of water contaminated by pathogens. It is estimated that only diarrheal conditions cause more than 1.8 million deaths per year, of which 526,000 correspond to children under five years. In addition, many water sources are contaminated with heavy metals, chronic organic pollution, and waste materials that have a destructive effect on public health and the environment. The shortage of drinking water is one of the most transcendental problems worldwide, affecting the most disadvantaged population and decreasing their quality of life. For decades, radiation has been used in water treatment, allowing the inactivation of microorganisms and the removal of chemical pollutants (Pai et al, 2022) One of the key aspects to ensuring the success of the process is the wavelength range of the employed radiation, with the use of UV light being necessary in most cases. The efficiency of UVC light for microorganisms inactivation, by alterations to their DNA chains, has been widely demonstrated (Baldasso et al., 2021). The efficiency of UVA light is too low for this purpose, with UVB being intermediate. In the case of chemical pollutants, for most compounds, the single use of radiation does not produce significant degradation being necessary the use of a catalyst or an additional reactive. These processes are mainly based on the generation of hydroxyl radicals which, through their high oxidising power, can remove a wide range of pollutants in water, either chemical or microbiological (Kebbi et al., 2020).

However, one of the major drawbacks of all the processes described above, and the main reason for their hindered industrial development is their high cost, due to the source of radiation. In recent years, the development of the LED industry has produced a great expansion of UVA LED, and a similar evolution is expected for UVC LED in the forthcoming years (Amano at al., 2020). An alternative is the direct use of solar radiation, since around 6-7% of the light that reaches the Earth's surface is within the UV range (mostly UVA and a small contribution of UVB). To improve the efficiency of the process, it is common to use compound parabolic collectors (CPC) to concentrate the light. Despite the apparent environmental advantage of using direct sunlight to drive the process, the availability of low-cost solar photovoltaic panels (PV) for feeding LED systems increases the interest in alternative solar-powered photochemical water treatment processes due to cost reductions. This work presents a comparative study of solar-driven photo-activated water treatment processes based on the use of three different lighting sources: direct solar light in a CPC photoreactor; UVA LED and UVC LED (both of which are powered by a PV system). Seven different processes involving the potential presence of H_2O_2 and TiO_2 were tested and the efficiency of two test reactions were analysed: oxidation of methanol and inactivation of *E. coli* bacteria, as representatives of water decontamination and disinfection, respectively.

MATERIALS AND METHODS

A solar CPC photoreactor was used for experiments using direct solar light. It consisted of a borosilicate tube 26 mm in inner diameter and 380 mm in length (0.2 L of illuminated volume) located in the optical axis of a CPC aluminium reflector with 358 cm^2 of collection surface area that provides 85% light reflection towards the central pipe. The reactor operates in a closed recirculating circuit with a 1 L reservoir tank of water, driven by a centrifugal pump at a flow rate of 12 L/min.

For experiments based on LED light sources, an annular photoreactor (15 cm long, 3 cm internal diameter and 5 cm external diameter) was used, operating in a closed recirculation circuit with a 1 L reservoir tank, the water being driven by a centrifugal pump with a flow rate of 36 L/min. As an illumination source, two different 8-LED based systems were used. For the experiments carried out with UVA light, LED with a maximum emission peak centred at 365 nm (LedEngin Model LZ1-00UV00) were used, while for the experiments with UVC light, LED with a maximum emission peak centred at 270 nm (Sum Tang ST-POBA20) were used. Total irradiation power was calculated by potassium ferrioxalate actinometry experiments.

To power the LED system, an ATERSA GS 160W Solar PV panel was used, with an output voltage of 12 V and a collection area of 1 m^2. The LED system was connected to an Eleksol Lead-Acid 110Ah battery, as an alternative energy source. The experiments were carried out at Universidad Rey Juan Carlos facilities in Móstoles, Spain (40.33° N, 3.86° W). Both the Solar CPC reflector and the Solar PV panel were placed with an inclination angle corresponding to the local latitude. Solar irradiance was measured using a PCE-UV34 radiometer (290-390 nm). The temperature was monitored, not exceeding 30 ºC in any experiment.

For the comparison of the different treatments, two different test reactions were used. Methanol (Sigma-Aldrich, LC-MS) at an initial concentration of 100 mM was used as an indicator of the efficiency in the oxidation of chemical pollutants. On the other hand, *E. coli* K12 strain (CECT 4624, corresponding to ATCC 23631, where CECT stands for "Colección Española de Cultivos Tipo") was used as a bacterial indicator for water disinfection experiments.

Experiments with H_2O_2 were carried out using an initial concentration of 50 mg/L, ensuring a negligible depletion by using TP01000PX (Scharlab) indicator strips. Sodium sulphite (Na_2SO_3) was added in a Na_2SO_3-to-H_2O_2 molar ratio of 1:1 after sample collection, to stop the oxidative action of H_2O_2. The experiments with H_2O_2 were not carried out in UVA radiation due to the need for a wavelength below 300 nm, to cause the H_2O_2 decomposition. Photocatalytic processes were studied using Evonik P25 titanium dioxide suspensions at a concentration of 0.1 g/L, previously optimised. Dark experiments were carried out both with TiO_2 and H_2O_2 to check if there was any interaction of these compounds in addition to the pure photocatalytic process for any of the pollutants studied.

RESULTS AND DISCUSSION

Methanol oxidation

Results obtained for methanol oxidation are shown in **table 1**. When kinetic constants are calculated for methanol oxidation considering the reaction rate as a function of the number of photons (E) that reached the reactor UVC processes show a significantly higher efficiency in comparison with those based on UVA and direct sunlight due to the high energy of this radiation. The efficiency of the UVC+H_2O_2 process is particularly remarkable, three orders of magnitude higher than that of the TiO_2 based photocatalytic process. On the other hand, if values obtained for the UVA LED and solar radiation are compared, it can be clearly seen that solar UV photons were used to a greater extent than those emitted by the LED source, probably due to the better light distribution throughout the reactor (Martín-Sómer et al., 2017). If kinetic constants are obtained for LED-based systems when the electrical consumption is selected as an independent variable. In this case, the UVA+TiO_2 process is much more efficient than the UVC+H_2O_2 process. The reason for this is that the unquestionably higher photochemical efficiency of UVC photons is counteracted by the very low efficiency in the conversion of electricity into UVC radiation of current UVC LED sources. On the other hand, when kinetic constants are calculated considering solar UV power, coming from the direct use of solar radiation collected in a CPC reactor, or the use of solar radiation in the PV power system to produce electrical energy for the UV LED reactor the results show that, despite the significant increase in the efficiency of UV LED and PV panels in recent years, the use of direct sunlight in a CPC photoreactor is still more efficient. However, another important aspect that must be evaluated when choosing a technology is the cost. In the specific case of the research carried out in this work, the price obtained by adding the different parts purchased for the assembly of the PV+UV LED systems (including solar panel, battery, UV LED, inverter, controller, and annular reactor) was 435 € and 377.8 € for PV+UVA LED and PV+UVC LED, respectively, while the estimated price of the solar collector was 417 €. Investment cost kinetic constants show that the most economic option for carrying out the oxidation process is the PV-UVA LED system with TiO_2.

Table 1. Zero-order kinetic constant for methanol oxidation in the studied processes as a function of time, photons, energy consumption, solar UV radiation and investment cost.

	Photons	Energy	Solar UV	Investment cost
UVA	$(7.58\pm2.15)\cdot10^{-1}$	$(3.68\pm1.05)\cdot10^{-3}$	$(9.21\pm2.61)\cdot10^{0}$	$(2.76\pm0.78)\cdot10^{-1}$
UVA + TiO_2	$(1.68\pm0.69)\cdot10^{1}$	$(8.16\pm3.35)\cdot10^{-2}$	$(2.37\pm0.84)\cdot10^{2}$	$(7.12\pm2.51)\cdot10^{0}$
UVC	$(3.76\pm1.45)\cdot10^{2}$	$(2.23\pm0.45)\cdot10^{-5}$	$(5.58\pm2.15)\cdot10^{-2}$	$(1.93\pm0.74)\cdot10^{-4}$
UVC + H_2O_2	$(1.68\pm0.43)\cdot10^{4}$	$(7.54\pm2.15)\cdot10^{-3}$	$(2.50\pm0.64)\cdot10^{0}$	$(8.61\pm2.22)\cdot10^{-2}$
CPC	$(5.85\pm1.70)\cdot10^{-1}$	-	$(1.17\pm0.34)\cdot10^{1}$	$(1.26\pm0.37)\cdot10^{-2}$
CPC + TiO_2	$(3.79\pm0.53)\cdot10^{1}$	-	$(7.60\pm1.35)\cdot10^{2}$	$(8.64\pm1.13)\cdot10^{-1}$
CPC + H_2O_2	$(2.26\pm0.61)\cdot10^{0}$	-	$(9.69\pm9.85)\cdot10^{0}$	$(8.90\pm3.29)\cdot10^{-4}$

Bacterial disinfection

Experiments similar to those carried out for methanol oxidation were performed for bacterial inactivation and the kinetic constants are shown in **table 2**. When considering the moles of photons (E) reaching the reactors the kinetic constant for UVC LED sources are five orders of magnitude higher, as expected from the selective DNA damaging mechanism. On the other hand, it was possible to verify how direct solar processes are much more efficient than UVA LED-based processes due to the remarkable effect of the UVB fraction of solar light. When referring to the electrical energy consumption, behaviour opposite to that previously described for methanol oxidation can be observed. Due to the great efficiency of UVC light in bacterial inactivation processes, and despite the poor electrical efficiency of UVC LED, the use of this type of radiation represented an energy improvement compared to the use of UVA LED. On the other hand, solar energy efficiency for bacterial inactivation showed that the use of the UVC LED+H_2O_2, powered by a PV system, allowed better use of solar radiation than the processes carried out in the CPC reactor. The sole use of UVC LED showed slightly worse results than the sole use of sunlight in the CPC reactor. However, it is necessary to consider that the electrical efficiency of UVC LED is increasing exponentially, so this result could be reversed very soon. On the other hand, the use of UVA LED for bacterial inactivation does not show these improvements and as seen in methanol oxidation, the use of direct solar light is more efficient. If the efficiency is calculated considering the cost results show an even more remarkable advantage of PV-UVC LED both with and without H_2O_2. Additionally, considering the costs, the use of PV-UVA LED with TiO_2 is now more profitable than the use of direct sunlight. These results highlight that the use of combined systems with PV+UV LED should already be considered when designing solar water disinfection systems.

Table 2. First-order kinetic constant for bacterial inactivation in the studied processes as a function of time, photons, energy consumption, solar UV radiation and investment cost.

	Photons	Energy	Solar UV radiation	Investment cost
UVA	$(1.01\pm0.10)\cdot10^{1}$	$(4.92\pm0.50)\cdot10^{-2}$	$(1.23\pm0.12)\cdot10^{2}$	$(3.69\pm0.37)\cdot10^{0}$
UVA + TiO_2	$(1.13\pm0.08)\cdot10^{2}$	$(5.65\pm0.33)\cdot10^{-1}$	$(1.38\pm0.10)\cdot10^{3}$	$(4.13\pm0.31)\cdot10^{1}$
UVC	$(2.39\pm0.48)\cdot10^{7}$	$(1.42\pm0.29)\cdot10^{0}$	$(3.54\pm0.71)\cdot10^{3}$	$(1.22\pm0.25)\cdot10^{2}$
UVC +	$(5.11\pm0.67)\cdot10^{7}$	$(3.04\pm0.40)\cdot10^{0}$	$(7.59\pm0.99)\cdot10^{3}$	$(2.62\pm0.34)\cdot10^{2}$
CPC	$(2.77\pm1.02)\cdot10^{2}$	-	$(5.52\pm2.04)\cdot10^{3}$	$(5.93\pm2.19)\cdot10^{0}$
CPC + TiO_2	$(2.97\pm0.55)\cdot10^{2}$	-	$(5.93\pm1.09)\cdot10^{3}$	$(6.37\pm1.17)\cdot$
CPC + H_2O_2	$(2.57\pm0.67)\cdot10^{2}$	-	$(5.13\pm1.34)\cdot10^{3}$	$(5.51\pm1.43)\cdot10^{0}$

Abstract

The capability of the combination of peroxymonosulfate (PMS) and natural solar radiation as a solar photochemical process for actual urban wastewater (UWW) purification at pilot plant scale has been investigated. A global analysis of the PMS (0-1 mM)/Solar process performance was assessed in a solar Compound Parabolic Collector (CPC) photo-reactor for simultaneous inactivation of naturally occurring bacteria and their antibiotic-resistant (AR) counterparts (*Escherichia coli*, Total coliforms, *Enterococcus* spp. and *Pseudomonas* spp.), the removal of selected antibiotic resistant genes (ARGs) (i.e., 16S rRNA, *intI1, sul1, qnrS, bla*$_{TEM}$, *bla*$_{CTX-M32}$, *tetM*) and the degradation of three contaminants of emerging concern (CECs) (Diclofenac-DCF, Sulfamethoxazole-SMX and Trimethoprim-TMP). An enhancement in the process performance was obtained with increasing oxidant load, obtaining the best results with 1 mM of PMS, at which the inactivation of naturally occurring bacteria and their AR-counterparts (Detection limit of 2 CFU/mL after 30 minutes, 2.6 kJ/L) was achieved, without observing bacterial regrowth after 48h. In addition, CECs (27 minutes, 2.0 kJ/L) were effectively degraded, but it was ineffective for ARGs removal. PMS/Solar process has been demonstrated to be an attractive, suitable and sustainable option as a decentralized system associated to a small volume of water in areas with a high solar radiation incidence, saving energy costs by using natural solar radiation.

Antibiotic Resistance; Compound Parabolic Collector; Contaminants of emerging concern; Peroxymonosulfate; Wastewater reclamation.

INTRODUCTION

The reuse of urban wastewater (UWW) in different activities, especially in agriculture, has been gaining attention as a reliable solution to address water scarcity, enhancing water balance, limiting water withdrawal from natural bodies (surface water and groundwater), promoting water savings according to the principle of circular economy, but also ensuring environmental and human health protection (Guerra-Rodriguez et *al.*, 2020). The microbiological quality of secondary UWW effluents does not fit the quality criteria for its direct reuse in irrigation, and, therefore, the application of tertiary treatments is needed to achieve the regulation requirements. Water remediation by peroxymonosulfate (PMS) alone has been considered a promising option, due to its characteristics, such as high water solubility, low cost, easily of storage and its capability to directly oxidize inorganic and organic compounds containing electron-rich moieties (Ding et *al.*, 2020).

In this work, the combination of PMS with natural solar radiation has been investigated at pilot plant scale for the simultaneous inactivation of naturally occurring bacteria (including *E. coli*, *Enterococcus* spp., *Pseudomonas* spp. and Total coliforms), their antibiotic-resistant (ARB) counterparts, the removal of naturally present antibiotic resistant genes (ARGs) and CECs spiked at 100 µg/L each, in UWW.

MATERIALS AND METHODS

Secondary effluents from the urban wastewater treatment plant (UWWTP) of "El Bobar" located in Almería, South East of Spain, were used. Each batch was freshly collected and physicochemical characterized. The enumeration and quantification procedures for bacteria, ARB, ARGs and CECs monitoring were performed as reported by Berruti et al. (Berruti et *al.*, 2021). All assays were performed at the installations of the Plataforma Solar de Almeria (latitude: 37.0909°N, longitude: 2.357°W), starting between 10:30-11:00 am local time and lasting 180 minutes under natural sunlight. Experiments were performed in a Compound Parabolic Collector (CPC) photoreactor with a total water volume of 10 L (50 % illuminated), which consists of a highly reflective anodized aluminium (MiroSun, Alanod, Germany) module and two independent systems with 2 borosilicate-glass tubes (50 mm), each one on a platform titled 37°, 0.44 m^2 of total irradiated surface and a flow rate of 30 L/min. Water temperature ranged between 22 to 39 ºC and solar UV-A irradiance between 25 to 45 W/m^2, while water pH was 8-8.5 in all cases, remaining constant along the treatment time. The accumulative energy per unit of volume (Q_{UV}, kJ/L) received in the photo-reactors was used to compare results under different experimental conditions (Berruti et *al.*, 2021).

RESULTS AND DISCUSSION

The inactivation profiles of the sum of all bacteria by PMS/Solar process with increasing oxidant concentrations (0-1 mM) at pilot plant scale (10-L CPC solar photo-reactor) are shown in Figure 1.

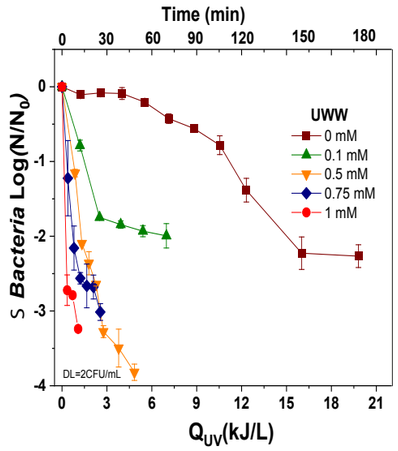

Figure 1. Inactivation profiles of the sum of all bacteria in the presence of increasing concentrations of PMS (0-1 mM) under natural solar radiation in UWW.

An enhancement in process performance was obtained as increasing oxidant concentrations and the best results were obtained with 1 mM, at which detection limit (DL) of 2 CFU/mL was reached for all microbial targets after 15 minutes (1.1 kJ/L of Q_{UV}), compared to 180 minutes with only solar radiation.

Moreover, the absence of bacteria regrowth was observed after 24 and 48 h in the presence of oxidant concentration higher than 0.5 mM, guaranteeing water safety during post-treatment storage.

Figure 2 shows the CEC profiles and a significant enhancement in comparison with only solar radiation (only 40 % of the total CEC removal after 180 minutes or 20 kJ/L of Q_{UV}) was obtained in the presence of added PMS. In addition, more than 80% removal of target CECs was attained with 1 mM after 27 minutes (2 kJ/L of Q_{UV}).

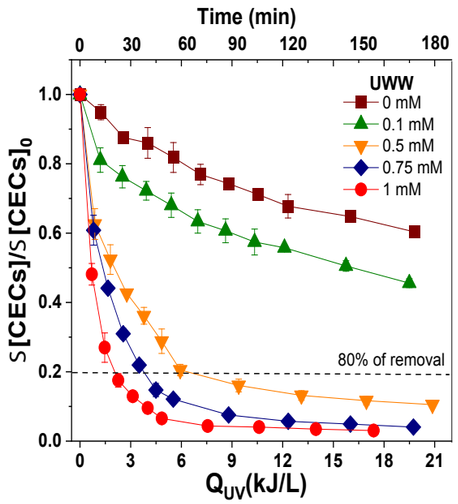

Figure 2. Degradation profiles of the sum of CECs in the presence of increasing concentrations of PMS (0-1 mM) under natural solar radiation in UWW.

In particular, the following CEC reactivity order was found: SMX (17 minutes, Q_{UV}= 1.2 kJ/L) > DCF (30 minutes, Q_{UV}= 2.3 kJ/L) > TMP (40 minutes, Q_{UV}= 3.2 kJ/L).

Moreover, inactivation of naturally occurring ARB, grown in the presence of sub-minimal inhibitory concentrations of three antibiotics (Ampicillin-AMP, Ciprofloxacin-CPX and Trimethoprim-TMP), was monitored in the presence of 1 mM of PMS. No significant differences in the inactivation of wild and AR-bacteria were observed, achieving the DL of 2 CFU/mL within 30 minutes of treatment for all microbial targets, in accordance with a previous study (Michael et *al.*, 2020).

Figure 3 shows ARGs removal in the presence of 1 mM of PMS under natural solar radiation in UWW.

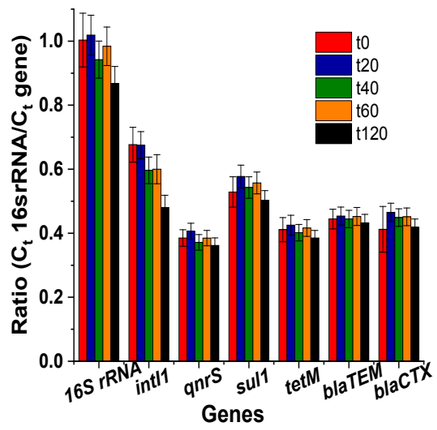

Figure 3. ARGs removal in the presence of 1 mM of PMS under natural solar radiation in UWW.

A decrease of 7 %, 13 % and 30 % was observed after 120 minutes of treatment (11.5 kJ/L of Q_{UV}) for *qnrS*, 16S rRNA and *IntI1*, respectively, while no significant changes in relative abundance were detected for the other genes, highlighting the resistance of this type of pollutants to be removed by this solar processes and being still a challenge to be addressed.

As conclusion, PMS/Solar process has been demonstrated to be an attractive, suitable and sustainable option for UWW reclamation and reuse in agriculture, especially as a decentralized system associated to small volumes of water in areas with a high solar radiation incidence, saving energy costs by using natural solar radiation.

Abstract

Thousands of people do not have access to a safe source of water and suffer from water-related diseases. Electrochemistry is a promising technology for decentralized and distributed water treatment. However, this water treatment usually leads to the formation of toxic by-products. In this study, graphene sponge electrodes were synthesized and employed for electrochemical water disinfection without the formation of toxic by-products. Two manganese oxide-based dopants, at two different concentrations of manganese oxide, were studied as anodes. 2-3 log removals of *Escherichia coli* were inactivated at 29 A m^{-2}. Storage experiments conducted with the treated samples demonstrated further inactivation of *E. coli* reaching 4.7 log removal, suggesting irreversible cell damage due to electroporation.

Keywords

Disinfection, electrochemistry, electroporation, reduced graphene oxide

INTRODUCTION

Clean drinking water is essential for the well-being of humans. The World Health Organization estimates that there are 829.000 deaths every year of diarrheal diseases caused by the lack of a safe source of water, sanitation and hygiene (World Health Organisation, 2017). Chlorination, ozonation and UV radiation are common techniques for water disinfection. However, they have important drawbacks: the first two generate toxic disinfection by-products (DBPs) and the latter can lead to microorganism reactivation and regrowth. Also, these systems are usually applied in centralized treatment plants and are not easy to apply on a smaller scale (Huo et al., 2020). Electrochemical systems have attracted attention because they enable a chemical-free water treatment, have a small footprint and modular design, and can be powered with renewable energies; hence, they are very well suited for decentralized water treatment. However, electrochemical disinfection using commercial anode materials is commonly achieved via electro-chlorination, which causes the formation of toxic chlorinated DBPs (Hand et al., 2021)"ISSN":"15205851","PMID":"33616403","abstract":"Electrochemical disinfection - a method in which chemical oxidants are generated in situ via redox reactions on the surface of an electrode - has attracted increased attention in recent years as an alternative to traditional chemical dosing disinfection methods. Because electrochemical disinfection does not entail the transport and storage of hazardous materials and can be scaled across centralized and distributed treatment contexts, it shows promise for use both in resource limited settings and as a supplement for aging centralized systems. In this Critical Review, we explore the significance of treatment context, oxidant selection, and operating practice on electrochemical disinfection system performance. We analyze the impacts of water composition on oxidant demand and required disinfectant dose across drinking water, centralized wastewater, and distributed wastewater treatment contexts for both free chlorine- and hydroxyl-radical-based systems. Drivers of energy consumption during oxidant generation are identified, and the energetic performance of experimentally reported electrochemical disinfection systems are evaluated against optimal modeled performance. We also highlight promising applications and operational strategies for electrochemical disinfection and propose reporting standards for future work.","author":[{"dropping-particle":"","family":"Hand","given":"Steven","non-dropping-particle":"","parse-names":false,"suffix":""},{"dropping-particle":"","family":"Cusick","given":"Roland D.","non-dropping-particle":"","parse-names":false,"suffix":""}],"container-title":"Environmental Science and Technology","id":"ITEM-1","issue":"6","issued":{"date-parts":[["2021"]]},"page":"3470-3482","title":"Electrochemical Disinfection in Water and Wastewater Treatment: Identifying Impacts of Water Quality and Operating Conditions on Performance","type":"article-journal","volume":"55"},"uris":["http://www.mendeley.com/documents/?uuid=16685472-f27d-43e2-b8af-1a58267382e3"]}],"mendeley":{"formattedCitation":"(Hand and Cusick, 2021. The formation of DBPs as well as other chlorinated organic byproducts and highly persistent chlorate and perchlorate, has been a major bottleneck not only of electrochemical disinfection but of electrochemical water and wastewater treatment overall, as chloride is a naturally occurring anion that gets rapidly oxidized at the anode.

To address these shortcomings of commercial electrodes, we have recently developed a low-cost graphene sponge electrode with record low electrocatalytic activity towards chlorine formation (<0.04% of current efficiency in 20 mM NaCl). Furthermore, graphene sponge anode does not form any chlorate and perchlorate (Baptista-Pires et al., 2021). It has shown excellent performance in the degradation of persistent organic pollutants such as PFAS (Duinslaeger et al., 2022), antibiotics (Ormeno-Cano et al., 2022) and the inactivation of *Escherichia coli (E. coli)* ATCC 700078 (Norra et al., 2021). In this study, we synthesised manganese oxide-doped graphene-based sponges and applied them as anodes for the electrochemical disinfection of a resistant strain of *E. coli* (ATCC 25922) in tap water. Manganese-based oxides are very attractive for environmental applications due to their excellent catalytic activity, low-cost and earth abundance. (Zhu et al., 2019) We evaluated the impact of the applied current density on the inactivation of *E. coli*, and their potential re-activation during storage after the electrochemical treatment.

MATERIALS AND METHODS

Graphene sponges were synthesized with a simplified hydrothermal method (Baptista-Pires et al., 2021), where a mineral wool template is coated with reduced graphene oxide (RGO) and a dopant. We tested two types of dopants, manganese oxide (Mn_xO_y) and amino-doped manganese oxide (Mn_xO_y-NH_2), at two different concentrations. The cathodes were nitrogen-doped RGO, as N-doping was found to enhance the production of hydrogen peroxide and its activation to hydroxyl radicals (Farzaneh et al., 2016). The sponges were connected to current feeders and employed for the disinfection in a one-pass, flow-through reactor, using real tap water spiked with 10^7 cfu mL^{-1} of *E. coli 25922*. Samples were taken in open circuit (OC) and galvanostatic mode at three applied current densities, (14, 20 and 29 A m^{-2}). The abundance of the bacteria was determined by membrane filtration using serial dilutions of the samples and Chromocult Coliform Agar. Samples were stored 18 hours at 25 and 37ºC and after, assessed to analyze the potential bacterial regrowth.

RESULTS AND DISCUSSION

Figure 1 shows the electrochemical inactivation of *E. coli* in tap water for the four synthesized graphene sponge anodes, i.e., Mn_xO_y and Mn_xO_y-NH_2 at low and high concentrations. Doping of Mn_xO_y with NH_2 was done to obtain strong covalent bonds between the oxide and RGO, which could enhance the electrochemical performance. (Xu et al., 2019)which is applied extensively in water treatment for disinfection, odor removal and organic pollutants degradation. To improve the performance of catalytic ozonation, we design and synthesize a catalyst of amino-functionalized hybrid of MnO2 and graphene oxide (MnO2-NH2-GO Approximately 0.7 log removal of *E. coli* was achieved in the OC with all four materials, due to the oxidative and membrane stress caused by the RGO coating (Liu et al., 2011)we compared the antibacterial activity of four types of graphene-based materials (graphite (Gt. The inactivation of *E. coli* increased with the application current. Stepwise increase in current density from 20 to 29 A m^{-2} yielded, for the "High Mn_xO_y" anode, an increase in removal from 1.5 to 2.7 log, respectively. After the current was switched off and the reactor returns to the OC mode, the effluent concentration of *E. coli* returned gradually to the initial values. This demonstrated that the removed *E. coli* were inactivated and not simply electrosorbed, which would lead to their accumulation and rise in the final OC concentrations above the initial values. The best-performing anode was the "High Mn_xO_y", which achieved 2.7 log removal at 29 A m^{-2}.

Storage of the electrochemically treated samples for 18 hours at 25 and 37ºC led to further inactivation of *E. coli* (**Figure 2**). This demonstrated that the chlorine-free electrochemical treatment caused irreparable damage to the cell walls of *E. coli*. The highest overall removal (i.e., due to treatment and posterior additional inactivation during storage) was observed for the highest current density (29 A m^{-2}), at the higher storage temperature (37 ºC), reaching 4.7 log removals. Higher quantities of Mn_xO_y-based dopants lead to overall higher inactivation due to having more catalytic active sites. The main mechanism of inactivation was electroporation, as observed by the scanning electron microscopy (SEM) of the treated cells (**Figure 3**). Electroporation is based on the formation of pores in the cell membrane, causing leakage of the intracellular material and cell inactivation (Liu et al., 2013)affordable, and low energy water disinfection methods are in great need to prevent diarrheal illness, which is one of the top five leading causes of death over the world. Traditional water disinfection methods have drawbacks including carcinogenic disinfection byproducts formation, energy and time intensiveness, and pathogen recovery. Here, we report an innovative method that achieves high-efficiency water disinfection by introducing nanomaterial-assisted electroporation implemented by a conducting nanosponge filtration device. The use of one-dimensional (1D. Furthermore, electrogenerated oxidants such as ozone, hydrogen peroxide and hydroxyl radicals were measured in the solution and also contributed to the inactivation of bacteria (Rahmani et al., 2019).

CONCLUSIONS

Manganese oxide-doped reduced graphene oxide sponges inactivated *E. coli* without the formation of toxic chlorinated by-products. The "High Mn_xO_y" anode achieved a 2.7 log removal of *E. coli* at 29 A m^{-2}, whereas storage of the treated samples led to further inactivation and overall removal of 4.7 logs, demonstrating that the electrochemical treatment is causing irreparable damage to the cell walls. This study demonstrates that the low-cost graphene-based sponges doped with manganese oxide could be feasible for point-of-use electrochemical disinfection for water. Studies in the treatment of organic contaminants in real second effluent waters will be performed.

Abstract

LIFE RECYCLO project aims at setting up a technical solution for the treatment of laundry effluents and water recycling. The present work describes laboratory tests carried out to size this treatment solution and to validate the operating parameters for 3 laundries. This solution includes a coagulation/flocculation step allowing the removal of particulate pollution and about 50% of the COD (initial =0.8-1.2 g/L). A UV/H_2O_2 treatment allows the removal of organic micropollutants and to reach a COD of 200 mgCOD/L (50-70% removal). Finally, adsorption on activated carbon allows to reach a COD of 100 mgCOD/L (50% removal) and to eliminate metals. The overall COD removal is 95 %. This treatment solution has been validated and the deployment of prototypes in 3 laundries is underway. A follow-up of the performance of the prototypes will be carried out for one year to ensure a treated water of sufficient quality to be recycled.

Keywords

Adsorption, Advanced oxidation process, Coagulation flocculation, Laundry, Water recycling

INTRODUCTION

Water is an essential resource for the economies of both industrialised and developing countries. With climate change, more and more regions will be constrained by water scarcity, which could eventually reduce the economic activity of industrial sectors, specifically large water consumers (Van Vliet et al., 2021). Moreover, agricultural, industrial, or urban activities result in the discharge of many emerging pollutants and pathogens into the environment (Schwarzenbach et al., 2006).

The EU laundry industry is a large water consumer with an estimation of 21 L/kg of dry textile (Gooijer et al., 2016). In the EU there are about 11,000 laundries, washing 2.7 billion kg of textiles annually, and using as much as 42 Mm^3 of water per year (Hloch et al., 2012). Moreover, laundries are an emission source of priority substances falling under the Directive 2013/39/EU such as nonylphenols, phthalates (DEHP), PAH and heavy metals with concentrations from ng/L to mg/L (Braga et al., 2014).

Recycling wastewater in laundry is therefore an ideal solution to limit the water consumption, the discharge of emerging pollutants that have an impact on the environment and health and to reduce the cost of water for the laundries (Kumar et al., 2022). Moreover, it sustains access to water for industries.

LIFE RECYCLO is improving water reuse systems by demonstrating the environmental, technical and economic feasibility of recycling laundry wastewater using an innovative advanced oxidation process (AOP) by UV/H_2O_2 combined with a pre-treatment by coagulation/flocculation and a post-treatment by adsorption on activated carbon. A patented 200 L/h pilot will be scaled-up to a pre-market ready prototype. LIFE RECYCLO will offer a water recycling solution to the small and middle size laundries (1 m^3/h to 10 m^3/h). The 3 laundries involved as partners will become a showcase for the textile sector by demonstrating that the system works for different sizes and different wastewater qualities. The results of this paper present the laboratory tests that validated the operating parameters of coagulation/flocculation, AOP and adsorption. These parameters will be used to operate the future prototypes implemented on the 3 laundries.

MATERIALS AND METHODS

Sampling and analysis:

Automatic samplers were set up in 3 laundries: BSJ (France, flow rate = 4m^3/h), KLIN (Luxembourg, flow rate = 2 m^3/h), GRUPFRN (Spain, 0.5 m^3/h). A 24h representative wastewater sample was sampled and homogenized. COD, BOD, TOC, TSS, salts, cationic and anionic surfactants analyses were performed at Treewater lab (DEEP Laboratory – INSA Lyon) as well as metals. All other parameter were analyzed by accredited external laboratories. The results obtained on the raw samples are available in the Table 1.

Pre-treatment by coagulation flocculation:

Lab scale tests were performed to identify a couple of coagulant and flocculant with the highest TSS and COD removal rate. Six Beakers were filled with 200 mL of laundry effluent and mixed at 200 rpm. Then 6 different concentrations of coagulation were injected (from 0.1 to 2.5 mL/L). After waiting time, flocculant concentration (from 0.5 to 3 mL/L) was injected and mixing was decreased to 15 rpm. Mixing was stopped and settling was observed. COD, TSS and pH were analyzed in the supernatant. The best concentration corresponded to the best floc formation and settling as well as turbidity removal. The amount of sludge was also measured to calculate the sludge production rate.

Treatment by H_2O_2/UV:

Advanced oxidation tests were performed to evaluate the degradation efficiency of the H2O2/UV. The tests were performed on a lab-scale pilot with volumes of 3L per test using a 24W low pressure lamp (254 nm). Different UV fluence and hydrogen peroxide concentrations were studied to define the optimal treatment parameters (ratio COD/H_2O_2). The effluent was recirculated in a UV cell for a given time accumulating UV exposure. A defined concentration of H_2O_2 was injected at time zero. COD_t conductimetry, pH and transmittance as well as H_2O_2 consumption were monitored to verify the efficiency.

Post-treatment by adsorption:

Three tests were performed to select the best activated carbon (AC) and determine its COD adsorption capacity:

- A) Adsorption kinetics: to define the maximum performance of different ACs at a given concentration. Six references of AC and biochar (biosourced AC) were tested in parallel: Filtrasorb 400, CycleCarb201, CSC5, GBC 8x30, Terra, Carbo. This test allowed us to identify the best performing reference in terms of improvement of the UV-C transmittance.

The effluent treated by H_2O_2/UV was injected in 6 beakers (500 mL), then mixed at 200 rpm with a reference of AC in each beaker at 30 gCA/L. The duration (contact time) of the test was about 22h, and 4 sample were collected in each beaker to follow pH, conductimetry, and COD.

- B) Isotherm: to determine the maximum loading rate and to pre-select a granular activated carbon, an isotherm of Freundlich is often applied. Several 500 ml beakers were filled with effluent (5 + 1 blank) and AC were added at different concentrations (0.5 to 50 g/L) and mixed continuously at 200 rpm for 18 hours to reach the adsorption equilibrium. Temperature, COD, UV transmittance, and pH were measured at t-0 and t-final.

-C) Dynamic column with CycleCarb201: The column test allows to get closer to a real treatment configuration and to establish a pre-sizing of an activated carbon reactor. This column is continuously fed with a volume of effluent (up to 6 L) with a hydraulic residence time of about 25 min. COD_t, transmittance and metals are measured at the column outlet.

RESULTS AND DISCUSSION

Pre-treatment by coagulation flocculation:

Alopolym 698 (based on cationic polymer, aluminium compound, and iron trichloride) and 632 AP (polymer) were the coagulant and flocculant referent with the best efficiency on the 3-laundry effluents. The selected coagulant concentration was about 0.25 mL/L for BSJ and GRUPFRN, and 0.5 mL/L for KLIN. Flocculant concentration was more variable, with 1.25 to 2.5 mL/L depending on the laundry. Supernatant presented higher UV transmittance, with 43%, 70% and 52% on BSJ, KLIN, and GRUPFRN, respectively, and TSS < LQ. This treatment step was able to remove TSS, turbidity and matter that decreased UVT_{254}. COD removal was 58%, 48% and 45% on BSJ, KLIN, and GRUPFRN, respectively.

Treatment by H_2O_2/UV

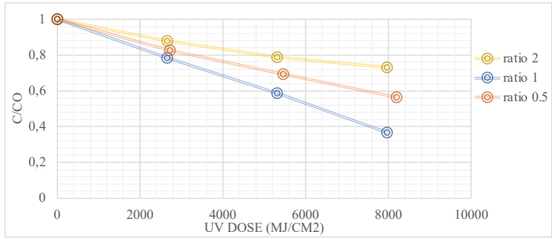

Figure 1 : Evolution of COD (C/C_0) during UV/H_2O_2 treatment of BSJ effluent with different hydrogen peroxide concentrations corresponding to COD/H_2O_2 ratio

The BSJ kinetics tests showed a linear trend for all the COD/H_2O_2 ratio (Figure 1). This reflected a good and constant degradation of organic compounds and no lack of H_2O_2. The degradation coefficients were variable, with the highest at 1 gCOD/gH_2O_2. Higher COD/H_2O_2 ratio was ineffective, with lower COD removal (28%) and lower H_2O_2 consumption (60%). Lower ratio involved higher COD removal with an optimum at 1 gCOD/gH_2O_2 with COD removal of around 44 to 66% (mean of 50%) and final COD is about 200 mgCOD/L. The BSJ tests were replicated on KLIN and GRUPFRN (after coagulation/flocculation treatment). Considering kinetics on each effluent as well as economic considerations, COD removal by AOP has been set at 50 %. The UV Fluence, used to size the UV reactor of the final process was in the range from 8,000 to 10,000 mJ/cm^2 with an associated COD/H_2O_2 rate of 1 gCOD/gH_2O_2.

Post-treatment by adsorption:

Four different AC were tested on the wastewater of the three laundries after AOP treatment to select the best AC reference. CycleCarb201 had clearly the highest COD removal among the AC references. The lowest was La Carbonnerie, which is a non-activated bio-AC. With CycleCarb201, the COD removal was already 45% after 1 h of contact for BSJ and similarly for KLIN and GRUPFRN effluents. CycleCarb201 is a re-activated carbon and has been selected for the 3 laundries. The second step was to determine the loading rate of CycleCarb201 on each effluent. To do so, Freundlich Isotherms were conducted. The calculated maximal loading rates were 223 mgCOD/gAC for BSJ, 343 mgCOD/gAC for KLIN and 220 mgCOD/gAC for GRUPFRN. The sizing of the adsorption step was calculated considering a COD removal of 50 to 60% and an outlet COD concentration targeted of 100 mgCOD/L. This reference value was determined in previous tests and allowed the washing of laundry with sufficient quality. KLIN had the highest loading rate, resulting in a more compact reactor AC volume. The reactor will have to be changed at saturation. Each reactor of AC is sized to be changed once a year.

Performance of the overall process

Laboratory tests with BSJ effluent evaluated the abatement performances on a list of physicochemical parameters and pollutants (Table 1). The results showed excellent removal rates with more than 90% removal of organic and inorganic micropollutants except for aluminum probably due to the contribution of this metal via the coagulant/flocculant. No significant AOX removal was observed. Further studies are needed as good results were obtained on other types of effluent with AOP technology. 95% of the initial COD and 100% TSS were removed. The selected coagulant contains chlorides and therefore an increase was observed. A resin treatment step or the adaptation of the recycling rate is under study. All these results show that the treated water is of very good quality and could be recycled and reused in the laundry washing water. The monitoring of the quality of the linen washed by the water treated by the prototypes will allow to verify this point.

Table 1: Assessment of the physico-chemical parameters of the BSJ laundry effluent before and after the treatment solution by Coagulation/flocculation, AOP, and adsorption

Parameter	Units	Raw water KLIN	Raw water GRUPFRN	Raw water BSJ	Treated water after AC (BSJ)	Removal (%)

Conclusion

LIFE RECYCLO will offer a water recycling solution to the small and middle size laundries. The work presented here has validated the proposed technical solution to obtain a water quality compatible with its reuse. The technical solution is composed of a pre-treatment by coagulation/flocculation, a UV/H_2O_2 process and a post-treatment by adsorption on activated carbon. This technical solution has achieved the LIFE RECYCLO objectives of reducing by at least 90% the emission of pollutants. Further studies are needed on AOX abatement performance. The next step of the LIFE RECYCLO project is to set up three prototypes in each laundry and to carry out a performance monitoring over one year.

ACKNOWLEDGMENT

The authors would like to thank all the partners of the LIFE RECYCLO project, especially Pop'Sciences and the 3 laundries (BSJ, GRUPFRN and KLIN). This work was financed by the LIFE Programme. Abstract

This study presents a novel short process consisting of a membrane-based pre-concentration (MPC) module and a reverse osmosis (RO) module. In MPC unit, municipal wastewater (MW) was directly filtrated by a submerged microfiltration module (HRT<1 h, SRT 2-4 days & flux 8-10 LMH), creating a particulate-free permeate and a concentrated organic stream. The permeate was then fed into the RO module (recovery rate of 75%-80%) for water reclamation. The high-concentration organic stream was then redirected into methane production system for energy recovery. A pilot-scale dual membrane system with a treatment capacity of 400 t/d was operated stably for over one year in Beijing. The advantage of this system included: 1) the organic energy was utilized in methane production rather than being mineralized in aerobic degradation; 2) the direct filtration of MW was stabled with the assistance of fouling control methods and therefore the footprint of the complete process is significantly reduced.

Keywords

Energy recovery; Reduced footprint; Water reclamation

INTRODUCTION

Rebranding as integrated resource factories is high on the agenda of the wastewater treatment plants (WWTPs). The membrane-based pre-concentration (MPC) is regarded as a promising approach to recovering organic resources in municipal wastewater (MW). The purpose is to extract the organics before it enters the subsequent treatment processes and redirects them to resource recovery units, such as anaerobic digestion (AD).

Generally, recent focuses in MPC research included: 1) the membrane fouling control, which is a prerequisite for MPC stability, 2) the effluent quality and corresponding subsequent treatment choices, and 3) the quality of recovered organics, usually in terms of methane production capacity.

Based on above background, this study established a pilot-scale MPC-RO system with a treatment capacity of 400 t/d. Main purpose including: 1) testing the effectiveness of fouling control methods combination proposed by our research team earlier on a demonstration scale, 2) investigating the characteristic of MPC effluent and the influence of operating parameters, 3) verifying the feasibility of MPC permeate as RO feed water and the operation performance of RO, and 4) evaluating the stability and technical-economic feasibility during long-term operation over one year.

MATERIALS AND METHODS

The pilot-scale MPC-RO system was in an MW WWTP in northern China. Fig. 1 presents the configuration and photos of the pilot plant. The detail configuration was similar with our previous report (He et al., 2022, 2023). The membrane fouling control methods tested in the MPC plant included on-site coagulation, adsorption, and surface aeration. Table 1 provides detailed operation information. RO system consisted of a security filter (5 μm), a high-pressure pump with variable frequency, a membrane module (18 Dupont Film Tec™ Fortilife™ CR100), a chemical dosing system, and a cleaning in place (CIP) system. The water recovery rate was 75-80% and neither permeate nor concentrate was recycled to the RO feed tank. The flux ranged between 17-18 L/m²/h (LMH).

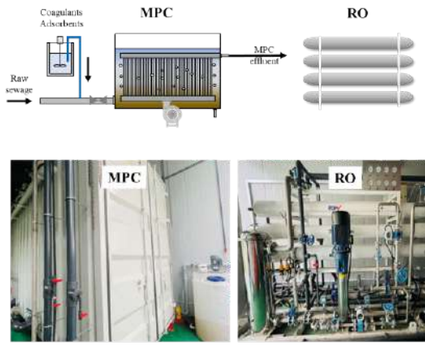

Figure 1. The configuration and photos of the pilot-scale MPC-RO system.

Table 1. Working conditions in the pilot-scale CE-HLMBR

Stages	SRT (Day)	PAC (mg/L)	AC (mg/L)	Aeration strength (%)
C1	4	25	25	100
C2	2	25	25	100
C3		25	0	100
C4		25	25	100
C5		0	25	100
C6	3	25	25	75
C7		25	25	50
C8		25	25	25

RESULTS AND DISCUSSION

The fouling control performance in MPC unit (Fig. 2)

Submerged filtration (8-10 LMH) was stable at SS concentrations of 15-20 g/L. The combination of chemicals and aeration was effective and either one was essential. Coagulation and adsorption have a synergistic effect in two ways: 1) promoting shedding ability and compression resistance of the cake layer and 2) reducing the SMP and especially the carbohydrate concentration. Aeration provided the necessary shear force.

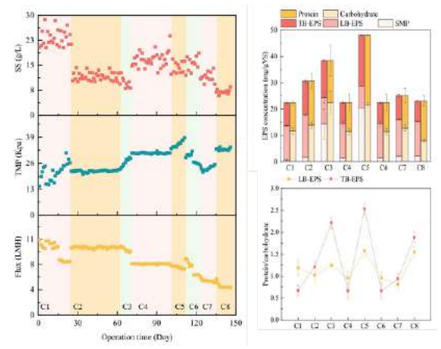

Figure 2. The filtration performance and EPS concentration in 8 stages.

The pollutant removal performance in MPC unit (Fig. 3)

Over 75% soluble organics and 80% sTP were removed in MPC unit via chemical precipitation, adsorption, and bio-degradation pathways. Both nitrification and denitrification occurred simultaneously due to uneven oxygen distribution. Effluent quality, activity tests, and functional microbial analysis all confirmed that nitrogen conversion occurred at 2-3 days SRT. Besides, in another work by our team, the biomethane production from concentrated organic matter was studied.

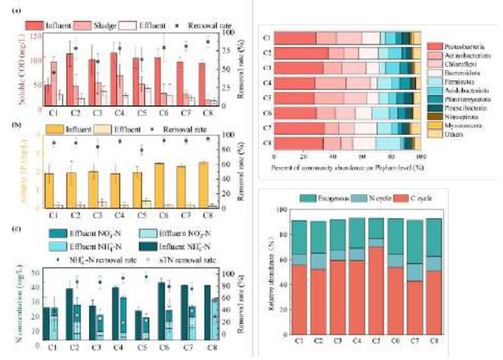

Figure 3. The pollutant removal performance and microbial community in 8 stages.

The performance of RO unit (Fig. 4)

Once the MPC conditions had stabilised, the RO was tested for over 300 days. RO showed a strong removing capacity, with a water recovery rate of 75%–80%. COD, TP, and NH_4^+-N were not detectable in RO effluent. The TOC was below 0.4 mg/L and the conductivity was below 30 μS/cm, which met the NEWater standard in Singapore and environmental quality standards (Class IV) for surface water in China. This study confirmed the feasibility of RO fed with MPC effluent. The changes in the pressure were subjected to a two-stage pattern: an initial negligible rising in 0–60 days followed by a rapid jump (0.15 bar/day) in 60–90 days. CIP was effective that the TMP returned to the low value. Besides, it should be noted that Al^{3+} deposition was observed on the RO membrane surface. Special attention needs to be paid to MPC coagulant overdosing in future studies.

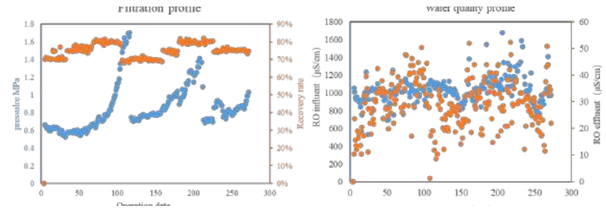

Figure 4. The filtration and water quality profile of RO unit in 300 days.

The technical-economic assessment of the combination system (Fig. 5)

The practical feasibility of "MPC-RO" has been confirmed. Therefore, an integrated "MPC + RO + AD" system for synchronous water-energy reclamation from MW was proposed here. The total energy consumption could be calculated as 0.619 kWh/m³. Considering the electricity recovery potential of AD, the net energy consumption would be as low as 0.273 kWh/m³. The operating costs for MPC and RO were estimated as 1.132 CNY/m³. Considering the typical energy consumption of an MBR-RO system (0.7 kWh/m³) and the price of ultrapure water in China (7.90 CNY/m³), the competitiveness of this proposed new system was emphasized. Compared with traditional double membrane systems such as "conventional activated sludge (CAS) + ultrafiltration + RO" and "MBR + RO". The whole traditional treatment process, including CAS, primary and secondary sedimentation tank, could be compressed into MPC with very short HRT (about 1 hour). Thus, the footprint will be greatly reduced.

Abstract

In this study, the removal of diclofenac (DCF) was evaluated by using UV-B and UV-C light-emitting diodes (LEDs) alone and in combination with hydrogen peroxide (UV/H_2O_2) and chlorine (UV/Cl). The kinetics followed a pseudo-first-order degradation, and their trend reflected the pattern of the molar extinction coefficients of the DCF and the oxidants, showing great potential for implementing LEDs in water treatments. The UV-LED driven AOPs were superior to the photolysis or the oxidation treatment alone, also confirmed by studies at different intensities. Nevertheless, the electrical energy per order parameter was slightly higher when using the oxidants. Finally, DOC analysis and phytotoxicity assessment were performed to evaluate the by-products' recalcination and potential toxicity.

Keywords

Advanced Oxidation Processes (AOPs), Chlorine, Degradation, Hydrogen Peroxide, Photolysis

INTRODUCTION

In the big challenge of water contamination, contaminants of emerging concerns (CECs) in treated water pose a risk to the safety of the environment and the health of human beings (Villanueva et al., 2014). UV-based light-driven Advanced Oxidation Processes (AOPs) exploit the generation of highly reactive radicals, and they are considered one of the most effective emerging technologies for environmental remediation (Rodriguez-Narvaez et al., 2017). However, a significant drawback is the use of mercury lamps (MPs) since mercury is a hazardous material for the environment and human health and requires a proper disposal protocol. Therefore, a major contribution to UV treatments can be made by the advances in light-emitting diodes (LEDs) in the UV-B and UV-C range. They provide a mercury-free solution other than high design flexibility, tuneable wavelength, and instant on-off. For the AOPs choice, a recent work (Pesqueira et al., 2022) assessed the life cycle impacts of UV-C combined with hydrogen peroxide (H_2O_2), peroxymonosulfate (PMS), and persulfate (PS), and it revealed that H_2O_2 was the best environmental choice. On the other hand, UV/chlorine is an emerging AOP and has become increasingly popular thanks to its low cost and since it is already used in water as a disinfection agent against re-contamination (Wang et al., 2017). Therefore, this study aims to evaluate the efficiency of UV/H_2O_2 and UV/Cl treatment by means of UV-B and UV-C LEDs, by tuning the working wavelength and the intensity to optimise the absorption of the pollutant and the oxidant. Finally, among the CECs, diclofenac (DCF), a non-steroidal anti-inflammatory drug, was selected for the optimisation of the system since it has been added to the first EU Watch List under the Environmental Quality Standards Directive, and it has been detected up to µg/L in water bodies (Sousa et al., 2019).

MATERIAL AND METHODS

Analytical methods

The detection and quantification of DCF were conducted through high-performance liquid chromatography (HPLC) with a reverse C18 column. The optimised mobile phase was acetonitrile and 25 mM phosphate acetate buffer (pH 3) in a ratio of 80:20 v/v. The flow was set to 1 mL/min and the injection volume to 5 µL, the pressure constant at 45 bar and the thermostat at 25 °C. Dissolved organic carbon (DOC) was measured with a TOC-VCPH analyser, and the phytotoxicity was tested for the *Raphanus sativus* (radish) and *Solanum Lycopersicum* (tomato) seeds and evaluated through the germination index (*GI*).

Photoreactor set-up

The reactor employed in the study is shown in Figure 1, where a PID controller was implemented in the Arduino code to work at a constant flow rate. The photoreactor consisted of a quartz tube where the LED lamp was positioned at around 2 mm from the outer diameter of the quartz tube. Chemical ferrioxalate actinometry experiments were carried out as described in the literature (Bolton et al., 2011) to calculate the total irradiation power of the lamps in the system, resulting in 21.98 ± 0.43, 31.18 ± 0.06, and 27.62 ± 0.61 mW/cm² for 265, 285, and 310 nm, respectively.

RESULTS AND DISCUSSION

DCF followed, in all cases, a pseudo-first-order kinetic, which can be described as a function of time (Eq.1) or UV fluence (Eq. 2) and considering the active volume of the reactor (V_R) over the total volume (V_T).

$$\ln\left(\frac{C}{C_0}\right) = -k_{obs,t}\cdot t \ln\left(\frac{C}{C_0}\right) = -k\cdot t\cdot\frac{V_R}{V_T}$$
$$\ln\left(\frac{C}{C_0}\right) = -k\cdot t\cdot\frac{V_R}{V_T} \quad \textit{Eq.1}$$

$$\ln\left(\frac{C}{C_0}\right) = -k_{obs,UV_{fluence}}\cdot UV_{Fluence}$$
$$\ln\left(\frac{C}{C_0}\right) = -k'\cdot UV_{Fluence,T}\cdot\frac{V_R}{V_T} = -k'\cdot UV_{Fluence}$$
$$\ln\left(\frac{C}{C_0}\right) = -k'\cdot UV_{Fluence,T}\cdot\frac{V_R}{V_T} = -k'\cdot UV_{Fluence} \quad \textit{Eq.2}$$

Figure 2 illustrates the degradation of DCF with respect to time and UV fluence via direct photolysis, dark oxidation, and UV-driven AOPs. A removal dependency on the wavelength was found in agreement with the extinction coefficient of the DCF and the oxidant employed, which are shown in Table 1. In almost all cases, except for the 310 nm/H_2O_2, a synergistic effect, measured following Eq. 3, was reached when coupling the UV treatment with the oxidants, Figure3.

$$F_S = \frac{k_{obs,combination}}{k_{obs,LED}+k_{obs,oxidant}} F_S = \frac{k_{UV/oxidant}}{k_{UV}+k_{oxidant}} F_S = \frac{k_{UV/oxidant}}{k_{UV}+k_{oxidant}}$$
Eq. 3

The electrical energy per order (E_{EO}), defined as the electric energy in kWh needed to degrade one order of magnitude of the pollutant in 1 m³ of water, was measured according to Eq. 4.

$$E_{EO} = \frac{P\cdot t}{V\cdot\log\left(\frac{C_0}{C}\right)} E_{EO} = \frac{P\cdot t}{V\cdot\log\left(\frac{C_0}{C}\right)}$$

Despite the higher degradation rate, the electricity demand is similar in almost all cases since the equivalent electric energy consumption to produce the oxidants was also considered. For the UV treatment alone, it was 0.61, 0.58, 0.85 kWh.m^{-3}.order^{-1}. respectively, for 265, 285, and 310 nm. When combined with chlorine, the total E_{EO} was 0.64, 0.56, 0.74 kWh.m^{-3}.order^{-1}, while during the UV/H_2O_2 process, it was 0.62, 0.65, and 1.11 kWh.m^{-3}.order^{-1}.

The DOC decreased only partially by 20-30%, regardless of the degradation process used; it can be concluded that the by-products might be more recalcitrant than DCF itself. Nevertheless, the phytotoxicity studies showed a decrease in toxicity towards tomato and radish seeds; however, the resulting *GI* value was still below the safe phytotoxic value.

CONCLUSIONS

In this study, DCF removal via photolysis alone and coupled with chlorine or hydrogen peroxide was assessed by investigating the advantages of applying different wavelengths. Tuning the wavelength considering the absorption spectra of the contaminants and the oxidants have high potential in water treatments. As expected, in almost all cases, the UV-LED-driven AOPs were superior to the photolysis or the oxidation treatment alone, but the overall treatments have similar energy costs. By-product removal was not achieved completely, and further treatment might need to be implemented for the complete DCF's by-product degradation.

Abstract

The combination between wetlands and raceway pond reactor (RPR) with the addition of hydrogen peroxide (H_2O_2) under natural solar radiation as advanced solar tertiary treatment for urban wastewater (UWW) simultaneous disinfection and decontamination at pilot plant scale has been investigated to determine the optimal water purification conditions for a further test at demonstrative scale. The contaminants of emerging concern (CECs) adsorption/degradation along the wetlands was 88% of average at ng/L concentration level. As a second step, disinfection results for *E. coli* and *Enterococcus* spp. in the RPR, showed that the most efficient oxidant concentration was 25 mg/L of H_2O_2 (<10 CFU/100 mL after 30 minutes, 0.57 kJ/L and 120 minutes, 2.7 kJ/L, respectively). In addition, two different RPR heights were also evaluated (10 cm and 15 cm), preliminarily concluding that the use of higher height was not detrimental, allowing the treatment of higher volumes of water. This combined system has been demonstrated to be an attractive and eco-sustainable alternative to treat large volumes of UWW secondary effluents by using nature based solutions and natural solar radiation.

Contaminants of emerging concern; Hydrogen peroxide; Raceway Pond Reactor; Water purification; Wetland system.

INTRODUCTION

The Mediterranean Region is characterized by great water stress and scarcity due to climate change and high water consumption in the agricultural sector. Therefore, the reuse of treated urban wastewater (UWW) is currently considered one of the most promising and suitable water sources to mitigate these problems. Conventional urban wastewater treatment plants (UWTPs) are poorly effective in the removal of contaminants of emerging concern (CECs), pathogenic microorganisms, antibiotic resistant bacteria and genes (ARB and ARGs) and disinfection by-products (Rizzo et al., 2020). Therefore, it is necessary to implement new integrated wastewater technologies that allow improving the quality of water for reusing purposes (Christou et al., 2017). A highly attractive solution are natural based solutions such as wetlands as they are a simple, profitable and low-cost technology, where the purification of pollutants is carried out by natural processes (Haghshenas-Adarmanabadi et al., 2016). The interactions of wetland plants, microorganisms and substrate media allow for obtaining an efficient, eco-sustainable and low-cost reclamation system when compared to conventional wastewater treatment processes (Abuabdou et al., 2020).

On the other hand, solar photochemical processes for the tertiary treatment of UWW have been receiving increasing attention as sustainable and green options (Berruti et al, 2022) and their high efficiency in raceway pond reactors (RPRs), extensive non-concentrating photoreactors, which allow large volumes of water to be treated (Cabrera-Reina et al., 2021). Therefore, combination of solar processes with a wetland system can be an interesting solution to comply with the new 22020/741 EU regulation on minimum requirements for water reuse. This regulation will enter into force in June 2023 and it establishes that the turbidity must be less or equal to 5 NTU and *E. coli* must be at the legislative limit (LL) less or equal to 10 CFU/100 mL.

The aim of this work is to investigate and optimize the advanced solar tertiary treatment based on H_2O_2 and natural sunlight at pilot plant scale (60 and 90 L) for further validation at a demonstrative scale. The DEMO plant consists on an already installed vertical wetland followed by a horizontal one finally connected to a raceway pond reactor (RPR) for wastewater reuse in the urban wastewater treatment plant (UWWTP) of "Blanca" in Murcia, South East of Spain (Figure 1).

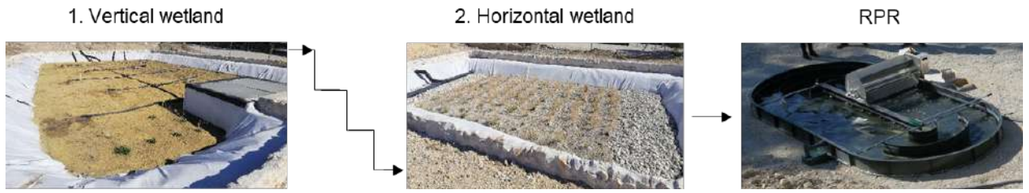

Figure 1. Demonstration system of natural based solutions coupled with advanced solar tertiary treatment in Murcia, Spain.

MATERIALS AND METHODS

Preliminary tests were carried out in a RPR pilot plant under different operating conditions. Three different concentrations of H_2O_2 (25, 50 and 100 mg/L) and two different water column heights in the RPR (10 and 15 cm, 60 L and 90 L of total volume of water, respectively) were tested. Actual secondary effluents from the UWWTP of "Blanca" in Murcia, South East of Spain, were used as a water matrix. In particular, the wastewater effluent from the entrance of the vertical wetland (EVW) and from the outlet of the horizontal wetland (OHW) were used and characterized. A total of 223 CECs along the wetlands were monitored by using an Exion AC UHPLC system (AB Sciex Instruments, Wilmington, DE, USA) coupled to a Triple Quad™ 7500 mass spectrometer (AB Sciex Instruments, Wilmington, DE, USA), including drugs, pesticides, antibiotics, personal care products and their metabolites. The enumeration and quantification of microbial concentration from UWW was performed as reported by Hernández-Zanoletty et al. (2022). Table 1 shows the physicochemical and microbiological characterization of both effluents.

Table 1. Physicochemical and microbiological characterization of the wastewater effluent at the entrance of the vertical wetland (EVW) and from the outlet of the horizontal wetland (OHW).

		Physicochemical	
	Units	(EVW)	(OHW)
Dissolved organic carbon (DOC)	mg/L	41.2 ± 7.9	14.5 ± 3.5
$[HCO_3^-]$	mg/L	713.4 ± 39.0	527.2 ± 33.5
Turbidity	NTU	35.5 ± 9.8	2.21 ± 1.7
pH	-	7.4 ± 0.1	7.5 ± 0.1
Conductivity	mS/cm	3.4 ± 0.4	4.1 ± 0.3
CECs	ng/L	87348 ± 7.6·10³	10088 ± 1.5·10³
		Bacteria	
E. coli	CFU/100mL	540000 ± 7.5·10⁴	70 ± 1.2
Enterococcus spp.	CFU/100mL	80000 ± 5.7·10³	67 ± 3.9

In addition, the following ionic content of both effluents (Table 2) was obtained by using ion chromatograph (Model 850, Metrohm, Herisau, Switzerland in a column METROSEP C4-250/4.0 (250 mm x 4.0 mm ID)).

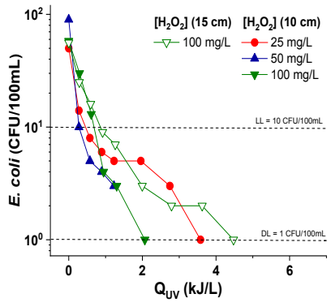
Table 2. Ionic content of the wastewater effluent at the entrance of the vertical wetland (EVW) and from the outlet of the horizontal wetland (OHW).

		Ionic content	
	Units	EVW	OHW
Cl^-	mg/L	615.1 ± 76.3	730.4 ± 76.3
NO_3^-	mg/L	1.8 ± 0.6	4.3 ± 1.6
NO_2^-	mg/L	0.1 ± 0.0	1.6 ± 1.1
PO_4^{3-}	mg/L	12.5 ± 0.4	6.3 ± 1.7
SO_4^{2-}	mg/L	310.9 ± 58.7	892.0 ± 49.0
Na^+	mg/L	396.6 ± 53.1	567.2 ± 45.5
NH_4^+	mg/L	44.2 ± 2.9	0.84 ± 0.4
K^+	mg/L	21.1 ± 1.5	20.4 ± 3.8
Ca^{2+}	mg/L	218.3 ± 33.2	359.7 ± 64.0
Mg^{2+}	mg/L	95.2 ± 11.5	122.9 ± 12.3

RESULTS AND DISCUSSION

Based on the characterization of EVW and OHW, the purification capability of the wetland systems was set on 88% in the average absorption/degradation of CECs. In terms of disinfection results, *E. coli* reached a 4 logarithm reduction value (LRV) and *Enterococcus* spp. 3 LRV. Therefore, taking into account the EU legislative parameters, the turbidity of water complies with the new legislation (≤ 5 NTU), but the *E. coli* did not, highlighting and justifying the need for an additional treatment step.

Figure 2 shows the inactivation profiles of both bacteria by the additional treatment investigated in this study, i.e., the solar photochemical process based on the use of H_2O_2 as an oxidant and natural solar radiation in RPR. The effect of different H_2O_2 concentrations (from 25 to 100 mg/L) and two different RPR water heights (10 and 15 cm) under natural solar radiation are shown.



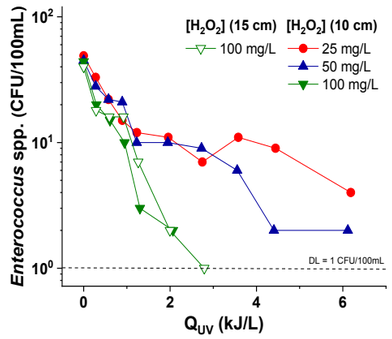


Figure 2. Inactivation profiles of *E. coli* and *Enterococcus* spp. in presence of different oxidant concentrations and different RPR water heights under natural solar radiation.

For *E. coli*, the LL was reached in the presence of all H_2O_2 concentrations, therefore, 25 mg/L of H_2O_2 (after 30 minutes or 0.57 kJ/L of Q_{UV}, accumulated solar UV-irradiance per unit of time and volume) was selected as the best condition. For *Enterococcus* spp., 10 CFU/100 mL was also reached in the presence of the lower oxidant concentration tested, but the LL for these bacteria is not yet regulated. Besides, two different water heights were evaluated in the RPR (in the case of 100 mg/L of H_2O_2), 10 cm and 15 cm (Figure 2), initially the highest H_2O_2 concentration was also tested to analyze its effect on the CECs removal. The bacterial inactivation profiles for both heights are similar, therefore, it is necessary to test the optimal H_2O_2 concentration (25 mg/L) at higher height to see if it is possible to improve the treatment conditions, treating a larger volume of water with the same amount of oxidant. It is important also to highlight that, after each treatment, it is important to evaluate the potential regrowth of inactivated bacteria after 24 and 48 hours, just to assure the safe use of treated wastewater after storage time. Under these experimental conditions, post-treatment regrowth was not observed, so the treatment of solar/H_2O_2 could be considered an effective method for bacterial inactivation. The percentage of CECs removal under the selected operating conditions is being measured.

As conclusion, combined wetland and RPR systems are an effective solution for wastewater purification, CECs average adsorption/degradation along the wetlands was 88% at ng/L concentration level. It was possible to reach concentrations ≤ 10 CFU/100 mL for both tested bacteria with solar and the addition of a low concentration of H_2O_2 (25 mg/L), being able to increase the height of the RPR to treat a greater volume of water, without losing efficiency.

Future research will be focused on the study of the effect of another oxidant (peroxymonosulfate, PMS) and comparison with H_2O_2. Finally, the best-selected operating conditions and oxidant will be evaluated at demo plant scale by monitoring CECs for several months and the presence or not of ARGs and ARB in OHW.

Abstract

This research was aimed to provide a system for treatment and reuse of municipal and domestic wastewater based on the combination of nature-based technologies, vermifiltration and a daphnia-based reactor. The study was conducted at pilot-scale (10 p.e.) and particular attention was dedicated to the removal of selected organic micropollutants (PPCPs) and potentially toxic elements. The integrated system delivered an effluent suitable for water reuse for agricultural irrigation and other reuse categories regulated in the Spanish legislation. Regarding metal removal, the integrated system achieved removals of about 30% for Cr, 50% for Zn, 60% for Ni and Cu and close to 100% for Pb. The system demonstrated a good efficiency for the removal of PPCPs with percentages higher than 80% for ibuprofen, naproxen, citalopram, gemfibrozil and triclosan and about 60 % for diclofenac and clofibric acid.

INTRODUCTION

Apart from high nutrient and pathogen loads, urban wastewater may contain thousands of organic micropollutants that are either extensively used on a day-to-day basis or present in products commonly used in industrialized areas. These compounds, also known as contaminants of emerging concern (CECs), comprise pharmaceuticals and personal care products (including antibiotics), perfluorinated compounds, flame retardants, among others. Although metals and metalloids reach the environment mainly through anthropogenic activities such as mining, smelting or excessive use of fertilizers and pesticides, they can also reach sewage treatment plants through paints, ceramics, textiles, pigments, pesticides, or cigarette butts. Micropollutants occur in low ($ng.L^{-1}$) to very low ($pg.L^{-1}$) concentrations in the environment and pose risks to aquatic and terrestrial ecosystems.

These substances are completely out of the ordinary standards of wastewater treatment, and most of the commonly used treatment technologies are ineffective against them. Different technologies are available to ensure that treated effluents achieve high levels of quality. These include physicochemical treatments (coagulation, flocculation, membrane-based treatments, chlorine and ozone disinfection, advanced oxidation, etc.). However, they involve the use of significant energy resources and/or chemicals. In this context, technologies based in natural processes emerge as low-cost and sustainable alternatives to remove micropollutants from wastewater.

Although some systems that mimic natural depuration utilizing solar energy and living organisms (including media filters, lagoons and ponds, aerobic treatments, and wetlands), have proved to be effective, there are still problems in their application due to the maintenance requirements and electricity consumption (media filters and aerobic treatments) while lagoons and wetlands require large areas of land and present difficulties in meeting the discharge criteria across a whole year. Seeking in other alternatives to improve the efficiency of nature-based treatments, the use of earthworms (Jiang et al, 2016) and zooplankton (Pau et al., 2013; Salvadó et al., 2021) has been also considered.

This work discusses novel and relevant results on the removal of metals and pharmaceuticals by the integration of a vermifilter (i.e., primary and secondary treatment) and a zooplankton-based reactor (tertiary treatment).

MATERIALS AND METHODS

The study was conducted at a pilot plant placed adjacent to the municipal WWTP of Quart (Girona, Nord east Spain) that serves approximately 4,000 inhabitants. Inflluent wastewater was taken from the WWTP inlet, passed through a hydraulic circuit to separate coarse solids and grease and pumped to the vermifilters. Vermifiltration was performed in two identical cylindrical reactors working in parallel (1.2 m diameter and 1.7 m height). Filling media was composed of three different layers: river pebbles, pozzolana and woodchip. About 15,000 earthworms (*Eisenia fetida*) were introduced in the reactors. Reactors were operated in fed-batch mode, with 5 min feeding and 25 min drawing. The Daphnia reactor (1,500 L) was fed with the effluent of vermifilters and inoculated with *D.magna* from a laboratory aquarium culture. The integrated system was designed to operate normally at 1,500 L.d-1. Short tests also were performed at 750 $L.d^{-1}$ and 3,000 $L.d^{-1}$.

Additional UV treatment was also available for further polishing of the effluent of the zooplankton reactor.

Influent and effluent samples were collected at the inlet/outlet of the vermifilters and at the outlet of the zooplankton-based reactor over a period of three months. Treatment effectiveness was evaluated in terms of removal of the typical physical and chemical gross parameters, pathogens, and also for the removal of selected PPCPs: sulfamethoxazole (SLF), fluoxetine (FXT), paroxetine (PXT), citalopram (CTP), clofibric acid (CFB), gemfibrozil (GMB), diclofenac (DCF), ibuprofen (IBU), naproxen (NPX), carbamazepine (CBZ), triclosan (TCS), and potentially toxic elements (Cr, Ni, Cu, Zn, As, Cd, Sn, Pb).

RESULTS AND DISCUSSION

The integrated system achieved average removals of 88±7%, 89±8%, 91±8%, 85±19%, 98±3 for COD, TSS, NH4+, BOD5 and pathogen (*E.coli*), respectively, providing an effluent suitable for water reuse for agricultural irrigation and other reuse categories regulated in the Spanish legislation (Pous et al., 2021).

Potentially toxic elements

Table 1 shows the concentration values of the seven potentially toxic elements studied though the different stages of the nature-based treatment. The maximum, minimum and median values are displayed. The joint data for the 750 and 1500 $L \cdot d^{-1}$ flows are shown, because no significant differences were observed in the results obtained at the two different flows (different hydraulic residence time).

Considering the complete process, Lead (Pb) was the metal with the highest removal with more than 95%. Chromium (Cr) and arsenic (As) were the least removed with values lower than 30%. Zinc (Zn) was removed at a value close to 50% and nickel (Ni), copper (Cu) and tin (Sn) at values close to 70%.

Most part of the metals and metalloids were removed in the vermifiltration tank and less than 20% of the total removal took place in the daphnia-based reactor in all cases, except for Cd, with a removal of about 30%.

Organic micropollutants

The compounds found at higher concentrations were the anti-inflammatory drugs ibuprofen and naproxen, followed to a lesser extent by the lipid regulators gemfibrozil and clofibric acid, in accordance with the consumption pattern for these pharmaceuticals. The antibiotic sulfamethoxazole, and the antidepressants fluoxetine and paroxetine were hardly detected in the influent of the treatment plant.

The results for the removal of the s pharmaceuticals and triclosan in the integrated treatment system at two hydraulic residence times are presented in Figure 1.

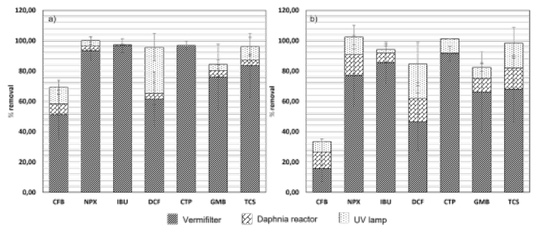

Figure 1. Removal of organic micropollutants by the different treatments integrated in the system.

operating at a) 750 $L.d^{-1}$ and b) 1,500 $L.d^{-1}$.

The efficiency in the removal of organic micropollutants by the integrated nature-based system were similar for the two hydraulic residence times tested, except for clofibric acid. Removals between 80% and 100% were achieved for ibuprofen, naproxen, citalopram, gemfibrozil and triclosan and about 65 % for diclofenac. For clofibric acid, the most polar compound, removals of about 60% were obtained when the system was operated at 750 $L.d^{-1}$, while for the shorter residence time the efficiency decreases, resulting in a removal of about 30%.

By taken a close look at the different treatments, when the system is operated at a nominal load of 750 $L.d^{-1}$, most of the removal takes place at the vermifilter and the daphnia-based reactor only contributes to a small percentage for the removal of gemfibrozil. For the shorter residence time, the contribution of the reactor increases at the expense of the decrease in the efficiency of the vermifilter.

Further treatment of the effluent of the daphnia-based reactor by UV radiation allowed removals higher than 90% for the organic compounds, except for clofibric acid, with maximum total removal of 25%.

This case study demonstrates that the integration of vermifilter and zooplankton- based reactors is a sustainable approach for the removal of micropollutants of different properties while providing reclaimed water that is of a high chemical and biological quality for agricultural irrigation and other non-potable uses. Moreover, this integrated system has a low energy consumption, a minimal maintenance, and a very small sludge production making the system presented here both eco-sustainable and economical.

AGNOWLEDGEMENTS

Abstract

The removal of a selection of organic micropollutants (OMPs) from wastewater was assessed by a hybrid system consisting of an MBR coupled to powdered activated carbon (PAC) added inside the biological tank. Two PAC concentrations were tested (0.1 and 0.2 g/L) in a full-scale MBR treating mainly hospital wastewater. Out of 232 OMPs tested, results of a selection of 25 compounds, mainly antibiotics, is presented regarding their frequency of detection, loadings and removal efficiencies and environmental impact. Results indicate that a PAC concentration of 0.2 g/L reduced the average loads OMPs tested by 77% with respect to MBR alone (41%).

INTRODUCTION

Among the multiple sources of wastewater entering in WWTPs, hospital wastewater has been considered a hotspot for organic micropollutants (OMPs), which may include a variety of pharmaceuticals and their metabolites, contrast media, among others. In particular, antibiotics have drawn the attention since their presence has been associated to chronic toxicity and the prevalence of antibiotic resistant bacteria in aquatic environments (Michael et al., 2013). Despite hospital wastewater is still considered of the same pollutant nature than urban wastewater, it has been an object of research around the globe (Verlicchi et al., 2015) and *in situ* dedicated advanced treatments have been developed (McArdell et al., 2011). Among them, the combination of innovative technologies with advanced biological treatment, as membranes bioreactor (MBR), in the so-called *hybrid MBRs* (Rizzo et al., 2019). In this study, we focus on the use of powdered activated carbon (PAC) added inside the biological tank of an MBR. In this way, the biological degradation is combined with the adsorption process, which results in a synergistic effect that enhances the removal of OMPs from wastewater. Despite the removal of OMPs by PAC-MBR systems has been a matter of interest in recent years, many of the research studies have worked with laboratory- or pilot-scale MBRs using synthetic wastewater, on which the contaminant is spiked at environmental concentrations (Alvarino et al., 2017, 2016; Echevarría et al., 2019; Li et al., 2011; Nguyen et al., 2013; Serrano et al., 2011). In this way, there are knowledge gaps related to the use of PAC under real conditions that hamper the implementation of this technology in the following years. In comparison with other hybrid technologies, PAC added to the biological tank is easy to implement and operate. However, special attention must be paid to ensure a constant concentration of PAC in the system, taking into consideration that many OMPs rely their removal on the adsorption onto fresh PAC (Alvarino et al., 2018).

The present study aims to test the addition of PAC in a full-scale MBR treating mainly hospital wastewater for the removal of OMPs and, in particular antibiotics. For that purpose, three experimental campaigns for a total of one year duration took place testing the MBR in absence and in presence of PAC (at two concentrations, 0.1 g/L and 0.2 g/L).

MATERIALS AND METHODS

Experiments were conducted in a full-scale MBR of a WWTP located in northeastern Italy. The average dry weather flow of the WWTP is 700 m^3/d. The WWTP treats mainly hospital wastewater (75% of the total average flow rate) and urban wastewater (25%). The WWTP consists of a pre-treatment; the MBR, composed by P removal (100 m^3), denitrification (250 m^3) and nitrification (350 m^3) tanks, followed by a tertiary treatment (UV radiation) for disinfection of final effluent. Three treatments were considered, *noPAC*, on which the MBR worked without PAC addition (March - August 2021), *0.1PAC*, where PAC was added and maintained at a concentration of 0.1 g/L inside the biological reactor (September – November 2021), and *0.2PAC*, with a PAC concentration of 0.2 g/L (April – May 2022). The PAC concentration was maintained constant through periodical and controlled additions of PAC to counterbalance the PAC losses associated with the excess sludge withdrawn from the system. WWTP operation was monitored through a set of conventional parameters for water quality. Potential changes in mixed liquor due to PAC addition were evaluated by performing DOC, UV_{254}, TSS measurements.

During the experimental campaigns, a total of 232 OMPs were analysed, from which 25 compounds were selected in the present study. Selected compounds include 17 antibiotics, 4 analgesics, 1 beta-blocker, 2 psychiatric drugs, 1 stimulant and 1 iodinated contrast media. Selection criteria was based on their frequency of detection and research interest. Compounds selected had a frequency of detection greater than 50% in the WWTP influent, and they were present in at least two treatments, thus the treatment efficiency was evaluated with a certain degree of confidence. For OMP analysis, three sampling campaigns took place: *noPAC* treatment (n=5), *0.1PAC* treatment (n=18) and *0.2PAC* (n=12). 24-h time proportional composite wastewater samples were taken once a week by automatic samplers in the influent and MBR permeate. For the permeate samples, the hydraulic retention time was considered. OMPs were determined by UHPLC–QTOF–MS.

RESULTS AND DISCUSSION

Since hospital effluent is considered a point source of OMPs in wastewater, the characterization of the wastewater entering in the WWTP is key to further evaluate the treatment efficiency (Fig. 1a). In this study, 4 OMPs stood out by their high average loads (>1 g/day) in the influent: azithromycin (AZIT) (2.4 g/day), acetaminophen (ACET) (4.4 g/day), caffeine (CAF) (2.2 g/day) and iopromide (IOP) (6.4 g/day). In the case of IOP, its presence is due solely to the hospital wastewater since it is used as a contrast medium for medical exams. In the MBR permeate (Fig. 1b), the OMP load was reduced by one order of magnitude in many cases, with decreasing loads from *noPAC* to *0.2PAC* treatments, indicating the effectiveness of the addition of PAC. Only ofloxacin (OFX) was found at a load higher than 0.1 g/day in *0.2PAC* treatment. Since the addition of PAC seems to reduce the loading of OMPs in the effluent of the WWTP, a risk quotient (RQ) analysis was used to evaluate the impact of the wastewater effluent in the receiving water body (Fig. 1c). Assuming a context of water scarcity with no dilution of the WWTP effluent in the receiving water body, only the *0.2PAC* treatment reduced substantially the RQ of the tested OMPs. 7 pharmaceuticals were found at RQ > 1 (high risk) in *noPAC* and *0.1PAC* treatments, while *0.2PAC* reduced the number to a total of 3 compounds (AZIT, carbamazepine CBZ and OFX). Albeit these OMPs still supposed a high risk, results show that the impact in the receiving water was significantly reduced by increasing PAC concentration for all OMPs except for amoxicillin and IOP. Indeed, the use of risk assessment analysis is a useful tool to evaluate the treatment efficiency of in full-scale investigations. For instance, the frequency of detection of OMPs in the MBR permeate (Fig. 1d) shows that in most of the cases OMPs, even if are highly removed, are still found in the WWTP effluent. The results are not surprising due to the high OMP loads arriving from the hospital effluent and confirms the necessity of *in situ* advanced technologies to deal with their occurrence.

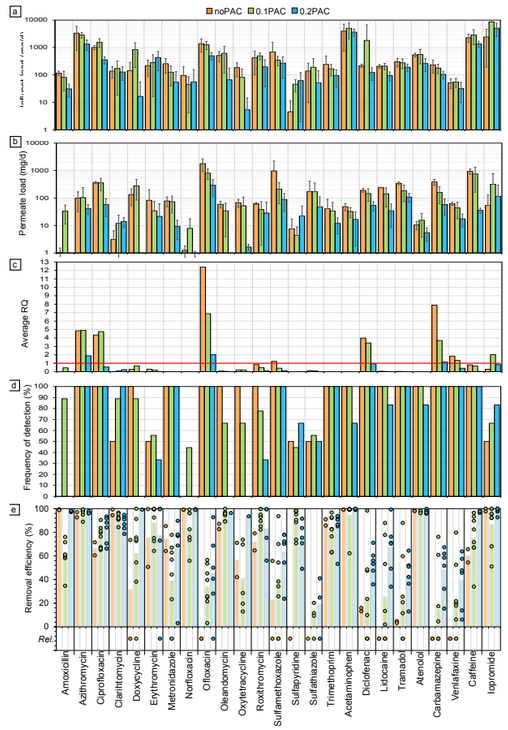

Figure 1. OMP values of a) influent load, b) MBR permeate load, c) average risk quotient and d) frequency of detection (%) in the MBR permeate, e) removal efficiencies (%) for *noPAC*, 0.*1PAC* and *0.2PAC* treatments. Note that bars indicate average values while dots individual measurements.
Rel. indicates release (negative removal efficiency).
Previous studies, with the same treatment configuration as the present work, used a range of PAC concentrations between 0.05 and 2 g/L (Alvarino et al., 2017, 2016; Echevarría et al., 2019; Li et al., 2011; Nguyen et al., 2013; Serrano et al., 2011). Considering the results obtained in those investigations, it was concluded that a PAC dose of 0.1 g/L is sufficient to achieve an 80% of removal for most of the compounds tested. In our study, we confirm that the increase of the PAC concentration up to 0.2 g/L implies a substantial improvement in the removal efficiencies of many recalcitrant OMPs. For antibiotics, the average removal efficiency of 11 out of 17 compounds was improved by the presence of PAC and, for many of them, the increase was correlated to the PAC dose. For instance, doxycycline increased its average removal by 40% and 80% with *0.1PAC* and *0.2PAC*, respectively, while ofloxacin and sulfapyridine went from negative to medium (34% - 45%) and high (74% - 89%) average removal. Some compounds, as sulfamethoxazole, required *0.2PAC* to achieve high removals (up to 72%). It seems that with *0.1PAC* the main removal mechanism is still biodegradation (Alvarino et al., 2017), and thus higher PAC doses are required to obtain synergistic effects of the adsorption and biodegradation processes (OMP biodegraded once it is adsorbed onto PAC surface). Increasing the PAC dose in the bioreactor had also an effect on the analgesics tested. Lidocaine, DCF and tramadol achieved a moderate average removal (43%- 67%) with *0.2PAC* compared to the very low removal or even release in the other treatments. Diclofenac is a recalcitrant compound with very low and variable removal efficiencies in MBR systems (Nguyen et al. 2013). In literature, its increased removal has been associated not only to the PAC dose but to the presence of fresh PAC (Alvarino et al., 2017). Indeed, the presence of PAC greatly influenced the removal of the compounds which rely their removal solely on adsorption. For instance, only moderate removals were achieved with *0.2PAC* for CBZ and venlafaxine. In fact, CBZ has proven to be greatly depends on the presence of fresh PAC, showing an abrupt increment after PAC addition and subsequent decrement over time (Alvarino et al., 2016, Echevarría et al., 2019). In our study, the removal likely varied depending on the sampling day with respect to the addition of fresh PAC.

Abstract

The addition of non-biological conductive materials such as graphene oxide (GO) into anaerobic reactors has been suggested to enhance their performance. In this work, an anaerobic membrane bioreactor treating municipal wastewater was operated for 385 days. During its operation, different additions of GO were conducted and its effect on COD and pharmaceutical compounds removal as well as on microbial community composition was monitored. Results showed no effect of GO on the stability of the reactor (e.g. no major changes in alkalinity and COD removal were detected) whereas an enhanced removal of some PhACs, specifically antibiotics was observed. A shift in the archaeal community was also detected after the addition of GO, with an increase in hydrogenotrophic methanogens.

Keywords: Anaerobic treatment, Bio-reduced graphene oxide, Municipal wastewater, Pharmaceuticals

INTRODUCTION

Municipal wastewater (WW) is usually treated using conventional aerobic activated sludge processes, incurring high costs due to aeration and sludge handling. Anaerobic treatment is gaining attention as a low-cost alternative as no oxygen is needed which results in lower sludge production. (Lew et al., 2009)30 and 60 min. During the past decade, increasing research efforts have been directed to study also the fate and removal of pharmaceuticals in WW treatment (Zhang and Li, 2018; Malmborg and Magnér, 2015)alkaline and thermal hydrolysis pretreatment. One of the most worrying groups of pharmaceuticals is that of antibiotics, since their relationship to the potential development of antibiotic-resistant bacteria in WW treatment plants (WWTPs).

The addition of non-biological conductive materials into anaerobic reactors (e.g., GAC, biochar, carbon cloth, carbon nanotubes, and graphene like-materials) has been suggested to enhance the performance of anaerobic processes within WWTP. Syntrophic bacteria can attach to the surface of these conductive materials and use them for electron exchange thus facilitating the direct interspecies electron transfer, enhancing the biotransformation of persistent pharmaceuticals (Lü, et al., 2020; Johnravindar, et al., 2020; Summers, et al., 2010). Nevertheless, there are no studies using graphene oxide in a continuous anaerobic membrane bioreactor (AnMBR), and preliminary studies in batch report contradictory results (Dong, et al., 2019; Bueno-López, et al., 2020). This study investigates the impact of different concentrations of biologically reduced GO in a continuous AnMBR that treats municipal WW supplemented with a mix of pharmaceuticals.

METHODS

Anaerobic Membrane Bioreactor operation

A bench scale AnMBR of 6 L working volume was operated for 385 days at a hydraulic residence time of 24 h to treat real municipal wastewater. An external module of 0.125 m^2 polyvinylidene difluoride hollow fibers membrane (0.4 µm nominal pore size) was connected to the reactor. A mix of seven pharmaceuticals (detailed list in **Figure 1**) was spiked daily to the influent tank in a final concentration of 0.02 µM for each compound. GO was provided from Graphenea (Spain) as a 4 g/L aqueous dispersion. DNA extraction was performed using a commercial kit and sequenced using illumine MiSeq platform.

The reactor operation can be divided into five different stages: i) baseline operation (0 g GO/g VS, days 0-49), ii) pharmaceuticals addition (days 50-175), iii) 1st addition of GO (0.005 g GO/g VS at the beginning of the period days 176-238), iv) 2nd addition of GO (0.05 g GO/g VS at the beginning of the period (days 239-301), and v) 3rd addition of GO (Weekly addition of 0.005 g GO/ g VS until reaching 0.1 g GO/g VS, days 302-385). After each GO addition, the reactor was kept without recirculation nor permeating for 8 hours to ensure GO biological reduction.

RESULTS

COD values for the influent and permeate are summarized in **Table 1**, as well as the COD removal percentage and partial/total alkalinity (IA/TA) ratio. For all five stages with different GO concentrations an average removal of COD higher than 85 % was achieved. This removal was similar to other AnMBR treating municipal WW (Lew et al., 2009). The reactor stability was controlled twice per week with the IA/TA, which had a value lower than 0.3 indicating no accumulation of volative fatty acids (VFA) (**Table 1**). Only during the early stage *i.* (start-up) was detected a slight VFA accumulation.

The different pharmaceutical compounds showed very different results in their removals (**Figure 1**). For four of the compounds monitored an increase in the removal was detected after the addition of GO. Trimethoprim presented an average removal of 64% ± 5% during the baseline operation, rising to 82% ± 2% during stage *v*. The antibiotic with the highest enhancement in removal efficiency was metronidazole, obtaining a removal of 66% ± 4% during de baseline and increasing up to 96% ± 2% after the addition of GO. Other compounds that showed a tendency for higher removal efficiency across the different operational stages were sulfamethoxazole and roxithromycin, reaching maximum values of 81% ± 3% and 51% ± 10%, respectively. However, the removals of other compounds such as naproxen and diclofenac were not enhanced with GO and presented similar removals compared with the literature, even after the addition of particulate activated carbon as carbon-based conductive material (Xiao et al., 2017; Liu et al., 2020).

The addition of GO promoted the enrichment of the hydrogenotrophic and methylotrophic archaea, which use hydrogen as substrate (**Figure 2**). Hypothetically, these microorganisms could be promoted because of the electrons provided through the GO structure. Chloroflexi and Firmicutes were the most common phyla, accounting for more than half of the bacterial population. A previous study reported the presence of GO stimulated the proliferation of many species of these phyla, notably *Rombustia* spp. and *Longilinea* spp.), during the anaerobic digesting process of waste-activated sludge (Casabella et al., 2023). The addition of GO also favored the proliferation of other bacterial genera, such as *Leptolinia* (Chloroflexi) and *Smithella* (Thermodesulfobacteriota).

Conclusions

The addition of GO doesn't have a negative impact on COD removal or reactor stability.

Pharmaceuticals removal from the liquid phase increased for trimethoprim, metronidazole, roxithromycin, and sulfamethoxazole with the highest GO concentration tested.

The addition of GO induced a shift in the microbial community, promoting Firmicutes and Chloroflexi bacteria, and those methanogens that could use hydrogen as substrate.

Abstract

The fate of organic micropollutants (MPs) in wastewater treatment plants remains uncertain on various aspects, hence the constant research on its elucidation. This work focuses on the elimination of 19 MPs of different physicochemical properties and the ability of native microbial community to eliminate them in a hybrid system fed with non-conventional wastewater. The hybrid process consists of a Moving Bed Biofilm Reactor (MBBR) coupled with Nanofiltration (NF). Essential process parameters such as chemical oxygen demand, mass of attached biofilm and MPs removal efficiency are comprehensively analysed. This study also strives to establish a correlation between the removals of MPs and the diversity of microbial populations.

Keywords

Biofilm, MBBR, Microbial Community, NF, Organic Micropollutants

INTRODUCTION

The perpetual increase in human activities has resulted in recurrent detections of various organic micropollutants (MPs) particularly at the outlet of wastewater treatment plants (WWTPs). The eventual discharge of such emerging contaminants, e.g., pharmaceutically active compounds, endocrine disrupting chemicals and pesticides, into water bodies remains a worrying issue due to their potential cumulative and toxic effects. Despite their presence at relatively low concentrations (< 1µg/L), the release of these molecules into the environment has been indeed associated with multiple significant risks to human health and aquatic ecosystems (Aemig et al. 2021).

The secondary treatments presently used in most WWTPs display noteworthy removal efficiencies of carbon- and nitrogen-based pollutants but the operating conditions applied in such treatments are not always well adapted for the elimination of MPs. This therefore leads to the implementation of tertiary processes to enhance their removal. Among those processes, the Moving Bed Biofilm Reactor (MBBR) is deemed promising not only for its economic and environmental advantages, but also for its robustness. In fact, biofilm formed on the fluidized plastic carriers has better resistance to constant variations in characteristics of the influent, e.g., organic load, pH, temperature (di Biase et al. 2019); and contributes substantially to the biodegradation of certain MPs (Abtahi et al. 2018).

Currently, on top of quantifying the removal efficiencies of diverse MPs, numerous studies were also conducted to investigate the influence of microbial populations diversity on the degradation of MPs in similar biological processes (Guo et al. 2019). In spite of the persistent progress in research on the characterization of the optimal degradation conditions of MPs and the elucidation of their removal mechanisms, knowledge on the latter is still insufficient due to its complexity.

In this study, the removal efficiency of 19 MPs and the diversity of microbial community in a hybrid system (MBBR + Nanofiltration (NF)) working under different operating conditions were evaluated. Besides, a comparative study of the microbial populations of biomass present in the system (attached and suspended) and those of activated sludge from a WWTP was conducted. The conventional pollution parameters were also analysed to assess the process general performance.

MATERIALS AND METHODS

A hybrid semi-pilot scale MBBR-NF system was operated to treat a non-conventional domestic wastewater from a municipal WWTP in Labège, France. The particularity of this wastewater is its atypically low carbon content, resulting in C/N ratio in the range of 0.8 to 2.0, which is not conventional for biological treatments. The MBBR-NF system presented in figure 1, consisted of an anoxic bioreactor, an aerobic MBBR and a dynamic NF pilot. The treated effluent flowrate varied between 1.5 to 2 l/h depending on the fixed hydraulic retention time. The aerobic MBBR was inoculated with activated sludge from the same WWTP and saddle-shaped, porous carriers (Christian Stöhr GmBH, Marktrodach, Germany) were used as bio-carriers. The carrier filling ratio of the aerobic MBBR was fixed at 44% (v/v).

The analysis of various conventional pollution parameters, i.e., soluble Chemical Oxygen Demand (sCOD), nitrogen based-compounds, mixed liquor suspended solids (MLSS), mass of attached biofilm, were performed systematically throughout the operating period of the hybrid system. MPs were extracted from the collected samples using a modified quick, easy, cheap, effective rugged and safe (QuEChERS) method and analysed by ultra-high-performance liquid chromatography with tandem mass spectrometry (UHPLC-MS-MS) (Cavaillé et al. 2021). DNA extractions were carried out using the procedure provided by DNeasy® PowerSoil® Pro Kit Solution (Qiagen, Germany). The DNA sequencing was executed by the Plateforme Génomique (GeT-PlaGe) - INRA Transfert (Castanet-Tolosan, France).

RESULTS AND DISCUSSION

Physicochemical Analysis

The hybrid system shows good elimination of sCOD with an average removal efficiency of 80.78 ± 3.66%. Moreover, ammonium (NH_4^+) and nitrite (NO_2^-) are almost completely eliminated in the system. However, nitrates accumulation (NO_3^-) is observed in the system due to the low C/N ratio, which hinders the occurrence of denitrification. As regards the core of the biological process, the average mass of biofilm is 12.01 ± 0.66 mg/carrier, thus resulting in a concentration of 10.06 ± 0.55 g/L of attached biomass in the aerobic MBBR (figure 2). The events I-V marked on figure 2 correspond to the different modifications made to the hybrid system.

Micropollutants Analysis

Hitherto, the removal efficiency of detected MPs (figure 3) obtained from a single sampling present compliant results with those from the literature (Blair et al. 2015). Upcoming analyses of the collected samples will be executed using the newly validated method; expected results will be available by May 2023.

Microbiological Analysis

Regarding the diversity of the microbial population at the phylum level, it is observed that the attached biofilm promotes different selectivity of phyla compared to the suspended biomass. Indeed, the abundance of nitrospirae and bacteroidetes varies notably when comparing both forms of biomass but to a lesser extent in respect of proteobacteria. The proliferation of autotrophic nitrifying nitrospirae, is better on the carriers mainly due to a longer contact time between the carriers and the biomass under aerobic condition. Besides, in figure 4, the influence of the hybrid system on the microbial diversity could be noted as the microbial community in the system (attached and suspended biomass) are well distinct from those of the activated sludge used during inoculation. Comprehensive investigations to correlate the influence of MPs are in progress.

Abstract

The presence of contaminants of emerging concern (CECs) in wastewater, such as organic micropollutants (OMPs) and antibiotic resistance genes (ARGs), entails a current concern in wastewater treatment. Innovative technologies, apart from implying lower operational cost and less environmental impact than conventional ones, are expected to improve the removal of CECs while achieving the discharge limits for conventional pollutants, such as COD, TN, SS. This research analyses the SIAM technology (methanogenic Anaerobic reactor and Membrane bioreactor Integrated System) operating with urban sewage at pilot scale. The aim of this work was to assess the removal of both, conventional and emerging pollutants. The characteristics of the technology enhanced the removal of selected OMPs, due to the presence of different redox conditions and biomass conformation, as well as higher solid retention time (SRT). Compounds like trimethoprim or ciprofloxacin were removed up to 92±3% and 93±13%, respectively. The ultrafiltration membrane achieved 1.78 log maximum reduction of ARGs.

Keywords

Antibiotic resistances, hybrid process, organic micropollutants, real sewage.

INTRODUCTION

The occurrence and fate of organic micropollutants (OMPs) in sewage treatment plants (STPs) has been studied in recent years by the scientific community, since their release to the environment presents a potential toxic risk. Among them, antibiotics are one of the most concerning groups, due to the potential development of antimicrobial resistances in some microorganisms (Phoon et al., 2020). Biological treatment of urban sewage seems to present some conditions that could enhance the spread of ARGs (Manaia et al., 2018).

Innovative wastewater treatment technologies are designed to fulfil the integrated protection of the environment, reducing conventional pollutants load at higher energy efficiency than conventional processes (Lorenzo-Toja et al., 2016). Some of this technologies include different characteristics that may enhance OMPs removal, including alternating redox conditions, a more diverse microbial community, or higher sludge retention times (SRTs)(Alvarino et al., 2018). However, antibiotic resistant genes (ARGs) could be promoted in certain conditions that benefit OMP removal (Karkman et al., 2018). Further research is needed to elucidate whether innovative technologies can achieve a reduction in both, conventional and emerging pollutants, with a better environmental performance than conventional processes.

The objective of this study was to evaluate the performance of an innovative technology treating urban sewage not only in terms of conventional pollutants removal (COD, TN, SS), but also in terms of reduction of the discharge of OMPs and ARGs.

MATERIALS AND METHODS

Experimental setup

The SIAM (patent ES 2 385 002 B2) pilot plant was operated in a NW Spain urban STP at ambient temperature. It consists of two main stages: UASB reactor (120 L); and a hybrid MBR posttreatment (56 L) composed of an anoxic chamber (36 L), aerobic compartment (8 L) and a aerated ultrafiltration chamber (12 L). The UASB contains anaerobic granular biomass, the anoxic and aerobic compartments contain Biochip carriers (20% of working volume), while flocculent biomass flows along the different MBR compartments thanks to the recirculation stream. The membrane chamber contains an ultrafiltration module Zenon ZW-500M-4M. The plant was fed with a mixture of low strength primary treated sewage of the STP and a concentrated medium that contained skimmed milk as extra COD supply and sodium bicarbonate as alkalinity source to ensure the stability of the anaerobic stage. In addition,a mixture of OMPs was added to the feed.

Analytical methods

Conventional parameters. Conventional pollutants (COD, N species, suspended solids, etc.) were determined according to the Standard Methods, and monitored twice a week.

Organic micropollutants. A selection of eight antibiotics was carried out according to the compounds included in the different EU Watch Lists: sulfamethoxazole (SMX), trimethoprim (TMP), erythromycin (ERY), roxithromycin (ROX), azithromycin (AZI), clarithromycin (CLA), ciprofloxacin (CIP). In addition, due to the presence of β-lactam resistances across WWTP in Southern Europe (Cacace et al., 2019), also cefalexin (CFX) was considered. Samples were preconcentrated and analysed according to the methodology presented by Alvarino et al., 2015. Three sampling campaigns were carried out.

Antibiotic resistance genes. A group of ARGs was selected according to their presence in the same WWTP in recent studies (Quintela-Baluja et al., 2019). DNA extractions were performed employing a commercial kit (NucleoSpin Microbial DNA). ARGs were analysed in a SmartChip qPCR (Resistomap). Three sampling campaigns were carried out for biomass samples and two campaigns for liquid streams.

RESULTS AND DISCUSSION

General results

The system was operated for 186 d treating 227.7±8.5 L d^{-1} of primary sewage. HRT was maintained at 12.7±0.5 h in the UASB and 5.9±0.2 h in the MBR posttreatment. Influent sewage contained 540±148 mg COD L^{-1} and 34.9±4.2 mg N L^{-1}. The treatment process obtained a permeate with 12.1±4.8 mg COD L^{-1} and 7.3±2.0 mg N L^{-1}, fulfilling the legal requirements. A 78±9 % removal of the influent COD was achieved in the anaerobic stage. In the MBR posttreatment, nitrogen and dissolved methane maximum removal rates were 124.91 mg N L^{-1} d^{-1} and 119.12 mg CH_4 L^{-1} d^{-1}. The removal efficiencies achieved for these compounds were 78.1±2.5 and 55.8±6.7 % respectively. The obtained results are similar to those observed in a previous study with synthetic wastewater (Silva-Teira et al., 2017).

OMP removal

OMP removal efficiencies achieved are presented in Figure 1. As expected, compounds such as TMP and CIP were mainly removed in anaerobic stage, while others like ERY and CLA were mostly removed in the anoxic/aerobic posttreatment. The overall removal efficiencies are slightly lower than those found in a previous work (Alvarino et al., 2019). In this research, the same system treating synthetic wastewater, at higher metabolic activities than this work: 1020 mg COD L^{-1} d^{-1} (UASB) and 143 mg N L^{-1} d^{-1} (MBR) compared to 786 mg COD L^{-1} d^{-1} (UASB) and 125 mg N L^{-1} d^{-1}. This reduction in the metabolic activity could explain the lower efficiency removal of some compounds found in this research.

ARGs assessment

ARGs analysis showed a different distribution of the ARGs in liquid streams compared to biomass. For biomass samples (Figure 2a), an increase in the concentration of some ARGs (macrolides and TMP) was observed when operating with real sewage. In water samples (Figure 2b), a 1.78 log reduction of the discharge was achieved in the second sampling campaign. Some genes were persistent across the process, like sulphonamide resistant genes *sul1* and *sul2*. This persistence was observed in other MBRs, where the ARGs content in the permeate was related to extracellular DNA (Le et al., 2018).

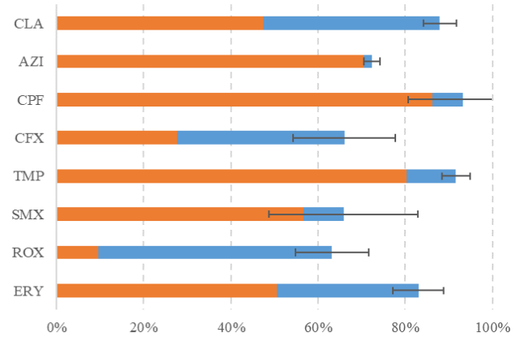

Figure 1. Removal efficiencies of the selected OMPs in the two main stages of SIAM.

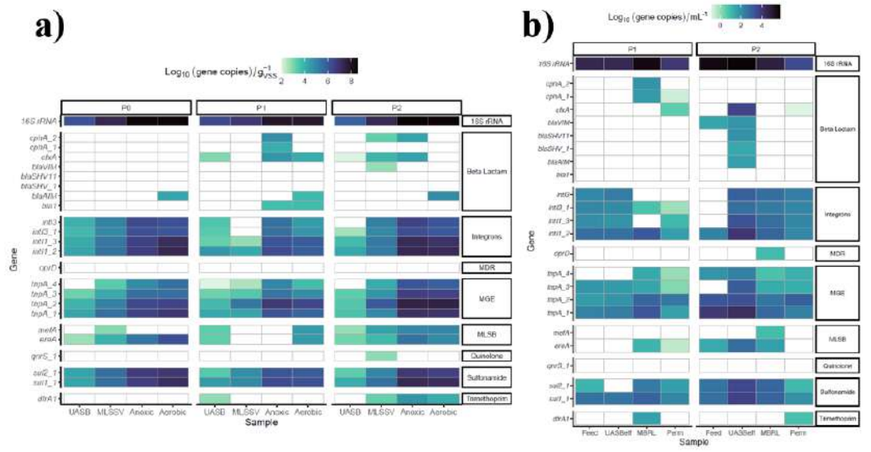

Figure 3. Heatmap of ARGs detected and quantified in the different biomass conformations a) and liquid streams b) for each sampling campaign.

Abstract
White-rot fungi are versatile in degrading a wide broad of xenobiotic pollutants, but the main problem encountered to real application is the maintenance of the fungal activity over a long period. Immobilization on wood has proven to be a suitable strategy for nutrient supply to the fungus, while reducing the competition with indigenous microorganisms. In this study, the performance of two bioreactors (trickle-bed reactor and rotary drum reactor) filled with colonized holm oak wood chips by *Trametes versicolor* was assessed during a continuous treatment for the removal of pesticides from agricultural wastewater during more than 6 months. The stablished consortia allowed to obtain high removal levels during the entire experimental period.

Keywords (maximum 6 in alphabetical order)
Continuous treatment, Bentazone, Diuron, Rotary drum bioreactor, Trickle-bed bioreactor, Wood chips.

INTRODUCTION

Pesticides are essential to ensure pest control and food production worldwide. Nevertheless, the growing occurrence of pesticides in water resources has become an emerging concern due to their persistence, bioaccumulation and toxicity to human beings and the environment, even at low concentration. Although pesticides are xenobiotic pollutants, bioremediation by white-rot fungi (WRF) can be a promising alternative due to its non-specific intracellular and extracellular enzymatic system, which is able to biodegrade a wide range of persistent organic pollutants including pesticides. Nevertheless, some drawbacks of fungal treatment need to be overcome for full application in a continuous treatment process, such as the maintenance of the fungal metabolic activity and the bacterial competition for nutrients (Mir-Tutusaus et al., 2018).

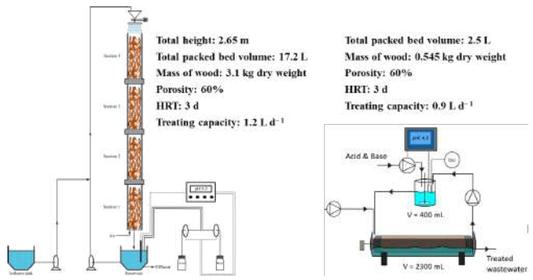
The fungal degradation of recalcitrant compounds is carried out co-metabolically, which requires nutrient supply, usually a carbon source such as glucose, but this promotes the indigenous microorganism competence by losing fungal biomass and reducing fungal activity. Immobilization of the fungus on lignocellulosic materials, such as wood, is a promising strategy to retain fungal biomass and support fungal growth.

A comparative study between two reactors configurations with *Trametes versicolor* immobilized on wood chips, a trickle-bed reactor (TBR) and a rotating drum bioreactor (RDB), was carried out to assess the continuous treatment of agricultural wastewater spiked with diuron and bentazone during more than six months of operation with a hydraulic retention time of 3 days. In addition to the removal, the key aspect is the persistence of the fungus in the bioreactor during long-term operation, among other practical issues to consider for scaling up the agricultural wastewater treatment, such as the contact time between the fungus and the water to be treated.

MATERIALS AND METHODS

Agricultural wastewater (AW) was collected from an irrigation channel located in Gavà, Parc Agrari Baix Llobregat, corresponding to the Llobregat River Basin (Catalonia, Spain), and stored at 4 ºC until use. To assess the removal capacity of the system by HPLC, AW was spiked with diuron and bentazon, reaching influent concentrations up to 8.43 ± 1.81 mg L^{-1} and 9.51 ± 2.02 mg L^{-1}, respectively.

The TBR was set up with four identical cylindrical methacrylate columns (Ø 11.7 cm, L 50 cm) that were filled with fungal colonized helm oak wood chips and then joined together. At the top of the reactor, fortified AW was loaded into the packing bed through a rotary distributor, and then collected in the reservoir tank placed at the bottom part, in which the liquid volume was kept at around 3.6L. The total height, from the reservoir tank to the distributor, was 2.65 m. The working volume of the packing bed was approximately 17.2L, with a porosity as 60%. The tank was equipped with a stirrer and a pH controller through which the pH of collected water was maintained at 4.5 by adding either 1M HCl or 1M NaOH. Air was introduced from the bottom of the reactor, thereby providing an aeration rate of approximately 0.5L min^{-1}. An external bottom-up recirculation loop was provided with a recirculation ratio between 71 - 284, and new spiked AW was also added via a peristaltic pump, reaching a continuous process with a hydraulic retention time (HRT) of 3 days (Fig. 1).



The RDB was constructed with a methacrylate tube supported on a polyvinylchloride gutter. The wastewater was contained within the channel while the colonized wood chips were placed inside the tube. The inner tube contained 1100g DW of colonized wood (2.2g DW·L^{-1} of fungal biomass). Approximately 30 % of the biomass was submerged in the liquid phase, while the rest was in direct contact with air. The inner tube was connected to an electric motor that rotated to alternate the submerged biomass fraction. The RDB was continuously fed with fortified AW to reach 3 days of HRT and a recirculation ratio of 5. The pH was automatically controlled at 4.5 by adding either 1 M HCl or NaOH (Fig.1)

Figure 1. Schematic representation of the TBR and RDB for continuously treating agricultural wastewater spiked with diuron and bentazone during more than 6 months.

RESULTS AND DISCUSSION

Immobilization of *T. versicolor* on wood can be a beneficial option for the treatment of pesticide-contaminated water, in which not only the immobilized biomass amount but also the contact time between the immobilized biomass and liquid phase represent a key factor.
For the TBR, the total contact time is positively related to the recirculation flow rate, but practical concerns such as energy cost, pump workload, biomass washing out, etc. should be taken into consideration. The recirculation rate (RR) is defined as the ratio between recirculation flow rate and the influent flow rate. During the treating process 4 periods were stablished with 3 different RR (71, 142 and 284) with contact times of 5.0, 6.72 and 9.04 h, and liquid hold-up rate of 1.32, 1.78 and 2.39, respectively for a 3 days HRT. Figure 2 shows the removal during the long-term operation with an average removal of 80% and 63% for diuron and bentazone, respectively.
After 186 of operation, fungal biomass increased 4-fold from the initial concentration therefore oak wood was able to support fungal growth in the reactor without nutrient addition. But fungal growth essentially led to enhancing the compactness of packing bed, and it easily caused clogging issue on day 130 of treatment, when it was necessary to reconstitute the packing bed. On the contrary, the bacterial contamination remained low enough to rise the predominance of the fungus *T. versicolor*. This fact overcomes one bottleneck of the fungal treatment which is the bacterial contamination and the consequent reduction of fungal degradation activity (Hu et al., 2022).
The analysis of the fiber content in lignocellulosic carrier evidenced that the consumption rate was constant to 0.35gDWd^{-1} (11% of wood mass/month), suggesting that the packing bed would need to be renovated every 6 months because the lignocellulosic carrier wood would become exhausted.

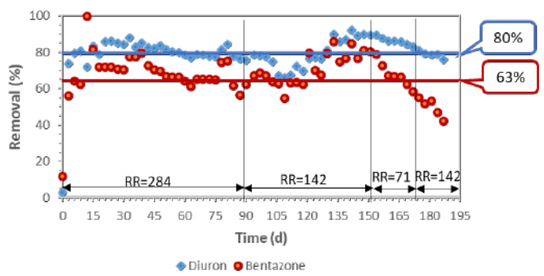


Figure 2. Time-course of the bentazone and diuron removals during the long-treatment in the TBR with an HRT of 3 days.

For the RDB, part of the fungus (approximately 30 %) was submerged in the water and might be limited in dissolved oxygen, hence the fraction of submerged biomass had to be alternated by rotating the inner tube. Two different rotation frequencies were used for each period, 1.5 turns every 4 h and every 24 h for the first and second periods, respectively. Fig. 3 shows the removal during long-term operation in the RDB. Compared to TBR, the average removals of diuron and bentazone were substantially lower in RDB, although this fact was mainly attributed to the lower biomass amount used in the latter case. Fig. 3 also shows that reducing the rotation frequency of the inner tube in the RDB had a positive effect in terms of diuron and bentazone eliminations, maintaining more stable removal yields throughout the second period. This more stable removal was related to a better biomass immobilization on the wood, which reached a 3-fold higher fungal content by the end of the second period compared to the first period. The higher abundance of *T. versicolor* in the second period also contributed to keeping bacterial growth under control. Wood fiber consumption was approximately 1 % wood/month, i.e. substantially lower than that in the TBR, which was associated with the lower *T. versicolor* content present in the RDB (Beltran-Flores, 2022)

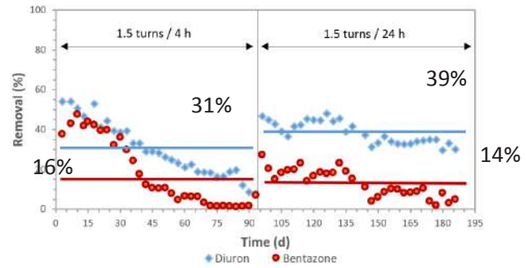

Figure 3. Time-course of the bentazone and diuron removals during the long-treatment in the RDB with an HRT of 3 days.

Table 1. Advantages and limitations of two reactor configurations for the removal of pesticides with fungi immobilized on wood chips.

Trickle bed reactor	
Advantages	**Drawbacks**
✓ Great operational flexibility ✓ Promotes fungal growth ✓ Nature conditions emulated ✓ No oxygen limitation	× Short contact time × Low mass transfer × Risk of clogging × Very high pumping energy × Lack of homogeneity
Rotary drum bioreactor	
Advantages	**Drawbacks**
✓ Reduced bioreactor volume ✓ Low energy demand ✓ Low fungal growth ✓ Low biomass/water relationship ✓ Adaptable for on-site application	× Only 1/3 biomass submerged × Possible oxygen limitation × Required recirculation to maintain homogeneity × Biomass detachment at high rotation speeds

Abstract

High-Rate Activated Sludge (HRAS) reactors could become key units in novel wastewater treatment plants (WWTP) to achieve a net or even positive energy balance. Apart from energy concerns WWTPs must also focus on removing organic micropollutants (OMPs), especially pharmaceutical compounds. Additionally, avoiding the spread of antibiotic resistant genes (ARGs) should also be addressed. HRAS processes are based on high food-to-microorganism ratios, thus they usually operate at low hydraulic retention times (HRT) and low oxygen concentrations(DO). In this contribution it is hypothesized that these operational conditions might affect the biotransformation efficiency of OMPs and the development of ARGs in HRAS reactors. Therefore, in this study, we aim to fill this gap by assessing the fate of OMPs and ARGs in HRAS reactors operating at different DO levels and HRT.

INTRODUCTION

High-Rate Activated Sludge (HRAS) reactors followed by nitrogen removal through partial nitritation and anammox processes are expected to be part of the next generation wastewater treatment plants (WWTP), substituting the conventional treatmentcomposed of a primary clarifier plus an activated sludge unit. The main advantages are the higher quality of the effluent and the increase in the energy efficiency of the plant, since the HRAS systems require less aeration and maximizes the production of sludgeto be transformed into biogas (Taboada-Santos etal., 2020). However, this novel treatment scheme will have to face new challenges, such as the increasing presence of emerging pollutants in wastewater; namely, organic micropollutants (OMPs) and antibiotic resistance genes (ARGs). Unfortunately, the information regarding the behaviour of OMPs in HRAS units is still very limited (Koumaki etal., 2021; Taboada- Santos et al., 2020), and unknown in the case of ARGs.

The objective of this study is to elucidate the influence of two key operational parameters of HRAS systems (i.e., hydraulic retention time -HRT- and dissolvedoxygen levels - DO) in the fate of OMPs and ARGs to find a proper strategy for their mitigation.

MATERIALSANDMETHODS

DescriptionandoperationalconditionsoftheHRASunits

Two HRAS lab-scale systems (2 L reactor + 1 L sedimentation tank) were inoculated with biomass from a conventional activated sludge reactor and operated for ~ 5 months at room temperature, which varied between 18 and 23 ºC. The sludge retention time (SRT) in both HRAS reactors (R1 and R2) was kept at around 4 d. Aeration was monitored and controlled so that the reactors operated at different levels of dissolved oxygen (DO):it was set at a low concentration (1 mg O_2/L) in R1, while in R2 it was maintained at an average value of 6 mg O_2/L (near saturation). The 5-month operationof each HRAS system was divided in 4 periods with different HRT (12 h, 8 h, 4 h and 2 h) to assess the effect of this parameter and DO in the fate of OMPs and ARGs.

The biological reactors were continuously fed with real sewage, taken from the municipal WWTP of Santiago de Compostela (Spain) after the pretreatment step (just before entering the primary clarifier). Due to dilution during rainy periods, the real sewage was supplemented with a mixture of sodium

acetate, acetic acid, yeast extract and several macronutrients to reach a minimum COD concentration of 400 mg O_2/L. Moreover, the reactors feeding was spiked with 18 OMPs (Table 1) including different families of pharmaceutical compounds typically found in WWTPs (Verlicchi etal., 2012).

OMPsandARGssamplingstrategy

Each operational period started with 2 – 3 stabilisation weeks, after which a sampling campaign was carried out. During this week of sampling, triplicate samples were taken in three consecutive days for OMPs and ARGs analyses. Figure 1 shows a scheme ofthe HRAS reactors with the different sampling points for each analysis.

Considering the low sorption coefficients of the selected OMPs and the low concentration of solids in the influent and effluent, OMPs were only measured in the liquid phase of the influent and effluent. Besides, OMPs were measured in the solid purge sludge. To conduct the OMP mass balance in the system, the concentration of OMP in the solid fraction of the reactor sludge was assumed equal to that in the solid purge sludge.

ARGs were determined in the influent and effluent samples, both in liquid and solid phases to study its distribution between both fractions. To further assess the effect of sedimentationonARGsfate,theyweredeterminedinthesolidphasesofthereactorand purge samples.

Analyticalmethods

Conventional parameters. The reactor performance was monitored twice per week in terms of pH, TS, VS, TSS, VSS, COD, NH_4^+, NO_2^- and NO_3^- collecting samples from the influent and effluent and analysing them according to the Standard Methods by triplicate. Sludge from the purge and samples from the reactor were characterised every week in terms of TSS and VSS. Temperature and pH were daily monitored inside the reactor while DO was continuously monitored.

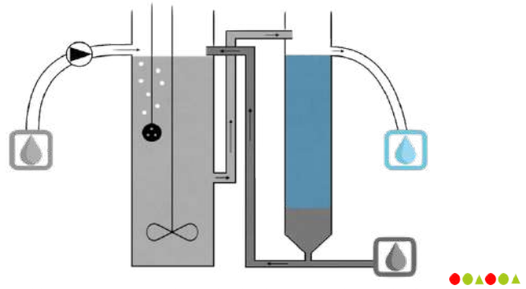
Organic micropollutants. OMPs analyses in the liquid phase were performed via LC- MS/MS after a preconcentration stage using a solid phase extraction protocol in 6 mL Oasis cartridges as described by(Martínez-Quintela etal., 2021). Solid samples were freeze-dried, and after an extraction step, the analytical procedure of liquid samples was applied.

Antibiotic Resistance Genes. ARGs quantification was performed for influent, effluent, reactor and purge samples.Different concentration protocols were followed. Briefly, for reactor and purge samples, 50 mL were collected and centrifuged to obtain a dry pellet was obtained, the extraction Influent (1 L) and effluent (2 L) samples were pre-filtered and subsequently concentrated in dialyzers (Rexeed-25A) and polyamide 0.2 µm filters. DNA extraction from concentrated samples was performed employing a commercial kit (NucleoSpin Microbial DNA) and quantified. ARGs quantification was performed on a SmartChip™ Real-Time PCR by Resistomap (Helsinki, Finland) on a Cycler

RESULTS

HRAS performance

The first two operational periods were carried out at a HRT of 12 h and 8 h (days 1 – 70 and 71 – 90, respectively). The third campaign (HRT 4 h) is ongoing (days 114 – 144) andwillbefollowedbythefourthandlastperiodwithanHRTof2h(expectedondays 145 – 166).



OMP,liquid OMP, solid ARG, liquid ARG, solid

A stable operation was achieved in both reactors during the first two operationalperiods, reaching total COD removals of 80 – 90%, (Figure 2). Soluble COD removal varied between 75 – 95% for both reactors. Low nitrification values were observed through the operation (<1% NO_3^- and <5% NO_2^-). VSS were maintained during the first operational period at 1200 and 1500 mg/L in R1 and R2, respectively. During thesecond period, biomass concentration increased up to 1800 and 2400 mg/L in R1 and R2, respectively.

Figure1.SchemeoftheHRASreactorswithsamplingpointsforOMPsandARGs analyses.

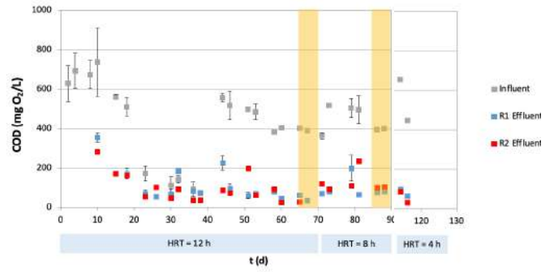


Figure ARGs analyses are in yellow.

Fateof OMPsand ARGs

Samples from the two first sampling campaigns have been processed, but unfortunately the results are not available yet. The last two sampling campaigns will be conducted in February. The data gathered will contribute to confirm some of the following hypotheses:

- **A reduction on HRT could reduce OMPs elimination as microorganisms do not have enough time to biotransform the, or either improve OMPs elimination as microbiological activity increases with a higher food to microorganism (F/M) ratio.**
- **A higher aeration could lead to a faster oxidation, increasing OMPs elimination, although the presence of different microbial communities would suggest alternative metabolic mechanisms that could also alter biotransformation efficiencies.**

Likewise, we expect to establish the effect of these parameters (HRT and DO) on the development of ARGs and determine its relationship with the fate observed for OMPs.

ACKNOWLEGGMENTS

This research was supported by the Spanish Research State Agency (AEI) through ANTARES (PID2019–110346RB-C21) project.

Abstract

A combination of thermophilic aerobic reactor (TAR) with mesophilic anaerobic digestion (MAD) was evaluated for its capacity to enhance the sludge reduction, increase the methane production and improve the efficiency of micropollutant biodegradation when applied to a primary sludge obtained after decantation of urban wastewater.

Higher elimination of organic matter was achieved in MAD-TAR (76% for VSS) compared to conventional MAD (47%). Nevertheless, the measured methane production was comparable for the two processes showing either a contribution of micro-aerobic degradation or a loss of diluted methane in the gas flow.

The removal efficiency of pharmaceutical compounds obtained in the two configurations was compared. The highest removal rates were reported for caffeine (CAF) and sulfamethoxazole (SMX) (>89%) with no significant differences between both processes. MAD-TAR increased significantly the removal for oxazepam (OXA) (73%), propranolol (PRO) (61%) and ofloxacine OFL (41%) and slightly for diclofenac (DIC) (4%) and 2 hydroxy-ibuprofen (2OH-IBP) (5%).

INTRODUCTION

Wastewater treatment plants (WWTP) are energy-consuming facilities. Management of digested sludge (often referred to as "biosolids") represents a large percentage of a WWTP's operational expenditures, up to 40 %. Anaerobic digestion (AD) reduces the organic matter content of sludge by 40 and 50% and plays a very positive role in the energy independence and the economic balance. Combined with pre- or post-treatment, it enhances the stabilization of sewage sludge and reduces pathogens and odor emissions. Therefore, AD is seen as one of the most sustainable options for sludge treatment. Unfortunately, most conventional AD systems still produce copious amount of biosolids due to limitation in sludge degradation. Advanced Anaerobic Digestion (AAD) has been proposed to create higher quality biosolids and more biogas through higher volatile solids reduction (Guo *et al.* 2013). For example, thermal pre-treatment at high temperature (around 160°C) showed a substantial sludge reduction and increase in biogas (Barber, 2016). However, a significant production of refractory compounds is observed leading to exceeding the standard values for the COD and TKN.

Over the last twenty years, various studies have quantified concentrations and occurrences of pharmaceutical compounds in WWTPs. Depending on the physicochemical properties of the molecules, a significant fraction can adsorb onto the sludge. The evaluation of the degradability of pharmaceutical molecules during digestion is essential for later recovery and valorization of digestates. However, although various studies have investigated the fate of pharmaceutical compounds in the water sector, their behavior during anaerobic digestion has been little studied. In addition, innovation on the process is still needed to improve the degradation of these compounds. Various thermal, chemical and enzymatic processes are known to improve the removal of recalcitrant organic matter (Paul and Liu, 2012). Among all these processes, micro-aeration pretreatment has shown interesting enhancement of particulate matter hydrolysis and substrate solubilization (Johansen *et al.* 2006).

In this work, a combination of two processes, a thermophilic aerobic reactor (TAR) with a mesophilic anaerobic digestion (MAD) is evaluated for its capacity to enhance the sludge reduction, increase the methane production and improve the efficiency of adsorbed micropollutant biodegradation.

MATERIALS AND METHODS

Reactors. The experimental set-up composed of a mesophilic anaerobic digester (MAD) coupled with a thermophilic aerobic digester (TAR). The MAD is a 260 L tank with an agitator and a double jacket connected to the TAR by means of an ALBIN peristaltic recirculation pump (type ALH15), whose flow rate was fixed at 100 $L.h^{-1}$. The TAR, with a volume of 40 L, was also equipped with an agitator and a double jacket. The aeration of the TAR was operated discontinuously to provide a dissolved oxygen concentration, measured by VisiFerm™ DO optical sensor (Hamilton) between 0.2 and 0.5 $mg.L^{-1}$. The two reactors were heated by two independent cryostats in order to maintain the temperatures suitable for aerobic thermophilic (55 °C) and anaerobic mesophilic (35 °C) processes.

The feed was performed with a primary sludge obtained after decantation of urban wastewater (WW) and the duration of feeding, withdrawal and recirculation were adjusted to maintain a total SRT of around 20 days and a residence time in the TAR of 1 day.

Analysis. To evaluate the performances of the two studied processes, daily-composite samples of primary and digested sludge were collected regularly during steady-state periods. Sludge samples were stored at 4 °C and analyzed on the same day. In addition, aliquots of the total and dissolved fractions (obtained after 4500 g centrifugation for 15 minutes) were stored at -20 °C for micropollutants analysis.

The sludge and the supernatants were characterized by Total Suspended solids (TSS), Volatile Suspended Solids (VSS) and Chemical Oxygen Demand (COD).

The degradation of nine compounds (caffeine CAF, ofloxacin OFL, sulfamethoxazole SMX, propranolol PRO, carbamazepine CBZ, oxazepam OXA, diclofenac DIC, ibuprofen IBP and 2 hydroxy-ibuprofen 2OH-IBP) was evaluated. Quantification of micropollutants was performed by UHPLC-MS-MS following a modified QuEChERS extraction.

RESULTS AND DISCUSSION

Performances of digestion

Although the feeding showed fluctuations, as can be expected when working with real WW, the VSS and COD_s concentrations after digestion remained constant with standard deviation below 4%. Considering comparable operating conditions, higher elimination of solid organic matter was achieved in the hybrid MAD-TAR system (around 76% for VSS) compared to the mesophilic one (around 47%) confirming lab results obtained a few years ago (Dumas et al., 2010). Operational conditions and main results are reported in Table 1 and figure 1.

Table 1. Methanisation performance

Operational conditions	MAD	MAD-TAR
OLR ($kgCOD/m^3/day$)	1.2	0.9
OLR ($kgVSS/m^3/day$)	0.8	0.6
SRT (days)	19.6	22.4
Reactor		
TSS (g/L)	11.7±0.5	4.9±0.6
VSS (g/L)	8.3±0.4	3.4±0.4
COD_t (g/L)	14.1±1.4	5.7±0.8
COD_s (g/L)	0.37±0.06	0.36±0.08
Removal efficiencies (%)		
COD	46.7	72.9
VSS	47.0	75.7

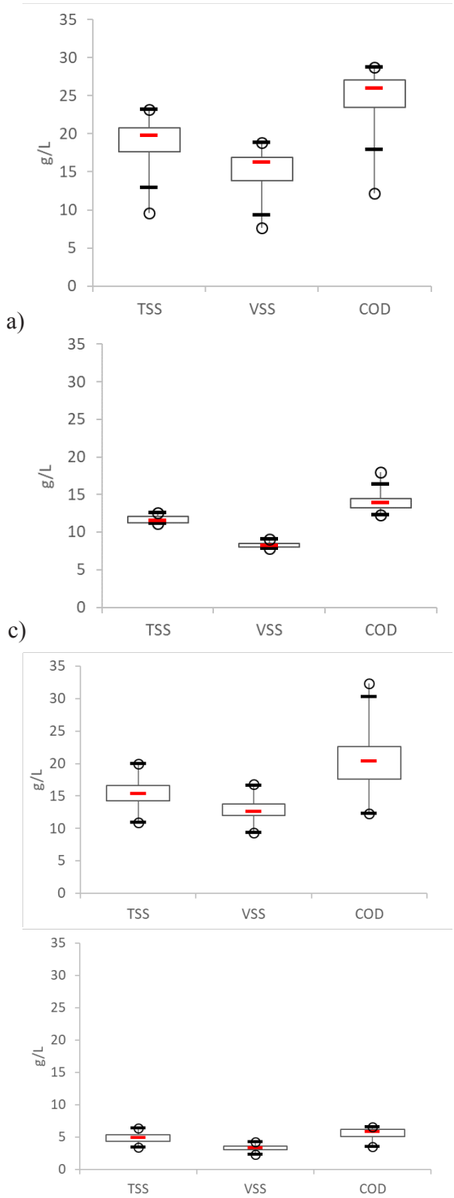

Figure 1. Characteristics of primary sludge (a,c) and digestate (b,d) for MAD (A,b) and MAD-TAR (c,d) configurations., n=17.

Despite the observed sludge reduction, methane production for the hybrid MAD-TAR system was found similar to the one of the conventional MAD. The difference in COD converted to methane could be either due to aerobic degradation or the difficulty to measure methane production in the TAR due to its high dilution in the gas flow. This aspect is still under investigation.

Fate of micropollutants during digestion

All the target molecules were detected and quantified in the primary sludge. Even if some variations have been observed between the two experimental campaigns (-23% in average during the MAD-TAR experiment) the order of magnitude were the same. The highest concentrations of targeted compounds were observed for OFL and CAF (more than 40 µg/L) while medium to low concentrations were reported for SMX, CBZ, PRO, DIC, OXA, IBP and 2OH-IB, around 1.0-10.0 µg/L.

The comparison of removal efficiencies in MAD and MAD-TAR are reported in Figure 1. Compounds placed above the dotted line show better removal efficiency by the innovative process (MAD-TAR) compared to conventional process (MAD). The highest removal rates were obtained for CAF and SMX (>89%) with no significant differences between both processes. The removal of others target compounds was significantly improved by MAD-TAR process. Medium removal ranging between 54% and 75% were observed for OFL and OXA respectively in MAD-TAR compared to only 9% and 49% in MAD. Moreover, while PRO was not removed at all during MAD process, a rate of 69% was achieved in MAD-TAR. DIC and 2OH-IBP present low removal during MADTAR (6-10%) while they were accumulated in MAD. Finally, a negative removal rate was observed for IBP and CBZ in both processes, MAD (-30% and -71%, respectively) and MAD-TAR (-35% and -91%).

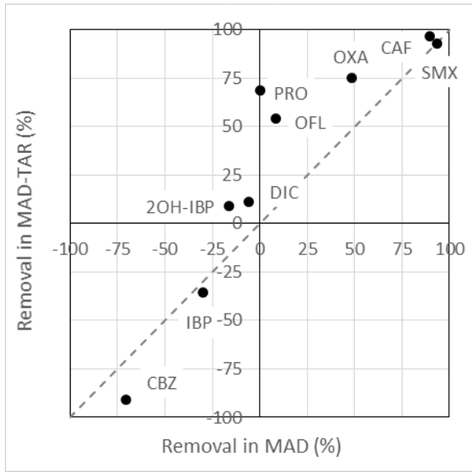

Figure 2. Comparison of compounds removal in conventional vs innovative process

Those experiments are currently being extended to a MAD-TAD (thermophilic anaerobic digestor) hybrid configuration in order to dissociate the respective effects of oxygen and temperature on the removal performances.

Abstract

Boron- and two-dimensional boron, i.e., borophene-doped graphene sponge anodes were synthesized and applied for the electrochemical oxidation of C4-C8 per- and polyfluoroalkyl substances (PFASs). Borophene-doped graphene sponge was the best performing anode demonstrating removal efficiencies in the range of 30.1-77.1%, obtained in one-pass flow-through mode using low conductivity supporting electrolyte (1 mS cm^{-1}) at 230 A m^{-2} of anodic current density, and with energy consumption of 9.4 ± 0.3 kWh m^{-3}. Moreover, the performance of the borophene-doped graphene sponge was subsequently evaluated using landfill leachate (30 mS cm^{-1}), at higher initial PFASs concentration (2 µM). Enhanced removal % for all target compounds, except PFHxA, were obtained with up to 86.3±7.7% and 71.7±3.0% removal for perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA), respectively.

Keywords

Chlorine-free electrochemical system; electrochemical water treatment; PFAS; reduced graphene oxide-coated sponge

INTRODUCTION

Per- and polyfluoroalkyl substances (PFAS) are a class of artificially manufactured compounds which widespread presence in the environment is a topic of major concern for both human health and the environment due to their persistence, bioaccumulation potential, and adverse effects on living organisms. Due to the strength of the C–F bond, currently applied wastewater treatment methods, both conventional and advanced, are not capable of degrading PFASs. Electrochemical oxidation is capable of C-F bond cleavage, but limitations such as high material cost and formation of chlorine, chlorate and perchlorate in the presence of chloride (Radjenovic, Duinslaeger, et al., 2020), are restraining its wider scale application. In our recent study(Duinslaeger and Radjenovic, 2022), we demonstrated that the newly developed boron-doped graphene sponge anode is capable of defluorinating PFAS, while displaying a remarkably low electrocatalytic activity for chloride oxidation, with no chlorate and perchlorate formation, and very low generation of chlorine (i.e., current efficiency of only 0.04% for chlorine production in the presence of 20 mM NaCl)(Baptista-Pires, Norra, et al., 2021). Furthermore, our previous study demonstrated that functionalization of graphene sponge electrodes with two-dimensional (2D) materials can enhance their electrocatalytic activity and modulate the interaction with specific organic contaminants, thus opening new possibilities for designing electrodes tailored to remove specific groups of pollutants(Cuervo Lumbaque, Baptista-Piresa, et al., 2022). In this study, we evaluated the impact of changing to 2D nature of graphene dopant by comparing the performance of boron- and borophene-doped graphene sponge electrode for electrochemical oxidation of six model PFASs, i.e., perfluorooctanesulfonic acid (PFOS), perfluorooctanoic acid (PFOA), perfluorohexane sulfonate (PFHxS), perfluorohexanoic acid (PFHxA), perfluorobutanesulfonic acid (PFBS) and perfluorobutanoic acid (PFBA). The experiments were perfomed using synthetic electrolyte solutions and a highly complex stream of ultrafiltrated (UF) landfill leachate. The obtained results indicate that the developed graphene sponge anode can electrochemically degrade C4-C8 PFAS without forming toxic and persistent organic and inorganic chlorinated by-products.

MATERIALS AND METHODS

Boron- and borophene-doped reduced graphene oxide (RGO) sponge anodes (B-RGO and Bph-RGO, respectively) were synthesized according to the previously published protocols (Cuervo Lumbaque, Baptista-Piresa, et al., 2022), by adding either boric acid or borophene solution to 4 g L^{-1} graphene oxide (GO) dispersion prior to the hydrothermal synthesis method. Borophene solution was obtained through liquid-phase exfoliation from bulk boron (Wang, Li, et al., 2020; Ranjan, Sahu, et al., 2019). All experiments were conducted in a flow-through reactor, operated in one-pass, continuous mode at flow rates of 5 mL min^{-1}. Stainless stell sponge was employed as a flow-through cathode, and leak-free Ag/AgCl as reference electrode. To evaluate possible losses of the target PFASs through adsorption onto the graphene sponge, initial open circuit ($OC_{initial}$) runs were conducted. Electrochemical degradation experiments were conducted in the chronopotentiometric mode at the anodic current density of 230 A m^{-2}. Electrochemical removal of target PFASs was evaluated in synthetic electrolyte solution (10 mM phosphate buffer (PB, 1 mS cm^{-1})) and a highly complex real waste stream of UF landfill leachate (30 mS cm^{-1}), obtained from a near-by landfill in Girona, Spain. In both cases, target PFASs were added at low concentration (0.2 µM) to evaluate their removal, and at higher concentration of 2 µM to evaluate their defluorination. The fluoride, which was determined to be incorporated into the graphene coating due to the high reactivity of the liberated HF (Duinslaeger and Radjenovic, 2022), was quantified using Combustion Ion Chromatography (CIC) of the Bph-RGO anode. At the end of each chronopotentiometric run, the effluent was sampled after the current was switched off (i.e., OC_{final}) to evaluate the loss of the target PFASs due to electrosorption only.

RESULTS AND DISCUSSION

The effluent concentrations were equal to their influent concentrations during the OC_{intial} for the six model PFASs, demonstrating that there was no absorption of PFAS on the graphene sponges or any other part of the reactor. **Figure 1** illustrates the observed removals of the target PFASs at low concentration (0.2 µM) for B-RGO and Bph-RGO in 10 mM PB. Application of 230 A m^{-2} resulted in an average removal efficiency 68.7±2.0% (PFOS), 32.6±5.0% (PFHxS), 26.2±1.8% (PFBS) for the perfluorosulfonic acids (PFSAs) and 41.1±1.5% (PFOA), 23.6±1.9% (PFHxA), 39.4±1.3% (PFBA) for the carboxylic acids (PFCAs). By changing from boron to borophene, the average removal efficiencies were increased for all model PFASs, with 77.1±1.3% (PFOS), 37.5±0.9% (PFHxS), 32.0±1.8% (PFBS) and 57.2±3.1% (PFOA), 30.1±1.7% (PFHxA) and 45.7±2.1% (PFBA) at the same applied current density (230 A m^{-2}). The increase was more pronounced for the perfluorocarboxylic acids (PFCAs) and more prominent with the lengthening of the chain length in the order PFOA>PFHxA>PFBA. This may be a consequence of a lower electrostatic repulsion between borophene active sites and the carboxylic moieties of the PFCAs compared to the perfluorosulfonic acids (PFSAs). In addition, borophene doping was demonstrated to yield an order of magnitude higher concentration of the electrogenerated hydroxyl radicals (OH·) compared with boron-doped graphene sponge anode (Cuervo Lumbaque, Baptista-Piresa, et al., 2022). Electrochemically generated hydroxyl radicals react with PFAS radicals, created after the initial direct electron transfer step from the PFAS to the anode, and assist in the decarboxylation and defluorination. In the OC_{final}, the effluent concentrations for the six studied PFASs rose above their initial concentrations for B-RGO, demonstrating that a fraction of the removed PFAS was only electrosorbed onto the graphene sponge anode and released back into the solution when the current was stopped. The % of the electrosorbed PFASs could be estimated based on the concentrations measured in the fractions in OC_{final} and the total removal efficiencies, and was 35±8.3% (PFOS), 12.1±6.5% (PFOA), 16.1±3.2% (PFHxS), 13.3±3.8% (PFHxA), 13.0±2.6% (PFBS), 7.4±0.5% (PFBA). Thus, the efficiencies of electrochemical degradation for B-RGO were calculated to be 32±4.4% (PFOS), 31.5±9.9% (PFOA), 15.3±6.1% (PFHxS), 10.2±5.9% (PFHxA), 13.7±1.5% (PFBS), and 9.3±1.7% (PFBA). In the case of Bph-RGO, we did not observe any increase in the effluent concentrations of PFAS in the OC_{final}, as they all returned to the initial values immediately after the current was turned off. This suggested that the removed fraction of PFAS was also further electrochemically degraded, evidencing higher electroactivity of the Bph-RGO anode. Doping with borophene lowers the resistance at the electrode-electrolyte interface, increased the material's electrocatalytic activity and enhances the generation of strong oxidants ($HO^{\cdot}$, O_3) (Cuervo Lumbaque, Baptista-Piresa, et al., 2022), thus leading to an improved degradation of the electrosorbed PFAS. The lower resistance at the interface also translates in a decreased overall energy consumption from 10.1 ± 0.7 (B-RGO) to 9.4 ± 0.3 (Bph-RGO) kWh m^{-3}.

Bph-RGO anode was employed for the degradation of single PFAS at high concentration (2 µM) in a real UF landfill leachate (**Figure 2**). For all target compounds, except PFHxA, the removals are higher in landfill leachate. Application of 230 A m^{-2} in 10 mM PB resulted in an ohmic drop-corrected anode potential of 4 V vs Standard Hydrogen Electrode (/SHE), resulted in 59.3±6.2% (PFOS), 53.6±3% (PFOA), 27±2.8% (PFHxS), 36.6±2.6% (PFHxA), 13.5±1.1% (PFBS) and 43.2±1.4% (PFBA) removal of the target PFASs in 10mM PB. We applied an anodic current density of 517.5 A m^{-2} to reach the same ohmic drop-corrected anode potential of 4 V vs Standard Hydrogen Electrode (/SHE) as in the case of 10 mM PB (polarized at 230 A m^{-2}). Despite the complexity of this stream in terms of both organic and inorganic content, we obtained higher removal efficiencies of PFAS, i.e., were 86.3±7.7% (PFOS), 71.7±3.0% (PFOA), 66.9±2.5% (PFHxS), 30.0±3% (PFHxA), 40.5±0.5% (PFBS) and 45.9±8.6% (PFBA). This can be explained by the impact of high leachate conductivity (i.e., 30-fold higher compared to the 10 mM PB). High supporting electrolyte concentration decreases the ohmic drop, minimizes the interfacial impedance between the electrode and the electrolyte, and ensures a more uniform distribution of current in the graphene sponge anode, thus enhancing its electrocatalytic activity. Furthermore, even though the UF leachate concentrate contained □7.3 g L^{-1} of chloride, we did not observe any formation of chlorine, chlorate and perchlorate.

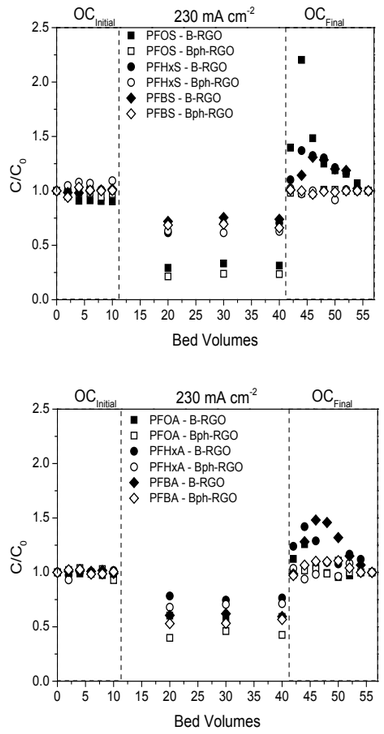

Figure 1. Measured concentrations of perfluorosulfonic acids (PFSAs) (left) and perfluorocarboxylic acids (PFCAs) (right) on B-RGO (full symbols) and Bph-RGO (hollow symbols) normalized to the initial value (C/C0, C0=0.2 µM) at anodic current of 230 A m^{-2} and using a flow rate of 5 mL min^{-1} (i.e., 173 LMH).

As for the determination of defluorination ratios in our previous study (Duinslaeger and Radjenovic, 2022), the Bph-RGO anodes employed for the degradation of individual PFOS and PFOA in both 10mM PB and landfill leachate were subjected to CIC analyses, and the F− concentrations obtained in the combustion of each sponge were used to calculate the fluoride recoveries for both PFASs. The fluoride recoveries in 10mM PB for PFOS (68.6%) and PFOA (81.8%) were comparable to recoveries obtained with B-RGO, 75.3% (PFOS), 74.1% (PFOA). However, in leachate, fluoride recoveries for PFOS and PFOA where 14% and 6.9% respectively. The low recoveries in landfill leachate can be ascribed by the high foam production observed during application of current which negatively impacted the defluorination reaction. The overall defluorination ratio ranged from 40.7±4.2% (PFOS), 43.8±2.5% (PFOA) in 10 mM PB, and 12.1±1.1% (PFOS), 5±0.2% (PFOA) in landfill leachate.

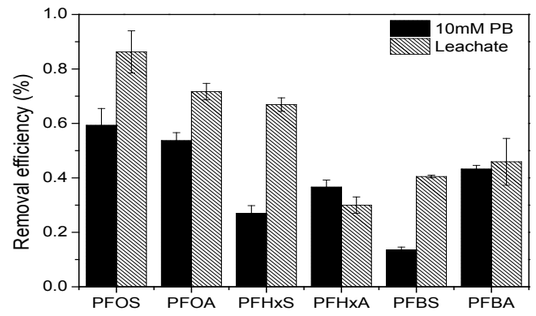

Figure 2. Overall removal efficiency for both perfluorosulfonic acids and perfluorocarboxylic acids in 10mM phosphate buffer (PB) and leachate at 230 A m^{-2} and 517.5 A m^{-2}, respectively.

CONCLUSIONS

In this study we have demonstrated the improved electrochemical removal of six model PFASs when changing from atomic boron to a 2D borophene-doped graphene sponge anode. In the experiments conducted using a Bph-RGO sponge electrode in a low-conductivity supporting electrolyte (1 mS cm^{-1}), and low initial PFASs concentration (0.2 µM), we achieved removal efficiencies with up to 77.1±1.3% for PFOS and 57.2±3.1% for PFOA. The enhanced performance obtained with the introduction of borophene was more pronounced for PFCAs and more prominent with the lengthening of the chain length in the order PFOA>PFHxA>PFBA. We also report an enhanced removal % for nearly all target PFAS in a complex real wastewater matrix, i.e., UF landfill leachate, with 86.3±7.7% and 71.7±3.0% removal observed for PFOS and PFOA respectively. The higher removal % was allocated to the increased electroactivity of the graphene sponge electrode due to the higher conductivity of the electrolytic solution. This study demonstrates that the patented graphene sponge anodes (Radjenović, Baptista-Pires, et al., 2022) effectively enable the degradation of PFAS in high chloride containing streams such as leachate, reverse osmosis concentrate, ion exchange resin regeneration liquids and others. This is a groundbreaking result which opens the door for safe electrochemical treatment of brackish PFAS concentrates using a low cost, easily scalable system.

Abstract

Per- and poly- fluoroalkyl substances (PFAS), are a group of substances, persistent and potentially dangerous for human health. Landfill leachate contains high concentration of PFAS and may be released into the environment through wastewater treatment plants (WWTPs). Sampling campaigns of three full-scale leachate treatment plants were carried out in Italy, in order to assess the fate of PFASs along the treatment chains. Conventional leachate treatment plants have demonstrated low ability to remove PFAS from landfill leachate. Advanced treatment technologies as reverse osmosis (RO) may provide a permeate "PFAS-free". However, high concentrations of PFAS are found in the treated RO concentrate or in the waste sludges, which resulted important ways for the contamination of the environment by these compounds. Therefore, the development of further technologies is needed in order to reach the aim of "zero pollution".

Keywords (maximum 6 in alphabetical order)

landfill leachate; pathways; per- and polyfluoroalkyl substances; wastewater treatment; zero pollution.

INTRODUCTION

Per- and poly- fluoroalkyl substances, so-called PFAS, are a group of substances, which are used to make fluoropolymers, employed in manufacturing clothing, furniture, adhesives, food packaging. They are persistent and mobile in the environmental medias, and potentially toxic (PM(T)) for human health. Therefore, they are considered among the main obstacles to the development of the circular economy, as the reuse of materials from waste could promote their spread in the environment. The project Horizon2020 PROMISCES (Preventing Recalcitrant Organic Mobile Industrial chemicalS for Circular Economy in the Soil-sediment-water system) aims to identify strategies and solutions for minimizing the occurrence of PFAS in the environment (e.g. surface water and drinking water) as well as in recovered resources (e.g. sludge, wastewater and sediments). The main ambitions of PROMISCES are to contribute to the European ambition of a "toxic free" environment with "zero Pollution" and ensuring the protection of human health during the implementation of circular economy practices. The Italian team partners of the PROMISCES project (UNIVPM, Acea Elabori and Simam) are focusing their research activities on the assessment of PFAS pathways for environment contamination during landfill leachate treatment as well as on the development of sustainable technologies for the separation and destruction of PFAS from sewage sludge and leachate.

Globally, landfills are considered to be one of the major sources of PFAS contamination in the environment. In landfills, PFAS-based products can release these compounds in the leachate and even in the air (ITRC, 2020). It is common practice to discharge landfill leachate, after initial treatment, into municipal wastewater treatment plants. Conventional WWTPs have demonstrated to be ineffective for PFAS removal and the presence of precursors in the influent may lead to an increase of PFAS concentrations in the effluent after biological transformation (Lenka et al., 2021). Thus, PFAS from landfill leachate may be released into the aquatic environment through WWTPs effluents but can also be adsorbed into municipal sewage sludges limiting their agronomic reutilization (Helmer et al., 2022; Fredriksson, et al., 2022).

MATERIALS AND METHODS

Within the context of PROMISCES activities, a first sampling campaign in full-scale leachate treatment plants was carried out in Italy, with the aim of determining the fate of PFAS and its precursors along the treatment chains. A robust and cost-effective methodology for the determination of eighteen target PFAS in complex matrixes, such as leachate, membrane concentrate, and sludge, was developed. Table 1 reports the target PFAS analysed during sampling campaigns and their relative limits of quantification (LOQs) in the investigated matrixes.

Therefore, sampling campaigns for the determination of PFAS fate were implemented in three leachate treatment plants. The first plant includes a conventional treatment with clarifloculation, biologic reactor and ultrafiltration membrane (Figure 1). The second plant is a conventional leachate treatment plant (Figure 2), it is composed of a biologic reactor with intermittent aeration (IA), the waste sludge is digested and dewatered together with municipal sludge of the wastewater treatment plant (WWTP). The last monitored leachate treatment plant (Figure 3) includes several advance treatments: i) pre-treatment sections with flotation and sand filter, ii) double-pass reverse osmosis (RO), and iii) RO concentrate treatment line.

Table 1. Target PFAS analysed (LOQ = limit of quantification)

Target PFAS	LOQ for leachate, concentrate and wastewater	LOQ for sludge	LOQ for permeate
PFBA, PFPeA, PFHxA, PFHpA, PFPeS, PFOA, PFHxS, PFNA, PFHpS, PFDA, PFOS, PFUdA, PFNS, PFDoA, PFDS, PFTrDA, PFTeDA	1.0 µg/L	10 µg/Kg	< 0.015 µg/L

RESULTS AND DISCUSSION

In the leachate treatment plant 1, only the compounds PFBA, PFHxA, PFBS and PFOA were detected in the liquid matrix. The observed concentrations remained more or less constant from the inlet to the outlet of the plant for PFHxA (1.3 µg/L) and PFBS (6 µg/L), whereas the concentration of PFBA and PFOA increased in the effluent suggesting possible release of these substances from sludge or transformation of precursors. Increases were from 1 µg/L to 2.2 µg/L for PFBA, and from 3.3 to 4.1 µg/L for PFOA. In the sludge samples of treatment plant 1 were detected PFBS, PFOA and PFOS. Particularly, PFOS was not detected in the liquid phase. Hence, PFOS may have been absorbed previously in sludge or produced by transformation products. However, release of this compound in the liquid matrix was not observed at concentration higher than LOQ.

In the leachate treatment plant 2, PFBA, PFHxA and PFBS were found in the liquid phase of the leachate at concentration of 3.7, 1.5 and 1.7 µg/L, respectively. In this plant, waste sludges are treated along with the municipal sewage sludge. In this mix of sludge only PFBA was detected at concentration of 11 µg/kg.

The Advanced leachate treatment plant (N°3), which utilize RO treatment, was able to obtain a permeate flux where none of the eighteen target PFAS was detected (LOQ = 15 ng/L). However, the obtained RO concentrate showed a relatively high concentrations of ΣPFAS (97.7 µg/L) and, the implemented concentrate treatment line only partially removed PFAS from the flux (39.8 µg/L). The treated RO concentrate is then discharged into the sewage system together with the RO permeate. Hence, the flux coming from the concentrate treatment line nullified the complete removal of PFAS obtained by RO filtration. Therefore, different treatments of RO concentrate are required for removing per- and polyfluoroalkyl substances and reaching the aim of "zero pollution". Particularly, innovative treatment will be tested within the PROMISCES research activities to obtain the complete destruction/removal of PFAS in RO concentrate.

Abstract

Per- and polyfluoroalkyl substances (PFAS), used in several industrial applications, are gaining increasing concern due to their spread in the environment, their stability and eco-toxicity. To avoid PFAS spread in the environment, reducing the environmental risk on receiving water bodies, removal strategies need to be implemented at both industrial and municipal wastewater treatment plants (WWTP). This study presents a case study in a textile district in northern Italy where PFAS monitoring campaigns were combined with testing at lab and pilot-scale of two promising removal processes (membrane separation, adsorption on activated carbon) and data used for environmental risk assessment. This combination was proved to be useful to support the identification of the optimal combination of prevention and treatment interventions to be applied at different system points to reduce the environmental risk.

Keywords (maximum 6 in alphabetical order)

Adsorption; Environmental risk assessment; Membrane separation; PFAS; Scenarios analysis; Textile Wastewater

INTRODUCTION

Per- and polyfluoroalkyl substances (PFAS) are used in numerous industrial applications, such as in textile manufacturing, for their unique chemical properties. The widespread use of PFAS and their persistence make them ubiquitous compounds of increasing concern due to their eco-toxicity (Lewis et al., 2022). To avoid PFAS spread, both prevention and removal strategies should be implemented at both industrial and municipal wastewater treatment plants (WWTP).
As for the prevention strategies, some studies evaluated the substitution of long-chain PFAS with short-chain ones or with non-fluorinated compounds. As for the treatment of textile industry wastewaters (WW), numerous articles investigated decolorization by several technologies, assessing the removal of dyes or COD from target WW (inter alia, Chollom et al., 2015). However, very few studies can be found on the use of such technologies in removal PFAS in these concentrated streams. Moreover, there are no literature studies comparing PFAS reduction strategies at the sources (i.e. textile industries) and at the centralized municipal WWTP.
Thus, the objective of this study is to combine field monitoring, lab- and pilot-scale experiments, and environmental risk assessment to evaluate the current risk in receiving water body in a textile district in northern Italy and compare prevention and removal strategies for risk minimization.

MATERIALS AND METHODS

The case study is focused on a WWTP collecting WW from textile industries (20-35% of the inlet flowrate) and civil origin. The WWTP comprises pre-treatments, activated sludge biological treatment (pre-denitrification, nitrification/oxidation), tertiary coagulation-flocculation followed by a lamella clarifier and ozonation.

Monitoring campaigns

Three monitoring campaigns have been performed in four textile industries: 1 textile printing, 1 fabric dyeing and 2 yarn dyeing companies. Concerning the WWTP, 11 campaigns have been performed, collecting four samples in each campaign: the WWTP inlet, the biological treatment outlet, the ozonation inlet and the WWTP effluent. Monitored parameters were: 14 PFAS (PFBA, PFHxA, PFBS, GENX, PFPeA, PFHpA, PFOA, PFOS, PFHxS, PFNA, PFDA, PFUnA, PFDoA, PFOSA), pH, conductivity, TSS and COD.

Lab- and pilot-scale experiments

As for textile WW, pressure-driven membrane separation has been tested, assessing both microfiltration (MF) and nanofiltration (NF) and their combination. A SEPA CF Cell cross-flow filtration unit was used in "feed and bleed" mode, under pressure and filtration rate conditions comparable to full-scale ones. Three tests were carried out on a mixture of textile WWs collected from the monitored industries with no PFAS spike. The water matrix was characterized by 23.9 g/L COD, 1440 µS/cm conductivity, pH of 4.5, sum of PFAS equal to 9.5 µg/L.
In the centralized WWTP, adsorption on activated carbon (AC) was tested at lab and pilot-scale. Rapid Small Sale Column Tests (RSSCT) and Field Adsorption Pilot Plant (FAPP) tests have been performed on two water matrices, collected before (IN-O3) and after (OUT-O3) the full-scale ozonation, spiking the samples with 14 PFAS to achieve a concentration of 4 µg/L per single PFAS. The water matrices IN-O3 and OUT-O3 were characterized respectively by: COD of 36 mg/L and 30 mg/L, pH of 7.7 and conductivity around 1350 µS/cm. Both RSSCT and FAPP were sized through the constant-diffusivity down-scaling equation (Crittenden et al., 1987), simulating the performance of full-scale GAC filters with 20 minutes of Empty Bed Contact Time (EBCT). 3 ACs were tested, differing for the porous structure and volume.

Scenarios analysis

To estimate PFAS mass balance throughout the system, the average measured values of flowrate (Q) and PFAS concentrations (C_{PFAS}) (Q_{CIV}=14,240 m^3/d; Q_{TEX}=6,765 m^3/d, $C_{PFAS,CIV}$=0.5 µg/L; $C_{PFAS,TEX}$=0,31 µg/L), and removal efficiencies observed at the lab- pilot-scale were used. The percentage of the total PFAS load leaving the plant through the dewatered sludge, according to the monitoring data, was 0.8%. In scenarios without additional treatments in the WWTP, PFAS concentrations were assumed stable along the treatment train, according to the monitoring data.
The following scenarios have been simulated:
- Scenario 0: Scenario in the current situation (Business As Usual, BAU).
- Scenario 1a: Scenario on voluntary action to reduce total PFAS in textile processes by 35%.
- Scenario 1b: Scenario on voluntary action to replace long-chain PFAS with short-chain PFAS in textile production processes, considering that on average twice the amount of short-chain PFAS is needed to produce fabrics with same performance of long-chain PFAS.
- Scenario 2: Scenario of treatment of textile WW by membrane separation: MF+NF.
- Scenarios 3a and 3b: Scenarios combining scenarios 1a and 2 (3a) and 1b and 2 (3b).
- Scenario 4: Scenario of treatment in the centralised WWTP through adsorption on AC after ozonation, operated for 100,000 bed volumes (BV) (equal to one year operation).
- Scenarios 5a and 5b: Scenarios combining scenarios 1a and 4 (5a) and 1b and 4 (5b).
- Scenarios 6a and 6b: Scenarios combining scenarios 1a, 2 and 4 (6a) and 1b, 2 and 4 (6b).

Environmental risk assessment for PFAS mixture

The environmental risk due to the concentration of the individual PFAS in the effluent of the treatment plant was calculated according to the methodology proposed in the new European Directive proposal for the Environmental Quality Standards (EQS) (European Parliament, 2022). The concentration of each *i-th* PFAS was multiplied by its relative potency factor (RPF_i) to convert it into equivalent concentration of PFOA. The overall concentration of PFAS was calculated as:

$$C_{PFAS,TOT}\ [\mu g/L\ di\ PFOA\text{-}eq] = \frac{\sum_{i=1}^{15} C_{PFAS,i} \times RPF_i}{\sum_{i=1}^{15} C_{PFAS,i} \times RPF_i}$$

The risk of the PFAS mixture was calculated through the risk quotient (RQ), that is the ratio between PFAS concentration, as PFOA equivalent, expected in the river (assuming a dilution factor DF of the discharge equal to 0.1, the default value of the risk assessment), and the EQS for surface water reported by the proposed Directive (0.0044 µg/L of PFOA-eq), with the following formula:

$$RQ_{PFAS,TOT} = \frac{C_{PFAS,TOT} \times DF}{EQS} \quad \frac{C_{PFAS,TOT} \times DF}{EQS}$$

RESULTS AND DISCUSSION

The monitoring campaign was useful to evaluate which PFAS are effectively present and their fate in the WWTP. The textile WW are mainly characterized by short-chain PFAS (91.7% of the total PFAS). In the raw WW a maximum of 7 PFAS was detected over the 14 monitored ones (Figure 1). In the WWTP, the biological treatment increases short-chain PFAS concentration. At the outlet of the final ozonation an average 5% concentration decrease was observed for PFPeA, PFHxA and PFOS, while no effects were observed for PFBA, PFHpA and PFOA. Overall, PFAS sum was not changed throughout the WWTP treatment train.

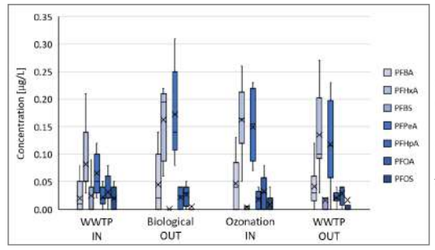

Figure 1. Boxplot of detected PFAS concentrations at each sampling point within the WWTP, for the 11 campaigns carried out.

As for tests on MF and NF on textile WW (Figure 2.a), PFAS rejections by MF were variable; the rejections by NF, fed with the permeate of the MF, were around 80%. Overall, the rejection obtained with the MF+NF sequence was between 88% and 93% and equal to 90% for PFAS sum. In the centralized WWTP, ozonation showed to reduce organic content and improve PFAS removal in the subsequent adsorption step. The breakthrough curves (Figure 2.b) show that AC adsorption improves with PFAS chain length and within 100,000 BV, the average removal for short- and long-chain PFAS is 11% and 56%, respectively.

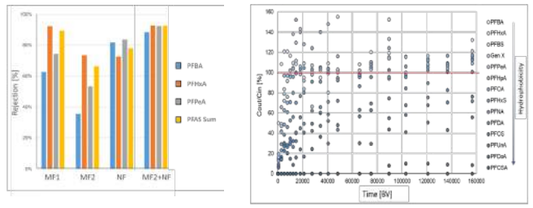

Figure 2. Results of the tests on: (a) PFAS rejections by MF and NF membranes; (b) PFAS breakthrough curves for AC RSSCT tests in OUT-O3.

The overall environmental risk due to the concentrations of each PFAS in the WWTP effluent and the contribution of each PFAS to the risk is depicted in Figure 3.

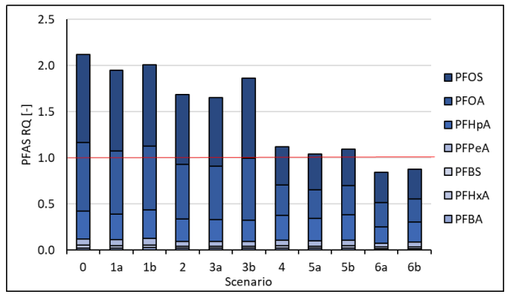

Figure 3. Overall environmental risk due to PFAS mixture for different intervention scenarios (the red line represents the risk threshold RQ=1).

CONCLUSIONS

The mass balance and environmental risk outlined the following evidences:
- Textile WW contribution to the PFAS load entering the WWTP is lower than the civil one.
- In the current scenario (Scenario 0), there is an environmental risk (RQ>1), mainly due to PFOS and PFOA, followed by PFHpA.
- The reduction of 35% of the total PFAS in textile production (Scenario 1a) leads to 8% reduction of the environmental risk, not enough to lower under RQ=1.
- Replacing long-chain with short-chain PFAS in production processes (Scenario 1b) leads to a deterioration in the final effluent quality, due to the higher quantities used.
- The treatment of textile WW through membrane separation (MF+NF) (Scenario 2) reduces by 20% the overall PFAS discharge and environmental risk compared to Scenario 0.
- Combining the reduction or replacement of PFAS in textile production and the treatment via MF+NF (Scenarios 3a and 3b) do not lead to a significant benefit compared to Scenario 2.
- The addition of activated carbon adsorption downstream ozonation in the centralized WWTP (Scenario 4) reduces the discharged PFAS mass by 20% compared to Scenario 0 and 2, and the risk by 50%, because the higher removal of long-chain PFAS that are the most eco-toxic ones. This result highlights that it is important to consider PFAS toxicity (through risk assessment) and not only looking at their sum concentration when prioritizing interventions.
- Combining prevention, treatment at source and treatment at WWTP) interventions (Scenarios 6a and 6b), an acceptable environmental risk is reached (RQ<1), even if it needs attention (RQ>0.1). Finally, to have a more comprehensive assessment and prioritization of the proposed interventions, the proposed environmental risk analysis should be combined with an economic evaluation.

Abstract

Anodic oxidation (AO) was able to achieve 90% mineralization after 6 h of treatment using a boron-doped diamond anode at 42 mA cm^{-2}. The AO process is widely recognized for the non-selective oxidation of organic compounds. However, the main objective of this study was to highlight some drawbacks in order to propose the most suitable way to integrate EAOPs in a full treatment system. Combination of AO with a biological treatment and/or electrocoagulation was investigated. The objective was to reduce the electric charge required during AO in order to lower the energy consumption (EC) as well as the formation of toxic by-products such as ClO_3^- and ClO_4^-. The membrane bioreactor (MBR) operated on-site reduced the organic load and ammonium content. Further treatment by electrocoagulation removed 40% of the remaining organic load with low EC. Therefore, 6 h of treatment by AO at only 8 mA cm^{-2} was then required for achieving similar mineralization yield than for direct treatment of the raw effluent, which corresponds to a 10 times lower EC of the AO process. Recirculation towards the MBR might also be considered based on the biodegradability enhancement of the effluent observed during the treatment by AO.

Keywords (maximum 6 in alphabetical order)

Anodic oxidation, biodegradability enhancement, by-products, combined process, landfill leachate

INTRODUCTION

Electrochemical advanced oxidation processes (EAOPs) are emerging processes with the capacity to achieve full mineralization of organic pollutants in complex effluents (Hien et al., 2022). Particularly, the anodic oxidation (AO) process is based on the generation of hydroxyl radicals (•OH) from water oxidation at the surface of suitable anode materials (Martínez-Huitle et al., 2015)as well as advanced oxidation processes (AOPs. The objective of this study was to compare different EAOPs for the treatment of a real landfill leachate. Several parameters were followed, including total organic carbon (TOC), chemical oxygen demand (COD), turbidity, inorganic ions (NO_3^-, NH_4^+, Cl^-, ClO_3^-, ClO_4^-), energy consumption and effluent biodegradability in order to highlight both advantages and drawbacks (Radjenovic and Sedlak, 2015). The electrocoagulation (EC) process was applied in order to remove a fraction of the organic load with lower energy consumption (EC). The effectiveness of the membrane bioreactor (MBR) operated on-site was also assessed. The objective was to investigate how electrochemical processes might be integrated in a full treatment system for removing the recalcitrant organic load while minimizing the main drawbacks of EAOPs (energy consumption, formation of ClO_3^- / ClO_4^-).

MATERIALS AND METHODS

An open cylindrical undivided reactor (V = 0.18 L) was used to perform EAOPs in batch mode under galvanostatic conditions. For the AO process, the anode was a thin film of boron-doped diamond (BDD) deposited on niobium plate. Results were compared with the use of a dimensionally stable anode (DSA, RuO_2/IrO_2). The cathode was a stainless steel (SS) plate. Results were also compared with the use of the electro-Fenton process (data not discussed in this abstract). The electrocoagulation process was performed in batch configuration in a reactor (V = 2.5 L) made of 10 iron electrodes (S_{tot} = 168 cm^2) placed in parallel.

RESULTS AND DISCUSSION

Characterization of the effluent

The raw leachate was sampled from the leachate storage tank before treatment. A second effluent was collected at the outlet of the MBR operated in the treatment plant. The main characteristics of both effluents are reported in Table 1. The raw leachate was characterized by its (i) high organic load, (ii) high turbidity, (iii) high concentration of N mainly as N-NH_4^+, (iv) high concentration of chloride. The MBR allowed for significant reduction of the organic load and total N (remaining N was mainly N-NO_3^-) and total removal of the turbidity. The biodegradability of the effluent was estimated from the ratio between the ultimate biological oxygen demand (BOD_u, after more than 20 days of incubation) and the COD. This ratio was below 5% at the outlet of the MBR, indicating the low biodegradability of this effluent and the presence of a recalcitrant fraction of the organic load.

Table 1. Main characteristics of (i) raw leachate and (ii) leachate after treatment by membrane bioreactor (MBR)

Sample	$TOC_{dissolved}$ (g/l)	N_{total} (g/l)	Turbidity (NTU)	COD_{tot} (g/l)	BOD_u/COD_{tot} (%)	NO_3^- (mM)	NH_4^+ (mM)	Cl^- (mM)
Raw leachate	1.1	1.0	570	4.0	15	0	68	58
MBR outlet	0.54	0.46	0	1.5	0	33	0.50	66

Treatment of the raw effluent by the anodic effluent process

The BDD anode was the most suitable electrode material for mineralization of the organic load (Fig. 1a). For example, 90% of TOC removal was obtained after 6 h of treatment at 42 mA cm^{-2}, corresponding to an energy consumption of 360 kWh m^{-3}. The DSA was not able to achieve such mineralization (Fig. 1a) because of the lower amount of •OH generated at the electrode surface. However, DSA is widely recognized for its capacity to accumulate active chlorine in the solution, which allowed for removing turbidity through degradation of particulate organic compounds into dissolved by-products (Fig. 2a). The high mineralization yield using BDD anode was accompanied by the formation of large amounts of toxic ClO_3^- and ClO_4^- (Fig. 3), which is one of the most important drawbacks of such EAOP. Partial conversion of ammonium to nitrate was also observed (Fig. 2b). Besides, the evolution of the UV-vis spectra as well as 3D excitation-emission matrices was followed in order to better understand reaction mechanisms in such complex effluent.

Combination with electrocoagulation and biological processes

The application of the EC process was tested on both the raw effluent and the effluent at the MBR outlet. Results reported in Fig. 1c show that application of EC during 20 min was able to remove 40% of the TOC remaining after treatment by the MBR. The corresponding energy consumption was only 0.5 kWh m^{-3}. However, a recalcitrant organic load with low biodegradability (Fig. 4), representing 29% of the initial TOC, was still remaining. Fig. 1d shows that 75% removal of this recalcitrant organic load was finally achieved by application of the AO process during 6 h at only 8 mA cm^{-2}, which correspond to an energy consumption of 36 kWh m^{-3}. This value was ten times lower than the energy consumption required for achieving similar TOC removal yield by using only AO for the treatment of the raw effluent. Moreover, such combined treatment strategy reduced the amount of ClO_3^- and ClO_4^- generated during the AO treatment step (Fig. 3).

Possible synergistic effect between AO and biological treatment was also assessed. AO was able to significantly increase the biodegradability of the effluent after partial removal of the organic load owing to the formation of more biodegradable by-products (Fig. 4). Therefore, treatment strategies might also include a recirculation of the effluent step between the AO treatment step and the MBR.

Abstract

This work has demonstrated that the coupling of the solar photo-Fenton process and granular activated carbon (GAC) filtration increases the removal of micropollutants (MPs). The solar photo-Fenton process was performed using commercial reagents, obtaining a poor MP removal. Fresh and regenerated GAC were compared with respect to MP adsorption, showing a higher competitive adsorption of the dissolved organic carbon in the regenerated GAC. The close removal rate values can entail an increase in the use of regenerated GAC reducing the carbon footprint of the treatment. The benefit of the coupling of the processes allowed decreasing the treatment time on the solar photo-Fenton reactor and an extension of GAC lifetime between 2 and 3 times magnitude depending on the type of GAC and the water matrix.

Keywords

Advanced oxidation process; Micropollutants; Process combination; Tertiary treatment; Water depuration

INTRODUCTION

Micropollutant (MPs) are continuously discharged on the water bodies in low concentration (order of µg-ng/L) but the potential risk for the ecosystems is very high. Conventional wastewater treatment plants (WWTP) are not designed and resulted not able to remove them, thus a further step is required for their elimination. Advanced oxidation processes are known as a powerful technology, being photo-Fenton one of the most promising processes. The high energy requirements for its operation mainly due to the use of the UV lamps is a drawback, thus the use of solar photo-Fenton (SPF) in raceway pond reactors (RPR) proposed by Carra et al., (2014) resulted as an efficient and lower-cost alternative. Granular Activated Carbon (GAC) filtration is a robust and well-known technology for the removal of MPs. As MPs are adsorbed in the GAC surface, the adsorption capacity decreases until its full exhaustion, needing to be replaced. In recent years the use of regenerated GAC has been widespread to reduce the cost and the carbon footprint (Larasati, Fowler, and Graham 2021).

This work proposes to couple the SPF process with GAC filtration. The goal is to reduce the treatment time on photo-Fenton process, minimizing the surface needed to place the RPR, and to extend the GAC life-time. From the best of our knowledge, the combination of SPF and adsorption process has rarely been performed (Della-Flora et al. 2020), and the combination with GAC filtration in particular never reported. In addition, the viability of commercial reagents instead of analytical quality ones has also rarely been tested.

MATERIALS AND METHODS

Analysis

Iron, H_2O_2, BZT, CBZ and DCF concentrations were quantified as previously described on Sánchez-Montes et al., (2020).

Water matrix

Three different water effluent were used: i) natural water, ii) simulated wastewater and iii) real wastewater. Real wastewater was collected from El Bobar WWTP (Almeria, Spain). The main characteristics of the three water matrices are shown in Table 1.

Table 1. Water matrix characterization.

	Natural water	Simulated water	Real wastewater
pH	7.4-7.5	7.0-7.1	6.3
DOC (mg L^{-1})	48-52	13.7	101
TIC (mg L^{-1})	33-36	0	75
Cl^- (mg L^{-1})	83-100	245-255	486-636
PO_4^{3-}(mg L^{-1})	0.5-0.8	2.4-5.4	3.5-6.8

Experimental set-up

Solar photo-Fenton system. Preliminary tests were performed with a solar simulator reported by Maniakova et al., (2021).Two RPR reactors were used to perform SPF experiments at pilot plant scale with three different depths, 5, 10 and 15 cm. The reactor and the UV irradiation measurement and calculation of UV energy per unit of treated volume (Q_{UV}, kJ L^{-1}) was described by Maniakova et al., (2021).

First tests of SPF were operated with natural water to find the best reagents dose. The natural water results were verified with simulated water, and those were confirmed with actual wastewater. BZT, CBZ and DCF were spiked to the water matrix, to obtain a solution of 100 µg L^{-1} each and homogenized for 5 minutes in dark. After this, the chelated iron ($Fe_3(SO_4)_2$ 12% from Lohmann GmbH and citric acid from Brenntag GmbH at a molar ratio 1:1 or 1:2) was added to the solution and mixed for 5 minutes until homogeneity. Finally, H_2O_2 was added, and the reactor was uncovered, being this time 0, H_2SO_4 was added to the matrix before adding the MPs, in the cases where bicarbonates were reduced

Rapid Small-Scale columns. The breakthrough of the GACs was carried out on rapid small-scale columns (RSSC) with the equipment described on Núñez-Tafalla et al., (2022).

The adsorption tests were performed on simulated and actual wastewater. Each of the columns was filled with a different GAC, one with a commercial fresh GAC, CarboTech DGF 8x 30GL (CarboTech AcGmbh) and the other with the regenerated GAC, CarboTech Pool W1-3 (CarboTech AcGmbh), being operated in parallel to compare with the use of a regenerated GAC source The main characteristics, working conditions and preparation of the GAC were described on Núñez-Tafalla et al., (2022). The selected MPs were added in the tank and mixed to a solution of 100 µg L^{-}1 of each of them. During the test, the samples were taken at defined time intervals.

When SFE and GAC filtration processes where combined, the treatment time by SPF was 5 minutes and this pre-treated water was then filtered through the RSSC.

RESULTS AND DISCUSSION

The best reagents dosage was determined on natural water (Figure 2a) in the solar simulator. Results showed that BZT is the most recalcitrant for SPF. Iron dose was between 1.5 and 6 mg L^{-1} and H_2O_2 between 20 and 40 mg L^{-1}. Initially, the chelating agent molar ratio was 1:1, obtaining a low removal rate probably caused by a limitation in iron availability, so then, the ratio was increased to 1:2. This increment showed a positive effect. High natural concentration of bicarbonates (here 170-180 mg L^{-1}) have been previously reported as hydroxyl radicals' scavengers, thus their concentration was decreased. The decrease of bicarbonates resulted in higher MP removal. Selected reagents dosage to scale-up to the RPR was 6 mg L^{-1} of iron (**molar ratio 1:2**) and 40 mg L^{-1} of H_2O_2. **Under these operating conditions, the removal was 56% for BZF, 61% for CBZ and 70% for DCF after the application of 0.16 KJ L^{-1} (12 min) of accumulated UV energy.**

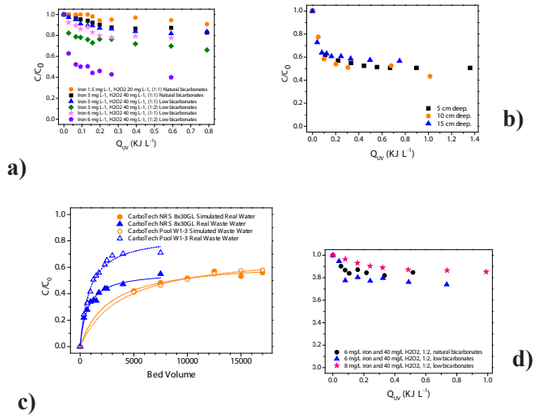

Figure 2. a) BZT removal in natural water by SPF in solar simulator, b) BZT removal in simulated wastewater by SPF in RPR, c) BZT removal in real wastewater by SPF in RPR, d) DCF adsorption.

RPR tests were performed firstly with natural water. Three different depths were tested, showing a similar trend regarding Q_{UV} to reach the desired goal. Thus, the 15cm depth was selected with the objective of increasing the volume of water treated per photoreactor area. The removal achieved on the 15 cm depth after applying 0.16 KJ L^{-1} was 46% for BZF, 50% for CBZ and 62% for DCF. The removal achieved on the 15 cm after applied 0.16 KJ L-1 was 40% for BZF, 44% for CBZ and 55% for DCF (Figure 2b). The results were slightly lower than those obtained with natural water due to the higher complexity of the water matrix. Finally, the removal of the MPs in actual wastewater with 15 cm depth was studied modifying the iron dosage between 4 and 8 mg L^{-1}. The results (Figure 2c) confirmed a dosage of 6 mg L^{-1} of iron and 40 mg/L H_2O_2 as the best. BZT, CBZ and DCF concentration decreased by 21%, 25% and 42%, respectively in 5 minutes. This removal showed the need to combine the SPF process with downstream technologies when using commercial reagents to get a rapid degradation.

The GAC filtration was studied standalone with simulated and actual wastewater since organic background has a high influence competing for active sites. MPs removal was compared taking as reference the 20% breakthrough (20BT) (C/C_0=0.2) meaning to achieve the 80% of MP removal. On simulated wastewater the fresh GAC 20BT was reached 20% and 70% earlier for DCF and BZT respectively in fresh GAC than in regenerated. For CBZ, it was reached a 13% earlier for regenerated GAC than for the fresh (Figure 2d). The similar adsorption capacity of the fresh and the regenerated GAC showed the feasibility of the use of the regenerated GAC. In the case of the real wastewater, the 20BT was achieved 28%, 57% and 85% for DCF, CBZ and BZT respectively for fresh GAC than regenerated. The difference between the water matrix can be associated to the high concentration of DOC (101 mg L^{-1}) in the real wastewater.

The combination was tested in synthetic and actual wastewater under the selected operating conditions. For simulated wastewater, the treatment by SPF reached between 35 and the 45% of MPs removal. In the treatment with GAC, the 80% removal of DCF was achieved till 3900 BV for fresh GAC and 2900 BV for regenerated GAC. Thus, the coupling of technologies allows extending GAC lifetime more than 3 times. The MP removal on SPF in actual wastewater was lower, between 20% and 41%, being BZT the one with lower removal rate and DCF the highest. The 80% removal of DCF in GAC filtration was reached till 910 and 950 BV for fresh and regenerated GAC respectively. Thus, the extended GAC lifetime was between 2 and 3 times.

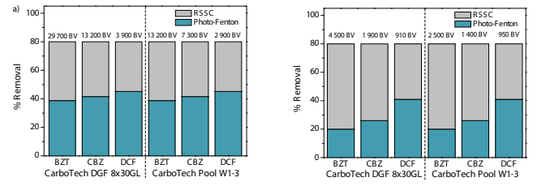

Figure 3. Contribution of each step (till 80%). Above the bars, bed volumes reached at 80% removal. a) Simulated wastewater; b) Real wastewater.

It has been proved that the coupling of processes allows decreasing the hydraulic retention time on the SPF reactor and extending GAC lifetime by 2 and 3 times.

ACKNOWLEGMENTS

The authors wish to thank the Plataforma Solar de Almeria for providing access to its installations, the support of its scientific and technical staff, and the financial support of the SFERA-III project (Grant Agreement No 823802). In addition, the financial support provided by Administration de la gestion de l'eau - Ministère du développement durable et des infrastructures of Luxembourg under the Fentastic Project.

Abstract

We fabricated the well-structured heterogeneous catalyst from municipal sludge using 2-step thermal modifications and investigated their role in a Fenton-like reaction to degrade emerging organics from water. The reactive sites (graphitic N, edge N species, and carbonyl groups) on the N-doped biochar (NOBC) catalyst heavily dependent on nitrogen precursors were scrutinized in this work. Accordingly, NOBCd exhibited superior catalytic activity in peroxydisulfate (PDS) activation, evidenced by the complete removal of phenolic organic pollutants. The mechanism of the PDS activation on the NOBCd is proposed to be the contribution of radical and non-radical pathways. In terms of practical applications, material stability, the effect of the natural water conditions, and the degradability of the other common organic pollutants were investigated.

The findings of this study suggest that sludge disposal could be turned into an efficient catalyst that boosts the degradation of emerging organics from the water via a Fenton-like reaction.

Keywords (maximum 6 in alphabetical order)

Fenton-like reaction; Metal-free catalyst; Peroxydisulfate; Stoichiometric efficiency; Water remediation; Waste valorization

INTRODUCTION

Massive amounts of municipal sludge waste, rich in nitrogen, phosphorus, heavy metals, organic micro-pollutants, and pathogens, have been released into the environment as humankind shifted to urbanization and industrialization in recent decades (Wu et al., 2019). Therefore, turning sludge waste into different materials has recently become a research hotspot instead of incineration or landfilling, which has caused secondary pollution (Guan et al., 2019). Namely, sludge could be turned into valuable functional carbon material (biochar) and some biofuel through thermal treatment (Hsu et al., 2020; Wu et al., 2019; Zhang et al., 2021). Biochar (BC) is a carbon-rich porous material that can be derived from various biomass and synthesis methods (Byambaa et al., 2023; Hsu et al., 2020; Wang and Wang, 2019; Zhang et al., 2021). Thus, BC helps reduce the leaching of secondary pollutants from sludge disposal into the environment and works as an efficient green catalyst in the Advanced oxidation processes (AOPs). Furthermore, biochar can efficiently activate persulfates as a heterogeneous catalyst, then directly decompose organic pollutants via oxidative species such as hydroxyl radical (•OH), sulfate radical ($SO4^{\bullet-}$), or singlet oxygen ($^1O_2$) are generated in PS-AOPs (Mishra et al., 2017; Wang et al., 2019). However, it is crucial to localize various functional sites on metal-free catalysts to uplift reaction efficiency and avoid blockage of the pristine carbon surface.

In this work, we created N and O co-doped biochar from municipal sludge with different N sources to efficiently remove phenolic compounds via the activation of peroxydisulfate (PDS). The chosen NOBCd nanocomposite has relatively high structure defects and more reactive sites by N and O doping. NOBCd/PDS degraded BPA rapidly without pH adjustment. Moreover, the effects of reaction conditions (pH, ionic strength, and coexistence of the natural organic matter (NOM) on the oxidation of the target pollutant are explored. Classical quenching and electrochemical experiments in NOBCd/PDS are conducted to identify the primary reactive species and reaction mechanism.

MATERIALS AND METHODS

The NOBCs were synthesized according to methods described in the literature (Byambaa et al., 2023) by varying nitrogen precursors, such as ammonium hydrogen phosphate ($(NH_4)_2HPO_4$), urea(NH_2CONH_2), melamine ($C_3H_6N_6$) and dicyandiamide ($C_2H_4N_4$), followed by a thermal treatment in N_2 atmosphere. In detail, sludge powder was added to the N source solution in the weight ratio of 1:3; the suspension was ultrasonicated for 10 min. Then, the mixture was transferred to a Teflon-lined autoclave and heated to 180 °C for 8 h. After the autoclave cooled down to room temperature, the black precipitate was dried in a vacuum oven. Finally, the powder was calcined at 800 °C for 1 h with a heating rate of 15 °C/min under N_2 atmosphere. The obtained sample was named NOBCa, NOBCu, NOBCm, and NOBCd, respectively.

The degradation experiments were conducted at room temperature (25 ± 2 °C) in 100 mL of a solution of targets with the BC, and PDS without pH adjustment. Periodically, the sample was fetched from the reactor, filtered through a 0.22 µm PTFE syringe filter, and terminated the reaction by sodium thiosulfate (0.2 M) immediately before the high-performance liquid chromatography (HPLC) measurement. The PDS concentration was measured by UV–visible absorbance of a yellow-colored solution due to the reaction between PDS and iodide in the presence of bicarbonate at 352 nm. All experiments were conducted in triplicate, and results were reported with error bars.

RESULTS AND DISCUSSION

Carbon skeleton defect was investigated by Raman spectra D-band (~1380 cm−1) and G-band (1607 cm^{-1}) intensity ratios (Wang et al., 2019). As shown in Fig. 1a, NOBCd owns the highest defects (ID/IG = 1.61) compared with NOBCa, NOBCu, and NOBCm. This higher defect might be caused by more active sites fabricated by N and O co-doping is further proven by X-ray photoelectron spectroscopy (XPS) survey and high-resolution spectra analysis. Accordingly, the NOBCd prepared using dicyandiamide as the nitrogen source has a higher nitrogen doping level among created NOBCs samples.

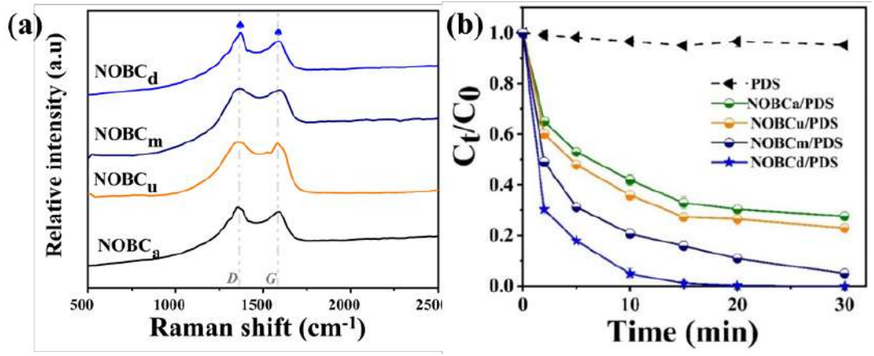

Figure 1. Raman spectra (a), XPS survey (b) of the modified biochar samples, BPA degradation curves in different PDS/NOBCs (c)

The role of structure defect, doped N, and specific active sites on the Fenton-like reaction of NOBCs was investigated through PDS activation to remove phenolic organic contaminants. BPA, one of the widely detected phenolic contaminants, was chosen as the target compound. Because, It is known as a xenoestrogen, an environmental contaminant, a xenobiotic, and an endocrine disruptor. As a chemical compound, BPA is a bisphenol that is 4,4'-methanediyldiphenol in which the methylene hydrogens are replaced by two methyl groups and are assumed to be not easily biodegraded in the environment due to their stability (Chen et al., 2021; Khan et al., 2021).

As shown in Fig. 1b, PDS alone could not degrade BPA without biochar. In comparison, BPA degradation was elevated with NOBC catalysts. Among modified biochar samples, NOBCd outperformed by degrading BPA (within 20 min), and the pseudo-first-order reaction kinetic constant (k_1) of NOBCd/PDS was calculated as 0.37 min^{-1}. Evidently, our optimal NOBCd/PDS system is not only shown superb degration of pollutant (Chu et al., 2019; Zhang et al., 2021), but also the reaction rate was over 10 times folds up the pristine biochar's performance.

Conclusions

Different levels of N-doped biochar (NOBCs) were synthesized by varying the N sources. Selected NOBCd exhibited superb catalytic activity for BPA degradation through PDS activation with huge enhancement compared to the unmodified biochar (SBC) activity. Structure–activity relationship unveils that the carbonyl group and graphitic N were key active sites for BPA degradation. Also, the utilization efficiency of PDS, and relationship between structure and stoichiometric efficiency was revealed in this work. Although the reactive sites on the material circulate both radical and non-radical oxidation during PDS activation, BPA degraded in NOBCd/PDS system via non-radical mechanism is assumed by classical quenching experiments and further investigated in details. As benefiting from the non-radical mechanism, NOBCd/PDS system manifested high resistance to inorganic anions but was still hindered by high concentration of humic acid in water. We believe this work will expand the knowledge of the carbon-assisted PDS activation mechanism, especially in the field of green-catalyst.

Abstract

Per- and polyfluoroalkyl substances (PFAS), used in several industrial applications, such as textile production, are gaining increasing concern due to their spread in the environment, their stability and eco-toxicity. To avoid PFAS spread in the environment, removal strategies need to be implemented at both industrial and municipal wastewater treatment plants (WWTP). This study presents a case study in a textile district in northern Italy where PFAS removal in wastewater (WW) through adsorption on activated carbon was tested at lab and pilot-scale at different points of the system (textile companies and municipal WW treatment plant). This lab-testing was proved to be useful to identify where to apply such process in the system and to optimize process configuration and operating conditions.

Keywords (maximum 6 in alphabetical order)

Adsorption; Isotherms; Ozonation; PFAS; Rapid Small-scale Column tests; Textile wastewaters

INTRODUCTION

In the last decades, the presence of per- and polyfluoroalkyl substances (PFAS) in the aquatic environment has become an issue of growing global concern (Griffin et al., 2022). PFAS are ubiquitous and persistent, since they constantly enter the environment through different sources, being the most important the wastewater treatment plants (WWTPs), especially those collecting industrial wastewaters (WW). Worldwide always more stringent limits are posed for PFAS concentration in WW (e.g., the proposed European Directive on Environment Quality Standards (EQS) (European Parliament, 2022)). Thus, to avoid PFAS spread in the environment, treatments need to be implemented at both the industry discharge and municipal WWTPs. As for the industrial discharge, some studies characterized PFAS occurrence in textile industries showing their constant presence at concentrations in the order of µg/L. However, very few studies studied treatment technologies for PFAS removal in these concentrated streams. One of the most successful well-established processes to remove PFAS from water and WW is adsorption onto activated carbon (AC), particularly for long-chain PFAS (Appleman et al., 2014). The majority of the available studies focused on PFOA and PFOS adsorption through lab-scale isotherm tests, and only recently few studies were performed to assess PFAS breakthrough in drinking water through rapid small-scale column tests (RSSCTs) (Cantoni et al., 2021). Finally, activated carbon adsorption directly after ozonation is a process combination extensively applied in drinking water treatment, and less applied for wastewater. Such process combination has been mainly investigated in municipal WW for Pharmaceuticals and Personal Care Products (PPCPs) and in textile WW for dyes, and very few studies analysed the performance of such treatment train towards PFAS. The objective of this study is to assess adsorption performance at the source and at the final WWTP stage through lab- and pilot-scale tests to evaluate where to apply such treatment in a textile district in northern Italy.

MATERIALS AND METHODS

The case study is focused on a textile district composed by 42 textile industries whose WW is discharged in a sewer system together with WW from civil origin. The sewer system conveys WW to a WWTP (20-35% of the inlet flowrate from industrial origin), composed by pre-treatments, activated sludge biological treatment (pre-denitrification, nitrification/oxidation), coagulation-flocculation followed by a lamella clarifier and ozonation.

Lab-scale batch experiments

To assess adsorption performance of different ACs towards PFAS, also considering the interfering action of organic matter, batch isotherm experiments were performed on three water matrices (Table 1): a mix in equal parts of four textile WWs (TWW), treated WW collected at the WWTP before (IN-O3) and after (OUT-O3) the full-scale ozonation unit. The TWW samples, with mean PFAS concentration equal to 4 µg/L, were not spiked. IN-O3 and OUT-O3 samples were spiked with 15 PFAS (from C4 to C12) (PFBA, PFHxA, PFBS, GENX, PFPeA, PFHpA, PFOA, PFOS, PFHxS, PFNA, PFDA, PFUnA, PFDoA, PFOSA, C6O4) to achieve initial concentration of 4 µg/L per single PFAS.

Table 1. Main characteristics (mean value ± standard deviation) of the aqueous matrices used in the experimental tests. UVA_{254} represents the absorbance at 254 nm (1 cm optical path).

Matrix	pH	Conductivity	COD	UVA_{254}
	[-]	[µS/cm]	[mg/L]	[m^{-1}]
TWW	4.4	1589	23900	-
IN-O3	7.7 ± 0.09	1332 ± 4.7	36 ± 1.2	20.5 ± 0.42
OUT-O3	7.8 ± 0.07	1401 ± 3.9	30 ± 1.4	16.0 ± 0.73

Four activated carbons (Table 2) were tested, having different origin, porosity pH of Point of Zero Charge (pH_{PZC}) and applicability (as granules, GAC, and/or powder, PAC, based on their availability on the market), at doses from 3 to 150 mg/L, with 48 h contact time. Only BP2 and G9 were tested for TWWs.

Table 2. Tested adsorbents' main characteristics: origin, iodine number, porosity, pH_{PZC}, applicability (characteristics provided by the AC supplier, Jacobi, except for pH_{PZC} which was determined).

Adsorbent	Origin	Iodine number (mg/g)	Main porosity	pH_{PZC}	Applicability
CP1	Coconut	1,000	Micro	8.0	PAC/GAC
BP2	Bituminous-coal	850	Meso	9.2	PAC/GAC
MP25	Bituminous-coal	1,000	Meso-macro/Macro	9.1	PAC/GAC
G9	Wood	950	Meso-macro/Macro	9.2	PAC

Processed water samples were analysed for PFAS, COD, pH, conductivity, absorbance spectrum, and fluorescence.

Pilot-scale column experiments

Rapid Small Sale Column Tests (RSSCT) and Field Adsorption Pilot Plant (FAPP) tests have been performed at the centralized WWTP on IN-O3 and OUT-O3 matrices. For RSSCT, water matrices were spiked with 15 PFAS at 4 µg/L per single PFAS, while for FAPP tests, no PFAS spike was performed, being the initial concentration of PFAS sum varying from 0.05 to 1.4 µg/L.

In the RSSCT and FAPP, respectively, three ACs (CP1, BP2 and MP25) and two ACs (CP1, BP2) were tested in single column configuration. In addition, RSSCT were carried out in lead-lag configuration: MP25 was selected as "lead", to reduce organic matter and hydrophobic PFAS, while both CP1 and BP2 were tested as "lag", to evaluate the improvement of their performance, especially on hydrophilic PFAS. In these tests, samples were taken at the Lead column inlet, at the Lead column outlet and at the Lag column outlet, to apportion each column contribution to the overall PFAS breakthrough.

Both RSSCT and FAPP, were sized through the constant-diffusivity down-scaling equation (Crittenden et al., 1987) simulating the performance of full-scale GAC filters with 20 minutes of Empty Bed Contact Time (EBCT) and 1.7 mm of AC granules diameter. Thus, RSSCT and FAPP wee characterized respectively by: EBCT of 0.2 min and 3.4 min, AC volume of 0.45 mL and 1.6 L, AC granules diameter of 0.16 mm and 0.5 mm. Based on this design, 100,000 bed volumes (BV) of operation correspond to 7 and 60 days.

RESULTS AND DISCUSSION

Looking at the PFAS removals (Figure 1) achieved by the two ACs for TWW, removal efficiencies are influenced by the type of AC, its dose and the target PFAS. In detail, mesoporous AC (BP2) showed worse adsorption (2-25% on the sum of PFAS) compared to meso/macro-porous AC (G9) (12-34%), due to decreased competition of organic matter. As for municipal WW (Figure 1.b), PFAS hydrophobicity and adsorbent type (porosity, origin) have great influence on the adsorption capacity. In detail, as PFAS hydrophobicity increases (greater Log D_{OW}), the removal increases. For long-chain hydrophobic PFAS (Log D_{OW}>1), efficiencies are higher compared to short-chain PFAS and significantly influenced by the ACs type. The efficiency, in fact, increases with the pore size.

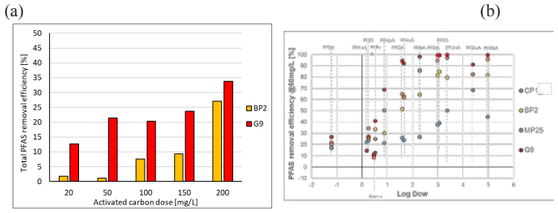

Figure 1. PFAS removal efficiencies for: (a) PFAS sum in TWW as a function of AC type and dose; (b) in IN-O3 at 50 mg/L of different ACs as a function of PFAS hydrophobicity (Log Dow).

Similar results were found with column tests: the breakthrough in RSSCT slows down with the PFAS hydrophobicity (Figure 2). The different porosity of the ACs significantly influences the results: a slower breakthrough of long-chain PFAS is observed as the porosity of the AC increases. For short-chain PFAS, on the other hand, the breakthrough is very rapid, and no significant differences were found between the 3 tested ACs. The competition between PFAS and organic matter for adsorption active sites plays a key role, especially in the case under examination where a real WW is used. Thus, in Figure 2.b it is assessed the effect of both ozonation, comparing IN-O3 and OUT-O3, and lead-lag configuration, comparing MP25 and MP25+CP1, on the adsorption performance. The influence of ozonation is greater than that of the lead-lag configuration in improving adsorption performance. In fact, the AC life (calculated at 100% breakthrough) increases in the OUT-O3 matrix with respect to the IN-O3 matrix by a range between 50,000 BV and more than 100,000 BV, depending on the tested PFAS. Instead, comparing the breakthrough of the single MP25 column with the lead-lag configuration, the AC life increases less significantly, in the range 10,000-25,000 BV, depending on the tested PFAS.

Finally, the correlations between organic matter (as UVA_{254}) removal and PFAS removal, obtained at the three testing scales for the MP25 AC in both tested water matrices, were compared (Figure 3). Despite a certain variability for removal of organic matter and PFAS lower than 30%, the relationships found at the three different scales of tests (batch, RSSCT and FAPP) follow the same trend. This is useful because this relationship can be estimated for the AC to be used at full scale through batch tests, which are faster and simpler to prepare; then, it can adopted in column operations at different scales, simply monitoring organic matter through absorption measurement (faster and cheaper) to estimate the overall removal of PFAS in real time, useful as an early-warning system.

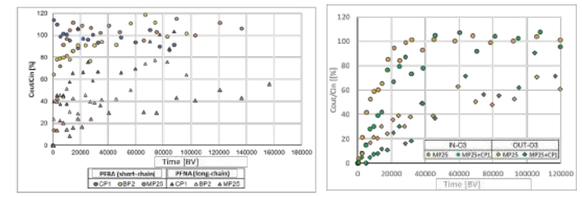

Figure 2. Breakthrough curves in RSSCTs for: (a) PFBA (short-chain) and PFNA (long-chain) with 3 ACs in IN-O3 matrix; (b) for PFNA with MP25 and MP25+CP1 in IN-O3 and OUT-O3 matrices.

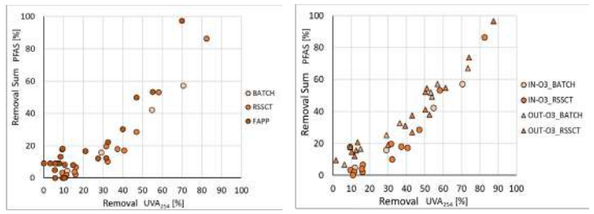

Figure 3. Proxy correlation between removal of UVA_{254} and the sum of PFAS for MP25: (a) in the two matrices for batch tests and RSSCT; (b) in the IN-O3 matrix for batch tests, RSSCT, FAPP.

Abstract

This study evaluates the performance of graphene sponges doped with atomic sulfur at two S-dopant concentration levels, for electrochemical degradation of six commonly used antibiotics, namely sulfamethoxazole (SMX), trimethoprim (TMP), ofloxacin (OFX), tetracycline (TTC), roxithromycin (ROX) and erythromycin (ERT), as well as for the inactivation of a multidrug-resistant *Escherichia coli (E. coli)*. The experiments were performed in a flow-through, one pass mode, and using real tap water. Highly polar antibiotics such as SMX did not adsorb onto the graphene sponge but were nearly completely removed at very low applied current densities, i.e., 14.5 A m^{-2}. Antibiotics rich in aromatic rings and with high affinity for π-π interactions such as OFX and TTC exhibited removal efficiencies >95% already in the open circuit (OC), whereas the application of current led to further degradation of the adsorbed fraction. S-doped graphene sponge anode with higher concentration of S-dopant resulted in 4.7 log removal of multidrug-resistant *E. coli* at 29 Am^{-2}. No regrowth of bacteria was observed during the storage of the electrochemically treated bacterial suspensions, suggesting that the treatment severely impaired cell viability.

Keywords (maximum 6 in alphabetical order)

Antibiotics, electrochemical oxidation process, graphene-based materials, chlorine-free disinfection, S-doped RGO

INTRODUCTION / MATERIALS AND METHODS / RESULTS AND DISCUSSION

The extensive and misuse of antibiotics for human and veterinary purposes resulted in the pollution of surface waters by antibiotic residues, either partially metabolized or unaltered (Wang, Shi, et al., 2021). This antibiotic pollution has exerted a selective pressure on environmental microbes and stimulated the spread of antibiotic-resistant bacteria (ARB) and their antibiotic resistance genes (ARGs) (Wang, Shi, et al., 2021). According to the latest report of the United Nations (UN), at least 700,000 people die each year due to drug-resistant diseases, and by 2030, antimicrobial resistance could force up to 24 million people into extreme poverty (Bryan-Wilson, 2016). Electrochemical processes are a promising technology for the treatment of contaminated water due to the *in situ* formation of strong oxidant species such as hydroxyl radical (OH•), hydrogen peroxide (H_2O_2), ozone (O_3), just by applying the current, which make them well-suited for decentralized (waste)water treatment (Radjenovic and Sedlak, 2015). However, most commonly used anodes such as e.g., boron-doped diamond (BDD), Magnéli phase and mixed metal oxide (MMO) are limited by a major drawback - the production of chlorine in presence of chloride and, in the case of highly oxidizing anodes (BDD, Ti_4O_7, Ti/SnO_2-Sb), further oxidation of chloride to chlorate (ClO_3^-) and perchlorate (ClO_4^-) (Radjenovic and Sedlak, 2015). In the scope of the ERC-StG ELECTRON4WATER, we have developed three-dimensional (3D), low-cost graphene sponge electrodes that are capable of producing strong oxidant species (e.g., O_3, H_2O_2, OH·) while being electrochemically inert towards chloride, thus avoiding the production of organochlorines, ClO_3^- and ClO_4^- even in the case of high chloride concentrations (i.e., 20–30 mM) (Baptista-Pires, Norra, et al., 2021). In this study, we have synthesized sulfur-doped graphene sponge electrode (SRGO) and used it for electrochemical degradation of sulfamethoxazole (SMX), ofloxacin (OFX), erythromycin (ERT), trimethoprim (TMP), roxithromycin (ROX) and tetracycline (TTC), as well as for the inactivation of a multidrug-resistance *Escherichia coli (E. coli)*, carrying genes as *sul1*, *tetB* and *dfrA16*, which confer resistance to SMX, TTC and TMP, respectively.

MATERIALS AND METHODS

Sulfur (anode) and nitrogen (cathode) -doped graphene sponges were synthesized using previously developed bottom-up synthesis methods (Norra, Baptista-Pires, et al., 2022). S-doped electrodes were synthesized at low and high concentration of S dopant, connected to current feeders, and employed in flow-through reactors in one pass mode, at 5 mL min^{-1}. We used N-doped graphene sponge (NRGO) as flow-through cathode. Target antibiotics were added at low concentration (0.2 µM) to real tap water (0.4-0.5 mS cm^{-1}) to investigate the system performance under realistic conditions of water treatment, where ohmic drop represents a major challenge. To evaluate the disinfection performance of the system, multi-resistant *E. coli* (DSM103246) were added at an initial concentration of 10^7 CFU mL^{-1}. The reactor was operated in chronopotentiometric mode at different applied anodic currents, 14.5 and 29 Am^{-2}. The abundance of *E. coli* was determined using the membrane filtration technique and serial dilutions of collected samples in Chromocult® Coliform Agar medium (Merck). To determine the concentration of target antibiotics from the flow-through reactor, samples were analyzed using an ultraperformance liquid chromatography (UPLC, Waters, USA) with an Acquity UPLC HSS T3 column (2.1×50 mm, 1.8 µm, Waters), coupled to quadrupole linear ion trap mass spectrometer (QqLIT-MS) with a turbo Ion Spray source (5500 QTRAP, Applied Biosystems, USA). The impact of storage was evaluated by storing the electrochemically treated samples at 37ºC for 18h.

RESULTS AND DISCUSSION

Electrochemical removal of antibiotics from tap water

Doping of graphene with heteroatoms such as S and others leads to the introduction of defects and generally enhanced its (electro)catalytic activity. In our previous study, poor adsorption and electrosorption of antibiotics onto graphene sponge electrodes was identified as a major limitation to their electrochemical degradation when working with low conductivity tap water (Ormeno-Cano and Radjenovic, 2022). In an attempt to improve this interaction, we employed S-doping of graphene, previously shown to provide more adsorption sites (i.e., -C-SOx-C-) (Pan, Li, et al., 2022; Omran and Baek, 2022; You, Liu, et al., 2022). **Figure 1** presents the observed removals of target antibiotics at two applied current densities, i.e., 14.5 and 29 A m^{-2}, using *high* and *low*SRGO anode. No significant difference in the antibiotic removal was observed between the two investigated concentration levels of S-dopant, except for TMP for which the removal at 29 Am^{-2} was 66.3 and 88.1 % when *low* and *high*SRGO were used as anode. Compared with our previous study, S-dopant significantly improves the adsorption of contaminants in tap water as electrolyte. E.g. , ERT was adsorbed up to 80 and 50% when sulfur-doped RGO and boron-doped RGO are employed as anodes. (Ormeno-Cano and Radjenovic, 2022) Only in the case of SMX, the removal in the initial OC was similar, with around 12% adsorbed with BRGO anode compared to ~8% in the case of SRGO anode. As expected, very limited removal of SMX was observed in both, *high* SRGO and *low*SRGO -NRGO system in the OC due to the low adsorption affinity of this compound, By contrast, TTC (99% removal in the OC) and OFX (98.5% removal in the OC) are completely adsorbed onto the graphene sponge electrodes due to strong π- π interactions and cation- π bonding between the protonated amino group of both TTC and OFX and the π-electron-rich aromatic structure of graphene (Ai, Liu, et al., 2019). Application of current had a pronounced impact only on the removal of poorly adsorbing SMX and as expected, led to limited increase in removal efficiencies for more strongly adsorbing compounds. Nevertheless, further experiments based on the extraction of the employed graphene sponge anodes with organic solvents will be performed to confirm that the adsorbed antibiotics were also degraded, via direct electrolysis as well as the electro-generated reactive oxygen species (OH•, H_2O_2, O_3).

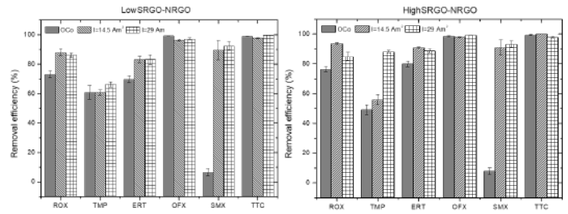

Figure 1. Removal (%) of TMP, ERT, SMX, OFX, ROX and TMP using: A) *low*SRGO anode, and B), *high*SRGO anode at 14.5 and 29 A m^{-2}, *vs.* NRGO cathode.

Electrochemical inactivation of multiresistant *E. coli*

As shown in **Figure 2**, the amount of S-dopant added impacted the extent of *E. coli* removal already in the OC, with 1.8 log removal obtained for *low*SRGO anode to 2.4 log removal for *high*SRGO anode. This effect of the sulfur dopant may be assigned to its bactericide activity, previously reported in other studies (Saedi, Shokri, et al., 2020; Shankar and Rhim, 2018). Application of current further improved the removal efficiency in both systems reaching 3.6 log and 4.7 log removal of *E. coli* when *low*SRGO and *high*SRGO anode, respectively. The highest inactivation of *E. coli* was obtained in *high*SRGO- NRGO system at 29 A m^{-2}. Higher removal of *E. coli* using *high*SRGO anode could be explained by the enhanced electrosorption of the negatively charged bacterial cells onto the anode surface having a greater number of electron-deficient sites after the S doping, and subsequent electroporation of the sorbed bacteria (Norra, Baptista-Pires, et al., 2022; Pan, Li, et al., 2022). Storage of the electrochemically treated bacterial suspensions resulted in an additional 1 log removal, evidencing the irreparable damage of the cells.

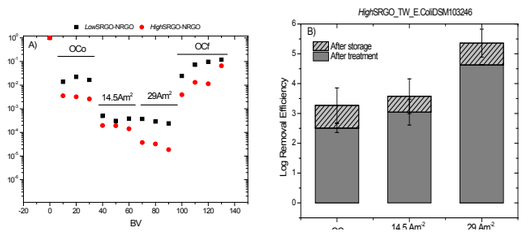

Figure 2. Removal of *E.Coli* in tap water A) for the experimental performed in a flow rate of 5 mL min^{-1}during the initial and final open circuit conditions at two different current 14.5 and 29 A m^{-2} in both *low* and *high*SRGO(A)-NRGO(C) systems B)in *high*SRGO(A)-NRGO(C) system determined after sampling the effluent (e.g "after treatment") and after storing the effluent sample at 37ºC for 18 h (i.e., "after storage"); experiment was performed using tap water at 14.5 and 29 A m^{-2} applied current.

CONCLUSIONS

S-doping of graphene sponge electrodes improved the adsorption of antibiotics onto the graphene sponge in low conductivity tap water. This enabled their further degradation with the application of current, and at very low current densities (i.e., 14.5–29 A m^{-2}). While the amount of the added S-dopant did not impact the removal and degradation of antibiotics, it influenced the extent of inactivation of the multidrug-resistant *E. coli*, with the highest overall removal (i.e., 5 log obtained with "high SRGO" anode at 29 A m^{-2}. Storage experiments confirmed no regrowth of *E. coli* and yielded their further inactivation, evidencing an irreparable damage cell walls caused by the electrochemical treatment.

Abstract
Sludge treatment reed beds (STRBs) are an interesting approach to dewater and mineralize sewage sludge. While these nature-based solutions are robust and efficient to dewater and stabilize activated sludge, they are also promising in providing as final product biosolids that can be used as fertilizer – if legislation allows for it. For this, the quality of the treated sludge is important from two angles: 1) the agricultural use potential based on dry content and nutrients composition, and 2) the content of harmful substances is below threshold limits. One of the critical steps to optimise STRBs performance, and therefore the quality of the final biosolid, is the operation regime which ensures proper sludge dewatering and mineralization. A larger study was carried to compare the performance and efficiency of three types of operation mode: passive aeration, draft aeration or forced aeration). The results herein focus on the different dynamics of degradation and/or accumulation of biocides and pharmaceuticals observed in one of the experiments carried out in Slovenia.

Keywords (maximum 6 in alphabetical order)
Circular economy, Emerging contaminants; Wastewater; Nature-based solutions

INTRODUCTION

Sludge treatment reed beds (STRBs) are an established technology for the management of sludge produced by wastewater treatment plants (Nielsen & Bruun 2015; Brix 2017). Reed beds were used for the first time in Denmark in 1988, when the first sludge processing system was introduced (Nielsen 2003). These systems are now a widespread and common sludge treatment practice in northern Europe, especially in Denmark, and are being used increasingly worldwide. Primary or secondary liquid sludge is loaded on the surface of the reed bed over several years, where long-term (10-12 years) sludge reduction takes place, partly due to dewatering and partly due to decomposition of the organic matter in the sludge (Matamoros et al. 2012).

It is known that the use of sewage sludge or biosolids as agricultural amendments can pose environmental and human health risks related to pathogens and/or antibiotic resistance. A study under Mediterranean climatic conditions demonstrated that the presence of ampicillin-resistant bacteria increased in amended soils 4 months after urban sludge application (Gondim-Porto et al. 2016). The long-term application of sewage sludge and chicken manure significantly increases the abundance and diversity of ARGs in soil (Chen et al. 2016).

In spite of the long-term of mineralization period (10-12 years), STRB operational procedures indicate that the ultimate load should be dewatered and stabilized for 6 months before sludge can be disposed as a biosolid for agriculture (Nielsen & Willoughby 2005). It is uncertain if this time period is enough to ensure the decay of antibiotics and other micropollutants to the environment.

The current project aims to evaluate for the first time the fate of micropollutants, including antibiotics, in STRBs.

MATERIAL AND METHODS

A pilot system was set up at Dragomer, Slovenia (Figure 1) and operated for several experiments until 2022. The pilot contains 9 basins in triplicates for the three of operation mode: passive aeration, draft aeration or forced aeration.

Experimental setup and sampling

Several bags containing the “initial” loading sludge of the beds were wrapped up with a permeable material to replicate natural conditions of water and micropollutant exchange. The bags were left while different sludge loading campaigns were performed onto the STRBs. After each loading campaign, three bags of each bed were pulled off and air dried. The air-dried sludge was used for organic micropollutant quantification.

Analysis

Sludge/biosolids samples were extracted by a two-step process, first water, second methanol, using an ultrasonic bath. The extracts were analysed by LC-MS/MS using two multi-compound methods, one targeting 13 biocides the other 36 pharmaceuticals (Thomsen et al. 2020). Concentrations are reported as dry weight of sludge.

Figure 1. Photo of the pilot at Dragomer, Slovenia in September 2019. The pilot contains 9 basins in triplicates for the three of operation mode: passive aeration, draft aeration or forced aeration.

RESULTS AND DISCUSSION

The biocides irgarol, pyraclostrobin and pirimicarb were detected in the initial sludge, while terbutryn (7 ± 1 ng/g) and the benzalkonium chloride 12-BAC (861 ± 83 ng/g), 14-BAC (210 ± 16 ng/g) and 16-BAC (28 ± 4 ng/g) were quantified. In terms of pharmaceuticals the occurrence was higher than for biocides. The pharmaceuticals tramadol, olmesartan and gabapentin were only detected in the initial sludge, while Azithromycin (75 ± 20 ng/g), Claritromycin (18 ± 4 ng/g), Ciprofloxacin (992 ± 151 ng/g), Propanolol (17 ± 3 ng/g), Carbamazepin (14 ± 1 ng/g), Citalopram (103 ± 13 ng/g), Diclofenac (38 ± 4 ng/g), Phenazone (2 ± 0.2 ng/g), Venlafaxine (21 ± 4 ng/g), Losartan (18 ± 1 ng/g) and Benzotriazole (274 ± 138 ng/g) were quantified.

In terms of fate, we observed three main behaviours of the compounds in time, decrease, no changes and increase in concentration, depending on the compounds (Figure 2). The pesticide terbutryin was stable, 12-BAC and 14-BAC shown a decrease trend, while 16-BAC concentration tended to increase. However, these variations were not significant. For the pharmaceuticals, several compounds showed decrease in concentration such as azithromycin ($p < 0.05$), propranolol, diclofenac ($p < 0.05$), venlafaxine ($p < 0.05$). Carbamazepine, citalopram, and losartan concentration did not change. An increase in concentration was observed for clarithromycin, ciprofloxacin, phenazone ($p < 0.05$) and benzotriazole ($p < 0.05$).

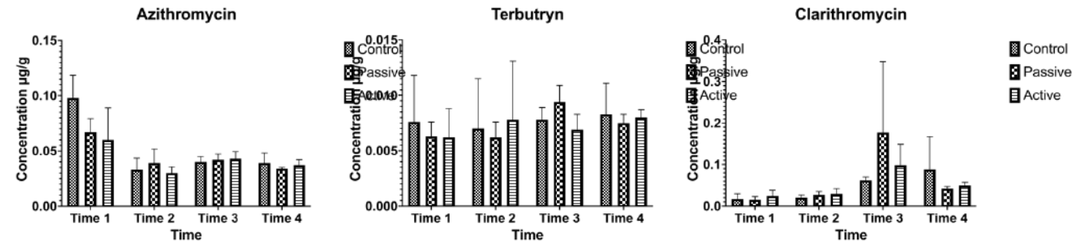

Figure 2. Selected results from representative organic micropollutants showing decrease, no changes and increase in concentration over time.

Statistical tests showed that time was the major variable affecting the micropollutants concentration, while operation mode did not provide any marked difference. It should be noted that the sludge samples in the bags were exposed to x new loadings, thus the increase in concentration. This also implies that a decrease in concentration implies not only biodegradation of the original sorbed compound, but potentially of new amounts that were inserted in the pilots. The experimental setup was considered interesting for understanding removal and accumulation rates in time, but does not allow to perform a mass balance, as the dynamics of a new load implies adding a liquid and a solid fraction and the potential percolation of compounds across de system. Nevertheless, the current results show that emerging contaminants have the potential to be both degraded and accumulated in STRBs in time. This means that it is very important in the future to characterize the stabilization of such systems during the last 6 months of operation without new loads.

Abstract

Increasing water demand is challenging water utilities to find alternative water sources. Interest is growing towards reclaimed wastewater (WW) potable and non-potable reuse. However, the risk for pollution by Contaminants of Emerging Concern (CECs) needs to be faced since current WW treatment plants are not designed to remove CECs. In this study, lab- and pilot-scale experiments were combined and performed at relevant environmental conditions to evaluate the performance of an innovative treatment technology, $MITO_3X$, based on advanced oxidation processes (AOPs), to remove CECs in several water matrices. CECs removal was found to be influenced by CECs properties, water characteristics and $MITO_3X$ operating conditions. Several AOPs configurations were compared taking into account also their energy consumption. Finally, water flowrate was found not to influence the process performance.

INTRODUCTION

As a result of population growth, urbanization, cyclical droughts, and climate change, natural water and conventional drinking water (DW) sources (i.e. groundwater and surface water) are expected to be more and more stressed (Van Rossum, 2020). Thus, to meet future water demand in agriculture, industry and to ensure sustainable access to DW, interest is growing towards reclaimed wastewater (WW) potable and non-potable reuse (Tchobanoglous et al., 2015).

However, besides the risk associated with the presence of pathogens, the simultaneous presence of multiple contaminants of emerging concern (CECs) in water has raised the issue of the overall risk of the reused water, since many CECs are not completely removed during conventional WW treatment processes. To avoid CECs spread into the environment, removal strategies need to be implemented at centralised and decentralised wastewater treatment plants (WWTP), being the main sources for CECs in natural resources.

State-of-the-art WW reuse processes are membrane-based filtration (e.g., microfiltration, ultrafiltration, and reverse osmosis), challenged due to their low feasibility and sustainability, and advanced oxidation processes (e.g., UV light/peroxide, UV light/chlorine, ozone (O_3)). Also, other advanced treatment trains have been tested at pilot-scale in the literature combining ozonation and AOPs (e.g. O_3/H_2O_2, granular biofiltration and UV_{254}/H_2O_2) with granular biofiltration (Piras et al., 2020). However, a comprehensive analysis of these processes evaluating and comparing their performance towards CECs in different water matrices and operating conditions is missing.

Thus, the objective of this study is to combine lab- and pilot-scale experiments at relevant environmental conditions to evaluate the performance of an innovative treatment technology, $MITO_3X$, based on advanced oxidation processes, to remove CECs in several water matrices.

MATERIALS AND METHODS

MITO3X is a technology able to dose and mix solid, liquid and gaseous reagents in a liquid flow. The whole system is designed to: (i) aspirate the waters to be treated, (ii) inject the specific reagents required by the process, (iii) mix the water to be treated with the reagents using the centrifuge of the suction pump, (iv) pump the effluent to the next steps of the treatment process. Reducing or oxidizing reagents are injected in 3 distinct points of the process: before ozone, simultaneously with ozone, after ozone to implement several chemical-physical treatment processes. Reagents release occurs through peristaltic dosing double pumps to increase solubility and accelerate reactions.

Two different experimental plans have been designed to test different configurations of $MITO_3X$.

Preliminary lab-scale experiments have been performed on O_3 and O_3/H_2O_2 processes on three water matrices: (i) tap water; (ii) tap water with 5 ppm NO_2 addition; (iii) tap water with 5 ppm NO_2 and 10 ppm TOC addition. Water matrices were spiked prior to the tests with: methylene-blue (5 ppm), pCBA (500 ppb), caffeine and acetaminophen (150 ppb), ciprofloxacin, carbamazepine and sulfamethoxazole (50 ppb). Design of Experiments (DoE) technique has been applied to test $MITO_3X$ configuration at a combination of the following operating conditions: O_3 concentration (0-10 ppm), H_2O_2 concentration (0-5 ppm), water flowrate (30-150 L/min) and pump rate (0-60 Hz). Inlet and outlet samples were collected and the following parameters were measured: residual O_3 and H_2O_2 concentration, target compounds concentration, TOC, NO_2, NO_3, water pressure.

Pilot-scale tests have been performed on a combination of O_3, H_2O_2 and UV processes applied on the effluent of a real WW treatment plant in Italy. The WWTP effluent was characterized by COD of 46.0 mg/L, pH of 7.5, UVT of 61.4%, conductivity of 2907 µS/cm and temperature of 26.5°C. No CECs spike was performed to the water prior to the tests. A total of 36 CECs, mainly pharmaceuticals and personal care products, were detected and average concentration of CECs sum in the tested water was 110 µg/L, with main contribution given by caffeine (24.9 µg/L), diclofenac (18.5 µg/L) and metformin (15.0 µg/L). Design of Experiments (DoE) technique has been applied to test $MITO_3X$ configuration at each combination of the following operating conditions: O_3 concentration (0-9 ppm), H_2O_2 concentration (0-9 ppm), UV dose (0-1 mJ/cm²) and water flowrate (0.6-3 m³/h). Such operating conditions were defined to have comparable energy consumption for O_3 production (440 W) and UV system (400 W). For processes combinations with both O_3 and UV, energy consumption of 840 W was considered for comparison. Inlet and outlet samples were collected and the following parameters were measured: residual O_3 and H_2O_2 concentration, 36 target CECs concentrations, TOC, NO_2, NO_3, water pressure, absorbance and fluorescence.

RESULTS AND DISCUSSION

The preliminary lab-scale tests were useful to evaluate whether water characteristics, CECs properties or $MITO_3X$ operating conditions had the major influence on CECs removal efficiency, displayed in Figure 1 for different target contaminants, as a function of water characteristics.

Figure 1. CECs removal at all $MITO_3X$ operating conditions as a function of CEC and water quality.

Obtained removal efficiencies show that $NaNO_2$ and TOC influence is a function of the contaminant and $NaNO_2$ has more influence than TOC on the final performance. However, for each CEC and water type, high variability can be seen in the obtained removals, especially in tap water (with no $NaNO_2$ and TOC addition). This is due to the different MITO3X operating conditions. Thus, to evaluate what aspect influences the most the performance, a multilinear regression model was build for the removal of CECs sum as a function of pump rate, water flowrate, O_3 and H_2O_2 initial concentrations, TOC and $NaNO_2$ water concentrations, whose results are shown in Figure 2.

Figure 2. Multilinear regression model factorial plots for CECs removal as a function of different operating conditions and water characteristics.

The main influencing factor was found to be $NaNO_2$ concentration followed by O3 initial concentration and the pump rate. Thus, both water characteristics and operating conditions can affect the obtained CECs removal. Low (but significant, p-value<0.05) effect was found for TOC concentration and water flowrate. In particular, an unexpected result showed that an increase in water flowrate do not decrease CECs removal, as it would be expected since the contact time is reduced. Two hypotheses for such a result are: (i) $MITO_3X$ at higher flowrates provides better O_3 mixing and reactivity with compounds, (ii) there is an influence of the water pressure and difference between gas and water pressure on the performance. Finally, no significant effect was found for the addition of H_2O_2 into the system.

To evaluate the validity of these results in more relevant environments, pilot-scale tests were performed. CECs removal results at pilot-scale tests are shown in Figure 3 for different processes combinations and different water flowrates.

(a) (b)

Figure 3. CECs removal as a function of different processes configurations: (a) normalized for the energy consumption, (b) as a function of different water flowrates, where each dot corresponds to one CEC in a specific process operating condition tested at the two flowrate.

When comparing single processes, processes based only on H2O2 or UV showed worse removal compared to O3. Combining two or three processes in the treatment do not provide significant improvement on the energy-normalized CECs removal, even if UV/O_3 and $UV/O_3/H_2O_2$ combinations, characterized by twice the energy consumption, reached always more than 80% removal efficiencies. When looking at Figure 3.b, the following preliminary findings can be summarized:

- Lower CEC removal efficiencies are expected when O_3 is not dosed;
- H_2O_2 alone has the lowest removal efficiencies but improves at higher water flowrates;
- UV and UV/H_2O_2: can reach higher efficiencies only when tested at lower water flowrates;
- When O_3 is dosed the removal improves at higher flowrate with the exception of the O_3/H_2O_2 process, suggesting that further studies need to be done to evaluate this interesting aspect.

Abstract

This study aims to assess the potential of microalgae grown in wastewater to produce biopesticides and biostimulants for crops, along with biogas from residual biomass. Bioassays confirmed the suitability of the microalgae biomass as a biostimulant since gibberellins-like activity, auxins- and cytokinin-like activity was observed in watercress seed germination, mung bean rooting, and wheat leaf chlorophyll retention. Biogas production and the kinetic profile from biostimulant-extracted biomass were 24 and 43% higher than raw biomass, respectively. Co-digestion with primary sludge increased biogas production and showed a positive synergistic effect. The applied downstream processes to get valuable compounds acted as a pre-treatment to enhance the anaerobic digestion performance. The proposed approach is a promising strategy for resource recovery from wastewater in a circular bioeconomy approach.

Keywords (maximum 6 in alphabetical order)

INTRODUCTION

During the last decades, microalgae have received focal attention in the biorefinery development, or boosting the plant's natural defense mechanisms. Conversely, antagonistic activity against various phytopathogenic agents, namely *R. solani* and *P. ultimum*, was not observed.

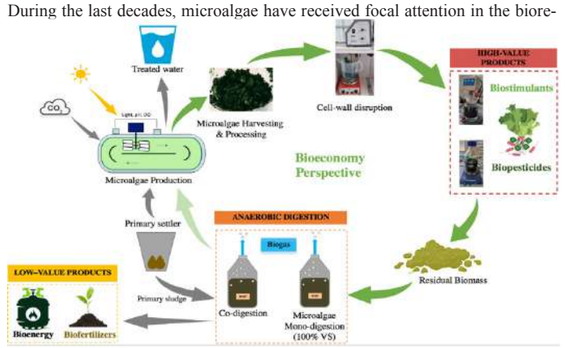

Figure 1. Microalgae biorefinery using microalgae grown in wastewater to produce biostimulants, biopesticides, and biogas. The residual biomass is then co-digested with primary sludge.

MATERIALS AND METHODS

The microalgae biomass was harvested from a pilot-scale raceway pond located at the pilot plant of the University of Almería. The raceway pond (12.6 m^3, 80 m^2) treated the primary effluent from a conventional activated sludge wastewater treatment plant. It was inoculated with *Scenedesmus* sp. and reached a biomass productivity of 23 g m^{-2}·day^{-1}. Downstream processes were applied to extract biostimulants (enzymatic hydrolysis) and biopesticides (organic solvent), with the residual and raw biomass tested for biogas production through anaerobic digestion. Biostimulant activity of microalgae biomass was tested by the gibberellin- auxin- and cytokinin-like effect through the germination index of water creed seeds (0.1 and 0.5 g L^{-1}), the mung beans rooting, and chlorophyll retention in wheat (both at 0.5 and 2 g L^{-1}). Biopesticide activity was detected by the antagonism bioassay with pathogenic fungi (*Rhizoctonia solani* and *Pythium ultimum*) at 1 and 10 g·L^{-1}.

Biogas production was analyzed through Biochemical Methane Potential (BMP) tests under mesophilic conditions (35 °C) and continuous agitation (90 rpm). The raw microalgae biomass (Raw MAB), residual biostimulant-extracted biomass (Stim-E), and residual pesticide-extracted biomass (Pes-E) were employed as substrates to study the effect of the downstream process in the anaerobic digestion performance. The co-digestion of each stream with primary sludge (PS) was also investigated (50:50 on a volatile solid (VS) basis). Mesophilic digested sludge from a wastewater treatment plant was used as inoculum, and microcrystalline cellulose was used as control. The pressure in each bottle (100 ml) was periodically measured with a digital manometer (GMH 3151 Greisinger, Germany), and the composition of the biogas from each batch reactor was analyzed using a gas chromatograph (GC-Trace, Thermo Fisher Finnigan). Specific methane yields were calculated by subtracting the blank (inoculum only) production and normalized to standard conditions. Process kinetics was modelled using a first-order kinetic model as a function of time. Experimental data were statistically assessed via parametric one-way ANOVA test.

RESULTS AND DISCUSSION

Biostimulant and biopesticide activities

Biostimulant activities were detected when two different concentrations of the microalgal extracts (0.1 and 0.5 g DW L^{-1}) were used for seed germination (Figure 2.a). The mung bean rooting tests (Figure 2.b) demonstrated auxin-like activity. Chlorophyll retention was detected when the samples were tested for cytokinin-like activity (Figure 2.c). For both assays, 2.0 g DW L^{-1} was the microalgal extract concentration showing bioactivity compared to the control (distilled water), auxin standard (IBA) and cytokinin standard (BPA).

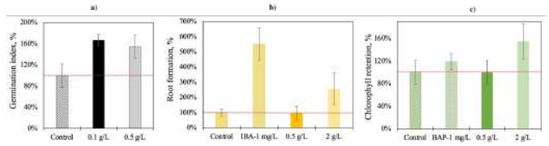

Figure 2. Biostimulant activity from *Scenedesmus* biomass extract, considering distilled water as control. **a)** Gibberellin-like activity through watercress seed germination at 0.1 and 0.5 g L^{-1}. **b)** Auxin-like activity through mung bean rooting at 0.5 and 2 g L^{-1} and indole-3-acetic acid (IBA) as the standard. **c)** Cytokinin-like activity tested using wheat leaf chlorophyll retention at 0.5 and 2 g L^{-1} and 6-benzyl aminopurine (BAP) as standard at 1 mg L^{-1}.

These results highlight the potential of microalgae grown in wastewater as a biostimulant for agriculture applications. Biostimulant microalgal extracts demonstrate the presence of molecules with biological activity that can enhance plant growth and health, often by improving nutrient uptake, promoting root

Biogas production by anaerobic digestion

Figure 3 shows the accumulated methane production of the mono-digestion trials: primary sludge (PS), raw MAB, residual biostimulant-extracted (Stim-E), biopesticide-extracted (Pes-E) biomasses and the co-digestion trials with PS. According to the results from mono-digestion tests, Pes-E achieved the highest methane yield (379 mLCH_4 g^{-1} VS), with an increase of 36% with respect to Raw MAB. Contrariwise, Stim-E achieved the lowest methane yield (251 mL CH_4 g^{-1} VS), corresponding to a decrease of 10% with respect to Raw MAB. This suggests that biostimulant extraction removed a more significant fraction of readily biodegradable organic material, reducing the biogas production. However, the kinetics of Stim-E were significantly higher (by 43%) than with Raw MAB ($p<0.001$), indicating faster hydrolysis due to the enzymatic hydrolysis applied, which increased the digestibility of residual solids.

Upon co-digestion with PS, the methane yield of Raw MAB and Stim-E was improved by 13 and 24%, respectively. Additionally, Raw MAB co-digested with PS improved the kinetics by 25% compared to the anaerobic digestion of Raw MAB. Similarly, the kinetics of Stim-E co-digested with PS showed a significant difference ($p<0.001$) with respect to the kinetics of Stim-E mono-digestion. Besides, Pes-E showed a diauxic behavior, since a sudden increase in methane production was observed after eight days of assay. Indeed, the cumulative methane yield showed two or more distinct growth phases, each one with a different substrate utilization pattern. The remaining organic solvent after biopesticides extraction could explain this behavior in Pes-E. However, the Pes-E biomass co-digested with PS showed a better response and synergetic effect between the two substrates. The double growth in the cumulative curve of Pes-E was diminished through the co-digestion with PS (Figure 3). To summarise, a synergistic effect between all microalgae biomass samples co-digested with PS resulted in improved biogas production and increased methane yield as compared to mono-digestion trials.

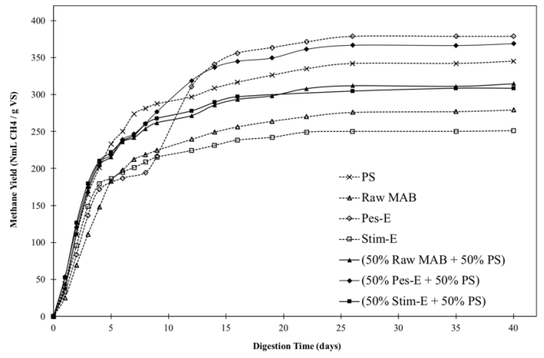

Figure 3. Cumulative methane yield of raw biomass (Raw MAB) and residual biomass after the extraction of biopesticides (Pes-E), and biostimulants (Stim-E), and primary sludge (PS) (mono-digestion and co-digestion).

Table 1. Final methane yield, methane content and first-order kinetic constant of Raw microalgae biomass (Raw MAB), residual biopesticide-extracted (Pes-E) and biostimulant-extracted (Stim-E) biomasses, and co-digestion of each one with primary sludge (PS) (50:50 on VS) (mean values ± stand. dev.; n = 3).

Substrates	Methane Yield, (NmL CH_4 g^{-1} VS)	Methane Content (%)	First-Order Constant Kinetic (day^{-1})

The kinetics and methane production improvement were attributed to the disruption of the microalgae cell wall upon bioproduct extraction, which acted as a pre-treatment step for the anaerobic digestion. Similar results were found after the extraction of lipids and aminoacids (Markou et al., 2022; Monlau et al., 2021) and natural pigments (Arashiro et al., 2020; van den Hende et al., 2016).

In conclusion, this study showed the possibility of recovering biostimulants for agricultural reuse from microalgae treating wastewater, along with biogas from the residual biomass in the framework of the circular bioeconomy. In this approach, the value-added bioproducts would provide economic profitability, while biogas would alleviate the energy demand of the facility, which in turn would provide sanitation to the population.

Abstract

The formation of algae-bacteria aggregated flocs (ABAFs) allows for fast and cost-effective microalgae harvesting alternative via gravity sedimentation, whilst exploiting the cooperative relationship between algae and bacteria. This leads to rapid nutrient removal and wastewater treatment. However, the key principles surrounding the formation of ABAFs and the conditions that lead to enhanced development of these floccular systems are not fully understood, and thus further investigation is needed. Therefore, in this study the effect of light cycles was investigated to ascertain the effect it has on ABAF formation.

Keywords

ABAF, Gravity Sedimentation, Microalgae, Wastewater

INTRODUCTION

Algae-bacteria aggregated flocs (ABAFs) are an emerging technology where flocs are formed from synergistic algal-bacterial consortia. These flocs exploit the cooperative relationship between algae and bacteria leading to rapid nutrient removal (Bacellar Mendes & Vermelho 2013; Fallahi *et al.* 2021). A major advantage is that ABAFs are able to settle rapidly via gravity allowing for easy separation between the ABAFs and the treated wastewater effluent. Consequently, this form of harvesting eliminates the need for energy intensive and costly separation techniques. However, the key principles surrounding the formation of ABAFs and the conditions that lead to enhanced formation of these flocs are not fully understood, and thus further investigation is needed. One such parameter is the effect light cycling has on the formation of ABAFs. As light availability and duration is considered an important factor in the production of EPS, the major binding factor of ABAFs, it is expected light cycling will effect ABAF formation (Arcila & Buitrón 2017). Therefore, in this study it was investigated whether 24hour light vs. a light and dark exposure (that mimics the daily outdoor day/night light cycle) effected the formation of ABAFs within an upflow column photo-bioreactor (UFCPB).

MATERIALS AND METHODS

Experimental Design

Four up-flow column photo bioreactor (UFCPB) with a working volume of 6L were used throughout. Reactors were operated in batch mode, when NH_3-N reached less than 5mg/L (approximately three days) in the system it indicated batch resolution. Screened raw wastewater was used as the feed. Wastewater was obtained from Luggage Point Wastewater Treatment Plant, Queensland, Australia. Microalgae inoculum during each experiment consisted of a wild-type wastewater algae consortium obtained from high-rate algal ponds located at the Luggage Point Wastewater Treatment Plant in Queensland, Australia. Mixing of the reactors was achieved via a pump that recirculated water from the top of the reactors to the base of the reactor. Upon batch completion, mixing ceased and a 30minute settling period occurred. Following batch completion settleability of algal biomass, and thus ABAF formation, was categorized. This was achieved through measurement of TSS/VSS of the biomass, supernatant and a mixed sample, chlorophyll analysis, microscopy, EPS analysis and algal cell counts. Upon batch restart a portion of the settled inoculum was reintroduced to the reactors with 6L of the screened raw wastewater.

Light Cycling

Reactors were run with 24hour light exposure and were compared to reactors run on 16hours with light on and 8hours without light, mimicking the daily outdoor day / night light cycle.

Wastewater Treatment Capabilities

The wastewater treatment capabilities of the experimental treatments were also determined. The parameters investigated included nitrogen and phosphate removal of the systems.

RESULTS AND DISCUSSION

Results from the experiment indicated that light cycling had a significant impact on the growth rate and formation rate of algae-bacteria aggregated flocs. ABAFs were formed in both treatments and the key indication of this was that >80% of biomass was able to be harvested via gravity sedimentation by batch 7 for both treatments (see Figure 1). This is further evident when looking at the TSS of the effluent from both systems (see Figure 2), which was below the local discharge licence requirements, and contained <1million algae cells/mL. However, the effect of 24-hour light periods is evident when comparing the amount of settled biomass present across the two systems. The systems with 24hour light exposure had ~1.46g/L of settleable biomass, whereas the systems with light cycling had ~0.31g/L of settable biomass upon the completion of batch eight. The amount of biomass, and hence algae present in the system, with 24hour light exposure is almost 5x greater than that of the system with light cycling. Thus, indicating that the light cycling had a significant effect on both the growth rate and formation of ABAFs.

Light cycling also had a detrimental effect on ammonia removal rates of the systems (Figure 3). It can be seen that the system with 24-hour light exposure was able to remove 95% of ammonia from the system during batch seven and eight. Whereas, during the same time frame, the systems with light cycling were removing <30% of the ammonia in the system. This is due to the shorter photosynthetic period occurring in the light cycle reactors. During the dark period the algae were not photosynthesizing nor growing. Consequently, there was less microalgae in the system and therefore ammonia uptake was significantly less in these systems. It is noted that the batch lengths for this experiment were short, three days, as it was in a small reactor with 24hour light exposure. Total ammonia removal from an ABAF system is achievable under light/dark conditions, such as those found in high-rate algal ponds (HRAPs) outside, but a longer batch length is required to achieve >90% ammonia removal rates.

These results indicate that light duration can be factor influencing ABAF formation. Whilst 24hour light periods are not suitable for upscale of ABAFs in outdoor HRAPs, the use of UFCPBs to grow an initial inoculum for HRAPs would allow for shorter start-up time frames. In conclusion, ABAFs were successfully formed, and a stable population cultivated, within the UFCPBs. The formation process was impacted by light cycling, showing that increased light duration increases the growth rate and consequently the formation rate of ABAFs. This research also indicates that whilst light cycling does affect the growth and formation of ABAFs, there are other factors that also lead to ABAF formation as stable ABAF populations were formed in both conditions. This research also highlights ABAFs effectiveness to settle, and thus it's simplified harvesting through gravity sedimentation, hence overcoming a significant bottleneck within the microalgae industry.

Abstract

Anaerobic and microalgae-based technologies for municipal wastewater treatment (MWWT) are sustainable alternatives compared to activated sludge systems due to their lower operating cost and resource recovery potential. Besides, the capacity of treatment technologies to inactivate viruses has been challenged by the COVID-19 pandemic, demanding from emerging technologies a higher potential for virus reduction. To assess virus decay in anaerobic and microalgae-based technologies, and to compare their performance with activated sludge, Phi6 and MS2 bacteriophages were spiked into batch bioreactors treating synthetic municipal wastewater (SMWW). All treatment and control reactors showed relatively similar performance in Phi6 inactivation, which occurred within 48-96h. However, MS2 showed an overall higher survival in all treatments, except in the microalgae-based reactor, which achieved a total removal in the soluble fraction at 96h, likely through photoinactivation and low partitioning to the biomass, thus exhibiting a higher potential to provide by-products of higher sanitary quality during MWWT.

Keywords: activated sludge, anaerobic treatment, bacteriophages, microalgae-based treatment, SARS-CoV-2 surrogate, virus inactivation

INTRODUCTION

The COVID-19 pandemic has questioned the current WWTPs' capacity to inactivate viruses and the underlying mechanisms behind high reductions in virus loads in municipal wastewater. These reductions are mainly achieved during advanced treatment and/or disinfection. However, secondary treatment in activated sludge systems has shown relatively high performance in virus' removal, with several works showing average reductions of up 3 log10 units for viruses such as F+-coliphages, enterovirus, and Norovirus (Delanka-Pedige et al. 2020). Unfortunately, the number of works assessing virus partitioning and survival in emerging wastewater treatment technologies, such as anaerobic and microalgae-based reactors, is scarce (Astals et al. 2012; Delanka-Pedige et al. 2020). These technologies have growing relevance due to their higher sustainability when compared to activated sludge, since they can cost-effectively recover energy and nutrients. However, the content of biological micropollutants, including viruses, is a major constraint during resource recovery from municipal wastewater (Markou et al. 2018).

On the other hand, the viability of viruses in wastewater and WWTPs has been studied using bacteriophages with no biosafety issues, among which Phi6 and MS2 have been more widely applied. Thus, this work assessed the decay of Phi6 (enveloped) and MS2 (non-enveloped) bacteriophages spiked into Activated sludge, Anaerobic digestion, and Microalgae-based treatment batch reactors. The performance of these technologies was compared in terms of bacteriophage reduction and decay kinetics, inactivation, and partitioning to solids during synthetic municipal wastewater treatment.

MATERIAL AND METHODS

Synthetic wastewater, bacteriophages and host strains

Synthetic municipal wastewater (SMWW) was used in this study as a model municipal wastewater. The SMWW was characterized by a pH of 7.39±0.1 and concentrations of dissolved total organic carbon (TOC) of 258.2±12.3 mg L^{-1}, dissolved inorganic carbon (IC) of 5.7±9.9 mg L^{-1}, and 50.7±10.0 mg L^{-1} of dissolved total nitrogen (TN). Bacteriophages Phi6 (DSM-21518) and MS2 (DSM-13767), and their respective hosts *Pseudomonas* sp. (DSM-21482) and *E. coli* (DSM-5695), were purchased from the German Collection of Microorganisms and Cell Cultures (DSMZ). The bacteriophages and their host were revitalized and handled according to DSMZ. High-titer stock solutions were achieved using amplification in plates and the double agar technique was applied to quantify the bacteriophage concentrations (Fedorenko et al. 2020)

Experimental set-up, virus reduction, and decay kinetics

Three batch experiments investigating the decay of Phi6 and MS2 were performed in 2.1 L glass sterile bottles (Fisher) using (i) Activated sludge (ASR), (ii) Anaerobic sludge (ANR), and (iii) a Microalgal-bacterial consortium (MBR). The tests were conducted in duplicate under constant magnetic agitation at 180 rpm (Cimarec I Multipoint, Thermofisher). The reactors were operated in a controlled temperature room at 25° C, 37°C, and 29°C for ASR, ANR, and MBR, respectively. ASR and ANR were inoculated with activated sludge and anaerobic sludge from the local WWTP. MBR used activated sludge and *Chlorella sorokoniana* as inocula. Each reactor was compared to a control reactor (SMWW Control), spiked with bacteriophages, and operated under the same conditions, except bacterial or microalgal inoculation.

The broth of the biodegradation and control reactors was spiked with Phi6 and MS2 suspensions at a ratio 1:1000. Samples were withdrawn at 0, 6, 12, and 24 h after inoculation of the viral suspensions and every 24 h until 96 h for Phi6 monitoring or 144 h for MS2 monitoring. Samples were collected using needles and syringes directly from the reactors and controls under sterile conditions, and were stored in sterile falcon tubes and microtubes. The partitioning to solids and virus reduction capacity of each reactor was estimated based on bacteriophage titers in both soluble and total fractions over time. Furthermore, log-logistic regressions were applied to assess the decay kinetics using the *drc* package in Rstudio (Ritz et al. 2015).

RESULTS AND CONCLUSIONS

Activated sludge, anaerobic and microalgae-based treatments showed high potential in the reduction and inactivation of enveloped Phi6 and nonenveloped MS2 bacteriophages (Table 1, Figure 1). Enveloped Phi6 showed a higher affinity for aerobic solids when compared to nonenveloped MS2, which showed overall low interaction with suspended solids, mainly in activated sludge and microalgae-based treatments (Figure 1). T_{90} values were calculated through log-logistic models, using the titers in the total fraction, showing values of 0.11, 0.17, and 0.39 days for Phi6 and 0.17, 0.98, and 0.44 days for MS2 (Figure 2). Phi6 was completely reduced in 48-96 h in treatment reactors, among which anaerobic treatment produced faster inactivation (before t= 48h). The microalgae-based treatment outperformed the activated sludge and anaerobic processes for the removal of MS2 from the soluble phase, achieving a complete MS2 removal at t=96 h. Photoinactivation and low solid partitioning to the microalgae-bacterial biomass were the main factors favoring bacteriophage inactivation in MBR. Therefore, microalgae-based treatments can potentially provide by-products of higher sanitary quality in terms of virus titers during municipal wastewater treatment.

* The Australian Centre for Water and Environmental Biotechnology at the University of Queensland, Queensland, Australia
(E-mail: a.ward3@uq.edu.au *and p.jensen@uq.edu.au)*

Abstract

This study demonstrates an innovative biological wastewater treatment process based on an aggregated microbial bio-floc comprising of an algae-bacteria based consortia. The aggregation of the algae-bacteria consortia into a stable floc was successfully demonstrated over a 12-month period in a pilot scale outdoor 4.5m^2 open High-Rate Algae Pond (HRAP) system. The robustness of the algae bacteria aggregated floc (ABAF) was demonstrated through utilisation of existing scalable high-rate algae pond culture techniques with continuous paddle wheel mixing. Results of the 12-month study demonstrate average domestic wastewater nutrient removal efficiencies for NH_4-N, PO_4-P and Total Nitrogen of 98%, 74% and 57% respectively. The HRAPs were operated in a novel process where they were run as a fill and drain sequencing batch reactor with gravitational sedimentation employed to recover biomass.

Keywords (maximum 6 in alphabetical order)

Algae, Aggregated Floc, Algae Harvesting, Bacteria, Wastewater Treatment

INTRODUCTION

Single celled microalgae-based wastewater treatment processes have been extensively researched; however, one of the main factors that limit these systems is the challenge of low-cost efficient biomass harvesting and dewatering. Harvesting microalgal biomass requires efficient solid-liquid separation technologies (Pahl et al. 2013). This technology is often the limiting step due to high equipment costs, excessive energy consumption and high operational costs (Uduman et al. 2010).

Combined algae-bacteria aggregated flocs (ABAFs) can overcome difficult and energy intensive biomass harvesting processes. The formation of bacteria and algae into aggregated flocs allows the ABAFs to settle quickly allowing simple gravitational separation processes for biomass harvesting and dewatering. ABAF systems have the benefits of typical high-rate algae processes whilst also having the potential of a more efficient solution for regional and decentralised wastewater treatment applications. Increased benefits of ABAF systems include the simple separation of the aggregated algal biomass by gravity sedimentation, high removal efficiency for organic carbon and nutrients, independence in terms of oxygen provision through algal photosynthesis and the resource recovery opportunity by producing a valuable biomass feedstock for value added products (Wang et al. 2022; Oswald et al. 1953).

To date no other pilot scale work on ABAFs has been undertaken under Australian climatic conditions. However, limited international laboratory scale studies have demonstrated that algal-bacterial granules / flocs for wastewater treatment can achieve better nutrient removal efficiency than single bacterial or microalgal systems (Muñoz and Guieysse, 2005, 2006; Ramanan et al. 2016; Gutzeit et al. 2004). Results from this initial study identified a novel process that utilises algae and bacteria combined in an aggregated floc to remediate wastewater nutrients.

MATERIALS AND METHODS

The experimental pilot raceways were located at Luggage Point Sewage Treatment Plant located in Pinkenba, Queensland, Australia. Four HRAP (5m L x 2.5m W x 0.4m D) with a surface area of 4.5m^2 each were used for the experimental work. The working volume for the raceways was 1000 litres and paddlewheels were used for culture mixing. The pilot experiment was conducted in unsheltered outdoor conditions over a 12-month period. ABAFs was inoculated into the HRAPs, and the system was then operated in a sequencing batch reactor configuration where the culture was mixed for 5 to 7 days. Following, a 30-minute settling period allowing for ABAF biomass to settle. The treated water was decanted and a percentage of settled biomass removed and used as an inoculum. The HRAPs were then refilled with post screened domestic sewage wastewater and the cycle repeated. The nutrient parameters NH_4-N, PO_4-P, NO_2-N and NO_3-N were analysed using FIA analysis. D.O., pH, turbidity, Soluble COD, TSS and VSS were also analysed over the experimental period. Molecular diversity of Eukaryote and Bacterial diversity was investigated. HRAP were sampled monthly to examine changes in microalgae and bacterial diversity over a 12-month period. This was undertaken by utilising 16s rRNA and 18s rRNA pyrosequencing methods and technologies.

RESULTS AND DISCUSSION

ABAFs industrial biotechnologies developed in this project represent a novel approach to wastewater treatment and algae production. Results demonstrated a stable ongoing 12-month operation of the ABAFs pilot system under outdoor conditions on domestic wastewater. A stable microbial population was also noted over the 12-month period. Average nutrient removal efficiencies achieved over the 12-month experimental period for NH_4-N, PO_4-P and total nitrogen were 98%, 74% and 57% respectively. Monthly average nutrient removal efficiencies are shown in Table 1. Ammonia removal did not show any significant disparity over the 12-month period however, phosphorous removal showed more variation over the experimental period. Total nitrogen removal efficiency reduced over the winter months when compared to the warmer summer months. This could be expected as lower solar radiation is received during the winter months. An average biomass recovery rate of 80% ± 11 % was achieved over the experimental period by using simple gravitational settling process.

CONCLUSION

ABAF biotechnologies developed in this project demonstrate a novel approach to water treatment and algae production. Specifically, the project results to date address major limitations of existing algal technologies by enabling rapid low-cost biomass harvesting. This ABAF technology has demonstrated significant advantages and can eliminate the major limiting step of biomass recovery from algae-based remediation systems.

Abstract

Worldwide, the majority of algal wastewater treatment systems have focused on using unicellular or colonial microalgae grown in suspension in either waste stabilisation ponds or more advanced high rate algal ponds. However, challenging operation issues warrant the investigation of filamentous algae instead. This study compared for the first time the nutrient removal performance and algal productivity of native New Zealand (NZ) microalgae and filamentous algae grown on human wastewater in outside high rate algal pond mesocosms. The high rate algal pond mesocosms comprised of 15-L plastic buckets with a 30 cm culture depth which were operated outdoors during summer and winter conditions. The cultures were grown on primary settled domestic wastewater in two mesocosms in series which were operated as continuous cultures each mesocosm with either a 3-day (summer) or 4-day (winter) hydraulic retention time, with hourly wastewater addition into the first mesocosm. The microalgae mesocosms were able to remove over half the influent ammoniacal-N and DRP concentrations. The filamentous algae mesocosms had slightly lower nutrient removal than the microalgae mesocosms under both winter and summer conditions. The microalgae mesocosms had higher productivity than the filamentous algae mesocosms under both winter and summer conditions. These encouraging results suggest that further studies should be undertaken to investigate opportunities to enhance the performance of filamentous algae systems.

Keywords (maximum 6 in alphabetical order)

Ammoniacal-N, Dissolved Reactive Phosphorus, Productivity

INTRODUCTION

Worldwide, the majority of algal wastewater treatment systems have focused on using unicellular or colonial microalgae grown in suspension in either waste stabilisation ponds or more advanced high rate algal ponds (Craggs, 2005; Sutherland 2014). However, challenging operation issues (including lack of process control due to the inability to separate the retention times of the water and microalgae, inefficient and costly harvest of microalgal biomass, and loss of performance due to zooplankton grazing of the microalgae) warrant the investigation of filamentous algae instead. Filamentous algae are comparatively easily harvested there-by enabling algal biomass to be removed and returned to simply adjust its retention time, independently of that of the water. This has the potential to enable much better process control. In addition, filamentous algae don't appear to be as susceptible as microalgae to zooplankton grazing pressure, presumably due to the comparatively much larger size of the algae filaments. However, the larger size of filamentous algae and reduced surface area to volume ratio may result on lower productivity and nutrient removal compared with planktonic microalgae. This study compared for the first time the nutrient removal performance and algal productivity of native New Zealand (NZ) planktonic and filamentous algae grown on human wastewater in outside high rate algal pond mesocosms.

MATERIALS AND METHODS

High rate algal mesocosm setup

This study was conducted outdoors during summer and winter conditions at the Ruakura Research Centre, Hamilton, New Zealand (37°47′ S, 175°190′ E). The high rate algal pond mesocosms comprised of 15-L plastic buckets with a 30 cm culture depth. The buckets were wrapped in opaque

foam to ensure that light entered only from the surface of the water and were placed on individual magnetic stirrer plates and mixed continuously by a novel vertical paddlewheel mixer (4-cm wide blade that hung from a bearing above the water surface to ~1 cm above the bottom of the mesocosm).

The mesocosms were inoculated with wastewater cultures of either mixed planktonic microalgae or mixed filamentous algae. The microalgae culture was dominated by the chlorophyte *Scenedesmus* sp. and Desmodesmus sp. The filamentous algae culture was dominated by *Oedogonium* sp.

Experiment were conducted during summer (22nd November 2021 – 24th January 2022) and winter (25th May to 14th July 2022) conditions and run for a minimum of six weeks. The cultures were grown on primary settled domestic wastewater in two mesocosms in series which were operated as continuous cultures each mesocosm with either a 3-day (summer) or 4-day (winter) hydraulic retention time, with hourly wastewater addition into the first mesocosm.

Dissolved nutrient analysis

For dissolved nitrogen and phosphorus determination, mesocosm culture was sampled twice a week and filtered through Whatman GF/Ffilters, and concentrations of ammonium (NH_4–N), nitrate (NO_3–N) and dissolved reactive phosphorus (DRP) were determined colourimetrically according to standard methods

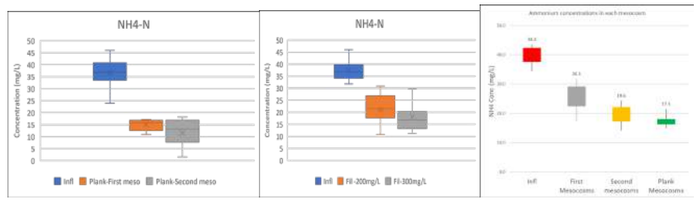
(APHA 2008).

Biomass determination

For organic matter, a known volume of mesocosm culture was sampled twice a week and filtered through a pre-rinsed, pre-combusted and pre-weighed Whatman GF/F filter, oven dried (105 °C) and weighed, once cooled, to determine the total suspended solids (TSS) concentration. Filters were then combusted at 450 °C for 4 h, cooled in a desiccator, and re-weighed to determine the ash concentration. The organic matter, also referred to as volatile suspended solids, was estimated as the difference between TSS and ash concentrations.

RESULTS

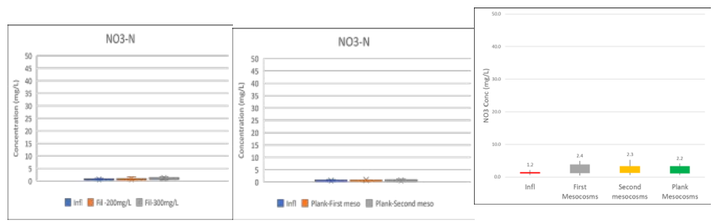
The nutrient removal and algal productivity of the microalgae and filamentous algae mesocosm are compared for both summer and winter conditions in Figures 1 - 4.



Winter Summer

Figure 1. Ammoniacal-N concentration in microalgae and filamentous algae mesocosms under summer and winter conditions

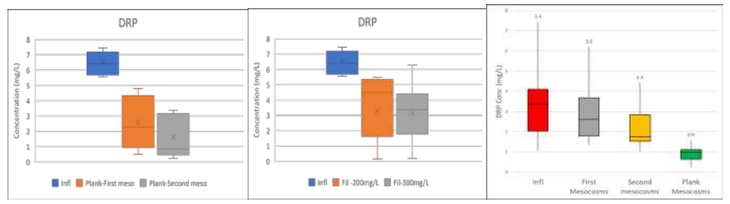
The microalgae mesocosms were able to remove over half the influent ammoniacal-N concentration. The filamentous algae mesocosms had slightly lower ammoniacal-N removal than the microalgae mesocosms under both winter and summer conditions (Figure 1).



Winter Summer

Figure 2. Nitrate-N concentration in microalgae and filamentous algae mesocosms under summer and winter conditions

Under winter conditions nitrification occurred resulting in slightly elevated nitrate concentrations in both the filamentous algae mesocosms and the microalgae mesocosms (Figure 2). Under summer conditions little nitrification was observed.

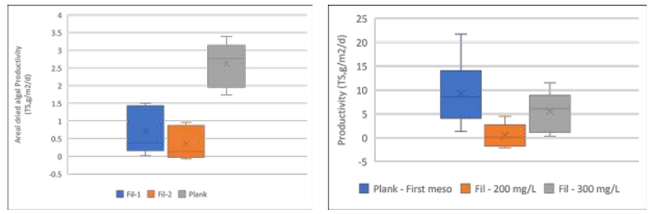


Winter Summer

Figure 3. Dissolved Reactive Phosphate concentration in microalgae and filamentous algae mesocosms under summer and winter conditions

The microalgae mesocosms were able to remove over half the influent DRP concentration. The filamentous algae mesocosms had slightly lower DRP removal than the microalgae mesocosms under both winter and summer conditions (Figure 3).

The microalgae mesocosms had higher productivity than the filamentous algae mesocosms under both winter and summer conditions (Figure 4).



Winter Summer

Figure 4. Biomass productivity in microalgae and filamentous algae mesocosms under summer and winter conditions

DISCUSSION

These results indicate the potential of growing filamentous algae instead of microalgae for wastewater treatment in High Rate Algal Ponds. The performance of the filamentous algae mesocosms was not as good as that of the microalgae mesocosms with respect to both nutrient (Ammoniacal-N and DRP) removal and algal productivity. These encouraging results suggest that further studies should be undertaken to investigate opportunities to enhance the performance of filamentous algae systems.

Abstract

Microalgal biomass cultivated in wastewater was used as biofertilizer for lettuce crop. Pathogens and heavy metals were measured in the biomass and compared to the threshold reported by the EU regulation for fertilizing products. Contaminants of emerging concern (CECs) were monitored in wastewater, microalgal biomass and lettuce leaves. In general, pathogens and heavy metals content of the biomass were below the threshold, except for cadmium. The agronomic assay revealed that microalgal biomass can reduce the use of mineral nitrogen fertilizer, obtaining similar fresh weight. Wastewater presented 25 CECs, which only 3 were found in the biomass in concentrations ranging 0.1 to 25 µg/g_{DM}. Both cadmium and CECs were detected in lettuce crops, but their presence could not be linked to the microalgal biomass.

Keywords

Agronomic tests; Biofertilizer; Circular bioeconomy; Emerging pollutants; Nutrients recovery

INTRODUCTION

In a circular bioeconomy context, the use of wastewater as a source of nutrients for microalgae cultivation has resulted in the reduction of production costs. Moreover, the biomass could be further used as biofertilizer (Ronga et al., 2019). However, wastewater might present contaminants like pathogens, heavy metals and contaminants of emerging concern (CECs). Therefore, it was considered the need to assess the fertilizing capabilities of microalgal biomass grown in wastewater, and at the same time to characterize the microalgal biomass in those terms reported in the European legislation about fertilizing products (European Union, 2019), as well as to track the presence and fate of specific contaminants in the wastewater, microalgal biomass and lettuce plants.

MATERIALS AND METHODS

Biomass cultivation and characterization

Two high rate algal ponds (HRAPs), with a volume of 470 L each, located outdoors in Barcelona (Spain) treated real municipal wastewater. The microalgal biomass from the HRAPs was harvested in secondary settling tanks, thickened in laboratory Imhoff cones at 4ºC, centrifuged and stored at 20ºC until use in agronomic tests.

The characterization of the microalgal biomass consisted in macro- (nitrogen (N), phosphorus (P), potassium (K), magnesium (Mg), calcium (Ca), sulphur (S)) and micronutrients (iron (Fe), sodium (Na)); pathogens (*Salmonella*, *Escherichia coli*, *Legionella* spp. and *Legionella pneumophila*); and heavy metals which include cadmium (Cd), cupper (Cu), chromium (Cr), hexavalent chromium (Cr(VI)), mercury (Hg), nickel (Ni), lead (Pb), zinc (Zn), aluminium (Al), arsenic (As).

Agronomic assay

The agronomic assay was performed in a greenhouse located in Castelldefels (Barcelona, Spain), using Lettuce (*Lactuca sativa* L. cv Maravilla) during November-January. Four treatments were tested: (**C-**) negative control without fertilizer; (**C+**) positive control with NPK 100% inorganic; (**M1**) microalgal biomass + inorganic N (half dose of C+) + inorganic PK (same dose as C+); (**M2**) microalgal biomass + inorganic PK (same dose as C+). Each treatment consisted in 30 pots of 2 L each. At harvest, fresh weight was recorded. Lettuce leaves were analysed in terms of macro- and micronutrients and heavy metals. Contaminants of emerging concern were monitored in wastewater, microalgal biomass and lettuce leaves. A leachate assay was performed after lettuces were harvested. For this, 1 L of tap water was added to each pot and the leachate produced was analysed in terms of water-soluble nutrients (nitrate, ammonium and phosphate).

RESULTS AND DISCUSSION

Biomass characterization

Regarding the nutrient content of the microalgal biomass, N presented the highest content (6.69 %$_{DM}$). It presented a NPK ratio (1:0.25:0.05) which is in accordance with previous studies. Pathogens and heavy metals content (Table 1) were below the threshold of the European regulation, except for Cd, (3.10 mg/kg_{DM} when the limit for organo-mineral fertilizers is 3 mg/kg_{DM}).

Microalgal biomass as biofertilizer: effects in lettuce growth

The agronomic assay revealed that C+ and M1 presented similar shoot fresh weight, with no significant differences ($p < 0.05$), 95.41 g/plant and 93.45 g/plant, respectively (Table 2). However, M2 (43.7 g/plant) presented lower weight than both C+ and M1 (Table 2). These results suggest that the amount of mineral N can be partially replaced with microalgal biomass (M1) without affecting the shoot fresh weight.

The nutrient content measured in lettuce leaves revealed that the nutritional status was similar in C+ and M1 for N and K (Table 2). This result supports the above-mentioned results. In addition, treatment M1 presented significantly higher P and S content ($p < 0.05$) than C+, with an increment of 37 % and 20 %, respectively. In general, M2 showed lower nutrient concentration in leaves, suggesting that the amount of nutrient supplied in this treatment was not enough to support lettuce's growth.

Regarding heavy metals, only Cd was above the threshold given in EU regulation. Therefore, this element was measured in lettuce leaves. There were not significant differences between C+, M1 and M2. This result demonstrates that the source of the metal in lettuce leaves was not linked to the biomass, but probably to the soil, which had a Cd content of 0.5 mg/kg_{DM}.

Contaminants of Emerging Concern: possible transfer to lettuce crops

Although 25 CECs were found in wastewater (Figure 1), only a few presented a concentration higher than 3 µg/L (caffeine, diclofenac, hydrocynamic acid, methyl dihydrojasmonate, and naproxen). In general, the microalgal biomass presented only 3 CECs with concentrations higher than the LOQ (Limit Of Quantification), which where hydrocinnamic acid, caffeine, and bisphenol A (concentration ranging from 0.1 to 25 µg/g_{DM}) (Figure 1). Taking into account these results, CECs were also measured in lettuce leaves. Although some replicates presented concentrations ranging from 0.1 to 0.8 µg/g_{DM} of a few CECs, they were also present in C+ and C- (Figure 1), which demonstrates that the source was not the microalgal biomass.

Nutrient leaching from microalgal-based biofertilizer

At the end of the experiment, after lettuce were harvested, some nutrients (ammonium, nitrate and phosphate) were monitored in the leachate (Table 3). The concentration of the different species of nitrogen in C+ and M1 were different, in spite of receiving the same amount of NO_3-NH_4 23 days prior to the harvest. For instance, C+ presented 128 mg/L N-NO_3^- and 3 mg/L N-NH_4^+ whereas M1 presented 204 mg/L N-NO_3^- and < 0.2 mg/L N-NH_4^+. These results suggest that the microalgal biomass could either promote the presence of soil nitrifying bacteria or provide nitrifying bacteria, which catalyse the oxidation of ammonium to nitrate. Regarding phosphorus, only C+ presented a concentration higher than LOQ in leachate (5 mg/L P-PO_4^{3-}) in spite of being provided with the same dose of P in C+, M1 and M2. This can suggest that microalgal biomass can avoid P leaching.

Table 1. Content of heavy metals (mg/kg_{DM}) and pathogens (CFU/g) in the microalgal biomass cultivated in wastewater. Third column shows the threshold value given in European regulation (EC 2019/1009) for mineral-organic fertilizers.

Heavy metal (mg/kg_{DM})	Microalgal biomass	European regulation limits
Cadmium	3.10	3
Hexavalent chromium	1.31	2
Mercury	0.52	1
Nickel	< 46.5	50
Lead	< 46.5	120
Arsenic	< 18.6	40
Copper	279	600
Zinc	437	1500
Pathogens (CFU/g)	**Microalgal biomass**	**European regulation limits**
Legionella ss	Not detected	-
Salmonella spp	Not detected	Absence
Escherichia coli	400	1000

Table 2. Fresh weight (g/plant) and nutrient content (%$_{DM}$) in the four treatments: C- (negative control), C+ (positive control), M1 (microalgal biomass with N supplement), M2 (microalgal biomass). Standard Error of the Mean is given in brackets (n=30 for fresh weight and n=4 for nutrients). Different letters indicate significant difference ($p < 0.05$).

	C-	C+	M1	M2
Fresh weight (g/plant)	28.28^{c} (0.93)	95.41^{a} (3.53)	93.45^{a} (3.21)	43.7^{b} (1.14)
N (%$_{DM}$)	0.88^{b} (0.03)	3.60^{a} (0.08)	3.69^{a} (0.03)	1.01^{b} (0.02)
P (%$_{DM}$)	0.14^{c} (0.01)	0.18^{bc} (0.01)	0.28^{a} (0.02)	0.19^{b} (0.01)
K (%$_{DM}$)	2.12^{c} (0.07)	5.04^{a} (0.10)	5.24^{a} (0.17)	3.24^{b} (0.09)
S (%$_{DM}$)	0.10^{a} (0.01)	0.24^{c} (0.01)	0.29^{d} (0.01)	0.14^{b} (0.01)

Table 3. Soluble inorganic nutrients concentrations (Ammonium; Nitrate; Phosphate) in the leachate in each treatment: C- (negative control), C+ (positive control), M1 (microalgae biomass with N supplement), M2 (microalgae biomass). Standard Error of the Mean is given in brackets (n=4).

	C-	C+	M1	M2
N-NH_4^+ (mg/L)	<0.02	2.7 (0.6)	<0.2	<0.02
N-NO_3^- (mg/L)	3.0 (0.3)	127.8 (5.5)	204.1 (14.4)	4.4 (0.6)
P-PO_4^- (mg/L)	<0.8	5.4 (1.7)	<0.8	<0.8

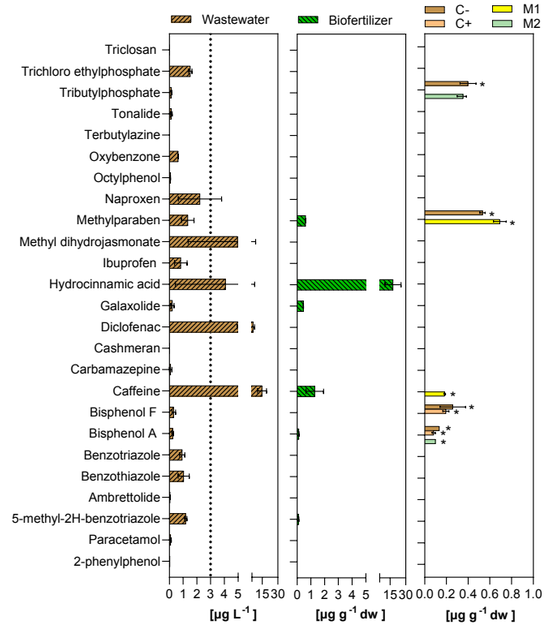

Figure 1. Mean concentrations of the detected CECs (25 out of 29) in the wastewater (n=2), biomass (n=2) and lettuce leaves of each treatment (C-, C+, M1 and M2) (n=4). Values are given in ***µg***/L for water and ***µg***/dDW for biomass or lettuce. Compounds with concentration <LOD in all samples are not plotted. Only replicates with values >LOD were used to calculate means. Error bars show the range of the measurements. *Compounds were detected on two or less replicates.

Abstract

Piggery wastewater treatment with microalgae has become a promising process for the treatment and production of valuable biomass, although the presence of emerging contaminants such as antibiotics or heavy metals can influence the biomass composition and the valorization processes. These pollutants affected the protein and carbohydrate solubilisation and recovery yields of different extraction methods. Enzyme activity was inhibited by metals, and the stress generated by combining both types of pollutants decreased the cell wall resistance to chemical treatments.

Keywords (maximum 6 in alphabetical order)

Biomass, carbohydrates, extraction, piggery wastewater, proteins, solubilization.

INTRODUCTION

Pig manure has become a huge source of environmental pollution which must be treated due to its high concentration of organic matter, nitrogen, phosphorus, and ammonium. Bioremediation with microalgae has emerged as a promising technology in terms of efficiency and potential use of generated biomass to produce high-added value products (Saavedra et al., 2019). However, the concern about the presence of certain veterinary antibiotics (used to treat and prevent animal diseases) and heavy metals (present in well water or/and used in animal feed as micronutrients) in piggery wastewater has increased in the last years (López-Serna et al., 2019). These pollutants could affect the biomass composition and the valorization processes. This research is pioneer in the study of the influence of various veterinary antibiotics (VA) and heavy metals (HM) in the extraction of proteins and carbohydrates from microalgal-bacterial biomass grown in a wastewater treatment photobioreactor.

MATERIALS AND METHODS

Three assays were carried out in a thin-layer photobioreactor of 1,200 L with a dilution rate of 0.2 d^{-1} treating 10%-diluted piggery wastewater as feed and inoculated with *Scenedemus almeriensis*. Starting each assay, the photobioreactor was run for 15 days until the steady state was reached to obtain undoped biomasses (UB) as controls. From day 16 to day 36, the feed was doped with three VA (sulfadiazine, tetracycline, and ciprofloxacin (100 µg/L)) in assay 1, three HM (5 mg/L of copper, 15 mg/L of zinc, and 2 µg/L of arsenic) in assay 2 and with both types of pollutants (3 VA and 3 HM) in assay 3 (with the same previous concentrations), to obtain the doped biomasses (DB). The biomass in each period of each assay was harvested, centrifugated, freeze dried, and analyzed.

Several extraction methods were carried out to solubilize proteins and carbohydrates from the different biomasses (UB and DB) collected in the photobioreactor, applying the operational conditions described in Table 1. The residual solids were analyzed to calculate the solubilization of macro-components. The recovery of peptides and monosaccharides was calculated from the analysis of the liquid phase. Protein, carbohydrate, and lipid content were determined using the Total Kjeldahl Nitrogen (TKN), a modified NREL protocol based on an acid hydrolysis and HPLC and the Kochert method respectively. The amino-acid content of the solid and liquid phases was analyzed by HPLC (Rojo et al., 2021). Least significant difference tests (LSD) were carried out to identify the significant statistical differences (95% of confidence level).

RESULTS AND DISCUSSION

Effect of VA and HM on macromolecular biomass composition

Figure 1 shows compositions of the biomasses before and after doping in each assay. VA doping had some influence on the microalgae biomass composition of the assay 1, with significant decreases in protein content (from 56.6% to 52.9%) and glucose content (from 23.6% to 18.1%). In the assay 2, microalgae composition was also altered by the presence of HM, decreasing the carbohydrate content from 25.1% to 19.7%, related to decrease on glucose content from 17.4% to 12.2%. Finally, biomass composition changed significantly in assay 3. The protein content did increase by 45% while carbohydrate content decreased by 29%. The presence of both types of pollutants could produce a big oxidative stress, increasing the protein synthesis to overcome the imbalance due to overproduction of reactive oxygen species (Wang et al., 2022).

Effect of VA and HM on protein and carbohydrate solubilization

Figure 2.A shows the protein and carbohydrate solubilization yields obtained from UB and DB after each extraction treatment in the assay 1. The presence of VA decreased significantly the solubilisation of proteins of the treatments UAEE-P (19%), NaOH 120 (10%) and NaOH 60 (17%). The VA presence also decreased the carbohydrate solubilisation yields when applying UAE (39%), HE-P (42%), NaOH 120 (42%) and NaOH 60 (47%). It was possible that the cell wall became more resistant in response to the presence of VA. Chemical treatments at 120ºC provided the highest recoveries of peptides (55% with NaOH and 50.9% with HCL) and monosaccharides (54.2% of glucose and 46.2% of xylose with HCl) with DB.

The presence of HM decreased significantly the protein, and carbohydrate solubilization yields from biomasses of assay 2 for most of the treatments (Figure 2.B). The decrease on protein solubilization yield resulted remarkable for the physical and biological methods (<35.6%), without significant differences for NaOH 120. Enzymes could be inhibited by the presence of HM, competing for biding sites and interfering the enzymatic activity (Smith et al., 2022). Carbohydrate solubilization were also negatively influenced in the UAE, UAEE-P, HE-P, HCl 120 and NaOH 60 treatments with reductions over 30%. Likewise, the peptide and monosaccharide recoveries obtained from DB were very low in almost all treatments (except for NaOH 120, NaOH 60 and HCl 120) being less than 8%.

Finally, Figure 2.C shows the protein and carbohydrate solubilization yields achieved for biomasses from the assay 3, doped with VA and HM. Protein solubilization yields were influenced by the presence of both pollutants in all experiments except HE-P and HCl 60, while the only treatment that was not affected by these contaminants in the solubilization of carbohydrates was HCl 60. The increase in solubilization yields in the chemical treatments is noteworthy, which could indicate that the cell wall was weaker due to the oxidative stress (Danouche et al., 2022). However, protein solubilization decreased in the UAE and UAEE-P treatments by 24% and 21% respectively. Again, peptide and monosaccharide recoveries were (<10%) in presence of VA and HM, except in HCl 120, where the recoveries yields increased in the DB.

CONCLUSIONS

The presence of veterinary antibiotics and heavy metals influenced significantly the composition of microalgae-bacteria biomass grown in wastewater treatment photobioreactors and the yields of further valorization processes. High negative influence of heavy metals on the enzymatic reactions with both enzymes (metal ions competing for biding sites). Alkaline hydrolysis was affected by the presence of veterinary antibiotics, while acid hydrolysis was mainly affected by heavy metals. The presence of both pollutants reduced the cell wall resistance, improving extraction yields from biomass grown in high stressing environment.

Abstract

The aim of this work was to evaluate the application of microalgae grown in digestate treatment ponds as fertilizer in soil and plant. Harvested biomass was tested before and after anaerobic digestion and co-digestion with food waste as possibilities of valorisation in a treatment plant located in the university campus. The experimental design consisted of applying treatments in randomized pots with hybrid brachiaria *Sabiá* in a greenhouse with three replications each. Assessed parameters showed comparable results on plant growth for fresh and digested microalgal biomass and inorganic fertilizer. Moreover, fresh microalgae provided the highest phosphorus content in the leaf and the also of nitrogen, phosphorus and organic matter in the soil. In conclusion, this study indicates that microalgae-based biofertilizer has potential as a nutrient source and can promote the association in circular valorisation of waste treatment and agriculture.

INTRODUCTION

Microalgae has been investigated with successful results for treating high-strength wastewaters, as digestate from organic waste anaerobic digestion (Torres-Franco et al., 2021). In these systems, microalgae produce oxygen needed for heterotrophic bacteria to degrade organic matter, while assimilating macro and micronutrients into their cells. Therefore, harvested microalgal biomass may be further valorized into products, such as biofuels, animal feed and fertilizers.

In particular, the current agricultural sector relies on the use of mineral fertilizers, which are obtained through energy-intensive processes. Moreover, its excessive use generally leads to negative environmental consequences on soil and water bodies (Tilman et al., 2002). In light of these issues, it is urgent to promote sustainable agriculture by applying fertilizer from waste and wastewater. Previous research has demonstrated the potential of microalgae biofertilizer in soil and plant as an alternative to mineral fertilizers (Garcia-Gonzalez e Sommerfeld, 2016; Lorentz et al., 2020; Alvarez-Gonzalez et al., 2022). However, there are still many aspects that require further study and improvement for its full-scale application.

This study was carried out in the context of a demonstration-scale facility implemented in the campus of the Federal University of Minas Gerais (Belo Horizonte, Brazil) for treating food waste, which consists in an anaerobic reactor and a high rate algal pond for post-treating the digestate. Harvested microalgal biomass was investigated as biofertilizer in its natural state and after anaerobic digestion and co-digestion with food waste, in terms of responses in soil and plant. The final goal is to recover resources from food waste and reduce the cost and environmental impacts associated with inorganic fertilizers.

MATERIAL AND METHODS

Food waste (FW) was prepared with rice (20%), beans (20%), meat (15%), lettuce (25%), carrot (10%), and tomato (10%), as determined from monitoring of real food waste composition fed to the demonstration-scale treatment unit at the university campus (UFMG, Brazil) (Figure 1). Microalgal biomass (MB) was collected from the high rate algal pond and was mainly composed of *Scenedesmus* sp. For assessing the microalgae use as biofertilizer after its anaerobic digestion and after co-digestion with food waste (75/25% of food waste and microalgae, in terms of VS), biochemical methane potential tests were carried out in bottles of 500 mL. For that, assays were performed using an inoculum to substrate ratio (ISR) of 2 g VS/g VS and incubated at 35 ºC.

Biofertilization was assessed in soil and plant samples. Productivity of hybrid brachiaria *Sabiá* (forager plant) was conducted in a greenhouse using five treatments: 1) harvested microalgal biomass (MB), 2) microalgal biomass after anaerobic digestion (DM), 3) microalgal biomass and food waste co-digested (MB+FW-dig), 4) urea as inorganic fertilizer (FI) and, 5) soil without fertilization (control). The experiment was set out in a completely randomized block with three replicates per treatment in 4 L capacity pots. For each pot, ten seeds of hybrid brachiaria *Sabiá* were planted at 3 cm profundity. All treatments were dosed at 50 mg N/dm^3 and 100 mg N/dm^3 in the first and second harvested cycle, respectively. For each pot, the source of N was applied into 4 equal parts throughout the 60 and 45 days in cycles 1 and 2, respectively. Fertilizer application was carried out in the soil manually with a graduated cylinder and the pots were irrigated daily.

Chemical properties of the soil were analysed in terms of pH, organic matter and nitrogen (N) as described in EMBRAPA et al. (2009). Phosphorus (P), Potassium (K), Calcium (Ca) and Magnesium (Mg), were determined in a Mehlich extractor and measured in atomic absorption spectrophotometry (Varian Mod. Spect. A 20). Plant parameters monitored were tiller number, fresh and dry matter, Chlorophyll Content Index (Chlorophyll SPAD-502 Meter, MCL502DL Minolta) and macronutrients (i.e. N, P, K, Mg, Ca), which were analysed through nitric-perchloric digestion and measured in optical emission spectrophotometry with inductively coupled plasma (ICP-OES; Perkin Elmer Model Optima 8300 DV).

Experimental data was analysed using with the one-way analysis of variance (ANOVA) test processed by R software, version 4.2.0. Tukey's post hoc test was used to compared different treatments (α = 0.05). Variance normality was tested by Shapiro Willk test and homogeneity by Fligner test. Variance no normality was tested by Kruskal-Wallis test and Dunn's test.

RESULTS AND DISCUSSION

Biofertilization response in plants

Biofertilization was assessed in two cycles with different N dosage (i.e. 50 and 100 mg N/dm^3). Results for plant parameters are summarised in Table 1. As can be seen, when compared to control, all parameters showed an increase in plant productivity after applying inorganic fertilizer or biofertilizer treatments. Especially in C2, when higher N dosage was applied, fertilization and biofertilization increased by 50-60% fresh and dry matter compared to control. Additionally, the leaf chlorophyll content index increased from 13.8 to 25-31, with the highest index found for urea and digested microalgal biomass application.

Although inorganic fertilizer showed the best results for evaluated indicators, results were quite similar to those using biofertilizer based on microalgae, with statistically equal values for almost all parameters. Moreover, plants grown with microalgal biomass after anaerobic digestion exhibited superior performance compared to fresh microalgae. This suggests that probably solubilisation of organic particulates during the biodegradation process led to an enhancement in the availability of compounds for plant uptake.

Macronutrients (N, P, K, Ca and Mg) were measured in the leaf tissue and results are shown in Figure 2. The results revealed that, although control plants had lower growth, those samples showed high content of nutrients, particularly K and Ca. This was probably due to initial conditions of soil. Anyhow, microalgae-based fertilizers revealed high contents of nutrients, with increased values compared to urea for P and K and equal values for Ca and Mg. This result demonstrates how microalgae have a richer diversity and balance in nutrients compared to commercialised fertilizer, as observed in previous studies (Garcia-Gonzalez and Sommerfeld, 2015). Remarkably for P, which is considered a critical nutrient, with lack of natural reserves, values demonstrated that plant was able to uptake the additional P provided by the microalgae-based biofertilizers (Fig. 2B). This result agrees with previously reported studies that found lower N content and higher P content in plants fertilized with microalgae compared to chemical fertilizer (Alvarez-Gonzalez et al., 2022; Lorentz et al 2020).

Biofertilization response in soil

Results for soil parameters are shown in Table 2. Cycles 1 and 2 were in sequence for assessing the recycling and wear of fertilization, as commonly applied in fields. After 60 days of cultivation, the analyses revealed that there were no significant differences among treatments regarding pH, organic matter, N, P and K. In fact, the organic matter content of the soil was found to be significantly higher after 105 days of cultivation when fresh and digested microalgae were applied compared to the control and urea fertilization (8-12% increase). The N and P soil concentrations were also increased after biofertilization, with 8-10% increase for digested microalgae and 10-16% increased for co-digested microalgae and food waste. The results showed that the longer application time of the first to second cycles of biofertilization may have allowed the mineralisation of organic matter from organic compounds in the soil.

CONCLUSIONS

This study assessed the used of microalgae-based fertilizers coming from high-strength wastewater treatment ponds. The results obtained indicated that microalgae-based biofertilizers results in soil and plant were similar compared to the use of inorganic fertilizers, having equal responses in relation to plant growth indicators, foliar macronutrients and soil organic matter and nutrients contents. Besides, this strategy contributes to the circular reuse of resources in organic waste for a sustainable agricultural approach.

Abstract

Researchers studying water resource recovery facilities (WRRFs) are putting much effort into improving the control and automation of WRRFs to obtain more robust, efficient, and economic facilities and move towards more sustainable operations. The advances in instrumentation and computer systems provide the opportunity to upgrade WRRF control systems. However, considering the complex, nonlinear, and time-varying nature of wastewater treatment processes, many challenges are still to be addressed. The main objective of this research is to exploit the recent advances in fault identification while utilizing the knowledge of the process in the form of case-based reasoning to improve fault identification and to integrate this information with fault-tolerant control to increase nutrient removal performance of WRRFs and, with it, a decrease in energy and chemical consumption and, thus, the operational cost.

Keywords

Case-based reasoning; fault detection; fault isolation; fault-tolerant control; WRRF

FAULT-TOLERANT CONTROL

Nowadays, efficient automation and control of wastewater treatment facilities are crucial for achieving a reliable and effective facility, increasing the capacity of nutrient removal and/or recovery while reducing energy consumption and greenhouse gas emissions. The changing characteristics of wastewater and the complex nature and dynamical behaviour of Water Resource Recovery Facilities (WRRFs), as well as the relatively low reliability of sensors and actuators, often affect the ideal control and automation of the facility. Considering the harsh environment of wastewater, faulty data due to sensor malfunction is unavoidable and is more challenging to deal with compared to other processes (Alferes et al., 2013). Hence, advanced control and automation of WRRFs still represent a challenging field for research and development.

Faults occurring in sensors, actuators, processes, and the controller can develop into a system failure and plant shutdown. A closed-loop control system can amplify the effect of faults or hide them to the point where complete system failure occurs. Preventing major failures due to simple faults and preserving the system's availability in the event of faults became essential concerns in control engineering (Blanke et al., 2000). A fault-tolerant controller can respond to the presence of the fault by adapting its actions to the plant's malfunctioning behaviour. If these modifications are effective, the system function is maintained even after a fault appears, sometimes after a small performance decay while the control algorithm adapts to the malfunctioning plant. Fault-Tolerant Control (FTC) aims to minimize the catastrophic impacts of failures to preserve acceptable process operation even in the face of severe faults by accommodating the set point or reconfiguring the control system (Blanke et al., 2016).

Two subsystems create a fault-tolerant system: the first system performs fault identification which includes fault detection and fault isolation, i.e. identifying the location of the fault (FDI). The second system redesigns the controller, i.e. adapts the controller to deal with the faulty situation and to keep the entire system accomplishing its objective. After fault identification, signals containing information on the situation will be sent to the supervisory level (fault-tolerant control) to take necessary actions to attenuate the effects of the fault (Figure 1) (Amin & Hassan, 2019; Blanke et al., 2016). Based on the fault type, control reconfiguration will be achieved by accommodating the controller setpoint (Zumoffen and Basualdo, 2008), altering the reference model for monitoring and control, adding soft sensors (Belchior et al., 2018), activating alternate controllers, etc.

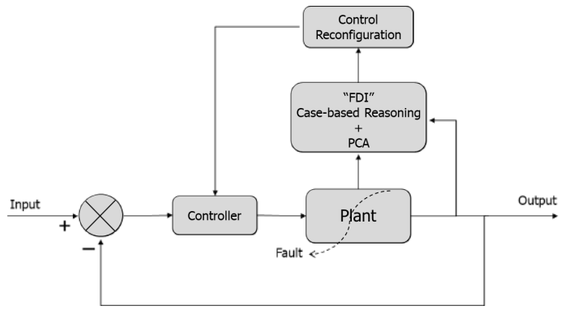

Figure 1. Schematic of fault-tolerant control

FAULT IDENTIFICATION and CASE-BASED REASONING

Fault detection and isolation (identification) are essential for the proper functioning of fault-tolerant control. Statistical and data-driven algorithms (e.g., Principal Component Analysis (PCA) and contribution plots) have already been demonstrated to be effective approaches for real-time monitoring, fault detection, and isolation in wastewater treatment (Nor et al., 2020; Lee et al., 2004). However, considering the time-varying and highly nonlinear characteristics of WRRFs, combined with the fact that some of the operational information in the processes is neither numeric nor quantifiable, such as smells, colors, foam patterns, and the appearance of bulking or floc microscopic characterization, led researchers to exploit the advantages of Knowledge-Based Systems (KBSs). KBSs use a combination of reasoning techniques, collections of facts, heuristics, common sense knowledge, and other types of knowledge to reach inferences. KBSs make an effort to emulate a human expert's thinking pattern in order to deal with the complexity of wastewater treatment systems (Rodriguez-Roda et al., 2001; Sànchez et al., 1997).

Case-Based Reasoning (CBR) is an artificial intelligence knowledge management approach that uses previous experiences to address new problems that emerge in a process. After a fault is identified, CBR retrieves the most comparable experience from an established case library to assist the fault isolation and even diagnosis, i.e. the explanation of the fault (Comas et al., 2006).

This study aims to take advantage of CBR to improve fault detection and isolation and to integrate it into a fault-tolerant control system to maximize the performance of WRRF. The proposed strategy employs PCA to reduce data dimensionality and monitor the process with Hotelling T^2 and Square Prediction Error (SPE) multivariate statistics that allow detecting faults. These monitoring statistics are subsequently used as case descriptors to build the case-based library (Ruiz et al., 2011) during the training of the FTC-system. When the trained FTC is applied, the most similar past experiences are retrieved by evaluating the similarity between a new case and the cases in the library.

APPLICATION OF FTC: an example

A good example that illustrates the role of fault-tolerant control in WRRFs is the practice of the AvN controller at the pilot plant located at Université Laval. The objective of AvN controllers is to maintain an equal concentration of NH_4-N and NO_3-N (NO_x-N preferably) in the effluent by manipulating the extent of aeration in the aerobic reactors. By maintaining this ratio, the effluent is optimized for a downstream deammonification process (anammox treatment). As such, the overall energy budget for aeration required to remove COD and N can be reduced. AvN is a cascade control where the AvN controller uses measurements of both NH_4-N and NO_3-N and cascades the DO controller to manipulate the DO concentration in the aerated tank (Kirim 2022).

The influent load to the WRRF follows a diurnal pattern (Figure 2). The intermittent AvN controller, which is a PID controller, controls NH_4-N and NO_3-N ratio by manipulating the Aeration Fraction (AF) width during the day (i.e., considering a fixed cycle time, the relative duration of the aerobic and anoxic periods is changed). Figure 3 illustrates the aeration pattern obtained. When the AvN controller faces a fault (e.g., the ammonia sensor failure), FTC acts as a system supervisor and replaces the real-time observations to calculate the fractions by historical patterns of aeration fractions such as the one of Figure 3 to fulfil the control goal as close as possible.

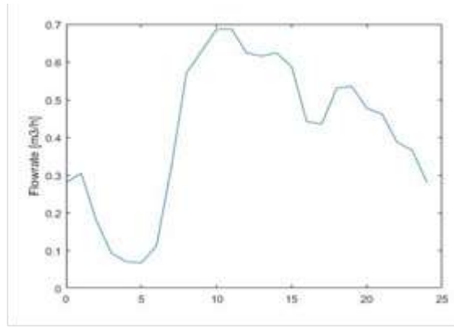

Figure 2. Diurnal pattern of wastewater flow rate

Figure 3. Diurnal aeration pattern

CONCLUSION

The efficient operation of WRRFs heavily relies on the quality of the control system; however, in the event of faults, the common control configurations might not be adequate to deliver the objective of the system. Exploiting the fault-tolerant control technique is a potential solution. Using FTC in the wastewater treatment sector, especially its practical implementation, rarely can be observed in the literature and must thus be considered a line for future research.

Efficient FTC requires powerful fault identification. Although data-driven fault detection and isolation methods have shown promising results, the accumulated knowledge and experience of previous situations (cases) that occurred in the plants can support to achieve more accurate fault identification.

Abstract

Urban wastewater management and the associated modelling has become indispensable today. Reliable calibration is essential for these models, and water level data is used as a standard. However, data collection can be limited due to high sensor costs and harsh conditions in the sewer. A novel solution is collecting data using low-cost temperature sensors, placing one in the stream, the other at the crest of the weir. In the case of dry weather, the sensor measures the air phase, whereas, in the case of Combined Sewer Overflow (CSO), the discharged storm and wastewater is measured. Autocalibration was performed using OSTRICH for a SWMM model in Berlin, with water level and fictional temperature data, and various number of measuring sites. Results showed that calibration using temperature data was as good as using water level data, with promising outcomes achieved by using one measuring site, offering a cost-effective alternative for water utilities.

Keywords

Calibration, OSTRICH, SWMM, Temperature data, Water level data

BACKGROUND

The management of urban wastewater systems and the associated modelling of these systems has become indispensable in today's world. In order for these models to represent reality as accurately as possible, a reliable calibration is essential. Water level data is used as a standard, but due to expensive sensors and harsh conditions, data can only be collected at a few key points of the system (DWC, 2022). One method that has experienced an upswing in recent years is data collection using low-cost temperature sensors (Montserrat, 2013, 2015). These sensors are inexpensive and easy to implement at Combined Sewer Overflow (CSO) weirs. Two sensors are needed, one is placed in the stream of the conduit, the other is placed at the crest of the weir. In the case of dry weather, the sensor measures the air phase whereas, in the case of CSO, the discharged storm and wastewater is measured. The start and end of a CSO event can be determined via the merging of measured temperature values in both points of the overflow structure (see Fig. 1a). Due to this method, the duration of CSO events can be detected (DWC, 2022). In this work, the potential benefits of this novel method and the number of measuring sites needed are assessed. This could be of interest for water utilities and practitioners to improve and lower the costs of their calibration of sewer models in the future.

MATERIAL & METHODS

Approach

In order to assess the potential of temperature data for the calibration of sewer models, fictional temperature data had to be created first. This is due to data inaccuracies which were caused in the measuring campaign of the original sensors. Next, the calibration approaches with different data types and different number of measuring sites where carried out by the autocalibration software OSTRICH. Here, an additional 'R-Script' was needed to transfer and evaluate the data generated by SWMM. After the calibration runs, a validation run was needed to ensure comparability for the different approaches. The final assessment was based on the R^2 values of the validation runs.

Study area

The model used is a coarse model of the catchment of *Wilmersdorf*, which is a district in the west of Berlin. It has a size of approximately 1900 ha and around 210.000 inhabitants, which results in a population of 110 person/ha. The catchment area gets represented by 257 subcatchments, which range in size from 0.04 ha up to 177 ha. The model is a combined sewer network, wastewater and rainwater are discharged into a single sewer and pumped to a wastewater treatment plant by pumping stations located in the catchment. In the case of rain events, these pumping stations get overloaded and the system has to discharge into nearby water bodies. In the catchment, three Combined Sewer Outflows are located, which all lead into the nearby *Landwehr Canal* (see Fig. 1c).

Data & Calibration parameters

Two different data types were used for calibration; i.) *water level data*, measured by the Berliner Wasserbetriebe (BWB) at three sites of the modelled catchment area (see Fig. 1c) and ii.) fictional *temperature data*, generated of the water level data of these three sites. Therefore, a threshold was set and the overflow duration, caused by a rain event, was measured when the threshold got exceeded. For calibration, 19 events which occurred from April - May 2021 were used and for validation purposes, 18 events of the period June - August 2021. The calibration parameters used were the roughness of the conduits (*Manning's N*), the roughness of the impervious area of the subcatchments (*Manning's N*) and the slope of the subcatchments (%), chosen based on a sensitivity study carried out and a literature review.

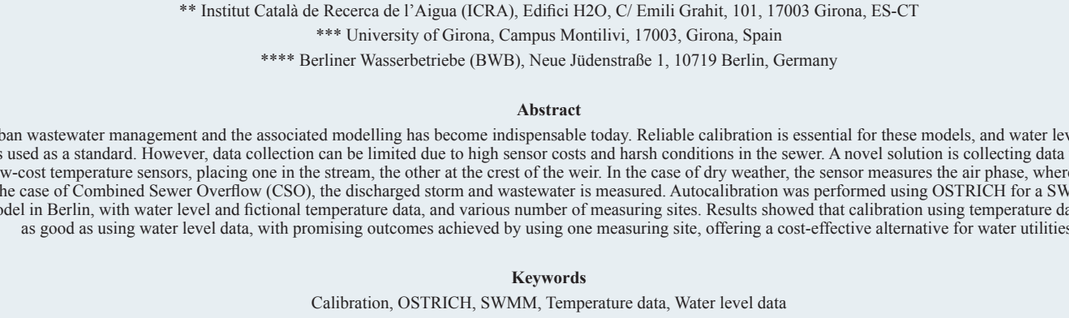

Figure 1. a) Temperature overflow detection concept, b) Calibration set-up and c) Catchment area

Setup

To compare the autocalibration approaches, a triangle relationship of the main components, consisting of OSTRICH, SWMM and an 'R'-Script, was needed (Fig. 1b). OSTRICH is a model-independent multi-algorithm calibration tool (Mattot, 2017). SWMM is a dynamic rainfall-runoff simulation model for single event or long-term simulation (Rossman, 2015). The 'R'-Script was used to convert the results of SWMM from binary to text format first, using the *swmmr*-package (Leutnant, 2019). Next, the Objective Function (OF) was calculated. For this purpose, each event was weighted over the event duration and a total R^2 was calculated. This resulted in the following OF which was to be minimised by OSTRICH:

Thus, a total of four different calibration approaches were carried out: 1.1) water level data, 1 measurement site; 1.2) water level data, 3 measurement sites; 2.1.) temperature data, 1 measurement site; 2.2.) temperature data, 3 measurement sites. Depending on the measuring sites, the OF consisted of 1 or 3 sites. *OSTRICH* completed 100 calibration runs and used the Dynamically Dimensioned Search (DDS) algorithm. After completion, a validation run was carried out for each of the calibration runs. Therefore, the detected calibration parameters were used and evaluated on the basis of the R^2 values of the three measuring sites of the model.

RESULTS & DISCUSSION

Calibration results

OSTRICH is able to perform an autocalibration by using temperature data. An example is shown in Fig. 2: on the left side, the calibration with water level data, and on the right site, with temperature data. It can be seen that the threshold of 31.5 mNN gets exceeded multiple times and therefore, the event has a specific pattern, which OSTRICH tries to fit by adjusting the calibration parameters.

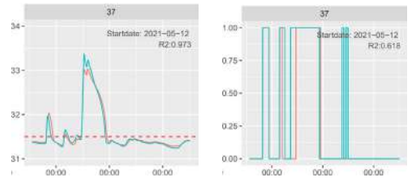

Figure 2. Calibration example for water level & temperature data (red = obs, blue = sim)

Fig. 3 shows the convergence of the calibration approaches 1.1 and 2.1. A convergence was given in all four calibration approaches. This ensures that an improvement or an adjustment of the calibration parameters has taken place and that OSTRICH functions.

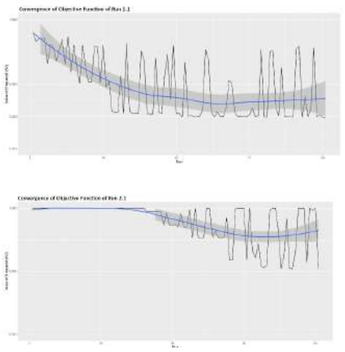

Figure 3. Convergence of Calibration Run 1.1 (left) & 2.1 (right), shown by the value of the OF

Validation results

The validation results for the period June - August 2021 can be seen in Tab.1. The runs 1.1 (water level data, 1 site) and 2.2 (temperature data, 3 sites) show the best results, having an OF value of 1.397. It can be seen that the R^2 of the individual measurement sites are all within the same range. The combined sewer conduit has the highest R^2 (all $R^2 > 0.65$), followed by R^2 of the Inlet Chamber RÜB (all $R^2 > 0.5$). Only the R^2 of the Inlet Chamber Pumphouse is slightly lower with $R^2 < 0.44$. It can be stated, that calibration with temperature data produces as good results as with water level data.

Table 1. Results of the validation runs & final calibration parameters

General Information	Calibration approach	**1.1**	**1.2**	**2.1**	**2.2**
	Data type	Water level	Water level	Temp data	Temp data
	Measurement sites	1	3	1	3
R^2-values of Validation Runs	Value validation function	1.397	1.409	1.411	1.397
	R^2-validation of Inlet Chamber Pumphouse	0.427	0.421	0.416	0.430
	R^2-validation of Inlet Chamber RÜB	0.515	0.517	0.513	0.514
	R^2-validation of Combined Sewer Conduit	0.661	0.653	0.660	0.659
Value calibration parameters	Manning N Conduit [0.005 – 0.4]	0.0076	0.0149	0.0112	0.0063
	Manning N Imperv. Area [0.006 – 0.4]	0.021	0.007	0.017	0.029
	Slope Subcatchments [0.01 - 10]	6.263	9.754	9.968	8.524

These observations are confirmed by similar insights in Montserrat, 2016. Looking at the number of measurement sites needed for a reliable calibration, no conclusion can be made. The water level data performs better with one measurement site, the temperature data with three measurement sites. One reason for these different results could be the lack of spatial distribution of measuring sites in the model. However, looking at the individual calibration parameters, it is noticeable that they are partly unrealistic, i.e. all *Slope* value are > 6%, which is improper for a model located in Berlin. This is caused by the wide boundaries for the calibration parameters given via OSTRICH and has to be adjusted in future calibration runs.

CONCLUSION

It can be stated that similar results can be achieved by autocalibration using temperature instead of flow measurements. This becomes apparent when looking at the value of the validation OF, but also when comparing the individual measuring sites with each other.
It cannot be conclusively clarified whether better calibration results are achieved if several measuring sites are included in the OF instead of just one. One reason for this could be the lack of spatial distribution of the measuring sites in the here used catchment area, as can be seen in Figure 1c.
Above all, the boundaries of the calibration parameters must be realistically defined, otherwise OSTRICH uses unrealistic parameter values to minimise the OF.
It can be stated that using low-cost monitoring methods, such as temperature sensors, could be a cost-effective solution for calibration purposes for water utilities and practitioners.

Currently, the calibration method is applied to real temperature data from a new measuring campaign, which shows appealing results. The fully updated results will be presented at the conference.

ACKNOWLEDGEMENT

The research has been conducted in the frame of the digital-water.city project, which has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 820954.

Abstract

Industrial Symbiosis (IS) is a particular form of Circular Economy applicable to industrial contexts. The H2020 project ULTIMATE is studying IS in different case studies. The Aretusa Italian case study is a successful example of symbiosis which allow 3.8 Mio. m3/y of treated municipal wastewater to be reused by Solvay industry. To increase the quality of the water to be reused, a pilot plant adsorption system has been developed to treat the final wastewater. Real-time monitoring of the pilot has been done through the installation of UV absorbance sensor reading at 254 nm and a fluorescence sensor. UV and fluorescence signals are being tested to monitor the breakthrough curve of organic material (in terms of dissolved organic carbon), but also the adsorption process of organic micropollutants (e.g., pharmaceuticals and personal care products).

Keywords

Fluorescence; Industrial Symbiosis; UV absorbance; Real-time monitoring; Water Reuse

INTRODUCTION

The worldwide concern about the availability of water for a growing world population has led to an awareness of the use of this resource, therefore, water scarcity is a problem affecting both domestic and industrial users which can potentially delay the continuous development of society (Thomé et al., 2019). It is therefore necessary to make the transition from the linear to the Circular Economic (CE) model. CE model is based on increasing resource efficiency, minimizing waste production to separate economic growth from resource use (Arias et al., 2021). Industrial Symbiosis (IS), as a particular form of Circular Economy applicable to industrial contexts, promises a new potential by systematically looking to reuse wastes between industries as raw materials (Daddi et al., 2017). ULTIMATE (indUstry water-utiLiTy symbIosis for a sMarter wATer society) is an Horizon 2020 project introducing a specific type of IS named "Water Smart Industrial Symbiosis" where both water and wastewater play a key role as a reusable sources (https://ultimatewater.eu/water-smart-industrial-symbiosis/). .

The ULTIMATE project in Italy

In Italy the ULTIMATE project is applied in Aretusa Case Study. Aretusa Consortium, established in Tuscany in 2001, is a successful example of industrial symbiosis between a water utility (ASA Livorno), a technology provider (Termomeccanica Ecologia), and an industry (Solvay Chimica Italia). The objective of the Consortium is to treat the effluent coming from the two municipal wastewater treatment plants of Cecina and Rosignano to reach the quality requirements necessary for cooling the towers of Solvay Rosignano Plant or for other forms of reuse. Up to 3.8 Mio. m3/y of treated municipal wastewater is already reused by the industrial partner Solvay, freeing up private industrial wells for drinking water use. Despite this, final quality often overcomes the required limits, mainly in terms of hardness, salinity, and COD concentration. In this context ULTIMATE has the objective of increasing the quality of the final water, maximizing the reuse possibilities in the industrial context, but also for other application, including agricultural irrigation.

MATERIALS AND METHODS

A pilot plant adsorption system has been designed for reducing organic loads from Aretusa effluent wastewater, using innovative materials (e.g., Hydrochar) as well as commercial carbons as adsorbent materials. The main innovations connected with the installation of the adsorption pilot plant are related to the use of alternative adsorbent materials derived by thermal treatment of waste sewage sludge, and on the use of innovative spectroscopic sensors (based on fluorescence measurements) to monitor the organic content in wastewater.
The pilot system has four adsorption columns, two with a bigger size and two smaller, hydraulically connected to be operated in series or in parallel. Considering a design empty bed contact time (EBCT) of 10 min, the big columns can be operated with a flow rate of around 3.5 m3/h, whereas the small columns can treat around 0.5 m3/h of wastewater. The adsorption pilot system has been equipped with different on-line sensors for real-time measurements, which include UV absorbance sensor reading at 254 nm and a fluorescence sensor reading at the excitation/emission couple of 325/445 nm. The main sensors are placed in a monitoring tank. A picture showing all the components of the adsorption pilot plant is shown in Figure 1.

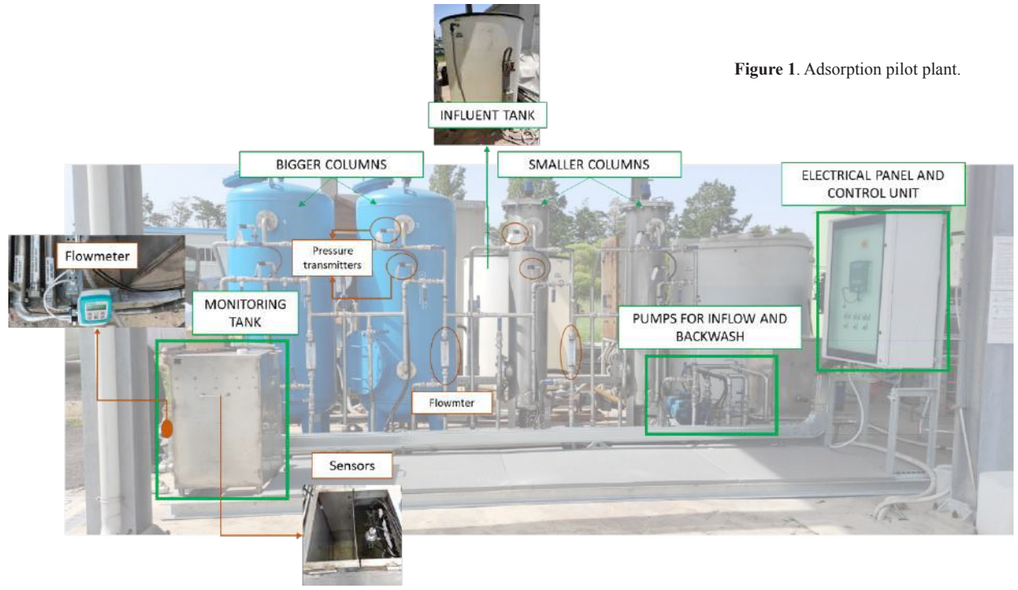

Figure 1. Adsorption pilot plant.

RESULTS AND DISCUSSIONS

Start-up of the pilot system was accomplished in July 2022 and it was focused on the calibration of the fluorescence sensor, which proved to be more sensitive than UV absorbance sensor in monitoring organic matter variation (Figure 2).

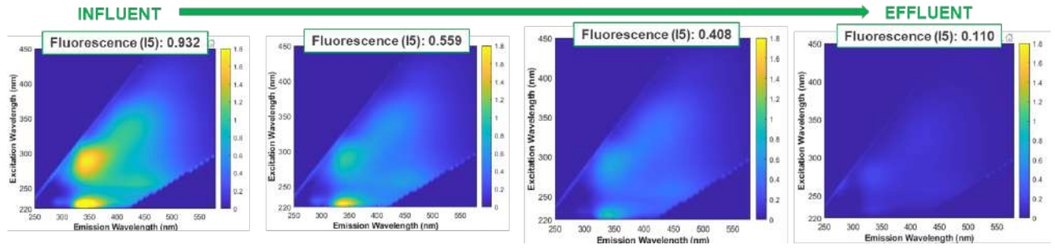

Figure 2. Fluorescence spectra of influent, effluent, and mixed (influent/effluent) samples collected in the monitoring tank of the adsorption pilot plant.

In September 2022 the pilot system was fully operational, and the real-time monitoring activities started. During the monitoring period, two samples per week have been taken to measure UV absorbance and Fluorescence by laboratory instruments for both influent and effluent of the pilot, and to perform comparison between on-line and off-line measurements. Particularly, UV and fluorescence signals are being tested to monitor the breakthrough curve of organic material (in terms of dissolved organic carbon), but also the adsorption process of organic micropollutants (e.g., pharmaceuticals and personal care products).
In Figure 3 is reported the trend observed in the effluent of the adsorption pilot plant for measurements provided by the fluorescence sensor and the UV254 sensor. The trend observed for the two measurements was different, and the fluorescence sensor showed higher performance to detect promptly changes in wastewater organic matter concentration. In addition, probe flurescence measurements showed a high agreement with laboratory measurements. On the contrary, comparison of on-line and off-line measurements of UV absorbance at 254 nm showed often some misalignment.

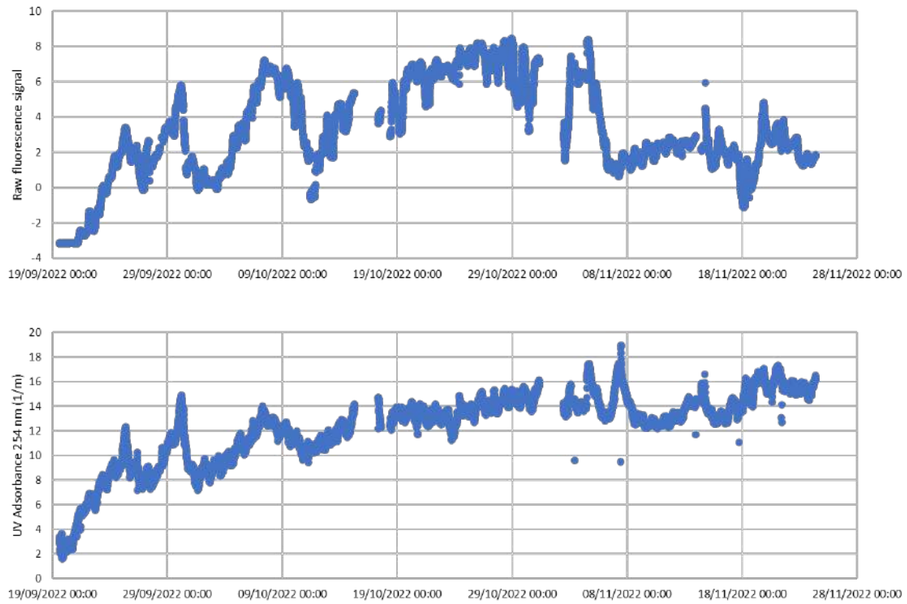

Figure 3. Fluorescence and UV trend.

Furthermore, preliminary data show important correlations between emerging contaminants concentrations in wastewater and fluorescence measurements performed by the on-line probe suggesting important potentialities for the real-time monitoring of the micropollutants.

Abstract

Water reuse projects have become essential primarily due to the increasing issue of water scarcity. However, manual or semi-automatic project design approaches are still common. This work makes progress on water reuse network design and planning through a demonstration of the usefulness of the REWATnet decision support tool which, based on open data sources and graph theory coupled with greedy optimization algorithms, is able to automatically compute the optimal reclaimed water network design for a given scenario, including the length and diameter of the pipes, the location of storage tanks, and construction costs. Furthermore, it maximizes the water served on limited budget availability scenarios. The usefulness of the REWATnet tool is illustrated in El Prat de Llobregat, planning the design of a city-wide reclaimed water network. The results demonstrate the fully automatic design of the water reuse network and the optimal limited-budget alternatives, improving current practice significantly.

Keywords (maximum 6 in alphabetical order)

Circular economy; clustering; graph theory; planning; reclaimed water; wastewater treatment

INTRODUCTION

Water scarcity and droughts are an increasing problem in many areas, therefore water reuse is becoming an indispensable alternative measure to complement conventional water resources, especially in the most significant water-consuming sectors on local, regional, and global scales (Masi et al., 2020).

Efficient and sustainable water reuse requires feasible water reuse projects (i.e., water reclamation treatment plants and reclaimed water distribution networks for potential uses). Planning and assessing water reuse projects require decision-makers to answer a number of questions concerning issues such as: (i) the best tertiary/advanced treatment to be implemented, (ii) how much wastewater needs to be reclaimed, and (iii) how to select the optimal water distribution network.

Previous research has been mainly focused on wastewater treatment, i.e., on the selection of the most adequate advanced treatment technologies for water reclamation (Chhipi-Shrestha et al., 2017) and on manual design solutions (Khurelbaatar et al., 2021), or sometimes requiring separating raw greywater from wastewater at the source, which is often not possible in many cities (Yerri and Piratla, 2019).

Water network modelling can be approached through graph theory but has not been used yet for the advanced and automated design optimization of water networks. Given this background, the aim of this paper is to illustrate the usefulness of a decision support tool for optimal planning of water reuse networks in cities. Our approach integrates several algorithms for designing water reuse networks based on graph theory coupled with existent greedy optimization algorithms (Calle et al., 2021; Kesavan and Chandrashekar, 1972; Kou et al., 1981). Our proposal (REWATnet tool), presented for the first time in Calle et al. (2023), uses advanced algorithms to design and optimize large-scale water reuse networks in one single tool, in contrast with the literature, thus avoiding the need for data exchange and thus resulting in potential savings in time and effort. This tool combines city characteristics (i.e., terrain characteristics, including plot and building usages, elevation, and slope) and water consumption rates to automatically propose an optimal network for water reuse. The usefulness of our solution is illustrated in this paper when testing it in El Prat de Llobregat (Catalonia, Spain). Construction costs and benefits in terms of water savings are estimated for each design scenario. Finally, the optimal water network can be provided when only a limited budget is available.

METHODS

Figure 1 describes the innovative REWATnet decision support tool for planning water reuse projects and highlights the steps involved and the outputs produced. First, the scenarios are defined based on the city identifier and cadastral files. With only these inputs information, the tool automatically extracts the initial graph from default values and open data sources, which includes the city street graph with neighbourhoods and node elevations, linked to terrain usages and inhabitants from the cadastral files, water consumptions, and the origin of water and potential destinations of reclaimed water, based on the selected water uses (Gascon et al., 2004).

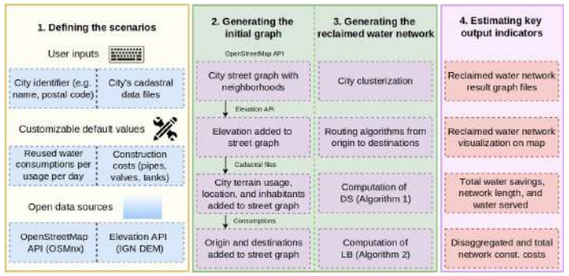

Figure 1. Simplified scheme of the REWATnet decision support tool (Calle et al., 2023).

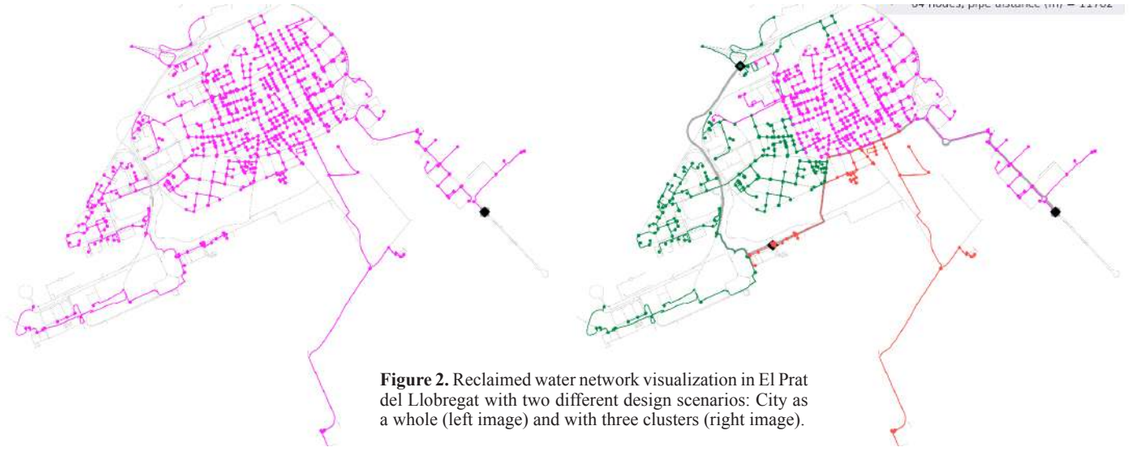

Figure 2. Reclaimed water network visualization in El Prat del Llobregat with two different design scenarios: City as a whole (left image) and with three clusters (right image).

RESULTS AND DISCUSSION

The tool is applied to generate and analyze a potential water reuse project for the city of El Prat de Llobregat, considering all the possible water uses and that the necessary tertiary/advanced treatment is already implemented.

Figure 2 shows the resulting reclaimed water network considering the city as a whole (left image) and with three clusters, each one with an intermediate storage tank (right image). The first scenario results in a 61 km network with a total construction cost of €5,508K. The second scenario results in a 73 km network, a total construction cost of €6,875K. The number of clusters is an input for the tool, allowing users to select the preferred quantity for each scenario based on city characteristics, available budget, or hydraulic constraints. The observed water consumption (i.e., water savings) is 3,418 m^3/d. Note that the whole infrastructure payback period considered is 30 years and the accumulative water savings are 37,427,100 m^3.

The usefulness of the REWATnet tool for network optimization when a limited budget (LB) is available is also illustrated and compared with a semi-manual current practice. The semi-manual approach is an algorithm that simulates the common current practice by adding the closest destination to the reclaimed water network for each potential destination until budget B is reached. As shown in Figure 3, the benefits of the optimal network LB approach are evident as the budget increases. Although this case study has a very similar consumption among all nodes and they are relatively close to each other (which makes the current practice a good approach), the LB algorithm implemented in the REWATnet tool also shows a significant increase in water served compared to the current practice (e.g., water served increased by 50% with a budget of 1M€).

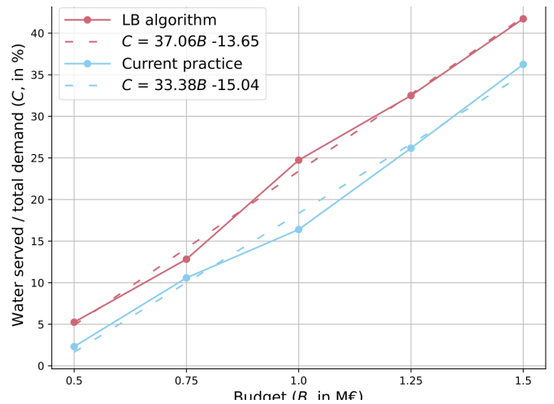

Figure 3. Results of water served with a limited budget: Current practice versus LB algorithm.

Future work

It is expected to improve the tool and its network designs not only by minimizing the cost but also maximizing water availability on destinations (i.e., resilience on failures). It is also expected to include advanced water treatment and network operational costs in the future based on the designs' hydrological validation through EPANET. Furthermore, the estimation of the generated network carbon footprint will be considered. Finally, the hydrological validation will also enable us to automatically detect the minimum number of clusters required for each scenario in order to save additional costs.

Abstract

Since water treatment and distribution is one of the most energy consumption processes all over the world, it is of great interest to develop a methodology to reduce energy costs. In the present work, a tool to reduce these costs was developed based on water quality, supply autonomy and energy costs. The used algorithm was used to modify water tank setpoints. With the proposed changes, significant economic savings were obtained.

Keywords: Costs optimization, water distribution network, energy tariff, water quality, supply autonomy.

INTRODUCTION

One of the most energy demanding in water sector worldwide is the water distribution and treatment. For instance, according to Griffiths-Sattenspiel (2009), the US uses roughly 4% of its total energy consumption in these processes, while Spain uses up to 7% (Hardy et al., 2010). Drinking water and wastewater utilities are primarily owned by local governments, and the energy used to purify the water can account for 30% to 40% of the municipality's energy costs (Copeland & Carter, 2014). In addition, some nations have adopted time-variable energy tariffs, which cause daily fluctuations in energy prices. This situation has increased the need to put initiatives in place to optimize energy expenditures (Chang et al., 2018). The goal of this study is to develop a data mining based solution to reduce the energy expenses associated with the water distribution systems.

METHODOLOGY

Storage tanks from ATL drinking water distribution network (Barcelona, Spain) were used as a case study to develop an energy-optimization methodology. In this study, the supplied water comes from three drinking water treatment plants (DWTP) and two seawater desalination plants. In order to distribute the water along the delivery points, pumps, tanks, and pipes are used. Supplying the water in this network has a variable energy price agreement which takes into account three energy prices throughout the day. Based on each one of these prices, three different time slots are defined. For each one of these time slots, a setpoint level is assigned to the water distribution tanks in order to control the water pumping. The process that makes it possible to cut energy costs is the optimization of the tank setpoints.

There are two restrictions on the tank setpoint configuration: on the one hand, the quality of the water being supplied (i.e., the formation of trihalomethanes (THM)) limits the maximum tank level. Higher tank levels increase hydraulic retention time (HRT), which increases the formation of disinfection by-products (i.e THMs).

On the other hand, tanks must always have a minimum volume to maintain a 24-hour supply of water in non-expected events (i.e. maintenance works).

The developed methodology aimed to increase water pumping in the cheap energy time slots and decrease it in the expensive energy time slots in order to lower energy costs. Also, a water distribution simulation algorithm was created to investigate and assess all potential setpoint levels in an effort to lower energy costs during the medium price energy hours.

To maximise pumping during the period of low energy prices, the maximum values for THMs formation based on tank level were calculated. This was accomplished using a THM predictive model (Godo-Pla et al., 2021). Low energy price timeslots received the highest setpoint level while also taking into account THM potential formation to prevent exceeding the THM concentration limit.

The minimum level that would permit supplying water for 24 hours was determined based on the tanks' capacity and water demand in order to reduce pumping during high-priced time periods.

The general scheme of the algorithm process can be summarized in Figure 1.

RESULTS

Different setpoint levels than those historically used have been suggested by the results obtained using the methodology described. The data obtained through the simulation algorithm was used to assess the economic effectiveness of water pumping. In relation to the electricity price at the time of its execution, the distribution of the pumped water over the hours with various energy prices has been examined.

The methodology that was suggested to optimize the energetic management allowed for either an increase in the proportion of pumped water during the hours with the cheapest energy (Figure 2, Tank 1) or a decrease in the proportion of pumped water during the hours with the highest energy costs (Figure 2, Tank 2). These adjustments were predicted to result in a 5% reduction in the cost of pumping energy overall. The results of the distribution of the consumed kWh in each energetic time slot are shown in Table 1.

DISCUSSION AND CONCLUSION

New tank management configurations could be generated by the tool that was developed. The setpoints produced by this algorithm have demonstrated cutting-edge methods that could lower energy costs related to the distribution of pumping along the various energy prices of the day. The effectiveness of the suggested management could be verified using the creation of a hydraulic simulation algorithm.

Abstract

Monitoring stations have been built at the neighbourhood level in Barcelona to cover a low, medium and high income neighbourhood. The stations incorporate online sensors to measure COD, pH, temperature, conductivity, and dissolved hydrogen sulfide. Herein we describe how the stations were designed, how they operate and what they can be used for. For example, using these stations dynamics of wastewater generation and pollutant dynamics have been uncovered and related to the usage habits of the inhabitants of these neighbourhoods. The richer neighbourhood generates more wastewater and shows distinct dynamics during the weekend that is attributed to people traveling outside of their residential neighbourhood, something that is not seen in the poor neighbourhood. Other such insights are presented from data collected through the stations.

Keywords (maximum 6 in alphabetical order)
Digitalization, wastewater, flow, intra-urban;

INTRODUCTION

This paper focuses on the real-time dynamics of sewage flow and its concentrations at the intra-urban scale i.e., neighbourhood-level. While there are many real-time applications at wastewater treatment plant (WWTP) level, only a few studies have looked at dynamics at the intra-urban level. Real-time monitoring sewer systems' water quality and flows is more difficult than monitoring of WWTPs because there is no infrastructure in place. Variations in small catchments (primarily residential with minor industrial contributions) have not previously been studied. Furthermore, a long-term assessment has not been carried out using a permanent monitoring station. The goal of this paper is to describe the design and deployment of three wastewater monitoring stations deployed at the neighbourhood level and to evaluate their performance in measuring wastewater flow and pollutant concentrations over a year (to study seasonality effect, mainly winter vs summer). In this paper we describe (1) the rationale for the site selections, (2) the components used and the configuration, (3) results dealing with diurnal flow, COD, TSS, conductivity, HS- concentrations, and (4) some insights into their operation over a year.

MATERIALS AND METHODS

Site selection. The three sites were chosen from the Barcelona sewer system, corresponding to residential areas with little contribution from industrial and commercial activities. Station 1 (S1) covers a catchment area of 0.72 km^2 serving 18,042 inhabitants with a household year income of €25,849; S2 has a catchment of 0.23 km^2 serving 8,914 inhabitants with a household year income of €38,430; S3 is a catchment of 0.18 km^2 serving 5,090 inhabitants with a household year income of €78,476.

Monitoring stations. The setup is shown in Figure 1. All equipment was housed in a stainless cabin measuring 2x1.4x2m and installed at street level near a sewer manhole. A large diameter plastic tube connected a peristaltic pump (Boyser AMP-22) in the cabin to the underground sewer system. The peristaltic pump fed a steady stream of WW to a 12 L acrylic glass reservoir, which is constantly emptied via a drain at the top. WW quality sensors from scan Messtechnik GmbH were installed within this reservoir (condu::lyser, spectro::lyser and pH::lyser –pH). A PLC unit (s::can con::cube) controlled these sensors as well as the actuators for emptying-filling cleaning cycles, allowed remote connection, uploaded data to the platform (via sFTP), and managed other equipment. The spectro::lyser sensor was cleaned automatically using compressed air and mechanical cleaning (s::can ruck::sack – a submersible automatic brush cleaner). In addition, flowmeters were installed directly in the sewer (S1-3 Nivus PCM 4 Nivus GmbH; Eppingen, Germany), S2 - FLO-DAR AV (Hach; Colorado, USA. Radar based sensor – contactless), S3 - NFM-550 (Nivus GmbH) coupled with a Nivus OFR level sensor.. All sensors were calibrated with in-situ measurements.

RESULTS AND DISCUSSION

Flow dynamics. The morning peak of wastewater discharge (WWD) occurs earlier on weekdays than on weekends (Figure 2 Column 1), which is due to people waking up earlier to get ready for work. S1 inhabitants may wake up earlier than in the other neighbourhoods as the morning peak on weekdays is earlier in S1 as compared to S2 and S3; note that the hydraulic residence times between point of WW generation and sampling points are similar across neighbourhoods (around 2 hours on average). Weekend afternoon WWD is higher in low- (S1) and medium- (S2) socioeconomic status neighbourhoods than weekday afternoons at the same time. This could be due to behavioural differences associated with inter-neighbourhood mobility. In S1, residents may find the cost of travelling out of the neighbourhood prohibitive, and staying at home would result in more WW discharged. In S2, the cost of travel is unlikely to be an issue; rather, the observed effect is the result of people visiting the neighbourhood from outside. S2 is a beachfront neighbourhood that probably receives more visitors than S1 and S3, which are highly residential. Figure 2 Column 2 compares summer and winter flow differences between the three neighbourhoods. Summer WWD levels are highest in S2. This is most likely due to S2 being in a popular tourist area, which sees more people during these months. Summer peaks in S1 and S3 are less intense, with moderate WWD observed in the afternoons (in terms of relative level to the morning peak of the same period). This lower summer activity in S3 could be attributed to residents in this high SES having summer homes outside of the Barcelona area; however, it is unclear what causes the lower WWD in S1. Differences in the behaviour of the citizens during different holidays can also be observed in the 3 neighbourhoods with different SES (Figure 2 Column 3).

Conductivity, COD and H_2S. The conductivity patterns (Figure 3) differ greatly between stations. S1 and S3 have the smallest intra-diurnal variation, with minimum-maximum ranges of approximately 500 µS/cm. S2 has much greater intra-diurnal variation, with peaks during the night. S2 is located in a catchment prone to seawater infiltration since it is close to the sea and at more or less sea level. The low flow of WW discharged at night (Figure 2 Column 1) means that seawater infiltration is not flushed away, and as a proportion, seawater infiltration becomes more dominant than during the day, which is then flushed away when WWD is higher, despite the fact that the lowest values at S2 are still higher than either S1 and S3. This is consistent with COD values (Figure 3 Column 2); seawater infiltration would increase conductivity but not COD because seawater contains negligible levels organic oxidisable components. Increased discharged blackwater would raise conductivity and COD. It is unclear why S1 and S3 exhibit opposite trends during the night, i.e. increasing conductivity in S1 and decreasing in S3. An increase in conductivity is expected because the blackwater-to-greywater ratio is higher at night, which would increase conductivity. The decrease in conductivity at night in S3 could be attributed to automatic watering of gardens at night in this high-income neighbourhood, which could partially drain excesses to sewers. WWD levels (Figure 2) at night in S3 are actually higher in summer (when irrigation is required) than in winter.

DISCUSSION

We demonstrate the utility of wastewater monitoring stations and the information that can be extracted from wastewater using online sensors. We see differences in flow patterns that are related to socioeconomic status, as well as differences in conductivity and H_2S that are related to catchment characteristics. According to Enfinger and Stevens (2006), S1 and S2 follow the typical flow pattern of residential areas. The S3 profile falls somewhere between a residential and a Hotel profile for two reasons: (1) the evening peak is much less pronounced than in S1 and S2, and (2) the weekend curve in S3 is never crosses the weekday curve. In terms of concentrations, we find a strong relationship between flows and COD, but no relationship between these variables and pH, H_2S or conductivity. Conductivity dynamics are highly dependent on catchment characteristics; S2 (located 350 m from the sea) received phreatic drains, which significantly influenced conductivity patterns; Atinkpahoun et al. (2018) observed no well-defined variation patterns for pH and conductivity; in our study, we did observe conductivity patterns, but they were not correlated to flows or COD patterns. Finally, H_2S is linked to in sewer-biological processes that are affected by temperature and residence time of wastewater in the sewer system (Zuo et al., 2019). Flow patterns and pollutants dynamics differ between the summer and the winter seasons. Whereas discharged wastewater volumes were lower in the summertime at S1 and S3, they were higher at S2; conductivity was lower at all three stations during the summer, and H_2S increased at S2. In contrast, we found no differences in COD concentrations between summer and winter. The main novelty of this study is the nature of the catchments under study (primarily residential areas with limited industrial activities), the differences in the socioeconomic status of the residents in these catchments, and the long-term (1 year) and high frequency (3 minutes) collection of monitored variables.

Abstract

This paper presents deep neural network based Reinforcement Learning (RL) to optimize the aerobic processes of the activated sludge process within an urban wastewater treatment plant (WWTP). The current challenge in WWTP is to obtain accurate models, which is difficult due to the complexity of their biological processes and the uncertainty caused by unforeseen situations. Many advanced control methods are based on plant models, failing in the mentioned situations. Therefore, RL is proposed in this work, which optimizes the process without knowledge of the models and is only driven by the process data. Consequently, the results demonstrate the advantage of RL in achieving the control objectives and adaptability according to the control requirements. Particularly, the trained RL agents aim to set the oxygen setpoint in the aerobic process to optimize the trade-off between environmental impact and operating cost.

Keywords

INTRODUCTION

WWTP modelling has been a very active area and activated sludge models (ASM1, ASM2) are readily available nowadays (Iratni et al., 2019, Revollar et al., 2017). However, they might fail in some real plant situations such as unexpected microorganisms' behaviour due to the intrinsic biologic uncertainty caused by extreme temperatures, peak influent loads, and bulking effects, among others. A possible approach to tackle this issue is the use of artificial neural networks as a methodology to obtain models of complex processes requiring only data, capturing in this way the full plant behaviour.

Deep reinforcement learning (DRL) (Sutton et al., 2018) is a model-free machine learning methodology that employs deep neural networks (DNN) trained by "Trial-Error," like biological brain training. Indeed, DRL algorithms use DNN as an approximation function of the strategy behind its actions, the policy. The Policy Gradient (PG) (Williams 1992) algorithm directly parameterizes policy in large uncertain states and action spaces, performing the gradient ascendent method searching for DNN optimal parameters. These deep neural networks act as intelligent agents (RL Agents), providing the optimal actions to be applied. For example, RL has been applied to provide the oxygen set point during the aerobic process in WWTPs (Hernández-del-Olmo et al., 2018), and in (Chen et al., 2021) optimization from an LCA perspective using RL has also been applied.

This work has developed this strategy with different RL agents trained by PG algorithm to control dissolved oxygen and nitrogen levels in an aerobic process of an activated sludge WWTP, considering environmental impact and operating costs.

MATERIALS AND METHOD

Our controller is trained, implemented, and evaluated in Benchmark Simulation Model n.1 (BSM1) (Alex et al., 2008). BSM1 is a simulation environment that includes a simulation model based on the activated sludge process, a plant design, performance criteria, and procedure evaluations. In the activated sludge process pollutants are removed through nitrification and denitrification processes, occurring in successive anoxic and aerobic bioreactors. In the aerobic zone, where the nitrification process occurs under aerobic conditions, dissolved oxygen (DO) concentration is important since most microorganisms use it to convert organic pollutants into energy and food.

BSM1's Default control strategy (Alex et al., 2008) has two control loops, representing a classical control structure for the plant. The first one controls the level of dissolved oxygen (SO) in the fifth reactor and manipulates the coefficient of aeration (KLa) to maintain a certain level of oxygen (SPSO5). The second loop controls the nitrate level (SNO) in the second reactor by the internal recirculation flow (Qa).

Our proposal aims to minimize the environmental impact and operation cost by manipulating setpoints in the default control strategy. RL Agents has been trained to provide SPSO of reactors 3, 4, and 5 in order to keep effluent ammonia under its limit with an efficient Aeration Energy Cost. For simplicity, $SPSO_3 = SPSO_4 = SPSO_5/2$. Nitrite and nitrate are considered because has an inverse relation with ammonia and have an environmental impact.

Reinforcement Learning Agents

From an RL-WWTP interaction point of view, the RL agent sends an action to the process, and this sends back a state and a reward, both consequences of the action. The action is an increase of $SPSO_5$, [-0.5 0 0.5] with respect to $SPSO_5$ at t-1. The states depend on the controlled variables and the $SPSO_5$. The reward qualifies the action in accordance with the control objectives and is the optimization criteria of PG. Consequently, optimization is driven by actions and states that obtain higher expected cumulative rewards. Therefore, our reward objective seeks that agents minimize environmental impact while reducing operating costs.

Six configurations of RL agents were trained and evaluated. Agents are divided into three groups (Table 1). The Agents differ in the configuration of their states and rewards. In the first and third groups, the states are the normalized errors, which are the difference between the corresponding concentration and its reference, selected as legal limits (4 mg/l for ammonia SNH_5 and 18 for total nitrogen TN) to get reasonable operating costs. In the second group, the states are just the normalized concentrations. As for rewards, in the first and second groups, they are selected heuristically as the weighted sum of squared errors of SNH_5, and SNO_5 with respect to the corresponding legal limit, together with an AE term if aeration costs are considered. The third group considers rewards, the OCI (Operational Cost Index), and the EQ (Effluent Quality). The SNH5 reference is the ammonia limit, while the SNO_5 reference is the total nitrogen limit. SNH_5, SNO_5, SS_5 (Readily biodegradable substrate in reactor 5), AE, EQ, and OCI were normalized to [0 1]. Also, the references were normalized.

RESULTS AND CONCLUSIONS

The results are compared against the default control ($SPSO_3 = SPSO_4 = 1$, $SPSO_5 = 2$) and analyzed using the BSM1 performance indic and time percentages of ammonia and total nitrogen violations of leg limits %VNH and %VN, respectively (Table 2). The evaluation peri considered spans 7 to 14 days, following the benchmark protoc sampling 15 minutes and under dry weather conditions. Episodes t training consisted of 14-day simulations sampling every 15 minutes.

The results are evaluated in terms of the reward objectiv Consequently, agents AG1 and AG2 show the lowest levels of SNl and high levels of AE because their rewards did not include AE. On t other hand. AG1P and AG2P agents display higher SNHe and low AE because their rewards also include AE. SNHe of both groups above the default because the reward was to decrease the margin error concerning its references, not a minimization of both, as in ((Table 2) (Figure 1).

In the case of G3, EQ, and OCI are closest to the default because th reward sought to minimize both, which are competing objectiv Among these results, the lowest %VN and %VNH by G3 is remarkab These improvements do not result in a higher OCI than the defa (Figure 1).

Table 1. Configurations of the RL agents. The episodes column sho the total episodes for training. Objectives within the reward have specific weight obtained heuristically.

Group	Agent	Episodes	Reward	States	Actu...
G1	AG_1	1000	$-(2\,.\,(SNH_5\text{-}4)^2 + 0{,}1\,.\,(SNO_5\text{-}18)^2)$	[(SNH_5-4) (SNO_5-18) $SPSO_5$]	[-0.5 0 0.5]
	AG_{1p}	2000	$-2\,.\,((SNH_5\text{-}4)^2 + 0{,}1\,.\,(SNO_5\text{-}18)^2 + 0{,}1\,.\,(AE)^2)$		
G2	AG_2	1000	$-(0{,}95\,.\,(SNH_5\text{-}4)^2 + 0{,}05\,.\,(SNO_5\text{-}18)^2)$	[SNH_5 SNO_5 $SPSO_5$]	[-0.5 0 0.5]
	AG_{2p}	2000	$-(0{,}9*(SNH_5\text{-}4)^2 + 0{,}05*(SNO_5\text{-}18)^2 + 0{,}05\,.\,(AE)^2)$		
G3	AG_3	1000	$-(2\,.\,EQ + OCI)$	[(SNH_5-4) (SNO_5-18) (SS_5-0.9) $SPSO_5$]	[-0.5 0 0.5]
	AG_{3p}	2000	$-(EQ + OCI)$		

Table 2. Evaluation of agents in dry weather conditions. In addition to the values of each agent, there are differences in percentages (%) with respect to the default control performance. Negative % values indicate that they are below their corresponding default value.

Control	OCI	EQ	SNHe (Effluent ammonia)	TotN (Effluent Total Nitrogen)	AE	% VNH	% VN
		kg poll.units/d	mg N/l	mg N/l			
DEFAULT	17452,94	6016,38	2,03	17,39	4989	14,73	20,98
AG_1	15703,08	6226,46	3,22	16,14	3226,14	28,27	13,54
AG_1%	-10,03	3,49	58,08	-7,2	-35,33	91,92	-35,46
AG_{1p}	15633,41	6280,91	3,48	15,91	3151,9	34,67	12,8
AG_{1p}%	-10,43	4,4	70,83	-8,51	-36,82	135,35	-39,01
AG_2	15952,11	6191,77	2,8	16,79	3485,97	20,98	16,67
AG_2%	-8,6	2,92	37,86	-3,44	-30,13	42,42	-20,57
AG_{2p}	15652,15	6323,06	3,45	16,2	3175,54	35,42	13,54
AG_{2p}%	-10,32	5,1	69,63	-6,86	-36,35	140,4	-35,46
AG_3	16076,73	6144,61	2,61	16,92	3612,53	17,11	17,86
AG_3%	-7,89	2,13	28,3	-2,66	-27,59	16,16	-14,89
AG_{3p}	15905,5	6169,87	2,79	16,7	3437,96	19,05	15,03
AG_{3p}%	-8,87	2,55	37	-3,94	-31,09	29,29	-28,37

Therefore, these results highlight that RL agents minimize environmental impact and operating costs as a function of reward. Specifically, the agents learned without prior knowledge of the model and were only guided by the process data. Moreover, an RL agent is easily adaptable according to requirements. As seen in the results of G1 and G2, which were rewarded with specific objectives, SNH5, SNO5, and AE, while in G3, their targets were global, EQ, and OCI.

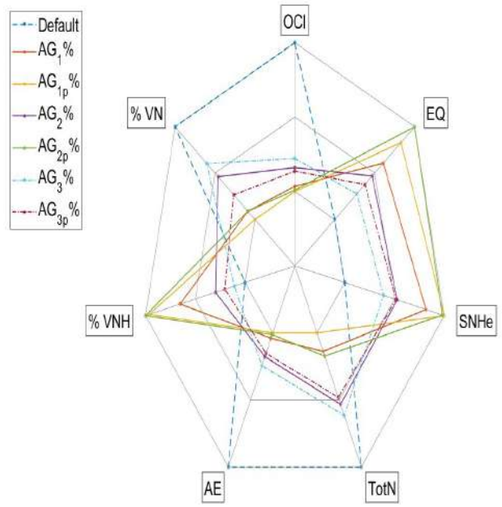

Figure 1. The radar chart displays the percentage difference with respect to the default performance control shown in Table 2. The limits of each axis are its own minimum and maximum values.

Abstract

This study is focused on the reuse of industrial wastewater (Solvay's peroxides effluent) inside the industry boundaries for the cooling tower needs. The possibility to treat this wastewater, characterized by high recalcitrant COD and relevant amount of Nitrates, by aerobic and anoxic biological processes was tested using a bench scale Sequencing Batch Reactor (SBR). The efficiency of the biological processes was evaluated by varying different parameters, such as Dissolved Oxygen (DO), concentration of Mixed Liquor Suspended Solid (MLSS), Hydraulic Retention Time (HRT), type of external carbon source and COD/N-NO3 ratio. Furthermore, pH and DO were monitored continuously during the bench scale process, while grabbed samples were analysed through UV-Vis and Fluorescence Spectroscopy, gathering relevant information to optimize the operation of the treatment processes increasing its economic abd environmental sustainability.

Keywords: Biological Treatment; Fluorescence Spectroscopy; Industrial wastewater; Industrial reuse; On-line monitoring; UV-Visible Spectroscopy.

INTRODUCTION

It is estimated that 20% of all freshwater consumption globally is used by industry and this share is increased to 50% in industrialized countries. The industrial sector is also a major water polluter, as only up to 60% of industrial wastewater receives treatment before being discharged into the environment (Forster J., 2014). Eco-efficient and sustainable industrial water management is a priority within the integrated water resources management strategy (Agarwal et al, 2000). In many ways, European communities are particularly well-placed to shift from a linear to a circular economy (CE) model. The concept of CE responds to the desire for sustainable growth in the context of increasing pressure on the environment at the global level due to the high demand and consumption of natural resources (Daddi et al., 2017). For this scope, the European Union is funding several research activities under the Horizon 2020 program, which coordinates actions across many policy areas to promote sustainable growth and employment through better use of resources. In light of these, the current study addresses the internal reclamation of wastewater in the Rosignano Solvay chemical plant framed in the H2020 AquaSPICE project. It aims at materializing circular water use in European process industries fostering awareness of resource efficiency and delivering compact solutions for industrial applications. The Rosignano Solvay industrial site is one of the oldest and largest in Italy, where a lot of different chemicals are produced, such as hydrogen peroxide and peracetic acid. In particular, the Solvay peroxides plant produces around 87600 m^3/y of wastewater, characterized by high COD partly recalcitrant, nitrates and sulphates that are subsequently discharged to sea. In this work, this real stream is treated through a biological bench scale Sequencing Batch Reactor (SBR) and the efficiency and feasibility in COD and Nitrates removal are evaluated. This study is supporting the development and design of a sustainable treatment train at the pilot scale (WAPEREUSE) in order to increase energy and carbon-efficient water reuse, and decrease the freshwater intake, the pressure on biodiversity, and the disposal of waste (Solvay One Planet, 2020).

MATERIALS AND METHODS

The biological Sequencing Batch Reactor (SBR), at bench scale, used for the experimental activity, was composed of: a 70L rectangular tank, a vertical mixer (140 rpm), a fine bubble disc diffuser (9 inches), a air blower (4 L/min), a peristaltic pump for influent feeding (26 L/min), a peristaltic pump for effluent discharge (30 L/h), one peristaltic pump for dosing the external carbon source (3 l/h), an on-line pH sensor (SenTix 940 ©, WTW), an on-line DO sensor (LDOsc Hach Lange), and a control&management system (myRIO, NI) to set cycles and to store data. To evaluate the process behaviour and the influence of operative parameters on the treatment efficiency, the following conditions were tested: DO at 8 and 4 mgO_2/L; Mixed Liquor Suspended Solid (MLVSS) between 3.5 and 6 gVSS/L, different COD/N-NO3 ratio (2, 3, 7 and 9), and different types of external carbon source (glycerol and a hydroalcoholic solution). During the experimental activity, the influent on the biological SBR and its performances have been monitored through sampling and analysis of specific parameters, such as alkalinity, COD, Anions, MLSS and MLVSS. Furthermore, UV-Visible and Fluorescence analyses were conducted to study the evolution/transformation of organic matter fraction by parameters that can be used during real-time monitoring

The SBR cycle consists of 1) influent feeding, 2) aeration phase for COD removal, 3) anoxic phase for denitrification, 4) decanting, and 5) effluent discharge.

RESULTS AND DISCUSSION

The characterization of the influent stream is reported in Table 1. The wastewater COD is made of a biodegradable fraction and a recalcitrant part. Volatile substances are also presents and recalcitrant constituents tend to polymerize over time.

Table 1. Characterization of the Solvay industrial stream

Parameter	U. M.	Average	Min	Max	Dev. ST
COD	mg/L	519	109	939	266
Chlorine (Cl)	mg/L	132	49	245	73
Nitrate (NO_3^{2-})	mg/L	969	770	1265	172.5
Phosphate (PO_4)	mg/L	29	2.7	69	23
Sulfate (SO_4)	mg/L	769	631	1007	134
Alkalinity	mg $CaCO_3$/L	92	37	131	27

Increasing DO concentration inside the reactor from 4 to 8 mgO_2/L, the efficiency of the aerobic phase improved from 29 to 47%, respectively (Figure 1). Particulalry, a highest COD removal rate was observed in the first 6 hours of the oxidation phase. Furthermore, most of COD was removed within the first 24 hours of treatment, whereas only an additional removal of 10% was observed if the aerobic oxidation conditions are maintained for two days (Figure 1.a). Otherwise, a higher concentration of biomass didn't lead to higher COD removals (Figure 1.b). Indeed, the obtained results underlined the specific COD composition of the Solvay wastewater: a fraction constituted by biodegradable compounds and a fraction of biological recalcitrant substances. Complete denitrification (around 99%) and a specific removal rate of 1.0 mgN-NO_3/gVSS,h were achieved by dosing glycerol, as an external carbon source, at a COD/N-NO_3 equal to 3. The increase in the COD/N-NO3 ratio, corresponding to higher treatment costs, did not lead to reaction rate improvement (i.e., reduction of HRT for the denitrification) but on the contrary, led to a COD overdose which was then removed by aerobic oxidation. On the other hand, at COD/N-NO3 lower than 3 an incomplete denitrification reaction, revealed by NO_2 accumulation, was detected. Similar denitrification rates were estimated for glycerol and the hydroalcoholic mixture (Figure 1.c). Results were in line with literature values (Cyplik et al, 2013). As a result of oxidation and denitrification reactions, alkalinity inside the reactor increased overtime (Figure 1.d).

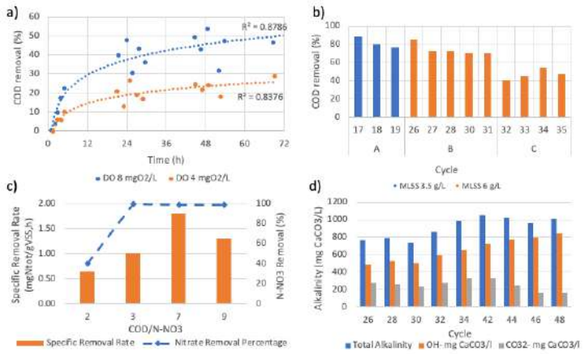

Figure 1. **a)** COD removal percentage at 4 and 8 mgO_2/L of Dissolved Oxygen monitored for 72 hours; **b)** COD removal percentage observed between cycles 17 and 35 at different MLVSS, 3 and 6 g/L; **c)** Comparison of different COD/N-NO3 ratio between specific N-NO3 removal rate (orange bars) and N-NO3 removal percentage (blue dotted line); **d)** Total alkalinity of the SBR effluent (blue), mineral alkalinity (orange) and inorganic alkalinity (grey), between 26 and 48 cycles.

Moreover, relevant information on the COD nature and its behaviour towards the biological SBR was obtained by applying the UV-Visible and Fluorescence spectroscopy. In Figure 2 are highlighted the information obtainable by these two spectroscopic tehniques. UV absorbance measurement resulted a suitable parameter to monitor COD removal during the biological process (Figure 2.a). However, fluorescence spectroscopy offered the advantage to differentiate the removal of the biodegradable and recalcitrant components (Figure 2.b and Figure 2.c). Particularly, Fluorescence spectra identified 3 main peaks: one peak at excitation, and emission wavelength 265/285 nm (I2), and a peak at 300/410 nm (I3). As shown in Figure 2, the peak I2 was removed almost completely, whereas I3 had very low percentage of removals (between 56 and 75%). This peak is mainly constituted by organic matter recalcitrant not easy to be removed biologically (Ou et al, 2014). Hence, treatment monitoring by fluorescence spectroscopy may be very useful strategy to optimize the operation conditions of biological processes since the COD concentration in the influent wastewater is highly variable and affected by the industrial cycle operation.

Abstract

The study proposes a more straightforward hydrologic-hydraulic model to assess impact in flow reduction due to improvements in surface hydrology generated by the use of Sustainable Urban Drainage Solutions (SUDS). The result exhibits higher spatial resolution than conventional catchment division models, based in terrain elevation or node-geometric criteria, and is less complex and time-consuming than usual methods for modelling green solutions. The novel approach uses a grid square layer with land use cover to create sub-basin with homogeneous land use type and size. Flow routing from the catchments to the network considers terrain slope and maximum path distance. A SUDS catalog with various techniques and designs was developed for their placement in multiple subcatchments, according to land cover classification. The study was conducted using open-source softwares with spatial data from the Montijuic neighborhood in Girona, Spain.

Keywords: SUDS, SWMM, GISWATER, Hydrology, Hydraulic-Model, catchment division.

INTRODUCTION

Climate change and urbanization pose significant threats to flooding and water quality in urban areas. Urban creep increases the impervious surface and a greater number of hazardous pollutants in water. Flooding has recently caused numerous problems and is one of the potential natural disasters in numerous researches. The lack of stormwater infrastructure also contributes to the increasing volume of Combined Sewer Overflows (CSO), that even as a small proportion of the total annual wastewater discharge, contribute to 30–95% of the annual load for different pollutants (Botturi et al., 2021). To face this scenario, communities must adapt, moving away from only conventional drainage methods that encourage water remotion as quickly as possible and deploy SUDS, solutions that mimic natural processes, controlling flood while also improving runoff water quality. Impacts provided in water quantity and quality by those practices are assisted by hydraulic-hydrological models, which are great tools in the evaluation of runoff generated by a watershed and enable the assessment of the flow effects in various scenarios as well as quantifying the benefits delivered by proposed modifications (Rossman et al., 2016). Usual methods for modelling green solutions (Lee et al., 2018) are time demanding in order to represent terrain, pervious and impervious areas to evaluate baseline properties.

The main goal of this work was to develop a simplified methodology, open source based, to build a high spatial resolution Hydrologic-hydraulic deploying SUDS. The key principles considered in the model include: **(i)** Creating homogeneous subcatchments based on land use type; **(ii)** Flow routing assumes the direction determined by the existence of a minimal surface level difference and maximum flow path distance from catchment areas to the network nodes; **(iii)** Accounting for baseline conditions of surface hydrology inside the catchments by considering flow routing between pervious and impervious areas within sub-basins; and **(iv)** Construction of a SUDS technic Catalog with distinct configurations in accordance with the aimed land use class.

MATERIALS AND METHODS

The model setup uses two main softwares, SWMM (Storm Water Management Model) and a free plugin dedicated to the integral management of the water cycle, named GISWATER, which communicates SWMM to a Spatial database using the interface of QGIS.

In order to establish the hydraulic and hydrological input characteristics of the Combined Sewer System (CSS), it was first necessary to collect network inventory and spatial and temporal data from public domain sources. These activities were followed by six steps, which are illustrated in **Figure 1** and are described in more detail below.

Step 1 – Catchment delineation. To create homogeneous unities with spatially averaged descriptive features, sub-basin delineations were relied on the Copernicus (2018) land use urban atlas data. A designed grid layer with square forms measuring 90 meters on each side was intersected with the land cover. This geoprocessing process intended to generate subcatchments of uniform size and shape (with the exception of building and other eventual cases due to the land use type). Subcatchment with homogeneous land present greater accuracy in their mean hydrological properties. Moreover, sizes with lower discrepancies are excellent to promote model continuity (Lee at al., 2018). Additionally, the grid layer with square shape aimed to estimate a median flow length path, generating median concentration times in accordance with the areas of each catchment, avoiding great discrepancies in peak flow.

Step 2 &3 – Flow routing from the subcatchments to the network and measuring mean values for surface properties. Each subcatchment was connected to the outlet (network nodes) using a QGIS plugin called *Buildings2sewer* developed by ICRA. The use of this plugin enables the sub-basins to be connected to the closest node considering surface elevation criteria and distance. The altitude tolerance was set as 2 meters, and the maximum distance 40 meters (due to the medium distance calculated between the nodes of the CSS). Afterwards, geoprocessing tools were used to calculate mean values for imperviousness and slope of satellite layer in the attribute table of the subcatchments.

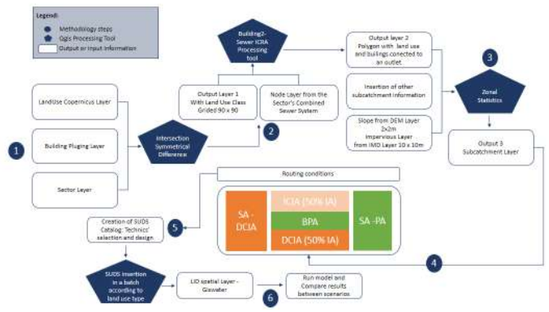

Figure 1. Sequence steps of a novel model methodology for SUDS deployment.

Step 4 – Assumptions about flow routing within the catchment area: The subcatchments delineation made any distinction between directed connected or undirected connected impervious areas. In contraposition, SWMM ability to define routing conditions was used to compensate the counter effects of this model abstraction. It was defined that 50% of the water in the IA (Impervious Area) would be directed to the PA (Pervious Area). In real conditions, flow direction is favourable to the pervious area in function of the natural hydraulic gradient, if considered a flat terrain. The 50% is a mid-value, and good estimation to avoid big deviations from what happens in the field. It means that half of the water is directly connected to the network system and the other 50% of the flow goes to the buffer pervious area. This value is a start point, and in a future calibration, this routing percentage could be changed for less or more, upon the difference between the model water flow and the measured value, if inferior or superior to the measured flow, respectively.

Based on previous basins' classifications (Lee et al., 2018) the routing condition implies three types of subcatchment composition. (**Figure 1, Step4**):

I. Stand Alone Pervious Area (SA-PA): for subcatchments landscape 100% perviousness;

II. Subcatchment with both pervious and impervious area: where pervious area functions as a Buffer Pervious Area (BPA), receiving flow from Indirected Connected Impervious Area (ICIA) and the impervious area directly connected to the outlet (DCIA); and

III. Stand Alone Directed Connect Impervious Area (SA-DCIA): representing landscapes, such as the buildings and streets.

Step 5 – Creation of a SUDS Catalog and their placement in multiple subcatchments according to the land use type: The SUDS selection and its site of installation considered the network surcharge, the existence of CSO that needed to be minimized and hydrogeological aspects. It was designed three different on source SUDS in accordance with the land use type: Permeable Pavement (PP) for the streets, Infiltration Trenches (IT) on parking lots, Rainwater Harvesting (RH) systems for storage of surface runoff from building's rooftops. The latter assumed three different configurations, due to the difference of rooftop sizes (subcatchment geometry): a residential, an institutional and another for commercial sites. Moreover, it was designed infiltration-detention basins upstream outfalls where CSO is a problem. The solutions were placed at once in multiple subcatchments, in accordance with land use classification.

Step 6 – Creation of different scenarios and running the model: In total, it was made nine simulations. Three simulations for each one of the proposed scenarios (SC01: Baseline; SC02: Implementation of on Source SUDS and flow diversion upstream the network study area; SC03: Implementation of on source and two storage SUDS).

RESULTS AND CONCLUSIONS

Subcatchments were represented in sizes of the same order of magnitude, to help maintain hydrologic continuity among them (**Figure 2**, left). The division based on land cover usage as an independent subcatchment helps in decreasing model output uncertainty (Sun et al., 2014).

The adopted methodology allowed an extreme discretization level of the model, counting to 1.570 subcatchments in an urban basin area of 39,12 km². Since buildings and streets were mainly SA-DCIA, it was possible to calculate median rooftop sizes to dimension cistern and propose pavements with the same dimension as the catchment, allowing placing the solutions in a batch (each technique to the proper land use type).

In total the model counted with 169 permeable pavements with, mostly, homogeneous sizes, 771 rain barrels for residential roofs, plus rain barrels for the school and a commercial site. Conventional subcatchment delineation such as the Digital Elevation – Deterministic 8 based and the thiessen - node based geometric method results in subcatchment with heterogeneous land uses (**Figure 2**, right), implicating that surface properties poorly represent hydrologic surface conditions, and impact due green infrastructural changes cannot be properly studied.

For example, considering the case study, using the Thiessen method it was obtained 440 subcatchments, for whom increases in standard deviation represented 57%, 63% and 124% for imperviousness, slope and surface level, respectively, reflecting the poor spatial resolution of those methods in comparison to the land use approach.

Figure 2. Visual comparison for Land Use (left) and Thiessen (right) catchments division methods.

This methodology might reflect unrealistic "green" development baseline conditions, because runoff from 50% of ICIA is evenly distributed throughout the entire PA, which means that all pervious area works like a BPA. On the other side, this impact can be resolved with model calibration and changes in routing percentage to PA.

As for the hydrological and hydraulic quantity impacts evaluated through SUDS usage, the data has shown a reduction in the CSS, an increase in the recharge of the aquifer, and the capacity of the network without having the transport capacity increased using bigger network diameters. The achievement was due to high SUDS efficiencies, ranging from 62 to 100% for a 10-year return rain of 60 minutes. The impact of SUDS usage in a non-calibrated model is still a good preliminary result, since the increased loss due to the new infrastructure does not count with the ones from baseline conditions (that could be over or underestimated in the same proportion in both scenarios). Considering the implementations of the distributed solutions in the terrain, the transition, for example, to permeable payments, could be done in long term period, according to eventual need of reforms on streets pavement.

Abstract
Due to the growing interest that aerobic granular sludge processes are witnessing today, proper modelling is crucial for process optimization and control, but the huge number of parameters and variables involved hinders the spreading of reliable and user-friendly mathematical models. Based on the rule by which "a model should be as simple as possible, and only as complex as needed", this work compares two models developed with different degree of complexity, namely the 0D-B/AGS-SBR and the 1D-B/AGS-SBR. Different process boundary conditions (influent pollutant concentrations, cycle time and phase duration, oxygen dosage) are tested in order to assess the reliability and applicability of both models. Preliminary results motivate the pursuit of this study, primarily aimed at providing wastewater treatment plants operators and modellers with adequate tools for different possible scenarios.

Keywords
Aerobic sludge model; Biofilm; Granular sludge; Half-saturation coefficient; Modelling; Plug-flow feeding.

INTRODUCTION

The advantages of aerobic granular sludge (AGS) technologies are increasingly attracting the scientific community as well as industrial and municipal wastewater treatment plants (WWTPs) operators. Accordingly, the practical implementation of process optimization and control strategies by means of the development of reliable and user-friendly mathematical models is assuming growing relevance (Zaghloul & Achari, 2022). Mechanistic models available in literature show a clear evolution over time towards increased complexity, involving not only biological and physio-chemical transformations as described in the IWA Activated Sludge Models (ASM), but also in terms of granule dynamics (e.g., liquid-granule mass transfer, intragranular transport, attachment/detachment, size distribution) and reactor hydraulics (liquid-phase transport, granule transport, settling) (Baeten et al., 2019).
The detection of a trade-off between model complexity and accuracy is a challenging objective, and although scarcely addressed, this task is of paramount importance for practical purposes, helping modellers to set proper assumptions/simplifications, once defined model goals and system boundary conditions (e.g., reactor size, wastewater characteristics). Recently, in order to simplify model parameter identification, Baeten et al. (2018) demonstrated the possibility of using apparent half-saturation coefficients ($K_{S,app}$) to lump the reaction diffusion process inside granules (zero-dimension biofilm model, 0D-B) in a fully mixed reactor model; on the other hand, a higher complexity model was investigated by Derlon et al. (2022) who integrated a 1D biofilm model (1D-B, with explicit description of diffusion processes) with an SBR (sequencing batch reactor) model explicitly describing plug-flow gradients during feeding.
In this work, two models were developed and compared to assess their accuracy and field of application, and to use them as practical tools for process optimization: i) a 1D-B/AGS-SBR model, where a 1D granule model was coupled to an SBR model including the description of plug-flow anaerobic feeding (AGS-SBR model), and ii) a simplified model (0D-B/AGS-SBR) where apparent half-saturation coefficients were used for biomasses included in the SBR model.

MATERIALS AND METHODS

Model development

The 1D biofilm code was developed in Matlab in spherical coordinates, based on Wanner & Gujer (1986). The system of partial differential equations was solved using a finite-difference method with fixed time step. Variable granule size and number of layers were considered.
The AGS-SBR model was implemented in Matlab-Simulink and simulates a SBR cycle at constant volume: a series of 4 CSTR with a correction code (Derlon et al., 2022) was used to mimic the ideal plug-flow feeding phase with simultaneous discharge. At the end of this phase, a very high recycle flowrate between the four CSTR is applied to create artificial mixing conditions for subsequent aerobic/anoxic phase. Sedimentation and flocs/granules stratification were not modelled, TSS concentration in the reactor was kept at a constant value by removal of excess biomass.
All the biokinetics processes were defined as in Kagawa et al. (2015), applying modified ASM 2d.
The 1D-B/AGS-SBR model was implemented by incorporating the 1D biofilm model into the SBR model and exchanging substrate fluxes between the two models. Flocs were modelled as suspended biomass with intrinsic half-saturation coefficients (K_S) within the SBR reactor.
As regards the 0D-B/AGS-SBR model, apparent half-saturation coefficients were defined as described in Baeten et al. (2018) but, conversely to what explored by the authors, in this case biomasses are subject to plug-flow gradients during anaerobic feeding.

Scenarios selection and research objectives

Different scenarios were selected and simulated using a SBR operated at constant volume (V = 1.45 m^3, h/D = 10, D = 0.57 m, VER = 60%), in order to meet the following targets: (i) verify the effects of using apparent half-saturation coefficients in a system describing the hydrodynamics of aerobic granular sludge reactors; (ii) assess if the use of a 0D biofilm model approach is reliable at varying wastewater strengths (low-medium and high strength wastewater conditions were studied); (iii) support process optimization by testing different operative conditions (e.g., cycle time and phases duration; dissolved oxygen concentration and aeration strategies).

RESULTS AND DISCUSSION

Figure 1 shows simulations obtained by using the 0D-B/AGS-SBR model fed with a low-medium strength wastewater (396 g COD/m^3, 50 g $N\text{-}NH_4^+/m^3$ and 20 g $P\text{-}PO_4^{3-}/m^3$). Different cycle time, phase duration and aeration strategies were tested. In more detail, Figures 1A and 1B compare a 4-hour cycle (C2 = 1 h anaerobic + 1 h aerobic + 1.5 h anoxic + 0.5 h sedimentation) with a 6-hour cycle (C1 = 1.5 h anaerobic + 1.5 h aerobic + 2.5 h anoxic + 0.5 h sedimentation) at same DO dosage and aeration strategy (2 mg DO/L for the aerobic phase and 0.5 mg DO/L for the anoxic phase). As regards effluent COD, ammonium and phosphate, negligible differences were observed, while effluent nitrate concentration was the most sensible variable. Positive effects of testing a different aeration strategy in the SBR cycle C2 are shown in Figure 1C: a linear increase of DO from 0 to 2 mg DO/L during the aerobic phase and a linear decrease from 2 to 0.25 mg DO/L during the anoxic phase, efficiently removes COD, phosphate, ammonium and also nitrate, resulting in an effluent concentration below 1 mg $N\text{-}NO_3^-$/L, compared to a value above 20 mg $N\text{-}NO_3^-$/L using a step aeration strategy (Figure 1A).
Diffusive mechanisms inside granules are shown in Figure 2, where biomass net growth rates and distributions, and substrate concentrations are displayed at increasing the distance from the centre of two differently sized granules. Conversely to heterotrophs (HET), PAO and GAO, the growth of both nitrifiers species (AOB and NOB) and ammonium oxidation are limited by DO penetration through the granule. Besides, for large-size granules, PAO and GAO prevailed on HET at increasing of anoxic and anaerobic conditions. Hence, the integration of the 1D biofilm model with the AGS-SBR model is expected to be of crucial importance, especially when treating high strength wastewater. Authors wish to prove that, for AGS processes too, modelling can be used to fine-tune operative parameters, provided that model complexity has been properly selected and implemented.

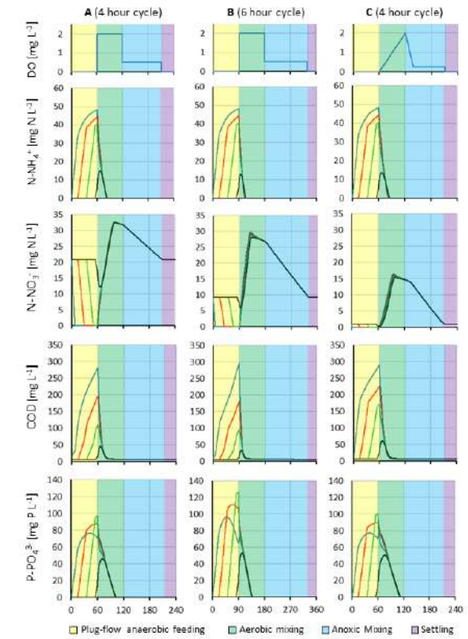

Figure 1. 0D-B/AGS-SBR model simulations at steady state for three cycles with different cycle duration and oxygen dosage strategies. The four lines during the anaerobic phase refer to the four CSTR used to model plug-flow feeding (blue: bottom, red: bottom up, green: top down, black: top).

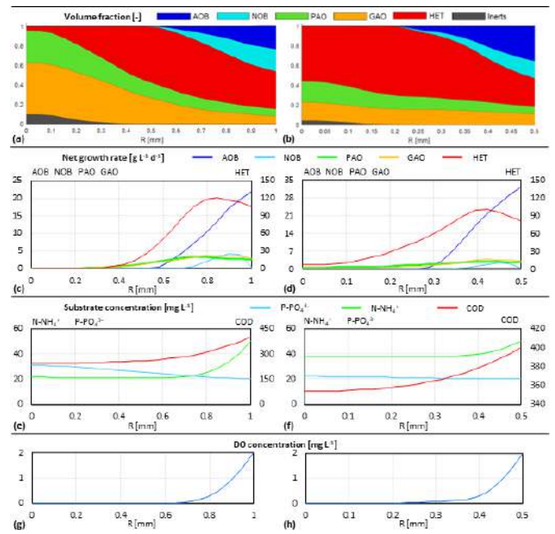

Figure 2. 1D biofilm model simulations at steady state using the SBR cycle C2. Results are shown for two different granule size (on the left, radius R = 1 mm; on the right, R = 0.5 mm).

Abstract

Population growth, tightening effluent discharge requirements and increasing energy costs are driving the wastewater treatment sector to strive towards energy self-sufficiency. This case study of Grüneck wastewater treatment plant (WWTP) in Germany evaluates the effectiveness of two different energy strategies and quantifies their plant-wide impact. Energy self-sufficiency at Grüneck WWTP increased from 64 to 88% by reducing energy consumption with aeration upgrades (-3.0 kWh PE^{-1} a^{-1}) and increasing energy production with food waste co-digestion (+5.6 kWh PE^{-1} d^{-1}). The increased power production from co-digesting food waste at 0.24 kg_{VS} m^{-3} d^{-1} energetically out-weighed downstream impacts of reduced dewaterability, increased solids accumulation and nitrogen backload. Findings from this case study provide practical knowledge of the trade-offs for different strategies commonly employed to improve energy self-sufficiency at WWTPs.

Keywords

Aeration upgrade; anaerobic digestion, energy self-sufficiency; food waste co-digestion

INTRODUCTION

Population growth and increasingly stringent discharge standards are increasing wastewater treatment energy requirements. This increased energy demand coupled with rising energy costs and environmental concerns is motivating the wastewater treatment sector to strive towards energy self-sufficiency, which can be achieved through a combination of reducing power consumption and increasing on-site power production. Prior to adopting an energy strategy, it is important to understand the plant-wide implications and trade-offs between maximising power savings and minimising process drawbacks. The objective of this full-scale case study was to analyse the effectiveness of two commonly applied strategies, aeration upgrades and co-digestion, to improve energy self-sufficiency and quantify their plant-wide impact.

MATERIALS AND METHODS

5 years of operational data for Grüneck WWTP (2013-2017) was obtained from consultations with the plant operators, annual reports, energy reports and sludge reports. During this period of operation, two energy saving strategies were implemented:

1) In September 2014 the blower system was upgraded from a HV Turbo paddlewheel blower system to an Aerzen rotary lobe blower system.
2) In May 2014, co-digestion with processed food waste commenced at 0.24 ± 0.06 kg_{VS} m^{-3} d^{-1} (20% additional organic load, 5% additional volume).

RESULTS AND DISCUSSION

A process flow diagram with mass balance and energy values from 2016 for Grüneck WWTP is displayed in Figure 1. The specific power consumption throughout the study period was 0.64 ± 0.08 kWh per m^3 wastewater treated. Figure 2 shows the energy consumption for different unit processes. The relatively high specific power consumption at Grüneck WWTP may be attributed to i) high power intensity of headworks and pumping, and ii) energy-intensive advanced treatment with UV disinfection applied during bathing season in the receiving water body.

Upgrading the aeration system reduced the aeration power requirements by 0.03 ± 0.02 kWh m^{-3} (-16 ± 2 %). This improved energy efficiency contributed to a 13 % (350 MWh a^{-1}) reduction in overall plant power consumption and an 8 ± 3 % increase in energy self-sufficiency. Food waste co-digestion boosted the electricity production by 0.11 ± 0.03 kWh m^{-3} (+25 ± 6 %), translating to a 16 ± 5 % increase in energy self-sufficiency. Aeration upgrades and food waste co-digestion successfully increased energy self-sufficiency at Grüneck WWTP from 64 % to 88 % (Figure 3).

The plant-wide analysis indicated that the aeration upgrades did not affect effluent quality. However, co-digesting food waste at 20 % additional organic load caused some minor downstream impacts including reduction in dewaterability (-10 %), fluctuating biogas quality, increased nitrogen backload (+3 t a^{-1}) and solids accumulation (50 kg_{TS} d^{-1}). A solar dryer was installed to manage the increased biosolids production resulting from co-digestion. The dryer reduced biosolids transportation costs by 30 % with minimal increase in total plant energy demand (below 2 %). Overall from an energy perspective, the increased power production from food waste co-digestion energetically out-weighed the downstream impacts.

The capital expenditures for the blower upgrade, food waste acceptance facilities and solar dryer were 50,000 €, 150,000 € and 2,000,000 €, respectively. Based on the current OPEX savings, the blower upgrade and food waste acceptance facilities have payback periods of 10 and 17 months, respectively. However, the solar dryer has a payback period of 30 years. Expanding the energy analysis to incorporate savings from the sludge incineration as well as off-sets associated with other food waste management options revealed that co-digesting food waste and installing the solar dryer save energy in the wider waste management context (Figure 4).

CONCLUSIONS

Grüneck WWTP increased energy self-sufficiency by 24% (from 64% to 88%) through reducing energy consumption with aeration upgrades (8% increase) and increasing energy production with food waste co-digestion (16% increase). This case study demonstrates that there is significant potential for WWTPs to achieve energy self-sufficiency through a combination of strategies, which both reduce energy consumption and increase energy production. Management of plant-wide impacts associated with each strategy however should be considered when selecting the appropriate mix of strategies (Sembera et al., 2019).

Abstract
Reliable data is important for performance monitoring, production accounting and model development of WWTP's. The aim of this paper was to propose fit-for-purpose measurement layouts/sampling strategies for the Tilburg WWTP that will improve the quality of the collected data by facilitating the mass balance validation and detection of errors for online measurements and grab samples, while keeping in mind the practical and economic feasibility of the measurement lay-out. Mass-balance based experimental design was used to propose these lay-outs and retain the most viable ones. For the Tilburg WWTP this resulted in three viable sampling strategies, each with different accuracies and costs. It could be concluded that a complex WWTP, such as Tilburg, can benefit from mass-balance based experimental design to obtain measurement strategies that can lead to more reliable data.

Data collection; Mass balance; Monitoring; Plant-wide modelling

INTRODUCTION

The wastewater treatment plant and "Energy Factory" (EF) Tilburg in the Netherlands was constructed as part of an ambitious Dutch national strategy to exploit the resources of wastewater and to make local water authorities the largest producers of green energy in the Netherlands. In this regard, the majority of the activities of EF Tilburg have focused on the sludge line, which should be considered the production line of the EF. The EF Tilburg produces approx. 6 million m^3 biogas, which makes the plant more energy neutral, and delivers surplus biogas to other facilities in the region. Since 2016, the plant has passed through major and incremental improvements/reconfigurations to optimize treatment, nutrient recovery and energy production.
In order to have reliable data for performance monitoring, production accounting as well as for plant model development, a data collection plan was designed using mass-balance-based experimental design (Le et al., 2018). The project aims to have fit-for-purpose measurement layouts that will improve the quality of the collected data by facilitating the mass balance validation, detection of fault or error of either online measurement and grab samples and at the same time would be practical and economically feasible (Figure 1). The approach of balance-based technique for measurement design was well established in chemical industry for decades (Kretsovalis and Mah, 1987; Madron and Veverka, 1992; Marie Luong Chang Trung Huynh, Jos´e Ragot, 1994) and is recently introduced to waste(water) process monitoring (Spindler, 2014; Villez et al., 2020, 2016).

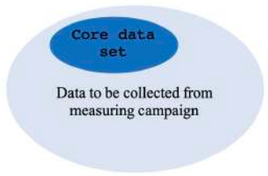

Figure 1. Core data set from mass-balance-based experimental design as a part of the data set to be collected from an extensive measurement campaign.

METHODOLOGICAL APPROACH

The mass-balanced based experimental design procedure of Le et al. (2018) was applied to achieve the main goal. The procedure has seven steps that can be grouped into three parts. The first part is collecting input information including (1) defining the main goal and key variables, (2) setting up mass balancing and (3) data inventory. The second part is finding solutions including (4) feasibility (5) clustering, (6) finding solution. The final part is (7) optimization to deliver optimal solutions in terms of cost and accuracy in the form of a Pareto-front.
Only the first part of collecting input information, the most important and time-consuming part, will be elaborated in this abstract. The second and third parts are automated procedures written in Matlab.

EF Tilburg

EF Tilburg has three main treatment lines. (1) The water line is a conventional activated sludge process. (2) The sludge line has a thermal hydrolysis unit and a digester to treat combined primary sludge and hydrolysed secondary sludge. The plant also receives dewatered sludge from sludge treatment site Mierlo and external secondary sludge from other plants. (3) The side-stream line treats rejected water from the sludge line with the Anammox process.

Collecting input information

The main goal and key variables: The main goal is to obtain improved data using mass-balance based experimental design and data reconciliation for monitoring sludge & biogas production, effluent quality monitoring as well as data for process optimization and modelling: COD mass balances, DO consumption, nitrification, denitrification and phosphorus removal. The main goals are translated into 71 key process variables of flow rate, total COD, nitrogen and phosphorus.
Mass balance setup: The simplified process flow diagram (PFD) of EF Tilburg has 22 (grouped) unit processes and 77 streams. From the PFD, 74 mass balances of total mass flow (22), the mass flow of total phosphorus (17), total COD (17) and total nitrogen (18) were set up including 44 streams and 166 variables.
Data inventory: Measured data were collected from the information system of the plant. The potential new sampling points were chosen taking into account practical aspects such as safety, accessibility and representativeness. The magnitude of standard error of the mean of the variable was estimated from the data set using available data and the set of mass balances. The cost of concentration measurements in each stream is set at 104 EUR/per parameter. The cost of installing a new flow sensor for nine potential streams is about 20,000 EUR/ per stream if flows must be measured in these streams. There are six out of twenty streams that potential sampling points need to be installed for safety reason, which cost 1,000 EUR/ per point.

RESULTS AND DISCUSSION

In the case of EF Tilburg, three different sampling strategies for mass balance validation have been proposed in Table 1. For each strategy, $9x10^{15}$ possible measurement layouts (in terms of flow and concentration) were evaluated, most of them were infeasible and could be quickly removed.

Table 1. Summary of three (03) sampling strategies. '#' denotes 'number of'.

	min cost(1)	max accuracy(1)	A	A+	B+
# improved key variables	69/71	69/71	69/71	69/71	67/71
frequency	1x/week	1x/week	1x/week	1x/week +3x/ week(2)	1x/week +3x/week(2)
# Pareto optimal solution			51	63	72
Selected solution	**#1**	**#51**	**#9**	**#12**	**#9**
total cost	€47,912	€190,680	€49,640	€51,136	€31,136
estimated accuracy	1.93	1.13	1.67	1.5	1.68
# additional variables	30	54	37	35	34
# additional flow sensors	2	9	2	2	1
# sampling points	14	23	16	15	14
# new install sampling point	6	6	6	6	6

(1) Min cost and max accuracy are based on sampling strategy A.
(2) x3 samples per week for specific sampling points

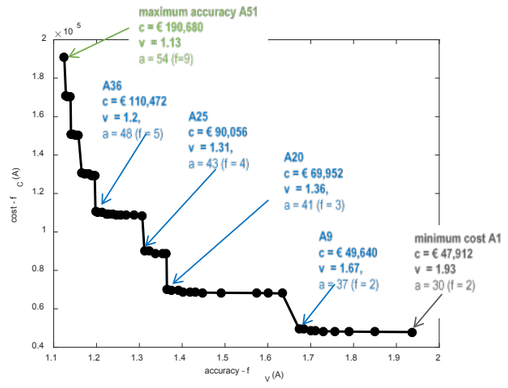

Figure 2. Pareto-front optimal solutions of sampling strategy A. a = number of additional measured variables, v = accuracy and c = cost of additional measurements.

Sampling strategy A is to improve 69/71 specified key variables. Sampling strategy A+ is a more accurate version of sampling strategy A by increasing the frequency of sampling to x3/week in certain streams. Sampling strategy B+ is a cheaper version of sampling strategy A+ with only one additional flow sensor instead of two in strategy A. As a result, B+ only improves 67/71 key variables. An example of a Pareto-front optimal solutions of sampling strategy A is illustrated in Figure 2. Six new sampling points need to be installed, the remain ones were already available as regular sampling points of the plant.
Note that the cost of installing an additional sensor as well as the related cost for maintenance afterward can be greatly reduced by using clamp-on flowmeters for certain streams during the measuring campaign. The accuracy objective function used in the optimization could be replaced by the '*number of redundant variables'* similar to the approach of Villez et al. (2016) that allows errors to be detected in key variables. In the end 3 sampling strategies were proposed. Sampling strategy A was considered

CONCLUSIONS

For such a complex EF as Tilburg, mass-balance based experimental design offers a systematic approach to establishing a core data set that allows the process engineer to validate the collected data, especially those in important streams related to the main goal, using mass balances.
Different sampling strategies were proposed providing a basis for decision-making on the optimal core data set with regard to additional sensors placement.

Opinions

Understanding the plant and setting up a comprehensive PFD are the most time-consuming part of the project in particular and in other similar projects in general.
Prior to mass-balance-based experimental design, data reconciliation of flow measurement should be done to first check the flow sensor availability since flow measurements are important in all mass balances. These additional measurements are very useful to validate the collected data in the sludge line since sludge content will be measured for the first time.

Abstract

Trickling filters are widely used on large sites. Their robust behaviour and their low economic cost (natural aeration) make them an interesting technology. However, there is no simulation tool (mathematical model) to optimise and fully understand this technology (hydraulics and biology). In this contribution a model considering both hydraulics and biology is shown which is able to reproduce the performance of a real trickling filter. The model-based assessment describes the biomass distribution in a primary and secondary trickling filters, which can help in the definition of the operational strategy of different trickling filters.

Keywords

Biofilm; hydraulics; mathematical model; simulation; trickling filter

INTRODUCTION

Trickling filters are fixed film secondary treatments that are simple and robust to build and have low energy consumption (Ferrer, 2008; Pal, Sarkar and Dasgupta, 2010). The principle of operation of a trickling filter is to pass wastewater through a solid filler that supports the attached bacterial layer. Bacteria attached to this packing (biofilm) feed on the pollutant load and grow on it.

The water quality obtained from this apparently simple operation is in fact a combination of complex internal biological mechanisms described elsewhere (Rauch, Vanhooren and Vanrolleghem, 1999; Almstrand et al., 2011) and an unknown hydraulic behaviour. The uncertainty associated to the combination of both effects has made historically difficult to predict and understand the performance of trickling filters (Saerner, 1986).

NILSA and Ceit-BRTA are collaborating in the construction of a mechanistic mathematical model that describes in detail the hydraulic and biochemical behaviour of trickling filters. This model will help to understand the operation of the technology and will be a useful tool for the design and optimization of new and existing trickling filters. In this contribution, the hydraulic model describing the behaviour of a trickling filter has been calibrated using data from a real WWTP and, in addition, the simulation outputs are compared with experimental tests performed on a real trickling filter with plastic packing media located in Tudela, Navarra. Finally, a first model-based exploration of the biological transformations and water quality has been carried out. This assessment helps in the definition of the operational strategy depending on the water characteristics (raw water or pre-treated water) or in the filling media material (plastic or rocks). In the near future, the model will be calibrated using both hydraulic and water quality data from different trickling filters.

MATERIALS AND METHODS

Experimentation

The experiment used to calibrate the hydraulic model, consisted on introducing a constant flow rate (340 m^3/h) for a given time (60 minutes) and the observing the behaviour of the outflow until the filter was completely emptied, this happened after 200 minutes from the beginning. To obtain the data, flow meters were placed at the inlet and outlet of the trickling filter.

In order to understand the operation of this technology, the compositions of the effluents from the different trickling filters located in Tudela's WWTP are obtained.

Mathematical model

The trickling filter has been divided in 8 virtual tanks. On one hand, the total height of the filter is divided in four levels. On the other hand, the existence of hydraulic short-circuits and retained water makes it necessary to consider in the model a fraction of the circulating water flow that is hardly treated (named circulating path) and another that is retained and biodegraded in the different zones of the biofilm (named retained path), being the effluent a mixture of both. In this way, the heterogeneities that exist in the reactor are represented. Figure 1 shows a schematic diagram, where is the fraction of the water flow that goes to the circulating path, the letter in the subscript ($_C$ for circulating path and $_R$ for retained path) indicates the path and the number the corresponding level.

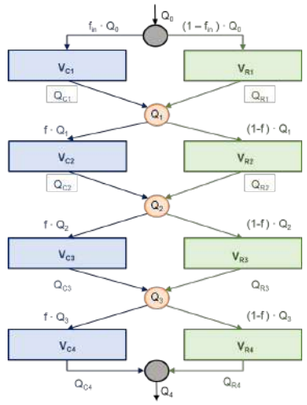

Figure 1. Schematic diagram of the paths and levels described in the hydraulic model.

The mass conservation equation is used to reproduce the variation of the water volume in each tank. This mass balance can be expressed as a volume variation, and considering constant the density of the water, Eq. (1).

Where is the volume of the fluid in the control volume, and the inflow and the outflow rate of the control volume, respectively. The outflows of each tank are modelled by a weir equation, Eq. (2), where is the opening coefficient of the valve and α is the exponent that regulates the emptying of the tank.

The biochemical model used in this contribution is based on the IWA-ASM2d model which is combined with a conventional 10-layer WEST model to describe the bacterial biofilm.

RESULTS AND DISCUSSION

Figure 2 shows the response of the hydraulic model to a pulse of influent flow used in the experiment in Tudela. The calibrated model is able to reproduce the behaviour of both the outlet flow rate and the stored volume. Four sections can be distinguished in the experiment: filling without significant outflow (A), accumulation of water volume (B), fast emptying (C) and slow emptying (D). Once the hydraulic transport model is able to adequately reproduce the hydraulic behaviour of the filter, biochemical model explorations can be performed in WEST. As an example, Figure 3 shows the difference in the effluent characteristics of a primary and a secondary filter. A clear nitrification is observed in the secondary filter, whereas in the primary organic matter is consumed (from 273 g/m^3 to 118 g/m^3). Figure 4 describes the biomass distribution in the biofilm of both trickling filters. As in the primary filter organic matter is removed, heterotroph biomass is predominant. While autotrophs prevail over heterotrophs in the secondary filter. Another important result is the presence of heterotrophic biomass in the outer layers when there is enough organic matter in aerobic conditions, enhancing the growth of heterotrophs. When organic matter is reduced, autotrophs gain importance and they move from inner layers to outer ones. Furthermore, if levels are observed, the presence of biomass in the secondary filter decreases as the water goes down, as ammonium and organic matter are consumed in higher locations.

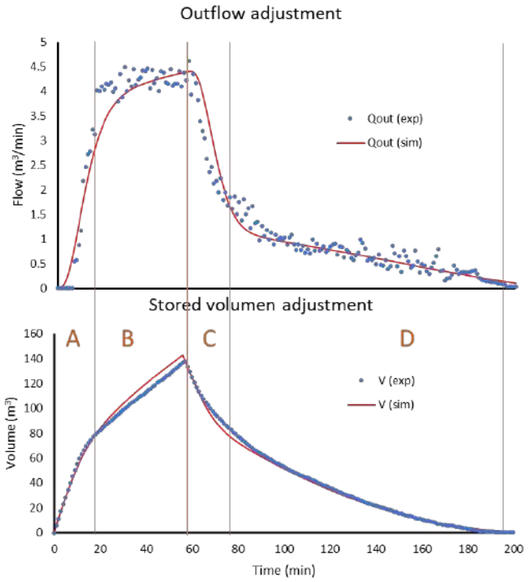

Figure 2. Results of the hydraulic model.

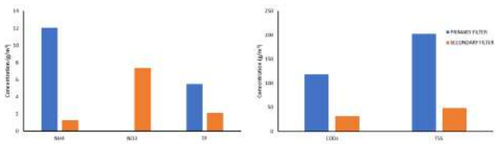

Figure 3. Effluent comparison between a primary and a secondary trickling filter.

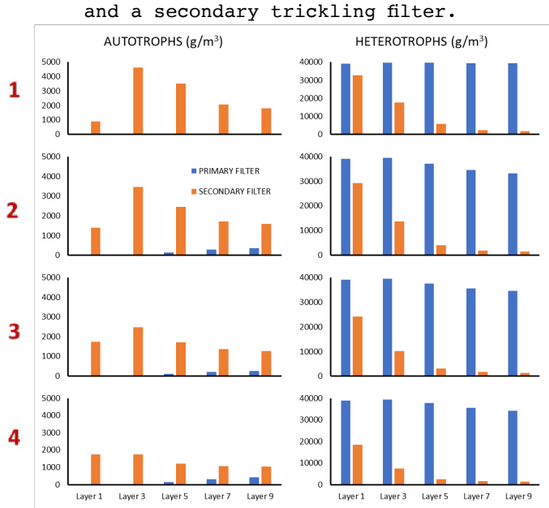

Figure 4. Biomass distribution in the biofilm depending on the trickling filter.

CONCLUSIONS

The new model proposes two routes (circulating and retained) to describe water transport. This provides a satisfactory description of the hydraulic and biochemical behaviour of different trickling filters. With the experimentation done to date, a preliminary replication of the real behaviour of the filters in the mathematical model has been achieved, this model helps in the definition of operational strategies depending on the season of the year or water characteristics. Once the calibration and validation of the model for different operating scenarios has been completed, a very useful tool will be available to optimise the design and operation of NILSA's trickling filters.

Abstract: The use of mathematical models is well established procedure in the field of water engineering to "virtually" evaluate the techno-economic feasibility of promising operational strategies. In this way, only options with the highest chance of success are further investigated to be full-scale implemented while less interesting proposals can be disregarded at an early stage. Nevertheless, there is a lack of studies where (plant-wide) comprehensive models are verified with full-scale data and applied in the field. In this paper, a computer simulation model is adjusted to assess alternative modes of operation in the largest industrial wastewater treatment plant (iWTS) in Northern Europe. Multiple economic and technical criteria are defined, verified with plant data and used to test the performance of three types of scenarios:

1) carbon refluxing (CR), 2) change of operational procedures (OP) and 3) the implementation

of new technologies (NT). Life cycle assessment (LCA) quantifies environmental stressors grouped in three categories: human health (HH), environmental qualtity (EQ) and resource scarcity (RS). The presented decision support tool has been used by the biotech company involved in the study on how to handle the future iWTS expansion.

Keywords: Computer Aided Process Engineering, Mathematical Modelling, Multi-criteria evaluation, Plant Wide Optimization, Resource Recovery

INTRODUCION

Although process modelling is a well stablished procedure in wastewater engineering, most of the previously published studies on virtual case studies, dealt with diluted streams, used non-validated models and neglectedprocess economics (Henze et al., 2000, Batstone et al. 2002). In order to circumvent these limitations, we present a model-based evaluation study of plant-wide operational strategies in an industrial water treatment system (iWTS) treating the effluents from two big biotech companies. The case study is the largest iWTS in Northern Europe and handles a pollution load of 2.5 PE in only 10000 m3/day. This will be done using a full-scale validated PWM capable to reproduce and forecast mass and volumetric flows. Finally, special aspects such as energy expenditures, use of chemicals, bio-solids handling and transportation cost, discharge fees and potential (internal / external) energy recovery will be combined with several technical criteria e.g. removal rates, capacity liberation.¨

PLANT CONFIGURATION, MODELS, DATA, SCENARIO & CRITERIA

The flow diagram of the WWTP under study is shown in **Figure 1**. A plant-wide model was developed to describe design / operational conditions. Flow diagram and model parameters were adjusted to reproduce the influent, effluent and process characteristics. A five week measuring campaign was conducted to compare full-scale measurements and model predictions (more details in Monje et al., 2022a,b) . A set of scenarios are defined to assess with multiple criteria (see **Table 1**). The fate of COD and N was quantified using mass balances/ computer simulations. Hence, it is possible to know the amount of a specific compound that can be recovered, removed, captured within the bio-solids and lost with the effluent. In addition, the analysis includes the assumed capacity for three critical units: the anaerobic granular sludge (AnGSR), the activated sludge reactors (ASR) and the inactivation tank (IT). In case of given scenario, the reactor volume is reduced to maintain the same hydraulic retention time (HRT), a certain degree of capacity liberation is obtained. Economic evaluation criteria are divided between *production* and *consumption* indicators. On the one hand, production includes 1) energy recovery (ER) and 2) mass of bio-solids ($M_{biosolids}$). On the other hand, consumption accounts for 1) energy use (EU), 2) quantity of dosed chemicals (CHEM) and 3) volume of bio-solids to be handled and transported ($V_{biosolids}$) and4) volume of treated water released to the environment ($V_{effluent}$). Once *production* and *consumption* indicators are quantified (plant data, model predictions), revenues (REV) and expenditures (COST) can be calculated using appropriate factors.

Table 1. Definition of the scenarios implemented, simulated and evaluated in this study

Scenario code	Scenario title	Description
S0	Baseline scenario	The default scenario representing the current status of the iWTS.
S1 (CR)	SBM dry inactivation + SEC_{WAS} separated dewatering	Around 1/3 of the spent biomass stream is treated with solid CaO. The remaining 2/3 is sent to the inactivation tanks + The WAS stream does not undergo the inactivation step. Instead, it is sent directly to the DEW
S2 (OP)	S1 + BTL + heterotrophic denitrification of liquid influents + AnGSR is operating at full capacity	The buffer tank liquid is made non-reactive by preventing bio-solids accumulation. Heterotrophic denitrification is promoted in the pre-acidification tank by recycling activated sludge liquor. The anaerobic granular sludge reactor is assumed to operate at its full capacity.
S3 (NT)	S2+inactivation with NaOH + anaerobic treatment of reject water	NaOH instead of CaO is used as dosed chemical to rise the pH in the inactivation tanks. Reject water is re-directed to the anaerobic granular sludge reactor instead of being treated aerobically in the ASR
S4 (NT)	S4 + PN/ANX + in-situ feedback control loop	An additional aerobic granular reactor is added running partial nitration/anammox. PAC dosage is based on in-situ phosphate sensors.
S5 (NT)	S3 + inactivation with heat + anaerobic treatment of reject water	Heat instead of chemical is used as inactivation agent. Reject water is re-directed to the anaerobic granular sludge reactor instead of being treated aerobically in the ASR
S6 (NT)	S6 + PN/ANX + in-situ feedback control loop	Aadditional aerobic granular reactor is added running partial nitration/anammox.PAC dosage is based on in-situ phosphate sensors.

RESULTS AND DISCUSSION

Baseline simulations. S0

The results summarized in **Table 2** indicate that for the incoming COD: 32 % is recovered as energy in the anaerobic granular sludge reactor (AnGSR), 23 % is removed in the activated sludge reactor (ASR), 32 % is captured within the bio-solids cake stream (DEW/IT), 12 % is lost during the fermentation process in the buffer (BTL) and pre-acidification tanks (PAT) and 1 % leaves the plant via effluent ($iWTS_{eff}$). With respect to N, 65 % is removed in ASR, 33 % is captured in DEW_{under} and 2 % end up in $iWTS_{eff}$. Finally when it comes to P, 2% leaves the plant via the effluent ($iWTS_{eff}$) and 98% is accumulated in the bio-solids stream ($IT_{EFF\text{-}ext}$, DEW_{under}) as a result of precipitation. **Table 3** includes additional technical criteria: COD/N and VSS/TSS ratio in the activated sludge effluent (ASR_{eff}) and dewatering underflow (DEW_{under}). Hence, one may see the non-standard values resulting from 1) the high organic/inorganic load arriving to the plant and 2) lime use during bio-solids inactivation. With respect to capacity data (**Table 5**), both ASR and inactivation tank (IT) are assumed to operate at 100 % of capacity. Nevertheless, the AnGSR is assumed to be underperforming. Both measurements and computer simulations (**Table5**) show that the plant´s main source of revenues are the income obtained from the (61%) electricity produced in the biogas turbine ($REV_{electricity}$) and (21%) external processing of the inactivated bio-solids (REV_{biogas}). The main expenditures are: the discharge fee (DF) (38 %), transportation and handling of bio-solids ($COST_{biosolids}$) (29 %), dosed chemicals ($COST_{CHEM}$) (19 %) and power consumption ($COST_{electricity}$, $COST_{pumping}$) (14 %).

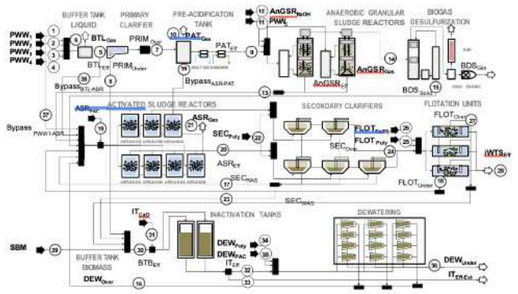

Figure 1. Flow diagram of the iWTS under study: **1–4** Process waste water (PWW_{1-4}), **5,6** - Buffer tank liquid output (BTL_{eff},BTL_{Over}), **7-8** – Primary clarifier overflow and underflow ($PRIM_{Over}$, $PRIM_{Und}$) **9-10** – PAT output (PAT_{eff},PAT_{Und}), **11** - Process waste water (PWW_{1-4}), **12** – Dosing NaOH anaerobic granular sludge reactors ($AGSR_{NaOH}$), **13-14** – anaerobic granular sludge reactors output ($AGSR_{Und}$,$AGSR_{Over}$), **15** – Elemental sulfur recovered (BDS_{Sulf}), **19** – Dosing PAC activated sludge reactors (ASR_{PAC}), **20-21** - activated sludge reactors output (ASR_{Eff},ASR_{Und}), **22** - Polymer dosing secondary clarifiers (SEC_{Poly}), **23,24,17** - secondary clarifiers output (SEC_{Over}, SEC_{Und}, SEC_{RAS}), **25,26** – Polymer and Fe(III) dosing flotation ($FLOT_{Over}$, $FLOT_{FeIII}$), **27,18,28** – Flotation units output ($FLOT_{Over}$, $FLOT_{Under}$, $iWTS_{Eff}$), **29** – Spent biomass stream, **30** - Buffer tank biomass output (BTB_{Eff}), **31** - Quicklime dosing inactivation tanks (IT_{CaO}), **32-33** - Inactivation tanks output (IT_{Eff}, $IT_{Eff,Ext}$), **34,35** – Polymer and PAC dosing dewatering (DEW_{Poly}, DEW_{PAC}), **36,16** - Dewatering under and overflow (DEW_{Under}, DEW_{Over}), **37-39** – Bypasses PWW_1 to ASR, BTL to ASR, ASR to PAT. Considered sub-systems are marked by a dashed line. Black/White arrows are inputs/outputs to the whole system.

Carbon refluxing: S1

As shown in **Table 2**, carbon refluxing increases the accumulation of COD and N in the bio-solids stream (DEW_{under}) up to 38 % and reduces the quantity removed in the ASR (18 % and 59 % respectively). **Table 5** shows that total revenues (REV_{total}) are increased by +9 % due to a higher profit from external treatment of biosolids ($REV_{biosolids}$). Lower energy use (EU), consumption of chemicals (CHEM) and sludge volumes ($V_{biosolids}$) reduce total cost ($COST_{total}$) down to -13 %. Inactivation tank (IT) and ASR capacity is liberated by 50 % and 25 %.

Operational conditions: S2

Change of operational conditions in the buffer tank/anaerobic digester promotes heterotrophic denitrification instead of dissimilatory nitrate reduction to ammonia. Hence, 5 % of the incoming COD is not lost due to fermentative process. COD recovery is increased up to 34 % and 11 % of nitrogen is handled in the pre-acidification tank (see **Table 2**). The latter has implications on $REV_{electricity}$, $COST_{energy}$ and $COST_{biosolids}$ increasing and decreasing REV_{total} and $COST_{total}$ up to + 13 % and down to – 13 %, respectively (see **Table 5**).

New technologies: S3, S4, S5 and S6

Usage of either NaOH or heat (instead of CaO) as inactivation agents allows anaerobic treatment of the reject water, which substantially benefits revenues derived from higher electricity recovery (+44%). However, there is a high toll paid on chemicals (+73%) or heat recovery (-19%) depending on the inactivation technology (see **Table 5**). In addition, partial nitration/anammox and a better poly-aluminum chloride (PAC) dosage strategy is necessary to achieve acceptable (<2%) N and P levels in the effluent (see **Table 2**)

Table 2. Fate of major components within the studied iWTS: plant data, baseline simulation and scenario analysis

	Plant Data	S0	S1	S2	S3	S4	S5	S6	Units
$COD_{recovered}$ – AnGSR	32	32	31	34	45	44	45	44	%
$COD_{removed}$ – ASR	23	23	18	18	13	9	12	9	%
COD_{lost} - BTL/PAT	12	13	12	10	11	12	11	12	%
$COD_{captured}$ bio-solids– DEW/IT	32	31	37	36	30	33	30	33	%

Abstract

Enhanced biological phosphorus (P) removal (EBPR) processes enable P removal and support resource recovery, but can suffer from low carbon availability. Primary or secondary fermentate dosing can support P removal, with approximately 30% of volatile fatty acids (VFAs) produced consisting of butyrate (HBu), valerate (HVa), and their isomers. These VFAs promote the growth of P accumulating organisms over competitors and produce polyhydroxyalkanoates (PHAs) novel to EBPR. An extended VFA model was developed to capture these dynamics and was compared with existing metabolic models. When compared on P-release predictions, the extended model had a NRMSD of 10% compared to the acetate-only model of 35%. This equates to a 60% over-prediction (50 mg P/L) by the acetate-only model, with clear implications for P removal and recovery. Furthermore, the mechanisms described by the extended VFA model support the performance of fermentation-enhanced EBPR processes and identify conditions to promote novel PHAs such as PH2MH.

Enhanced Biological Phosphorus Removal (EBPR), Fermentation, Metabolic Modelling, Polyhydroxyalkanoate (PHA), Resource recovery, Volatile Fatty Acid (VFA)

INTRODUCTION

Enhanced biological P removal (EBPR) processes enable both P removal and support resource recovery. EBPR has been limited due to several factors, namely carbon availability and the resulting process instability. The former can be addressed via dosing of primary or secondary fermentate from on or off-site, however in-situ fermentation is also possible. Of the VFA produced via fermentation, upwards of 30% can consist of butyrate (HBu), valerate (HVa), and their isomers, and could favour the growth of P accumulating organisms (PAOs) over competitors such as glycogen accumulating organisms (GAOs) (Cai, Huang et al. 2019, Gu, Tooker et al. 2019). Mathematical models are used to assist in the design and operation of these processes, however, existing EBPR models describe only acetate (HAc), and occasionally propionate (HPr) uptake. Along with the unique uptake dynamics of these VFAs, this may result in a shift in PHA profile (Wang 2021). This results in a significant shift in predicted process behaviour and therefore undermines the reliability of existing models. The aim of this study was to develop an extended VFA model describing the underlying mechanisms of EBPR when fed these higher order VFAs, and thereby support the design and operation of fermentation-enhanced EBPR and subsequent resource recovery.

MATERIALS AND METHODS

Literature on EBPR process performance, when fed a combination of HAc through to HVa, was used to identify the stoichiometry and kinetics of PAOs and GAOs (Tong and Chen 2007, Wang 2021). Novel PHAs and isomeric VFAs were modelled according to metabolic pathways known to be available in similar organisms. These include the availability of beta-oxidation, conditions for PHA production, redox balancing mechanisms, and VFA uptake. Carbon, energy, and redox balances were conducted over the observed stoichiometry, using modelled pathways and established constraints on metabolite accumulation to identify reaction yields. When conducting these balances, it was identified that further fermentation of HBu and HVa may be occurring, resulting in PAO/GAO uptake of additional HAc and HPr. The stoichiometry of these systems also suggested synergistic uptake of VFAs, acting as a redox balancing mechanism for novel PHA production from HBu/HVa substrates. External fermentation, relative to modelled PAO/GAO populations, and simultaneous substrate uptake was therefore included to capture these dynamics. Furthermore, observed PHA fractions indicated reversible external or internal isomerisation of HBu. This was modelled as a kinetic impact, rather than stoichiometric, given the equivalence of these isomers on metabolite balances. Maintenance, inhibition, sequential use and regeneration of storage products, and state variables to describe PAO/GAO metabolism were modelled according to established methods (Santos, Rieger et al. 2020). The extended model was implemented within Dynamita's Sumo. Model fit was assessed between observed and predicted values via the normalised root mean squared deviation (NRMSD). The extended model was compared to established models over both calibration and validation datasets.

RESULTS AND DISCUSSION

Existing metabolic models were found to over-predict P-release by 35-60% (or 30-50 mg P/L) under fermentation-enhanced EBPR conditions, as shown in **Figure 1**, with the latter representing the more commonly used HAc-only metabolic model. This is compared to the 10-30% (or 10-25 mg P/L) over-prediction by the extended VFA model, with the former more closely representing an acclimatised yield calibration on the full range of VFAs. These discrepancies in P release have direct consequences when modelling P removal and recovery processes, particularly over-time. As shown in **Table 1**, acclimatisation to these VFAs relates to the reliance of the system on external fermentation of HBu and HVa. As shown in **Table 2**, as this reliance declines, and more HBu/HVa is directly consumed by PAOs, the extended VFA model validation fit improves. For GAOs, the acclimatisation process is hindered by their relatively inflexible metabolism. Due to their reliance on glycogen for anaerobic ATP, to consume HAc or HPr, GAOs require electron sinks to balance their internal redox. GAOs achieve this by reducing the products of glycolysis to Pr-CoA, rather than oxidising them to Ac-CoA. As HBu and HVa are more reduced than HAc or HPr, this ratio of reduction to oxidation is increased accordingly. Alternatively, HAc or HPr could be balanced with HBu or HVa uptake to manage reducing equivalents. In contrast, PAOs can freely utilise both balancing mechanisms as required, producing PHAs of PHH/PH4MV from either simultaneous HAc/HBu uptake or glycolysis. Interestingly, the increased production of Pr-CoA required by GAOs with the uptake of HBu is likely what promotes the novel PHA, PH2MH, over the more readily formed PHH/PH4MV.

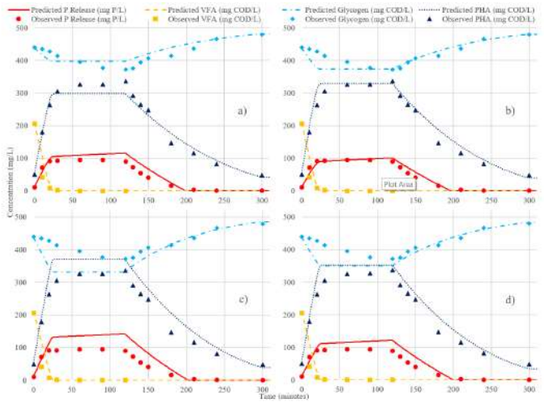

Figure 1. Comparison of extended VFA models (a and b) and existing metabolic models (c and d) on the validation dataset (20 °C, acclimatised to/fed HAc/HPr/HBu/HVa/i-HBu/i-HVa to a ratio of 29:28:9:3:14:17). a) Calibrated yields for SBR acclimatised to HPr feed at 30 °C, fed equal ratio of HAc/HPr/HBu/HVa, b) Calibrated yields for SBR acclimatised to HPr feed at 30 °C, fed equal ratio of HAc/HPr/i-HBu/i-HVa, c) HAc only metabolic model, d) HAc and HPr metabolic models.

Table 1. Calibrated extended VFA model yields (C-mol basis) according to acclimatisation, population, and VFA uptake ratios, compared to existing models. $C_{2\text{-}5}$ refers to equal ratio feed (5.4 C-mmol/L of VFA) of HAc through to HVa, i-$C_{2\text{-}5}$ refers to isomeric HBu and HVa components.

CONCLUSION

These results indicate that existing EBPR models relying on individual HAc or HPr metabolism are inadequate for fermentation-enhanced processes and subsequent P recovery applications, over-predicting P-release by up to 60%. Furthermore, the interactions of substrates and their impact on stoichiometry suggest that individual uptake models are generally insufficient to describe processes with a variety of carbon sources. Acclimatisation to the feed substrate was also shown to impact stoichiometry. This finding demonstrates the importance of metabolic flexibility to fermentation-enhanced process modelling, and highlights the importance of acclimatisation in study design. The improved process stability of fermentation-enhanced EBPR configurations can be partly explained by these findings, as GAOs possess fewer means of adapting to the variety of substrates produced through fermentation and therefore competing with PAOs. Finally, the extended VFA model provided insight into the conditions required to produce PHAs novel to EBPR processes.

Abstract

In this work, a mathematical model was developed to describe the long-term operation of a sulfate-fed 2.5L UASB reactor targeting non-methanogenic, sulfidogenic conditions initially inoculated with methanogenic, non-sulfidogenic sludge. Crude glycerol was used as electron donor to achieve sulfate reduction. The hydraulic model of the UASB was described as a set of CSTRs in series to represent its plug flow-like behavior. The kinetic model included 8 fermentation processes using glycerol as the primary electron source, 5 sulfate-reduction processes using organic and inorganic electron sources, and 2 methanogenic processes. The gradual loss of methane production capacity was described by adding a non-competitive inhibition term as a function of the long-chain fatty acids concentration. A sensitivity analysis and calibration of the most relevant parameters was performed using the experimental data from 300 days of continuous operation of a lab-scale UASB. Carbon and sulfur species profiles as well as microbial dynamics from initial methanogenic conditions to non-methanogenic but sulfidogenic conditions were properly predicted by the model under dynamic simulations.

LCFA inhibition; mathematical modeling; model calibration; sensitivity analysis; sulfate reduction; UASB reactor

INTRODUCTION

Treatment of sulfate-rich effluents in sulfidogenic reactors has been proposed as a sustainable alternative for the recovery of metals from S- and metal-rich effluents (SULFATEQ process) as well as the recovery of elemental sulfur from SOx-rich waste gases (SONOVA process, Mora et al., 2020). In such processes, the first stage of the biological treatment is based on sulfate reduction (SR) to sulfide, often carried out in UASB reactors. Amongst others, crude glycerol has been shown as a proper electron donor for SR (Mora et al., 2020). However, Zhou et al. (2022a) reported a progressive loss of performance after 100 days of operation due to degranulation and granule flotation related with the formation of a slime-like substance that contained a high concentration of long-chain fatty acids (LCFA), particularly palmitic acid, which can inhibit methanogenesis (Deaver 2020). In addition, several authors have reported a change in the performance of UASB reactors inoculated with methanogenic sludge when sulfidogenesis becomes a competitive process for the C source. Under certain conditions, methanogenic activity is lost, leading to an increase in the outlet chemical oxygen demand (COD), primarily in the form of volatile fatty acids (VFAs), essentially acetate.

In this work, data from Zhou et al (2022a) from the long-term operation of a lab-scale UASB reactor targeting SR using glycerol as an external carbon source was modeled. A sensitivity analysis of the model was conducted in order to determine the most relevant parameters, and the model was calibrated using the experimental data from the operation of the lab– scale reactor. The model targeted the representation of long-term dynamics of the main C and S species, as well as VSS, including a gradual inhibition of methanogenesis caused by LCFA accumulation inside the reactor.

MATERIALS AND METHODS

The UASB was discretized in a set of *n* mini-CSTRs – vertical layers – in series as previously reported (Rodriguez-Gomez et al., 2014). The kinetic model is based on the anaerobic digestion model no 1 (ADM1, Batstone and Keller 2003) with additional processes accounting for glycerol fermentation and SR, which had been studied and mechanistically determined by Zhou et al. (2022b). The model considers 5 biomass trophic groups (fermentative bacteria X_{FB}; heterotrophic and autotrophic sulfate reducers, X_{HSRB} and X_{ASRB}; hydrogenotrophic and acetoclastic methanogens, X_{HM} and X_{AM}) which carry out 15 biochemical processes: glycerol fermentation and acidogenesis of fermentation products (8), heterotrophic SR (4), autotrophic SR (1), hydrogenotrophic methanogenesis (1) and acetoclastic methanogenesis (1). Consumption rates of a given substrate (S_i) in process *j* followed a Monod – type kinetic equation, which is defined by the maximum specific growth rate km_j (mg S_i mg VSS^{-1} d^{-1}) and the semisaturation coefficient, ks_i (mg S_i L^{-1}). Accumulation of LCFAs and slime formation were simulated according to the experimental results reported by Zhou et al. (2022), and the inhibitory effect of LCFAs on biomass growth was modeled with a non-competitive inhibition term (Ma et al., 2015).

A sensitivity analysis was performed in order to assess the most sensitive parameters of the model by means of a local analysis, i.e., the effect each parameter over the simulated output variables was assessed varying each parameter one at a time, with increments and decrements of ±10%. The local sensitivity of all parameters was evaluated throughout the 300 simulated days of operation. After performing the sensitivity analysis, the most sensitive parameters (i.e., the parameters with the highest relative sensitivities) were selected for calibration. The fitting of the experimental data considered VSS (mg VSS L-1), methane and total inorganic carbon (TIC) flows (mg C d^{-1}) and acetate (mg C L^{-1}) to minimize the objective function. Sulfide was not included in the objective function because the formation of organosulfur compounds experimentally observed was not mechanistically described. Model implementation and calibration was done using MATLAB R2021b.

RESULTS AND DISCUSSION

Prior to the sensitivity analysis, the active fractions of each biomass population were calibrated using the experimental data of the first 30 days of operation. Additionally, other key parameters were pre-calibrated to values within a range known to impact the model in order to improve the reliability of the sensitivity analysis.

The preliminary sensitivity analysis results are shown in Figure 1, which suggest a particularly strong impact of the parameters influencing solids dynamics along the reactor.

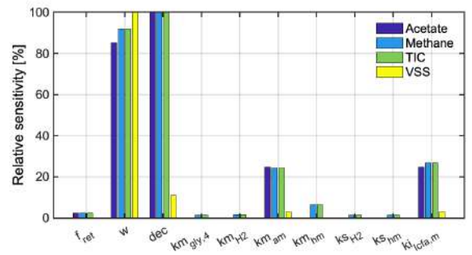

Figure 1. Sensitivity analysis results, where the relative sensitivity of each parameter (%) over a variable is calculated based on the maximum sensitivity value obtained for such variable. Relative sensitivity (%) values of each parameter over acetate, methane, total inorganic carbon (TIC) and volatile suspended solids are represented. Only parameters that displayed a relative sensitivity above 1% over any of the analyzed variables are shown.

After sensitivity analysis, the following parameters were selected for model calibration: *w, dec*, km_{am}, km_{hm}, $ki_{lcfa,m}$. The preliminary calibrated values are shown in Table 1.

Table 1. Calibrated parameters of the model. A brief description of each parameter is shown, as well as the units, the preset value and the final calibrated value.

Parameter	Description	Units	Preset value	Calibrated value
w	Wash-out constant for solids, which factors the flow-rate thus affecting the retention time	-	0.0012	0.0011
dec	Decay rate for all biomass populations	d^{-1}	0.02	0.033
km_{am}	Maximum specific growth rate of acetoclastic methanogens	mg C mg VSS^{-1} d^{-1}	27.6	53.28
km_{hm}	Maximum specific growth rate of hydrogenotrophic methanogens	mg H_2 mg VSS^{-1} d^{-1}	11.28	333.6
$ki_{lcfa,m}$	Inhibition constant of long chain fatty acids over methanogens	mg COD L^{-1}	50	4.5

Figure 2 represents the profiles of TIC, methane, acetate and VSS after model calibration.

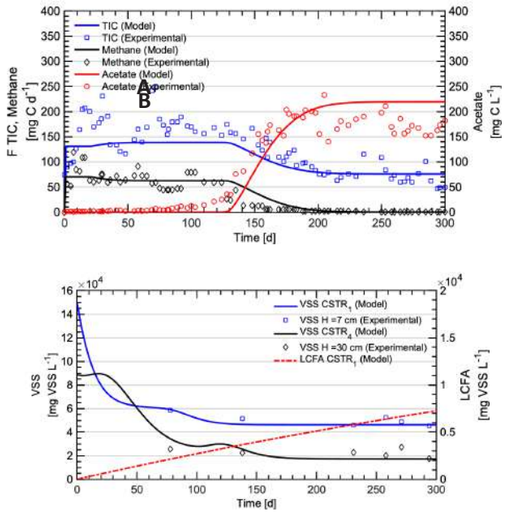

Figure 2. Model calibration results. A) Fit of total inorganic carbon (TIC), methane and acetate outlets (CSTR at the top); B) fit of volatile suspended solids (VSS) at two different heights of the UASB reactor (corresponding to CSTRs 1 and 4), and LCFA at the bottom of the reactor (CSTR 1).

As it can be observed, the model was able to accurately predict the long-term dynamics of these species including acetate accumulation as a result of the loss of methanogenic activity. As shown in the simulated biomass profiles (Figure 3), such inhibition started taking place on day 80 at the bottom of the reactor, with a LCFA concentration around 2 g VSS L^{-1}, which is in agreement with other studies (Ma et al., 2015). Methanogens were washed out from the bottom layer by day 173, whereas a small fraction was still present in CSTR4 (equivalent UASB height = 28 cm), which is in line with the results obtained by Fernández et al. (2022), which showed a total wash-out of methanogens from the system by day 230.

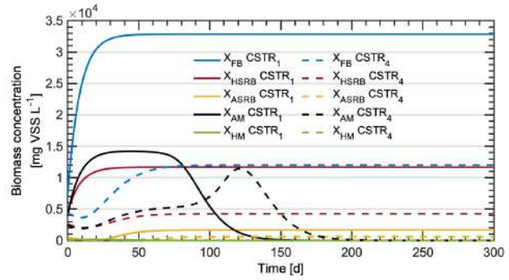

Figure 3. Simulation of the 5 biomass populations at two different heights inside the UASB: 7 cm (CSTR 1) and 28 cm (CSTR 4), after model calibration.

The results from this work, albeit still in process, portray the capacity of the model to predict long-term dynamics of biomass, C and S species in a sulfidogenic UASB accounting for LCFA inhibition.

Abstract

Trace metals (TMs) are often dosed into anaerobic digestors to improve biogas yield. TM bioavailability driven by metal speciation influences stimulatory, inhibitory or toxic effects of trace metals on anaerobic digestion (AD) process. Metal speciation is affected by chemical equilibrium and kinetics of physiochemical processes. This study presents a modified Anaerobic Digestion Model 1(ADM1) where the biochemical and physiochemical framework is extended to include trace metal effects on AD. The model includes processes like uptake of metals, precipitation of metals, inorganic complex formation and organic complexation with metabolites. Model results shows influence of trace metal and sulphur concentration present in the substrate on anaerobic digestion process and significance of trace metal dosing to improve the digestor performance.

Keywords

ADM1; bioavailability; metal dosing; anaerobic digestion; trace metal speciation

INTRODUCTION

Anaerobic digestion (AD) is proven to be one of the most economical and effective technologies for the treatment and recovery of waste. AD offers benefits such as biogas production, electricity, heat, high-quality fertilizers, complete recycling of organic waste, greenhouse gas reduction and environmental protection, in addition to reduced operating costs and smaller carbon footprint. Supplementing trace metals (TMs) to enhance AD performance is one such proven technique (Choong et al., 2016; Feng et al., 2010; Thanh et al., 2016). Trace metals are required at optimum concentrations in an AD system as they play an essential role in composition of enzymes and cofactors involved in AD pathways. For example, Iron (Fe) serves as a redox carrier in an AD system and is an important structural component of majority of enzymes present in anerobic digestion processes. Dosing Fe has been discovered to useful in AD for reducing hydrogen sulphide (H2S) formation, increasing propionate conversion rate, accelerating hydrolysis and acidogenesis and reducing volatile fatty acids (VFAs) accumulation (Choong et al., 2016).

Optimum concentration of trace metals (TMs) is essential for an effective operation of an anaerobic digestion system. Metal bioavailability is driven by metal speciation and is influenced by factors like operational conditions (temperature, pH, organic loading rate), reactor type and feedstock. Supplementing TMs can result stimulatory, inhibitory or toxic effects of trace metals on anaerobic digestion (AD) process. Moreover, excess supplementation is costly and causes undesirable metal concentration in the final digestate. Hence, optimisation of TM dosing is significant and a model-based approach will help in obtaining tailor made solutions applicable to each individual case.

Trace metals are commonly supplied to biogas plants through feedstocks and bioavailability of TMs greatly varies with feedstock characterisation, mainly classified as phosphate rich, sulphur rich, lignocellulose rich and lipid rich feedstock (Roussel et al., 2019). Wheat stillage for example has low trace metals with high sulphur concentration and is not an ideal substrate for anaerobic digestion whereas swine wastewater contains high concentrations of Cu and Zn (Thanh et al., 2016). Characterisation of maize silage indicated deficiency of Ni and Co (Evranos & Demirel, 2015). This study evaluates the influence of substrate on trace metal dosing during anaerobic digestion using a dynamic model-based study. The dynamic model is an extension of Anaerobic Digestion Model 1(ADM1) and major process influencing TM speciation are added to capture dynamic behaviour of the metals and its influence on cumulative methane production.

METHODOLOGY

This study presents a modified ADM1 where the biochemical and physiochemical framework is extended to include trace metal effects on AD (Figure 1). Extensions made in biochemical module are according to Frunzo et al. (2019). The physicochemical model includes 13 precipitation/dissolution reactions, 96 aqueous phase reactions (acid-base and complexation reactions) and 4 gas stripping processes. The aqueous phase chemistry module is defined under non-ideal conditions to consider ionic strength effects by considering ion activity instead of molar concentrations. Kinetics of all possible inorganic complex formation and organic complexation with metabolites like volatile fatty acids are also included in the model. Aqueous phase reactions are formulated as nonlinear algebraic equations and modelled as equilibrium reactions as happen very fast and reaches chemical equilibrium rapidly (Barat et al., 2011). Precipitation reactions, biochemical reactions and gas transfer occur relatively slow and are modelled as kinetic reactions. Ordinary differential equations formulated based on mass conservation principle for each of soluble, particulate, gaseous and precipitate components define dynamics of those model components. for soluble (, Eq. (1)), particulate (Eq. (2)), gaseous (Eq. (3)) and precipitate (, Eq. (4)) components.

Process equations are implemented in an original MATLAB code and simulations were performed to study influence of substrate type – phosphate rich, sulphate rich and metal concentration in the sludge.

RESULTS AND DISCUSSION

Simulations were performed to test model performance. Figure 2 shows the effect of concentration of trace metal (iron) on cumulative methane production. Methane production increased when iron concentration in the substrate is increased stepwise from 0 µM to 100 µM. This shows stimulatory effects of iron on anaerobic digestion. However, when iron concentration is further increased to 1 mM, methane production drastically decreased. This is due to inhibitory effects of iron on methane production. Similar effects were observed for Co and Ni (plots not shown). Hence concentration level of TMs in substrate is significant during anaerobic digestion. This shows that dosing TM under deprivation during anaerobic digestion can significantly improve yield of the digestor. However, excessive dosing can cause negative effects due to inhibitory and toxic effects. Speciation of iron over time for different iron concentrations is given in Figure 3. For a defined sulphide concentration present in the system, FeS precipitation increases with increase in Fe until no more sulphide is available. Other non-labile Fe species present in the system are negligible. It is evident that sulphide precipitation drives the speciation and bioavailability of iron in the system. Hence, sulphur concentration in the substrate is another important factor and a thorough characterisation of substrate (particularly metal and sulphur concentration) is significant before dosing trace metals. The model is also tested for its adaptability under various scenarios like changing ionic strength, pH and sulphide concentration. Model presented in the study is a good prediction tool to decide metal dosing concentration during metal supplementation.

Abstract
This study demonstrates the application of CFD (computational fluid dynamics) modelling for the design optimization of WWTPs through two different case studies. In the first case, three configurations of the aeration system in a tank were investigated by studying the gas hold-up and mass transfer efficiency. A second case is about comparing two mixers' efficiency in a certain sludge buffering tank. Out of each case, one design scenario was selected based on the desired design parameter. As a result, using CFD modelling aided the analysis of various design scenarios with less amount of time, cost and effort.

Keywords
aeration; CFD; digitalization; mixing; sludge buffer; digital design

INTRODUCTION

The smart design of prospective wastewater treatment plants (WWTPs) needs to provide optimal performance in addition to efficiency in energy consumption and low-emission output [1]. Renovation and upgrading of the existing units of a WWTP require fulfilling the same criteria. To achieve these, common methods are investigations on lab or pilot scale and scale-up. However, limitations in the number and type of tests and safety issues as well as the cost and time, call for more promising methods. With the aid of CFD modelling, principally, there is almost no limitation to trying different design scenarios either for optimization or scale-up. At the same time, the costs of simulation are substantially lower especially compared to the build-up of a pilot scale set-up [2]. Moreover, considering the time that it takes from construction to experimentation, CFD results will be available faster. In this paper, design scenarios for two different wastewater treatment units were investigated and aided by CFD modelling: one aeration unit and one sludge buffer tank. Including all the aforementioned advantages, the outcomes assist in selecting a final optimized design.

MATERIALS AND METHODOLOGY

To perform CFD simulations, the first step is making the computational domain which includes the geometry (CAD drawings) and meshing (discretizing the geometry to sufficiently fine cells for the processing phase). The next step is defining settings and methods to run the simulation and finally post-processing to present the results in an illustrative and intuitive form. All these steps were employed for two cases: the design of an aeration tank and the mixing strategy of a sludge buffer.

Aeration tank

Used as the main part of the secondary treatment process, aeration tanks play a vital role in biological wastewater treatment plants. However, due to the high energy demand for providing sufficient air in the tank, an optimal layout of this process is required.
Using CFD modelling, three different setups (Figure 1) as design scenarios are compared for an Aquafin WWTP aeration tank in Belgium. The air flowrate is 800 m^3/h and an assumed bubble size of 2 mm diameter is applied for all configurations to allow for efficiency comparison.

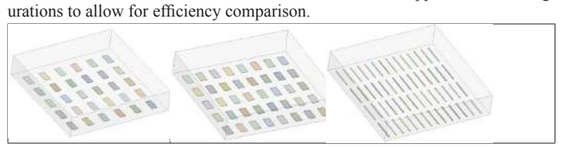

Figure 1. Three configurations of aerators in the same tank: 1) 30 rectangular plates 2) 40 rectangular plates 3) 56 rectangular narrow plates

Sludge buffer tank

The main application of a sludge buffer tank is known to blend and homogenize sludges from different feeds (primary, secondary or digested). Since the content of the tank will be sludge with a high viscosity, a mechanical mixer is needed for better homogenization. Hence, the selection of a fitting mixer design becomes crucial.
In the studied case, Aquafin is designing a sludge buffer and wants to compare two possible types of mixer (Figure 2). In both cases, there is one centrally placed mixer. Its position depends on the type: the top-entry mixer is place 6 meters deep, the hyperboloid mixer at 4 meters deep. The mixing is quantified with the tracer method.

Figure 2. Geometries of two basins with the mixing systems: 1) 2-blade impeller 2) hyperboloid mixer

RESULTS AND DISCUSSION

Aeration tank

The modelling outcomes allow visualizing the flow of both water and air. Water flow profiles at 0.92m from the bottom (Figure 3) imply that the 3rd configuration provides lower velocities, point-wise, but results in more uniform velocity inside the tank with fewer dead zones.
The aeration efficiency is quantified based on the kLa value. As illustrated in Figure 4, for configuration 3 the tank experiences higher kLa overall than other configurations which follow the discussed results of water velocity profiles.
Additionally, based on the gas hold-up and volume-averaged of kLa (Table 1) it can be concluded that configuration 3 performs better with the same air inlet conditions.

Table 1. Gas hold-up and volume averaged of kLa for three configurations

	Gas hold-up [m^3]	kLa * 10^{-3} volume averaged [1/s]
Config. 1	2.7	2.5
Config. 2	2.9	2.6
Config. 3	3.2	2.9

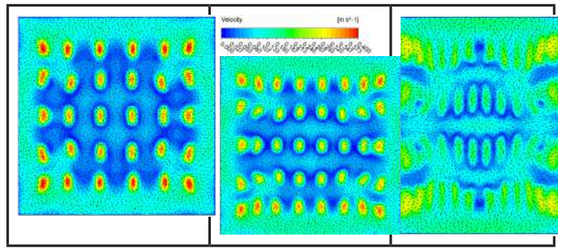

Figure 3. Velocity profiles of water in three different configurations

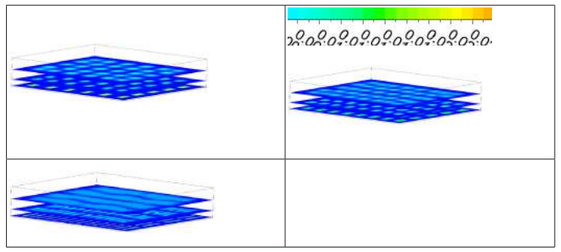

Figure 4. Distribution of kLa at three different depths of the tank for each configuration

Sludge buffer tank

In this case, the simulations aim to compare the performance of two different mixing configurations and check whether both options mix the sludge equally well over the entire volume. For a fair comparison, the mixers' rotation speed was modified with the goal to use the same available power input. Comparing the velocity profiles (Figure 5), it is observed that the 2-blade mixer delivers higher velocity at the top of the tank while the hyperboloid mixer has more impact at the bottom. However, both set-ups aid the recirculation of sludge in the tank. Table 2 gives a better insight into the velocity distribution and mixing by comparing the volume fraction of similar velocities. The 2-blade impeller provides more high-velocity regions than the hyperboloid mixer which implies more active mixing.

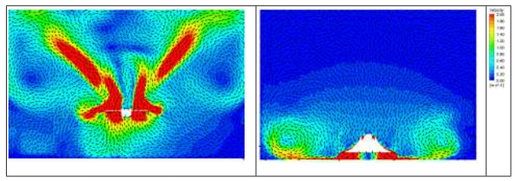

Figure 5. Velocity profiles of sludge at two mixing systems

Table 2. Velocity distribution inside the tank based on volume percentage for two mixing systems

	2-blade imp.	Hyperboloid mix.
Volume % of 0.5 m/s velocity and less	29.3	13.7
Volume % of 0.1 m/s velocity and less	98.1	35.3
Volume % of 0.01 m/s velocity and less	99.9	93.0

Last but not least, doing a virtual tracer test gives an overview of the residence time distribution of each configuration. A Rehman-Nopens (RN) [3] curve (Figure 6) is used for the calculation of the Cumulative Variables Distributions representative of the tank homogeneity. Typically, steep RN curves indicate homogeneous zones in the variable, while less steep slopes indicate a higher degree of heterogeneity. Although both curves are steep, which implies sufficient mixing for both configurations, it is even steeper for the 2-blade mixer which indicates more homogenous mixing. The hydraulic retention time (HRT) has been calculated based on the volume flowrate through the inlet and the volume of the tank. Better performance of the 2-blade impeller is observed again.

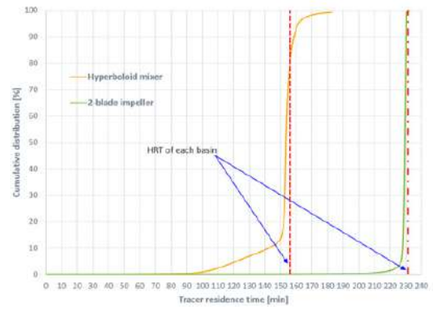

Figure 6. RN curve of residence time distribution based on the tracer test for two mixing systems

CONCLUSION

Two case studies are presented to highlight the potential of CFD modelling for aiding the water technology sector. This helps to achieve optimized designs in a shorter amount of time and at a lower cost. The technique is able to do virtual tracer tests, to observe the velocity magnitude and trajectories at any point in the design. Additionally, extracting local and average gas hold-up and kLa values assist in making design decisions.

Abstract

Produced water (PW) is a waste stream of crude oil extraction with high content of organic materials, metals and high salinity. Membrane aerated biofilm reactors (MABRs) can be a method to reduce the organic matter and toxicity of this streams prior to discharge in the sea. Given the limited space on offshore platforms, it is preferred to locate the reactor on the seafloor. This could result in energy savings due to more efficient oxygen mass transfer at high pressures. Treatment of PW by three MABRs operating with lumen pressures of 0.2, 0.6 and 1.0 bar oxygen was investigated at laboratory scale. Reactors were fed continuously at hydraulic retention times (HRTs) of 24, 12 and 6 hours. After adaptation, 24 h batch experiments were conducted to assess biokinetics. All reactors removed a large fraction (up to 55 – 75%) of the organic content. The initial toxicity was completely removed with 24 hours.

Keywords

Produced water; membrane aerated biofilm reactors; toxicity removal.

INTRODUCTION

Produced water (PW) is a term used in oil and gas industry, which refers to the water discharged during crude oil extraction. This water typically contains high concentration of organics, metals and other pollutants and is toxic to aquatic ecosystems. Over the years, the amount of PW generated has been steadily increasing with the ageing of oilfield production wells. The nature of PW and the discharge limits in water bodies do not permit its direct disposal into these recipients. The need for effective and efficient treatment is growing significantly. Membrane aerated biofilm bioreactor (MABR) is a compact technology that can effectively treat recalcitrant and toxic organics. In a MABR, a biofilm grows on an oxygen permeable membrane where it is immobilized. Oxygen diffuses through the biofilm from the dry side and pollutants from the water side (i.e., counter diffusion) allowing for water treatment. It is more competitive than other biofilm systems due to high oxygen transfer efficiency, high chemical oxygen demand (COD) removal and energy efficiency. In case offshore crude oil extraction a compact technology with small footprint due to offshore restrictions (weight and space) is needed, preferably operating at seafloor level. Aeration plays a significant role in pollutant removal efficiency in MABRs and its efficiency is affected by pressure. The purpose of this study is to evaluate MABR treatment capacity in terms of organics removal and associated toxicity using PW from an offshore oil field in the North Sea at different oxygen partial pressures.

MATERIALS AND METHODS

The reactors were made of clear acrylic sheets and had a working volume of 250 mL. Thick silicone sheets (Aaa-Acme Rubber Co) were chosen as membranes, placed in-between the acrylic sheets. PVC tubes were used for the influent and effluent from the MABRs while a recirculation line was introduced by using a PharMed® BPT tubing. The influent flow was adjusted to achieve 24, 12 and 6 hours of hydraulic retention time (HRT) respectively. A recirculation flow was set high to ensure complete mixing inside the reactors. Each reactor was aerated from the dry side with different oxygen partial pressures (1.0 bar and 0.6 bar O_2), from cylinders supplied by Air Liquide Danmark A/S, and pressurized air at 0.2 bar. As a result, the simulation of partial pressures at sea level, 40, 20 m below sea water level depths were achieved. The oxygen in the reactors was fed intermittently and the oxygen load was controlled at 0.3 L-O_2/hour, 0.6 L-O_2/hour and 1.2 L-O_2/hour for HRT of 24, 12 and 6 hours respectively, matching the COD load. The inoculum was taken from the detached biomass from biofilm reactors adapted to onshore PW from oil and gas production, adjusted to have similar salinity and organic load as PW from the offshore platform in the North Sea. Both had characteristics which were within the range reported by (Al-Ghouti et al., 2019; Nasiri and Jafari, 2017) for different types of PW (Table 1). The same water was used as a feed to grow the biofilm in the MABRs. In the first month, the reactors run in batch mode with the onshore PW until steady state was reached. Then changed to continuous mode using the same feed. Samples were taken frequently from the reactors to measure the total nitrogen (TN), total phosphorus (TP) and COD (total and soluble). Batch experiments were carried out with PW from the offshore platform in North Sea aiming to understand the organic compound kinetics removal based on soluble COD removal. First, the reactors were adapted to the new feed by operating with continuous flow for 48 hours. Starting batch conditions consisted of half treated and half untreated PW. Each batch lasted 24 h. Samples for pH, TN, TP, conductivity, COD, BTEX (benzene, toluene, ethylbenzene and xylene), VFA (volatile fatty acids) and ecotoxicity were taken from each reactor in predefined times. An air-segmented continuous-flow analyzer (SKALAR San^{++}, Netherlands) was used for colorimetric analysis of dissolved inorganic nutrients. Prior analysis all samples were filtered by nylon 0.2 µm filters (Agilent Technologies). The dissolved oxygen concentration (DO) was monitored with an FDO® 925 sensor attached to a Multi 3430 digital meter. The pH, conductivity, COD, BTEX, VFA and ecotoxicity were measured offline as described by Ferreira et al., (2022). For the soluble COD analysis, the samples were pre-filtered with nylon syringe filters 0.2 µm (Agilent Technologies).

RESULTS AND DISCUSSION

The MABRs were monitored for 66 days at HRT of 24 hours of continuous operation, until steady state in terms of sCOD removal and DO concentration was reached. All three reactors achieved similar removal of organics (Fig.1). The sCOD removal reached 83.3%, 81.0% and 82.8% for the reactors with 0.2 bar, 0.6 bar and 1.0 bar respectively, while the DO remained below 0.5 mg/L. Samples from the feed and reactors effluents were measured for total nitrogen and total phosphorus to evaluate potential nitrification and possible phosphorus precipitation. The influent and effluent total nitrogen were on similar levels with almost all of it being in the form of ammonium, indicating no nitrification by the biofilm. Phosphorous was also on similar level in the influent and effluent. Minor removal of both nutrients occurs mostly via microbial assimilation. The biodegradation curves (Fig. 2) from the batch experiment with offshore PW showed that the partial pressure of oxygen did not have a significant effect. The sCOD degradation followed a 1st order reaction kinetics with total achieved sCOD removal at 74%, 49% and 76% for reactors operating with 0.2 bar, 0.6 bar and 1.0 bar oxygen respectively. The lower removal of the 0.6 bar reactor can be attributed to the less developed biofilm. BTEX were removed by 70% within the first hour and by 96% after 9 hours. VFA are removed by 55% after 3 hours and completely after 9 hours of operation. An ecotoxicity assessment (Fig. 3) showed that the initial toxicity was removed (below the toxicity threshold of 3.3 TU_a) after 24 hours. After adjusting the HRT to 12 hours and doubling the oxygen supply the steady state was reached with sCOD removal at 61.1%, 62.6 and 57.4% for the 0.2 bar, 0.6 bar and 1.0 bar reactors respectively. The batch experiment with offshore PW revealed that the majority of the sCOD degradation started after 12 hours of operation in all three reactors while the sCOD removal in the end was 57%, 51% and 46% for the 0.2 bar, 0.6 bar and 1.0 bar reactors, respectively. The lower removal rate can be either due to having already reached maximum biofilm thickness hampering mass transfer or due to toxic compounds with concentrations above the inhibition level for the biomass. The sCOD degradation in this case did not follow a 1st order reaction kinetics (Fig. 2). After 24 h batch, only the MABR operated with 100% oxygen was able to remove all toxicity. When HRT was at 6 hours, sCOD removal efficiency was at 36%, 41% and 49% for the 0.2, 0.6 and 1.0 bar MABRs, respectively. Again, toxicity was only removed by the MABR operated with highest oxygen pressure. This revealed that at high COD loading rate, higher oxygen partial pressure can lead to better performance. The COD removal percentages in this study are comparable to values reported by (Janson et al., 2015) at 54 – 63% and (Kose et al., 2012) at 80 – 85% for real PW treatment with biological treatment processes. Dong et al., (2011) showed also that lower HRT can affect the COD removal from PW.

Table 1. Produced water characteristics comparison.

Water type	pH	Conductivity (mS/cm)	COD (mg/L)	TN (mg/L)	TP (mg/L)
Onshore PW	7.6	68.1	1223	49.6	7.2
PW from oil platform	6.1-8.7	65.4-114.3	440-1794	41-85	0-0.2
Typical PW	4.3-10	4.2-586	1220-2600	0-92	0

Abstract

A mathematical correlation between biomass kinetic and membrane fouling can potentially improve the understanding and the spread of membrane bioreactor (MBR) technology, by solving the membrane fouling issues. On this behalf, this review presents the current state-of-the-art regarding the modelling of biomass kinetic processes, focusing on modelling production and utilization of soluble microbial products (SMP) and extracellular polymeric substances (EPS). The key findings of this work show that the new conceptual approaches focus on the role of different bacterial groups in the formation and degradation of SMP/EPS. There is still a lack of substantial information regarding SMP modelling due to the highly complicated SMP nature. The EPS group has seldom been addressed in the literature, probably due to the lack of knowledge concerning the triggers for production and pathways. Finally, the successful model applications showed that proper estimation of SMP and EPS by modelling approaches can drive the optimization of membrane fouling, which can influence the MBR energy consumption, operating costs, and greenhouse gas emissions.

Keywords
Biomass kinetic models; extracellular polymeric substances; membrane bioreactors; soluble microbial products

INTRODUCTION

Membrane bioreactors (MBR) are widely known as reliable elements of water resource recovery facilities (WRRFs) in terms of effluent quality, low sludge production, well-arranged operation, and spatial requirements (Zuthi et al., 2017). However, membrane fouling issues and, by consequence, high operating costs, are still presented by managers and researchers as significant obstacles to an ever more spread application of this technology (Qin et al., 2018). Studies focusing on experimental data gain to be completed by others using mathematical modelling to obtain answers with less time consuming, predictive possibilities and low cost of implementation (Sun et al., 2016).

The activated sludge model (ASM) family (Henze et al., 2000), formerly developed for conventional activated sludge (CAS) systems, have been expanded to consider the specific biomass kinetics related to MBR bioprocesses. The biomass kinetic models are the modified versions of the ASM-types with the ability to account for the formation and degradation processes of soluble microbial products (SMP) and extracellular polymeric substances (EPS) that are acquainted as being responsible for membrane fouling, which has been one of the main constraints of the MBR technology (Armbruster et al., 2019). Thus, considering the formation/degradation of SMP and EPS is a reasonable approach while assessing the MBR's performance. The aim of this review is to update the findings of the past studies by providing the current state-of-the-art regarding the modelling of biomass kinetic processes, with special attention to the novelties regarding modelling the SMP and EPS formation and degradation processes. Then, the past and current application of hybrid models to MBR is presented with a focus on updates related to bioprocesses. Finally, the main outlooks and conclusions retrieved from the review are presented.

MECHANISMS OF SMP/EPS FORMATION AND UTILIZATION IN MBR

The term SMP has been adopted to define soluble cellular components or debris that are released during cell lysis, lost during synthesis, excreted for some purpose, or diffuse through the cell membrane. SMPs are divided into two groups, as originally proposed by Namkung and Rittmann (1986), including utilization-associated products (UAPs) and biomass-associated products (BAPs). The EPS is a term that encompasses numerous types of organic macromolecules (Gkotsis et al., 2014). They are ensuring the stability and cohesion of the microbial aggregates, such as flocs, granules and biofilms. The EPS can be divided into two fractions, including bound EPS (bEPS) and soluble EPS (sEPS). The first fraction is bound to the sludge flocs, whereas the soluble fraction is able to move freely between sludge flocs and the surrounding liquor. Recognizing SMP and EPS existence and characteristics transformed the mathematical modelling of MBRs since they play an important role in the initial and late fouling stages, respectively (Meng et al., 2017). Despite their importance in membrane fouling, it has to be acknowledged that analytic determination of these compounds is challenging and often inaccurate.

KINETIC MODELS FOR FORMATION AND UTILIZATION OF SMP/EPS

The need to expand the ASM to be applied to MBRs product is based on two rationales: (i) the ASMs were originally designed to address issues related to CAS systems, by considering their specific features (e.g., lower sludge retention time and low organic load with respect to MBR); (ii) they were based on the Monod equations, which are characterized by the prediction that the effluent concentration of the rate-limiting substrate should be independent of the influent substrate concentration (Barker and Stuckey, 1999). A brief historical review of their conceptual approaches is presented in the following section, with a particular attention to the latest progress.

CONCEPTUAL APPROACHES APPLIED TO SMP/EPS FORMATION AND DEGRADATION MODELLING

Historical overview regarding SMP/EPS modelling

The first modelling attempt to estimate SMP was proposed by Luedeking and Piret (1959). The purpose was to characterize microbial product formation from the fermentation of glucose to lactic acid, including the SMP formation as production/utilisation rate based on a growth-associated product (i.e., UAP) and a non-growth associated product (i.e., BAP) (Barker and Stuckey, 1999). Namkung and Rittmann (1986) presented a model in which the UAP formation is controlled by the substrate utilization and the UAPs comprise the direct by-products of substrate utilization and microbial growth. Lu and co-workers (2002) were the first to combine the concepts of SMP presented by Namkung and Rittmann (1986) to the ASMs for MBR studies. Aquino and Stuckey (2008) proposed a new approach to model EPS formation under anaerobic conditions as a non-growth associated process. Jiang et al. (2008) assumed that BAP degradation was the hydrolysis process yielding readily biodegradable substrate (S_s).

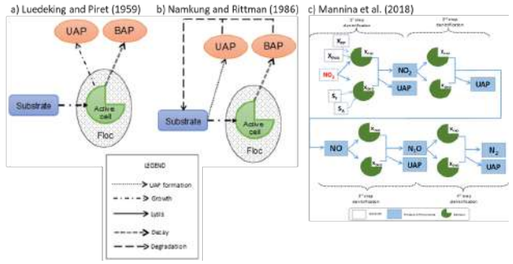

Figure 1. Some conceptual models of the formation/degradation of SMPs used in typical modelling studies (a and b); (c) Four steps of denitrification process considered by Mannina et al. (2018).

New development of conceptual approaches regarding SMP/EPS modelling

This section contains the most recent information regarding modelling SMP and EPS in MBR systems during past ten years. Janus and Ulanicki (2010; 2015) presented ASM-based models being able to account for the formation of SMP and EPS. The work of Janus and Ulanicki (2010;2015) inspired a new model proposal by Mannina et al. (2018), which presented a comprehensive integrated MBR model to assess organic matter, nitrogen and phosphorus biological removal, and greenhouse gas (GHG) formation (Figure 1 c). The processes of SMP formation and degradation and MLSS concentration are considered as an interaction among the biological and physical processes.

PERSPECTIVES

The establishment of modelling approaches is recommended in view of encouraging new findings that may lead to a wider knowledge regarding the EPS formation/degradation. MBR models should be calibrated and validated on the basis of data retrieved from full-scale WRRFs treating real wastewater in order to consider their real response to dynamic changes in influent composition and operating conditions. Finally, the influence of these components on MBR optimization could appropriately be validated provided that, during model simulations, they could be correlated to optimization outputs (e.g., membrane fouling, energy consumption, operating costs, GHG emissions), which has been successfully done before. In practical MBR operations multiple factors may inflict membrane performance. These can be eventually mistaken as genuine fouling but actually may have causes that lie outside the scope of a model. The inevitable but neglected presence of other adverse effects on membrane performance (e.g. coarse fouling, module blocking, filter integrity, uneven flow distribution etc.) which are common at full-scale installations might lead to an overestimation of the role of EPS and SMPs in a model. Thus these modelling approaches have to be used with caution and uncertainties on all stages of the model formulation, data collection, set-up, calibration and validation should be taken into account while rules of good modelling practice are applied.

CONCLUSIONS

- There are some remaining gaps in the literature about SMP and EPS, due to highly complicated nature of SMP and to the lack of information on triggers for EPS production.
- Most of the data used for modelling SMP and EPS from experimental estimation does not represent the dynamic changes in the influent composition and operating conditions.
- The novel conceptual approaches presented focused on the role of each bacterial group in the release of SMP. However, these studies did not consider the direct influence of SMP and EPS over membrane fouling issues, which is an opportunity for future developments.
- Finally, a proper estimation of SMP and EPS can stimulate the optimization of membrane fouling, which directly influence energy consumption, operating costs, and GHG emissions.

Abstract: MembraneAeratedBiofilmReactors(MABR)aregainingmoreandmore acceptanceintheplethoraofwastewaterprocessintensificationtechnologies. Computer simulations have contributed to showtheirfeasibility intermsofenergyconsumption and footprint. In this paper, the prediction capabilities of an integrated modelling approach is tested usingfull-scaledatafrom EjbyMølleWWTP+MABRsite(Odense,Denmark).Process performance under two sets of operational conditions could be reproduced with the model. Finally, membrane area is balanced against cost of nitrogen removal for current and future influent loading conditions.

Keywords:processsimulation,nitrificationrates,flowforecasting,sulfideinhibitionand precipitation

INTRODUCION

Mathematical models have proven to be useful tools to virtually study MABRs. The scientific literature offers numerous works dealing with different aspects related to process understanding and optimization. Even though the previous works made a substantial progress in the field of water process systems engineering, there are important aspects that remained untouched. First and foremost, in all these studies, MABR are studied as separate units, but never integrated within the context of a full wastewater treatment plant (WWTP). This is mainly attributed to the softwarelimitation on all these studies (Reichert et al., 2004). The latter made it impossible to study how changes in the operational conditions /control strategies may affect MABR performance (Gernaey et al., 2014). Second of all, previous studies did not includehow water chemistry may change through the biofilm. pH, weak acid/base and precipitation potentially are important aspects when predicting the phosphorus, sulphur and iron cycle (Solon et al., 2017) and the competition between microorganisms and inorganics withinthe biofilm (Feldman et al., 2019). Last but not the least and strongly related to the first point, there are very few references where MABR has been fully modelled as intensification technology given a process layout. Onlyvery fewtheoretical studies have been published up to date (Carlson et al., 2021) . Hence, it is quite difficult to assess the extra value of adding MABR cassettes from a holistic way when it comes to nitrogen removal and/or energy savings

PLANTDESCRIPTION,DATA,MODELS&OPERATIONALCONDITIONS

TheEjbyMølle(EM)Wastewatertreatmentplant(WWTP)inOdense,Denmark,has a 410,000 population equivalent treatment capacity. The MABR is adjacent to an anaerobic zoneat the EM WWTP. Afull-scale hollow-fiber MABR cassette with a total volume of 11.3 $m^3$and a total membrane surface area of 1920 $m^2$is used. External aeration (EA)wasprovidedwithfinebubblediffusers ononesideofthetank to increase the redox conditions inside the reactors. The latter divided the operating space between strategy#1 (#S1) and strategy #2 (#S2). The measured data used in this study comprises 3 years of measurements between June 2018 and December 2020 (1-2 measurementsper week). Samples were taken from 6 locations: 1 point at the raw wastewater inlet, 2 points after the primary (over and underflow), 2 points at the activated sludge section. Hydraulic retention time (HRT), nitrogen load (NL), oyxgen transfer (OTR) and nitrification rate (NR) are obtainedfromtheSCADAsystemandcalculatedasdescribedinUriCarrenoetal.(2021, 2022) and Flores-Alsina et al. (2022). The model is based on the extended version of the ASM2d (with P, S and Fe interactions) (Solon et al., 2017). The multi-scale approach suggested by Feldman et al. (2017) is used to construct the biofilm model. Mass transfer is modified to account for counter-difussional conditions. Biofilm thickness is 1 mm. Steady state is assumed to be achieved after 500 days of simulation. In #S1 and#S2 a PI controller is implemented in order to maintain the DO concentration to 0.01 and 0.15 g/m^3respectively

RESULTS AND DISCUSSION

Results show a 10% mismatch between flow, COD, N and P predictions and measurements in different plant locations (Figure 2). Using the adopted hydraulic retention time (HRT), nitrogen loading (NL), membrane area (MA) and oxygen transfer rate (OTR) it was possible to predict nitrification rates (NR) within the interquartile range. This has been done under the two considered MABR operational conditions:with (#S1) and without (#S2) external aeration (EA) in the bulk liquid (Figure 3). Both dataand model simulations suggest substantial differences in nitrogen conversion. The proposed approach provides additional insights about process perfomance. More specifically, simulations suggest the potential undesirable effects that sulfate (SRB) and iron (IRB) reducing bacteria may have on the overall process performance under #S1. Thelattercould:1)inhibitAOBduetoH2S,2)decreaseO2availabilityforAOBdue to presence of SOB and 3) increase the volume of inorganics (FeS, HFO and S_0) within the biofilm . Figure 4 (a,d) reveals that the higher content of biomass is found in the inner part of the biofilm (in close contact with the membrane). Inert material resulting from biological activity is generated within the biofilm and pushed towards the bulk by convective movement. Organics are rapidly consumed. Results also show the quantityof precipitates will be higher for #S1. With respect to microbial composition (Figure 4b,e),amoniaoxidizingbacteria(AOB)aredominantinsidethebiofilm.Thisis attributed to high affinity of these microbial groups for O2and the availability of substrategiventhe masstransferlimitations. Ordinaryheterotrophicbacteria(OHO) are clearly favoured in the outer parts of the biofilm. Sulfide oxidizing bacteria (SOB) are only present for #S1 in middle layers. It is important to highlight that phosphorus accumulating organisms (PAO) + sulfate (SRB) and iron reducing bacteria (IRB) are only present in thebulk. Figure 4 c and d shows the changeof inorganicsconcentrations along the horizontal axis. Hydrous ferric oxide (HFO) and mineral sulphur (S_0) will be preferentially formed close to the membrane as a result of the re-oxidation of $Fe^{+2}$and H_2S. The middle and outer parts of the biofilm will favour the accumulation of FeS. EDX and qPCR results will be compared with model predictions (Uri Carreno et al., 2022)

A seconario analysis is included where the performance of the EM WWTP is assessed in terms of kgW.h/kg N removed. This is repeated increasing load up to 50%. Model predictions using baseline conditions can be compared to plant data. Additional are included assuming that 3rd anaeaobic reactor is converted into a full scale MABR (with the same A/V ratio as the pilot). Results show that with an MABR N can be removed with a lower energetic expenditure compared to the default activated sludge configuration (Figure 5a).

Assuming an electricity cost of 0.062 Euro/kWh, it is possible to calculate the yearly savings (in terms of electrical costs) when comparing the two treatment solutions. Hence, at the default loading conditions, the model reveals that the WWTP + MABR implementation would save around 25,000 Euro/year. This difference would be increased up to 70,000 Euro/year in the event of having an increase of the incoming N load. More details in Figure 5b

Abstract
Optimization of biogas production, limitation of energy requirements as well as innovative fouling control are among the challenges to be studied to allow the expansion of anaerobic membrane bioreactor (AnMBR). In this regard, Granular Anaerobic Membrane Bioreactor (G-AnMBR) is a promising biotechnology that incorporates anaerobic digestion, granular sludge and membrane separation processes. The study revealed the ability of the G-AnMBR to meet excellent treatment performance and to increase the organic to methane conversion rate in comparison to a granular anaerobic digester (i.e. UASB), resulting in a positive net energy balance of 0.58 kWh produced per m3 of treated water. The supernatant fraction (dp < 0.125 mm) was identified as key driver in G-AnMBR fouling, in contrast to the granules (dp ≥ 0.125 mm) whose effect was negligible. Synergetic interactions between granules and supernatant compounds lead to a decrease in both fouling intensity and fouling rate, demonstrating the benefit of using granular biomass. Thus, this research highlights the high potential of G-AnMBR with submerged membrane and without biogas sparging for the treatment of domestic wastewater at ambient temperature.

Anaerobic digestion; domestic wastewater; energy recovery; granular sludge; membrane bioreactor

INTRODUCTION

Granular Anaerobic Membrane Bioreactor (G-AnMBR) is a promising bioprocess for energy-positive domestic wastewater treatment through the combination of anaerobic digestion, granular biomass and ultrafiltration membrane separation. If properly exploited, the synergy between these three technologies would allow the implementation of treatment systems that are efficient, energy self-sufficient, low-cost, low-maintenance, low-resource and with a potential for wastewater reuse. Nevertheless, the applicability of G-AnMBR to domestic wastewater treatment is hampered by the difficulty of achieving a positive energy balance (i.e. lower biological activity at ambient temperature, loss of dissolved methane within the effluent, low organic loading rate) and sustaining high filtration fluxes due to membrane fouling. Thus, the overall objective of this study was to implement an innovative G-AnMBR configuration in order to (i) maximize the conversion of organic matter into methane and (ii) minimize energy consumption. This G-AnMBR integrates a granular anaerobic digester (UASB type) combined to an immersed ultrafiltration membrane and does not use gas sparging for fouling mitigation.

MATERIALS AND METHODS

A granular anaerobic membrane bioreactor (G-AnMBR) and an upflow anaerobic sludge blanket (UASB), as a control reactor, were continuously operated in parallel during 120 days. The two reactors were inoculated with granular sludge previously acclimated during 12 months to the domestic wastewater characteristics (i.e. low COD concentration (400 $mg.L^{-1}$) and ambient temperature of 25°C). The two experimental lab-scale reactors had equal working volume of 6.7 L and functioned in the same operating conditions with a hydraulic retention time (HRT) of 13 h and an organic loading rate (OLR) of 0.5 kg $COD.m^{-3}.d^{-1}$. An intermittent filtration cycle of 10 min was operated as follows: (i) 8 min 15 s of filtration, (ii) 30 s of initial relaxation, (iii) 45 s of backwash and (iv) 30 s of final relaxation. The net filtration flux was maintained at 1.45 ± 0.35 $L.m^{-2}.h^{-1}$ (LMH). Treatment efficiencies were evaluated in terms of tCOD, sCOD, DOC, VFA, nutrients and MLSS removals. The granular sludge behaviour was evaluated through particle size distribution (PSD). Transmembrane pressure recording (TMP) and three-dimensional excitation-emission (3DEEM) analysis were performed to evaluate membrane fouling during long-term experiment. In addition, specific analyses were conducted to determine the fouling behaviour of the anaerobic granular sludge. Raw mixed liquor of G-AnMBR was split by sieving at 0.125 mm into granules (d_p ≥ 0.125 mm) and supernatant fractions (d_p < 0.125 mm). Then, the fouling potential and reversibility of the different samples (granules, supernatant and raw mixed liquor) were assessed by filtration tests. Various hydrodynamic conditions, i.e. gas sparging and recirculation, were applied to evaluate the impact of shear stress on fouling propensity. Hence, a liquid recirculation of 24 L/h (RE) and two aeration flow rates of 25 L/h (A25) and 100 L/h (A100) were applied resulting in shear stress of 15, 205 and 409 s-1 respectively.

RESULTS AND DISCUSSIONS

Long-term treatment performances

Following the 12 months of acclimation and the 4 months of operation, it has been demonstrated that:

i. G-AnMBR was stable and efficient almost from the beginning whereas a transient period of 1 month was observed for UASB (Figure 1).

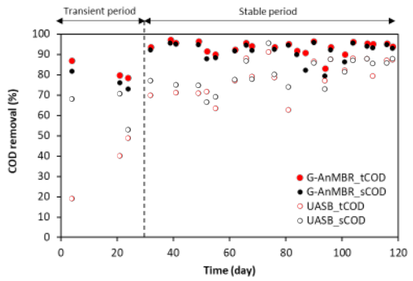

Figure 1. Total and soluble COD removal efficiencies of the UASB and AnMBR during the 120 days of operation.

ii. G-AnMBR performed higher organics and suspended solids removal (92% COD, 98% TOC and 100% MLSS) in comparison to the UASB (79% COD, 86% TOC and 99% MLSS) (Figure 1) due to the UF membrane separation that retains all particulate and colloidal matter and macromolecules.

iii. Higher quantity of methane was produced in the G-AnMBR (0,27 vs 0,22 L-CH_4/kg-$COD_{removed}$). The 3DEEM analysis suggested that the matter retained by the membrane is slowly-biodegradable and non-settleable compounds or by-products that are later converted into biogas thanks to a longer contact time between biomass and organic material. The increase of the organic to methane conversion rate, resulting in a positive net energy balance of 0.58 kWh produced per m^3 of treated water.

iv. The membrane allows to maintain the PSD tendency of the granular sludge within the G-AnMBR while large granules became predominant in UASB sludge bed.

Granular sludge fouling behaviour

Following the filtration tests for the raw granular sludge, the supernatant fraction and the granules fraction, the following conclusions can be drawn:

i. Granules (dp ≥ 0.125) had the lowest fouling potential whatever the hydrodynamic conditions used (Figure 2).
ii. The supernatant fraction, composed of fine compounds and flocs (dp < 0.125), was the key driver of membrane fouling in G-AnMBR (Figure 2).
iii. In the raw mixed liquor, where supernatant and granules are mixed, the fouling rate was lower compared to the supernatant fraction (Figure 2). It is suggested that granules diminished the impact of the fines and micro-particles over membrane permeability through mechanical scouring action and the formation of a more porous and loose cake layer structure.
iv. Hydrodynamic conditions were of high importance in mitigating membrane fouling. In tested conditions, gas sparging was more efficient in limiting membrane fouling than recirculation. However, a plateau was reached in gas sparging rate, above which the increase gas flow does not lead to a decrease in fouling rate.

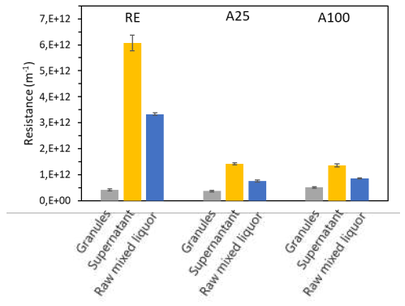

Figure 2. Filtration resistance at the end of the filtration test for the raw mixed liquor and the two fractions at different operating conditions (RE, A25 and A100).

v. Based on the 3DEEM analysis, at least 68% of the fluorescent organic matter from the reversible fouling came from the protein-like region regardless of the fraction. Hence, colloidal proteins seemed to be the main organic foulant in G-AnMBR.

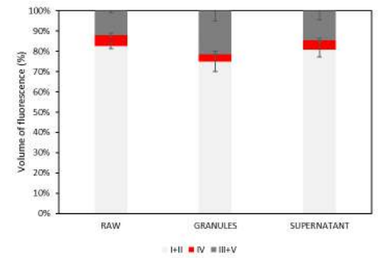

Figure 3. Repartition of the volume of fluorescence within 3DEEM regions of the superficial cleaning for the three fractions.

Abstract

Until recently, application of AnMBRs was limited to tropical climates and only tested at pilot scale in temperate climates. This project scaled up a pilot design to a 500 m^3/d AnMBR demonstrator plant to assess viability when the reactor was fed with primary effluent wastewater. Methane production was highly variable at overall low yield 0.088 ± 0.078 kg CH_4/kg COD. An uncontrolled increase in the influent COD:SO_4 ratio was noticed after day 28 due to a change in the return liquors line. This influenced the methane production, a phenomenon not conventionally expected. The average COD removal (67%) also underperformed compared to pilot scale (90%). This study establishes how influent characterisation changes impacted the overall performance, potentially linked to centrate tank overflow into the return liquors line. This shows that the impact of digestion returns on the AnMBR process needs to be further understood to enable large scale implementation.

Keywords: Anaerobic, Circular economy, Membrane, Sulphate Reducing Bacteria, Wastewater

INTRODUCTION

Transitioning to more circular operation by reducing the amount of energy and chemicals required in treating wastewater and recovering the energy, materials and water is a prescient objective for water utilities. Similarly reducing the emissive footprint of wastewater treatment is vital for achieving net-zero targets.

Anaerobic membrane bioreactors (AnMBRs) allow for wastewater treatment whilst recovering methane, removing organic contaminants, and it does not produce nitrous oxide and allows for nutrient recovery. Research from Cranfield University optimised this process to be viable in northern European climates at pilot scale. To be more energy self-sufficient, a dissolved methane recovery is required at full scale. A demonstrator scale AnMBR was therefore installed as part of the NEXT-GEN horizon 2020 project at Spernal wastewater treatment plant (WWTP) in 2021. This paper discusses the performance of the demonstrator and investigates important factors for interfacing anaerobic treatment with existing wastewater treatment systems.

MATERIALS AND METHODS

AnMBR demonstrator plant

The AnMBR combined an upflow anaerobic sludge blanket reactor (UASB) with physical separation ultrafiltration (UF) membranes for solid-liquid separation and membrane contactor for gas-liquid separation. The UF membrane system was integrated with the UASB through a recirculation line side-stream configuration.

The AnMBR treated 200 m^3/d fixed speed flow (max 500 m^3/d including recirculation) of primary effluent from one of Spernal WWTP primary settlement tanks. The UASB reactor (supplier Waterleau), was inoculated with mesophilic industrial granular sludge (twice during the demonstration, June 2022 for data presented). Recirculation flows (with the UASB effluent and/or from the UF membrane tank) sustained an up-flow velocity of 0.8 m/h and a hydraulic retention time (HRT) of 8-10h. The three-polyethylene hollow fibre ultra-filtration membrane reactor (C-MEM from SFC-Trant) had a total membrane area of 1074 m^2 and was sparged with the biogas produced in the UASB reactor. The HRT in the UF was 1.3h and the flux was 10 LMH.

Operational history of the AnMBR

The UASB was first inoculated in June 2021. Attempts to run the AnMBR system from July 2021 to Dec 2021 were compromised first due to septic influent and then numerous equipment failures across the plant (UASB inlet pump blockage, compressor failure). This resulted in unrepresentative performance and inconsistent operation. Following a plant shutdown to fix mechanical faults, the AnMBR was re-seeded on 08/06/2022 to guarantee fresh active biomass in the reactor and also to ensure that methanogenic activity could be re-established, after the issues with septicity and a long period without any feed or recirculation.

Sampling

Data presented in this report consists of:

- **Wastewater characterisation: instantaneous samples obtained for influent, UASB, UF and degas plant effluent analysed by an external laboratory (ALS, UK).**
- **Gas volumes and composition: instantaneous measurement of UASB, UF and degas plant gas using GFM 436 portable analyser.**

RESULTS AND DISCUSSION

Table 1 summarises the influent concentrations to the AnMBR. The inlet sewage contained high levels of sulphate (111.1 ± 21.9 mg SO_4/L) compared to relatively low levels of COD. A significant range in influent COD was measured.

Table 1: AnMBR influent characterisation

	pH	*COD*	*soluble COD*	*BOD*	*TSS*	*VSS*	*NH_4-N*	*Total P*	*PO_4-P*	*SO_4*	*Alkalinity*	*VFAs*

n	61	60	63	61	62	62	25	25	25	59	58	61

Table 2 summarises the AnMBR effluent concentrations. BOD and TSS concentrations in the effluent (10.3 ± 7 mg TSS/L) were significantly higher than anticipated for a membrane process (pilot <5 mg TSS/L). The discharge quality observed for BOD/COD/SS was 27/81/10. This effluent quality would be insufficient for large scale implementation. The average COD removal was 67%.

An increase in nutrients (ortho-P, NH_4-N) was observed across the UASB. Effluent pH was compliant with UK discharge requirements for recycled wastewater (pH <9). Sulphate removal was significant (58% across the AnMBR). The effluent was compatible with nutrient recovery processes (operated at Cranfield University and not discussed further in this paper).

Methane and gas production

The overall gas production from the UASB and the methane content is shown in figure 1.

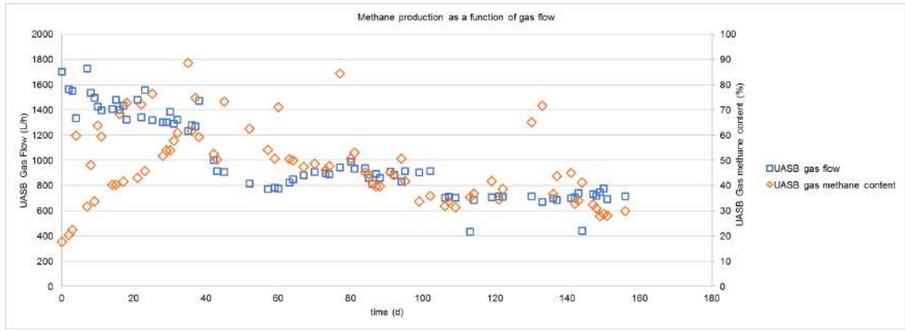

Figure 1: Gaseous methane production

Initial start up (day 0 – 20) showed a relatively stable UASB gas production with the methane content increasing as biological maturation generated methanogenic communities. Day 37 (20/07/2022) demonstrated a decrease in gas production. The gas production from this point reached a lower steady state (~1000 L/h) with a lower gas methane content between 30 – 40% (v/v). The membrane degassing (for gas-liquid separation of dissolved methane post-UF) was not operational due to a water trap on the vacuum side failure due to corrosion. Supply chain and manufacture issues prevented reinstatement of methane gas-liquid separation during the trial phase.

Discussion

Compared to pilot expectations and literature (Aslam et al., (2022) shows multiple references above 80% COD removal), the COD removal was below expectations (Table 1, 67%). The methane yield observed was 0.088 ± 0.078 kgCH_4/kgCOD. Converting this into a gas phase equivalent (i.e. if degassing of dissolved methane was operational and 100% efficient) yields 0.13 ± 0.12 m^3 CH_4/kg COD). Methane production generally declined after day 37 and varied significantly (Figure 1). On certain days, the total production reached ~3 kg CH_4/d. The average total methane production was 1.3 kg CH_4/d.

With degassing assumed operable, the yield is lower than most references though comparable with some reference municipal wastewater AnMBRs (Aslam et al., 2022). This implies that influent characterisation and wastewater site operation impact COD removal and methane performance. Figure 1 shows that the gas production and methane content of the gas decreased after day 37. Figure 2 shows that the influent characterisation and biological behaviour changed after day 28.

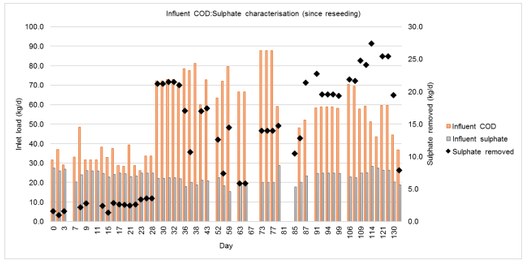

Figure 2: Influent characterisation during trial (COD, sulphate) and sulphate removal.

The trial initially operated at a COD:SO_4 ratio at around 1.5:1. At this ratio, inhibitory effects on the COD removal and methane production would be expected (Song et al., 2018). As can be seen in Figure 2, the influent characterisation (increased COD, COD:SO_4) changed significantly after day 28 – 11/07/2022. Sulphate removal increased from day 30, implying sulphate reducing bacteria outcompeted the methanogenic bacteria intermittently from this point forward despite the increase in COD:SO_4 ratio.

Spernal WWTP post digester centrate balance tank is believed to have intermittently overflowed to the demonstrator plant (not the design intent) from day 28. Limited sampling evidence suggests that the centrate is higher in COD that is not biodegradable (full COD fractionation sampling ongoing at time of writing), explaining the increased COD:SO_4 ratio's lack of impact on methane production. The centrate may have also reduced the oxidation reduction potential (ORP) of the system to prioritise sulphate reducing bacteria (ORP data to be presented in full paper). The trial observed septic conditions caused by very negative ORP feed value due to long retention times in the feed system.

Further work to understand the compatibility of the anaerobic treatment with digester site liquor returns is therefore required to translate the AnMBR demonstrator to full scale.

Abstract

Membrane filtration models for membrane bioreactors (MBRs) present a lack of homogeneity in the nomenclature used. The main objective of this work is to propose a new notational framework that allows a single and systematic naming. The proposal takes into account the different nomenclature used in literature, trying to minimize specific problems encountered with regards to current notation. An standardized notation for both state variables and model parameters are proposed, including different levels of subscripts to be applied. Standardization within MBR modelling field would allow easily comparing different modelling exercises aimed to advance on the optimization of MBR systems for resource recovery from municipal wastewater.

Keywords

AnMBR; MBR; membrane filtration model; municipal wastewater; standardization.

INTRODUCTION

Due to water stress, the need to recover water for reuse has strongly emerged in the last years. Moreover, wastewater has become in a source of other valuable resources, such as carbon and inorganic nutrients. Therefore, current efforts within the wastewater field focus on transforming the existing wastewater treatment plants into water resource recovery plants. In order to achieve this transition, membrane technology is playing an important role. Mathematical modelling of membrane technology allows advancing on the development and optimization of MBR-bases systems for resource recovery from municipal wastewater (MWW).

Understanding and optimizing membrane-based filtration systems (e.g. MBR and AnMBR) is a complex and time-consuming effort due to the sub-processes that occur simultaneously and are usually correlated. To this aim, mathematical modeling is a key tool that aims to predict and explain the behavior of these systems. Regarding membrane filtration, a several models can be found in literature, most of them having been developed for a given system due to the need of assessing the complexity of membrane fouling phenomenon in each specific scenario. However, there is not consensus regarding their notation and nomenclature.

Hence, it is necessary to propose a new framework for standardized notation in membrane filtration modelling providing the basis for future model developments or that could be applied to existing models in order to compare and implement them in a more consistent way.

MATERIALS AND METHODS

Table 1 shows the relation of models used in this work. An up-to-date review of selected membrane filtration models has been assessed, indicating also the MBR-based technology used to calibrate and validate each model. A matrix summarizing the main parameters of each model was constructed to provide an overview of the symbols and subscripts used in each case. Based on this matrix, a framework for standardized notation has been proposed. The proposal is mainly based on two previous works on standardization in water treatment modelling: Corominas et al. (2010) and Brepols et al. (2020).

RESULTS

In this work, state variables and model parameters have been evaluated individually. For each type of state variable and parameter, the notation for both main symbol and related subscripts has been proposed.

Special attention was put when proposing the notation (symbol or letter) for thickness, specific mass and specific resistance, due to the high variability in the nomenclature found in literature. For instance, the symbol δ was defined for representing thickness (L) as it was widely used in the collection of models studied. In the case of specific mass ($M\ L^{-2}$), ω was selected as reference symbol against *m* or *M* since these are more frequently associated with dry mass and membrane, respectively. For specific resistances ($L\ M^{-1}$), a very similar situation arises, proposing the symbol α instead of *R* and *r*, maintaining *R* for model general resistances (L^{-1}) and *r* for radius (L).

By way of example, Table 2 illustrates the proposed standardized notation for state variables. To establish the subscripts that give rise to the nomenclature, some proposals coming from Brepols *et al.* (2020) have been considered, *e.g.*, *Iv* for irreversible fouling, *M* for membrane, or *PB* for pore blocking. On the other hand, Table 3 shows the proposed subscripts for the state variables shown in Table 2, according to the category they belong to (*i.e.*, mechanisms, location...).

It is important to highlight that differentiation is not considered between AnMBR and MBR neither between other membrane-based systems (e.g. membrane photobioreactors, tertiary filtration, direct membrane filtration, etc.). Thus, the proposed framework aims to provide a general notation for any membrane filtration model applied within the wastewater treatment field. Additionally, a general framework for integrated MBR modelling would be available (examples not shown in this abstract) when combining the current proposal with the work from Corominas *et al*. (2010).

DISCUSSION

The review conducted on MBR filtration models revealed that standardization of membrane filtration modelling is a necessary step in order to advance on the development and optimization of MBR-based systems for resource recovery form MWW. In this respect, a standardized notation framework would improve the exchange of information between modelling professionals and researchers. The parameters included in this work entail those considered to be the most common or general ones. However, from the proposed framework it is possible to easily infer the proposal of other parameters that are case-specific or considered in (more) mechanistic models.

ACKNOWLEDGEMENTS

This research work was supported by the Spanish Ministry of Science and Innovation (Project PCI2020-112218) jointly with The Partnership for Research and Innovation in the Mediterranean Area (PRIMA program, Project EADANMBRT, Reference Number: 2019-SECTION2-10), both of which are gratefully acknowledged. It was also supported by Generalitat Valenciana via a pre-doctoral ACIF fellowship to co-author Valeria Sandoval-García (ACIF/2021/384).

Abstract

Household water treatment and safe storage (HWTS) systems are modular water treatment system used for water sanitation in rural and isolated areas. They provide world health organisation (WHO) water quality standards for families and communities in rural and isolated areas. Membrane technology is used in high-tech HWTS, being numerous commercial systems available in the market. However their configuration is limited to flat sheet and hollow fiber membranes. This work investigated the usage of recycled spiral-wound nanofiltration and ultrafiltration membranes driven by gravity (0.15 bar) to treat part of the secondary effluent of an urban wastewater treatment facility, located in Girona (Spain). From the experiment, initial membrane permeability rapidly decreased when the system was operated continuously (non-stop filtration). Relaxation time followed by flushing helped to partially recover the permeability and control membrane fouling. Membrane permeate achieved the water quality standard for several water reuses according to the Spanish water reuse legislation.

Keywords (maximum 6 in alphabetical order)
Nanofiltration, membrane recycling; membrane regeneration; reverse osmosis, ultrafiltration, water reuse

INTRODUCTION

Household water treatment and safe storage (HWTS) systems are modular devices, designed normally to filter water using the gravity force and to be used for families and communities (having to produce at least 3-15 L day^{-1} per person) [1]the negative impact of exposure of children to fecal bacteria includes long-term consequences on children's physical and mental development, as indicated by undernutrition, poor weight-height ratios, stunting, and Disability Adjusted Life Years (DALY's. HWTS are easy to use, operate, and maintain, which make them interesting for water sanitation and hygiene promotion actions for disease prevention in rural and isolated areas [1]the negative impact of exposure of children to fecal bacteria includes long-term consequences on children's physical and mental development, as indicated by undernutrition, poor weight-height ratios, stunting, and Disability Adjusted Life Years (DALY's.

Ultrafiltration (UF) and microfiltration (MF) membranes are filters frequently used in HWTS as gravity driven membrane (GDM) systems. The pressure-driven is achieved by height difference between the feed tank and the membrane unit (i.e. typically requiring 40-200 mbar of pressure). There is a great spectrum of HWTS commercially available that includes membrane technology. However, the most common membrane configurations for this application are flat sheet and hollow fiber. In fact, GDM systems using spiral-wound nanofiltration (NF) or UF membranes has been only investigated in laboratory scale [4].

On the other hand, in the last two decades, recycling of end-of-life reverse osmosis (RO) membranes from desalination industry into NF and UF membranes has been already proven to be a feasible and green alternative management to avoid landfill deposition and to extend their lifespan [2,3]. García et al. [4] reported that recycled membrane filtering in gravity-driven mode are able to remove low molecular weight and small-sized neutrals organics and, eventually, shows additional high interests such as: large membrane filtration surface area (between 37m^2 and 41m^2), lower cost (between 1 USD m^{-2} [5] and 6 USD m^{-2} [6]), and versatility in terms of system configurations (i.e. used in standard pressure vessels, submerged in deposit or in alternative configuration [4]). Lawler et al. were the first to report the use of recycled UF membranes in flatsheet submerged configuration for HWTS [7].

In the present study, an alternative membrane housing to the standard spiral-wound pressure vessels, recently developed by the authors, was scaled up [4]. The focus of this investigation is on a systematic approach comparing recycled ultrafiltration and nanofiltration membranes (from 8 inches diameter end-of-life RO membranes) for filtering secondary effluent of an urban wastewater treatment plant. Membrane filtration performance and fouling were assessed providing new data set for the GDM field, particularly useful for emergency response and isolated rural areas. This study is part of the OSMO4LIVES project and beneficial for developing compact GDM systems based on recycled spiral-wound membranes for both rural areas and emergency response.

MATERIALS AND METHODS

2.1 Membranes types and recycling process

Discarded RO spiral-wound modules (with 1 m length, 0.2 m diameter and a 37-41 m^2 surface area) were used. Membrane transformation into NF and UF membranes was carried out according to standard protocols already published [4,8,9]end-of-life, reverse osmosis (RO.

2.1 Gravity driven set up

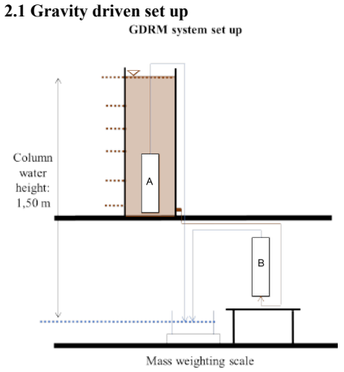

Figure 1. GDM set up for submerged configuration (A) and external (B) configurations

A pilot-scale GDM system was set up for two distinct membrane system configurations: submerged (membrane inside a water deposit) and external (membrane out of the water deposit), as shown in Figure 1. During the experiment, the system was operated under dead-end filtration mode at ambient temperature. Feed water was constantly pumped to the storage tank to keep a constant level of water in the tank, which was 1,50 m above the membrane. Thus, the gravity pressure was constant at 0.15 bar. All the containers were opaque in order to avoid algae growth.

The GDM system was operated in two modes: continuously and intermittently. The continuous mode consisted of cycles of 15 days of filtration, followed by 30 minutes relaxation time, followed by 10 minutes flushing. In the intermittent operation, the filtration cycles, relaxation and flushing were applied every 24 h. No chemical cleaning was applied.

2.1 Membrane performance

The permeate was collected in 2L graduate plastic jars during a given period of filtration. Therefore, the membrane permeability (L m^{-2} h^{-1} bar^{-1}) was obtained by dividing the permeate flow rate by the membrane surface area and the transmembrane pressure (TMP). The TMP was estimated considering the effective water head, which includes the height of the water level of the tank and the height of the end of the permeate tube. Membrane permeability was normalized at 20ºC.

Permeability was measured every day (taking at least 6 L of water). Several samples per week were collected from the feed and permeate to assess water quality according to the Spanish law for water reuse RD1620/2007 (e.g: suspended solid, turbidity and *E.coli*). Rejection coefficients were calculated (% R) following Equation 1, where, C_p and C_f are the specific concentration measured in permeate and feed, respectively.

Eq. 1

RESULTS AND DISCUSSION

Preliminary results using TW30 membrane recycled into UF membrane showed that after 15 days of continuous filtration the membrane was already fouled. The initial permeability declined from 46 to 22 L·m^{-2}·h^{-1}·bar^{-1} (52% reduction, Figure 2) in the firs filtering cycle. In Figure 2 filtering cycles 2, 3 and 4 have dark and light dots representing the measured permeability. Dark colour corresponds to the permeability measurement after 24 h continuous filtration, while the lighter colour shows the permeability after applying relaxation time and flushing. Intermittent operation mode slightly mitigated fouling during the next 18 days (cycle 2 and part of cycle 3), as the permeability dropped from 22 L·m^{-2}·h^{-1}·bar^{-1} to 15 L·m^{-2}·h^{-1}·bar^{-1} (32% reduction). Afterwards the permeability was decreasing up to a minimum of 5 L·m^{-2}·h^{-1}·bar^{-1}. In all the cases, the permeability after applying relaxation and flushing is slightly higher than the value measured after 24 h of filtration. In cycle 4 different frequencies of relaxation and flushing were tested (e.g. after filtering continuously during 2 days, 3 days and 5 days). The observations suggests that relaxation and flushing should be applied at the latest every 3 days.

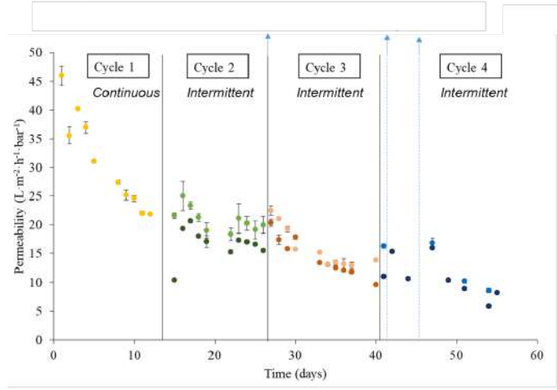

Figure 2. Permeability of TW30 recycled into UF membrane submerged in a water deposit and filtering by gravity-driven conditions. Cycle 1 was continuous (non-stop filtration). Cycles 2 to 4, the membrane was filtrating during 24 h, followed by a relaxing time and flushing.

In average the water quality of the secondary effluent was 1.39 mS/cm, 65.5 ppm COD, 10.7 ppm BDO, 36.5 ppm TKN, 0.3 ppm suspended solids and 3·10^5 CFU/100 mL. The TW30 recycled membrane rejection was: 70% COD, 76% BDO, 9%TKN, 100% suspended solids and 5 LRV of *E.coli*. The regenerated water fulfilled the water quality standards required for several water reuse applications, such as, irrigation without contact with the raw part or in contact with a cooking part, services, industrial cleaning, watering golf courses, ornamental water masses and irrigation of green areas and forest.

CONCLUSIONS

Recycled membranes have shown to be a potential alternative to be reused in gravity-driven filtration systems for tertiary treatment of urban wastewater. Intermittent filtration (regular break and drainage) contributes to control the reduction of permeability, probably resulting from fouling layer detachment from the membrane surface thanks to relaxation and flushing. Flux and permeability were similar within the cycles except for the first cycle, in which the continuous filtration led to higher permeability decrease due to fouling.

A >99.9 %, 100% and >83.7 % of rejection of *E.coli*, suspended solids and organic matter, respectively, was observed; while <2 % of rejection was achieved for nutrients and ions (except N-NO$_2$ and N-NO$_3$, which reach up to >80 % in the first 2 cycles). The values of these parameters, included in the Spanish Royal Decree for water reuse (RD1620/2007) are below range.

The following experiment will apply UF and NF recycled membranes from different brands and origins, aiming at reaching higher recycled membranes permeabilities.

Abstract

The energy transition of the last decades has as consequence the increase of demand of energy storage systems, lithium batteries being the most important. Therefore, there has been a dramatic rise in the global lithium consumption. At present it is necessary to take advantage of new sources of natural lithium, for which reason alternative methods for lithium recovery are being investigated. Brines with relatively high concentrations of lithium are obtained as waste from desalination plans. In this study, an electrochemical system based on discarded (end of life) batteries is evaluated to recover lithium from desalination brines.

Keywords

Brines; Electrochemical systems; Lithium battery waste; Lithium recovery.

INTRODUCTION

Lithium batteries are the predominant storage system in the automotive and renewable energy market. Currently, the battery sector is supplied by brines and ore, however, in the future it is expected that the increase in lithium demand will lead to shortages. (Srimuk, Su, et al., 2020) The total amount of lithium in seawater reaches 230 billion tons, however, its concentration in seawater is around 0.17 mg/dm^{-3} (Yu, Yuan, et al., 2022). Other alternative sources of lithium are recycling of end-of-life Li-ion batteries and unconventional lithium resources such as jadarite or hectorite,(Tabelin, Dallas, et al., 2021). Additionally, mine drainage/ water, (Mohr, Mudd, et al., 2012) and brines of desalination process are sources of maximum interest.(Flexer, Baspineiro, et al., 2018) with significantly higher concentrations than in seawater. Therefore, the recovery of lithium these currents is a priority for the scientific community.

Several techniques have been studied for lithium extraction from seawater, such as evaporation-based techniques, ionic sieve adsorption, nanofiltration, solvent extraction, electrodialysis, the ionic pump and lithium-ion battery-based electrochemical extraction. Lithium extraction using electrochemical technologies has been shown to be beneficial in aspects such as low energy consumption, versatility and high selectivity. (Zhao, Yang, et al., 2019)

The lithium-ion battery-based electrochemical extraction is based on the application of an electric field to increase the adsorption of lithium and selective materials are used as a working electrode for the lithium embedding/stripping process. (Zhao, Yang, et al., 2023) At present, materials with a spinel and olivine structure are generally used as the cathode of batteries,(Santos and la Mantia, 2022) therefore, using the active material from battery waste to manufacture new electrodes is an interesting alternative. In the present study, new electrodes are synthesized from battery waste cathodes, this active material is pre-treated by chemical and thermal methods and subsequently, the new electrodes are characterized by electrochemical methods, studying the stability and diffusion kinetics of lithium.

MATERIALS AND METHODS

Herein, self-supported LFP electrodes were fabricated from waste batteries. The active material has been immersed in a 0.5 M solution of potassium persulfate at 333 K for 2 hours to favour the release of lithium from the olivine structure and later it was deposited on a conductive sheet using the *doctor blade* technique. To determine the crystalline structure of the electrodes, it was characterized by XRD. Additionally, for the electrochemical characterization, cyclic voltammetry (CV) was performed from which the diffusion coefficient of lithium was obtained.

RESULTS AND DISCUSSION

Figure 1 shows how the diffractogram coincides with the diffraction pattern of the olivine structure (LFP), with peaks that are associated with the planes (200), (101), (210), (111), (211) and (311).

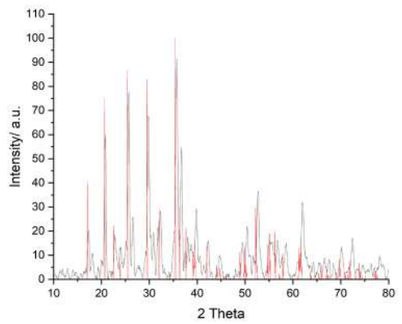

Figure 1. XRD patterns of LFP electrodes synthesized from battery waste. In black, XRD pattern, and in red, olivine diffraction pattern of reference.

Cyclic voltammetry curves are shown in **Figure 2**. One reduction peak appeared near 0 V vs Ag/AgCl, which is associated to intercalation into LFP. Correspondingly, one oxidation peak near 0.2 V is assigned to de-intercalation from LFP. Cyclic voltammetry demonstrated that the embedding/stripping process and transformation were controlled by the diffusion rate. (Takahashi, Tobishima, et al., 2002)

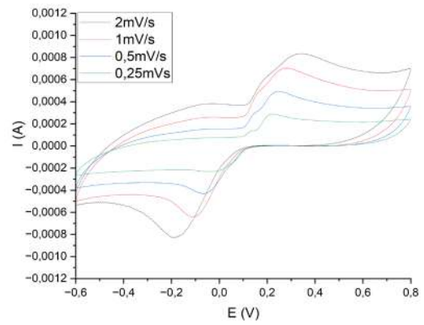

Figure 2. CV of electrode in 0.1 M LiCl solution with different scan rates.

Diffusion coefficients for intercalation/deintercalation were obtained from the CVs, resulting in and , respectively. These values are consistent with literature. (Zhang, Zhang, et al., 2013)

Lithium recovery from brines is possible by using battery waste to synthesize LFPs electrodes. The fabricated electrodes showed high stability and promising Li-ion diffusion kinetics. Finally, the use of battery waste in the synthesis of new electrodes favours the circularity of waste and represents a benefit for the environment.

Abstract

Co-fermentation of primary sludge and external organic waste for volatile fatty acids (VFA) production without pH control was studied using 15 L and 2 m^3bench-scale and pilot-scale reactors, respectively. In the bench-scale experiments, the VFA production reached a maximum of 25,000mg COD/L and a VFA yield of 500 mgCOD/gVSfed. The VFA mixture was dominated by caproic acid with a percentage of ≈ 50%. The pilot-scale reactor showed that substrate variability influences the VFA yield and the individual VFA types. The study also showed that VFA production is feasible with positive economic outlook. In comparison with acetate and methanol, the VFA-rich liquid showed the highest specific denitrification rate and a nitrate equivalent removal efficiency of a maximum of 98% was obtained for the continuous denitrification experiments. VFA separation and purification to obtain pure acid type is being investigated and results will be presented during the conference.

INTRODUCTION

Waste is seen as a resource which can be processed to produce valuable products. Resource recovery from waste will reduce consumption of primary raw materials and greenhouse gases (GHG) emissions. Thus, recovery of biobased product as an alternative petrochemical will help achieve to achieve a sustainable society.

One of the important bioproducts with a high bioproduction potential from waste streams are volatile fatty acids (VFAs). VFAs are important building block chemicals with a greatly increasing market demand (Atasoy et al., 2018; Bhatt et al., 2020). Despite the promising developments in VFA from waste, there are still challenges to overcomes which include obtaining pure VFA product and increasing production efficiency. On the journey towards full-scale production of VFAs from waste streams, there is the need to ultimately understand how such the waste-based system respond to changes.

The current study has sought to understand the technological and economic feasibility of long-term VFA production from municipal organic wastes. The study elucidated the long-term system resilience and the microbial community dynamics of the VFA production system. The direct application of the waste-derived VFA mixture in the wastewater treatment plants (WWTPs) for denitrificationassustainablealternativetopetroleum-basedcarbonsourceswasexplored.Thestudy also includes the possibility of separation and purification of the VFA mixture to obtained pure biobased product.

MATERIALS AND METHODS

VFA production

In this study, co-fermentation of primary sludge (PS) and external organic waste (OW) for VFA productionwascarriedout. ThePSwasfromHammarbySjöstadverket.ThreedifferentkindsofOW were used which include OW1-organic waste from Himmerfjärden WWTP which ishygienised for 61 minutes at 71°C; OW2-organic waste from Himmerfjärden WWTP which is not hygienised;andOW3-organicwastefromScandinavianBiogas'digestionplantwhichishygienised for 61 minutes at 71°C. The study was carried out two scales: bench scale and pilot scale with afeed consisting of feed of 70% v/v PS and 30% v/v OW. Both experiments were carried out without pH adjustment and at a temperature of 35°C.

The bench scale reactor had a total volume of 15 L with a working volume of 10 L and wasoperated in semi-continuous mode with retention time of 7 days. The bench-scale reactor was operated for 315 days with PS and OW1 as the substrate. The pilot-scale reactor had a total volume of 2 $m^3$with a working volume of 1.5 m^3. The pilot-scale reactor was operated for 264 days in continuous mode with the same conditions as the bench-scale reactor. Unlike the bench-scale reactor, there four different periods of operation for the pilot-scale reactor when different kinds of OW were used as substrates. These included: period I when PS and OW1 were fed; period II when PS and OW2 were fed; period III when only PS was fed; and period IV when PS and OW3 werefed. A limited techno-economic analysis was done for the different periods of the pilot-scale reactor operation.

Denitrification

The VFA-rich liquids were tested for its denitrification potential in comparison with acetate and methanol. Denitrification was done in batch test using the manometric tracking method with different carbon/nitrogen (C/N) ratios (from 0 to 7.5). Furthermore, the denitrification efficacy of the VFA-rich fermentation liquids was explored by operating dentification reactor in a continuous mode with real nitrified wastewater for 63 days. The VFA-rich carbon source was dosed to the continuous denitrification reactor at a C/N ratio of 4.5.

Separation and Purification

Separation of the VFA-mixture with nanofiltration/reverse osmosis technique to obtain one-type VFA with high purity is being done. The study is carried out with FilmTec NF270, NF90, BW30, XUS1207 Acid Stable NF and FilmTec SW30HRLE membranes from Dupont using dead-end stirred cell.

RESULTS ANDDISCUSSION

Volatilefattyacidproductionyieldandcomposition

The VFA production started to increase and peaked at a value of about 18,000 mgCOD/L at day 14 thereafter it began to decrease (Figure 1). The decrease in VFA production was attributed to accumulation of undissociated acid due to a low pH. Accumulation of undissociated acids is known to be toxic to microorganisms (Xiao et al., 2016). However, the system recovered due to acclimatization and increase of pH and the VFA production started

to gradually increase and reached a maximum VFA concentration of 25,000mgCOD/L and a yield of 500 mgCOD/gVS_{fed}on day 98.It was observed that VFA composed of mainly caproic acid with relative abundance of ≈ 50% (Figure 2). Caproic acid is more valuable and has now become the focus of many bioproduction (Angenent et al., 2016).

During the pilot-scale reactor operation, it was revealed that the substrate types influenced the VFA production and composition. The periods with hygienzed OW yielded high VFA and percentage of caproic acid. The pilot-scale reactor had a maximum VFA production of 22,000mgCOD/L with caproicacidpercentageof45%. Thetechno-economicanalysisshowedthatalthoughhyginzationat 71°C added to the cost operation, the economic gains from the yield and VFA types gave a positive economic outlook.

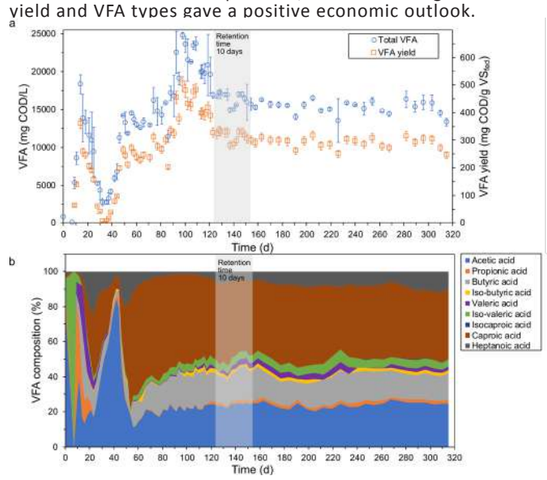

Figure 1. a) VFA production and yield; b) distribution of various VFA components of the bench- scale reactor (Owusu-Agyeman *et al*, 2023)

Denitrificationresults

Denitrification test results showed that the VFA-rich liquid achieved the highest specific denitrification among the three carbon sources (Figure 2). The results also showed that the COD/N ratio of 4.5 is sufficient for complete denitrification with a high denitrification rate. An average nitrate equivalent removal efficiency of 87±14% with a maximum of 98% was obtained for the continuous denitrification experiments. Thus, VFA production from waste has the potential to close the loop for carbon management of WWTPs.

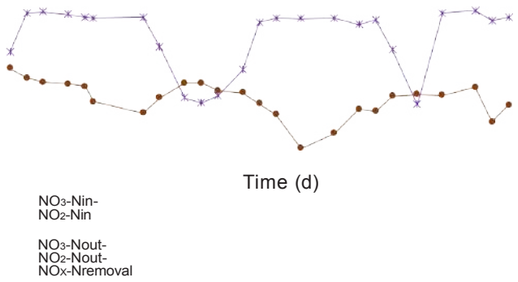

Figure 2. Results of a) batch denitrification experiments and b) continuous denitrification experiment (Owusu-Agyeman *et al*, 2023)

The separation and purification of the VFA to obtained pure products are being worked and the results will be presented in the conference.

The study has revealed the technological and economic feasibility of VFA production through co- fermentation of municipal organic wastes. The finding of the study could be the reference point for full-scale application of VFA

Abstract

The conversion of organics in wastewater to added value chemicals, such as medium-chain carboxylic acids (MCCA) has gained increasing attention over the past years. This work investigates the impact of nutritional requirements and operational conditions on the performance of granular fermentations to produce MCCA. First, we show that MCCA selectivity remains unaffected within an influent concentration range of 11-44 gCOD·L^{-1}, and that this selectivity decreases at higher concentrations, likely due to product toxicity. Second, we show that a complex source in the feed is needed for successful MCCA production. Last, we investigate the impact of two critical operational parameters, pH and HRT. Results showed that a mildly-acidic pH (5-5.5) favourschainelongators,andtheseseemtobeinsensitivetochangesinHRTintherange0.25-1

d. This works paves the road to a wider application of granular fermentations for MCCA production from wastewater.

INTRODUCTION

To date, biogas production is the state of the art approach to valorise the carbon and energy present in waste(water). Yet, the small economic margins of biogas installations, coupled to the limited applications for biogas beyond energy production have driven the development of novel technologies for the recovery/valorisation of carbon from wastewater in the form of e.g. bioplastics, biochemicals, new protein sources, etc. (Kleerebezem et al. 2015).

The production of monocarboxylic acids (also known as volatile fatty acids, e.g. acetic acid, propionic acid, butyric acid, etc.) -either as final products or intermediates to a subsequent process (e.g. PHA production)- is central to the majority of these alternative routes (Alloul et al. 2018). Medium-chain carboxylic acids (MCCA) are monocarboxylic acids with a carbon length of 6-12 carbon atoms, and are considered platform chemicals with multitude of applications as feed additives, antimicrobial compounds and can be utilised in production of fragrances, rubbers, dyes and pharmaceuticals (Angenent et al. 2016). Their production from waste streams, including wastewater (Duber et al. 2018) and sludge (Han et al. 2019) has attracted increasing interest due to their higher market value and higher hydrophobicity, which makes their recovery easier and less costly (Carvajal-Arroyo et al. 2021). MCCA are produced via a microbial process called chain elongation, which uses e.g. ethanol, lactic acid, carbohydrates, etc. as an electron and carbon donor to elongate short chain carboxylic acids. As such, acetic acid is elongated to butyric acid that is in turn elongated to caproic acid (Angenent et al. 2016).

Despite their promise, microbial MCCA production is not yet at full scale. Most technological studies have struggled to achieve high production rates, and the few that did achieve high rates eitherusedsyntheticmedia,orusedmethodsthataredifficulttoscaleup(Carvajal-Arroyoetal.

2021). Recently, a novel approach has been developed that uses granular sludge to convert a sugar- richwasteandsidestreamsintocaproicacidinonereactorstep.Inthissystem,productionratesof

0.5 g caproic acid.L.h^{-1}were achieved, the highest reported production rate on an industrial stream without the addition of supplementary substrates such as ethanol, lactic acid or sugars (Carvajal- Arroyo et al. 2019).

In this contribution we explore the development of a fermentative granular technology for the production of MCCA from carbohydrate-rich wastewater and other industrial side-streams, with special focus on the impact of feedstock and operational conditions on the process performance.

MATERIALSANDMETHODS

Experiments were conducted in laboratory-scale expanded granular sludge bed (EGSB) reactors (1.5-2.5L) fed with various watery streams, namely: i) thin stillage; ii) synthetic wastewaters mimicking its composition; or iii) pre-fermented wastewater. Experiments investigated aspects related to the nutritional requirements of the chain elongation microbial community or the effect of target operational parameters (pH & hydraulic retention time (HRT)) on the MCCA productivityand selectivity.

RESULTS AND DISCUSSION

First, we investigated the impact of substrate concentration on product conversion and MCCA selectivity to assess whether or not this technology could be applied to wastewater containing lower or higher COD levels (Figure 1). Experiments were conducted in a fermentative granular system by either diluting thin stillage or supplying additional carbohydrates to it. Results showed that concentrations in the range of 11-44 gCOD·L^{-1}(25-100%) did not have a significant effect on product selectivity, withMCCA representing about 50% of the end products. Selectivity dropped as carbohydrate concentrations increased above 125%, in favour of butyric acid, likely due to MCCA product toxicity (Figure 1.B). We also observed that the higher the concentration, the lower the substrate conversion efficiency and hypothesize this observation was caused by enhanced toxicity due to increasing carboxylic acid concentrations.

Subsequently, we assessed the minimum nutritional requirements to achieve stable MCCA production (Figure 2). We step-wise replaced thin stillage by a mineral medium containing glucose as electron donor. We observed that upon reaching 100% synthetic feed, granules remained but caproic acid production had dropped from 3.5-5 g·$L^{-1}$to 0.3 g·L^{-1}. Caproic acid production wasonly recovered upon adding complex carbon and nitrogen sources such as tryptone to the medium.

Last, we assessed the impact of two key operation parameters, pH and HRT. We observed that pH governed the competition for lactic acid between propionic acid bacteria and chain elongators, with mildly acidic pH (around 5-5.5 favouring the latter) (Figure 3). We also observed it was possible to maintain high MCCA productivities (>10 g·L-1·d-1) throughout the HRT range 1-0.25 d.

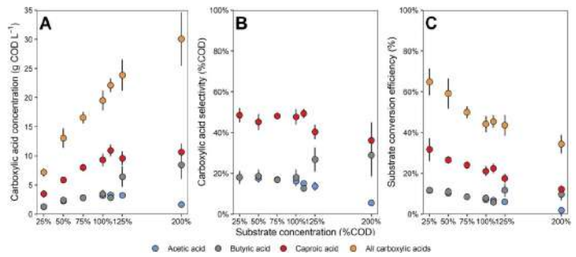

Figure 1. Panel A: Carboxylate concentration in function of substrate concentration. Panel B: Carboxylate selectivity, defined as the ratio of COD of a specific carboxylate to the COD of all produced carboxylates, in function of substrate concentration. Panel C: Substrate conversion efficiency in function of substrate concentration.

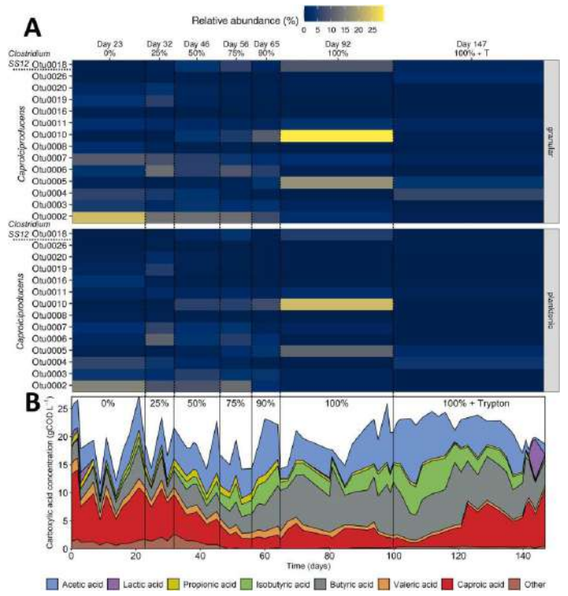

Figure 2. Theeffect ofnutrient composition on theproduction and microbial composition. Panel A: Heatmap of relative abundance in *Caproiciproducens* and *Clostridium sensu stricto 12* OTUs. Only OTUs with a relative abundance above 1% in either planktonic or granular phase are shown. Sampling days for the DNA are shown on top. Panel B: Evolution of the product profile. Shown percentages in bold indicate the volumetric fraction of the medium fed as synthetic medium while the complementary fraction was solids-free thin stillage.

Abstract

This study presents the bio-recycling of greenhouse gas carbon dioxide (CO_2) into organic valuable compounds. Low-gap electrically efficient electrolytic cells were operated in order to optimize selective butyric acid production. A selectivity of up to 78% and a production rate of 14.5 g/(m^2·d) were achieved at a remarkably low energy requirement of 34.6 kWh/kg. *Megasphaera* sp. was identified as the key chain elongating player. Besides, the reactor microbiome was capable to trigger butanol production ceasing CO_2 feeding (famine conditions), maintaining pH_2 > 1.5 and pH below 4.8

Keywords

Bioelectrochemistry; Carbon utilisation; Energy; *Megasphera* sp.; Selectivity; Ohmic resistance

INTRODUCTION

The development of carbon capture and utilization (CCU) approaches together with low power demanding processes is compulsory to achieve the sustainable development goal (SDG) 13 on climate change (Ioannou et al., 2023). Microbial electrosynthesis (MES) has emerged as a bio-recycling of carbon dioxide (CO_2) into platform chemicals and alcohols.

MES typically converts CO_2 into short-chain organic products such as acetic acid and ethanol (Blasco-Gomez et al., 2019) which can act as precursors to obtain higher-value products, such as butyric acid (Romans-Casas et al., 2021) which can be further upgraded to butanol, a medium-chain alcohol with large industrial applications (Pinto et al., 2021).

However, previous studies on MES, reported high cell voltages (up to 7 V) and power demand (64.3 kWh/kg of butyric acid) which, besides resulting in unsustainable operation costs, lead to a collateral effect on other SGDs such as population health and water scarcity (Ioannou et al., 2023; Romans-Casas et al., 2023; Jourdin et al., 2018). Thus, testing more efficient cell designs with low ohmic resistance was considered. This study aimed to selectively produce butyric acid from CO_2 through a low-gap electro-cell giving special attention to the conditions that trigger its further conversion to butanol.

MATERIALS AND METHODS

Two commercial MES cells (EC-1 and EC-2) with a total volume of 150 mL per chamber, were assembled and operated in galvanostatic mode. EC-1 was inoculated with a mixed culture dominated by *Clostridium* sp. (Romans-Casas, et al., 2023). CO_2 was periodically fed to the cathode chamber, and operated at different current densities (from 0.3 to 3.0 mA/cm^2). After 110 days of operation, EC-2 was started up using as inoculum the enriched microbial community developed in EC-1. Two tests interrupting the CO_2 supply were done during EC-2 operation to test the impact of hydrogen (H_2) accumulation.

The electrochemical cell characterization was performed through electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV). Optical density (OD), pH and electrical conductivity were monitored over time, and samples were collected to determine carboxylic acids and alcohols concentration, gas composition and microbial community.

RESULTS AND DISCUSSION

Figure 1 presents the OD, pH and accumulated concentration of main products throughout the operation of cells (EC-1 and EC-2). During the first days, no products were detected in EC-1. When the current applied was increased 0.6 mA/cm^2 pH decreased, due to acetic acid formation, which was the only carboxylate produced for the first sixty days of operation. It showed a linear production rate up to 10.0 g/(m^2·d) between days 12-19 of operation (Table 1), reaching a concentration of 2.6 g/L at the cathode (Figure 1). Such production rate did not changed after increasing the applied current to 1.0 mA/cm^2. Ethanol was detected from day 30 onwards, probably due to the pH decrease and reached a maximum titer of 0.35 g/L. From day 60 onwards, ethanol and acetic acid concentrations dropped due to the activation of chain elongation reactions. butyric acid was produced with an average production rate of 14.5 g/(m^2·d), reaching a cathodic concentration of 3.6 g/L. Caproic acid was detected from day 70 onwards, obtaining a total amount of circa 0.5 g/L.

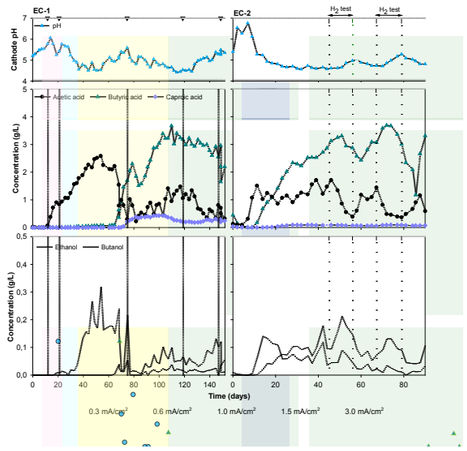

Figure 1. Cathode pH and product concentration in EC-1 and EC-2 along the experimental period under different applied current densities. Inverted triangles mark the changes of applied current.

EC-2 was operated from the beginning at a current density of 1.5 mA/cm^2. The inoculation with an enriched culture, as well as the higher current density, resulted in a lag phase 82% lower than EC-1 for butyric acid production. The production rate obtained for butyric acid was 14.2 g/(m^2·d), similar to the one of EC-1, confirming the replicability of the process. The product selectivity towards butyric acid was 78 % (Table 1), higher than in the few previous studies focusing on the butyric acid production from CO_2 (Ganigué et al., 2015, Raes et al., 2017). According to 16S rRNA metabarcoding analyses of the microbial community, *Megasphaera* sp. appeared as the most abundant genus. Members of this genus have been described as having the ability for chain-elongation (Wang and Yin, 2022).

Besides, the power required to produce the target compound was only 34.6 kWh/kg. This was due to the low ohmic resistance of the cell (15.7 mΩ·m^2) that can be further reduced by using zero-gap configurations (Baek et al., 2022)

Table 1. Average operational and performance parameters of the cells during periods of linear ($R^2 \geq 0.97$) production periods.

		EC-1			*EC-2*			
	Period (days)	12-19	21-54	65-79	7-11	14-28	18-28	46-51

Operation conditions	**Current applied (mA/cm²)**	0.6	1.0	1.0	1.5	1.5	1.5	1.5
	Cell voltage (V)	2.40	2.57	2.58	2.67	2.66	2.67	2.68
	Cathode potential (V *vs* SHE)	-0.55	-0.51	-0.50	-0.42	-0.47	-0.46	-0.40
	pH range	5.4 - 6.1	4.5 - 5.8	4.9 - 5.6	5.3 - 6.8	4.7 - 5.3	4.7 - 4.9	4.6 - 4.7
	pH_2(atm)	0.91	1.14	0.85	1.34	1.38	1.50	1.80
	OD (UA)	0.12	0.11	0.28	0.22	0.38	0.41	0.17
Performance parameters	**Production rate (g/(m²·d))**	10.0	5.5	14.5	27.3	14.2	0.8	2.2
	Production rate (mg/(L·d))	125.4	68.8	181.5	340.9	177.4	10.1	27.0
	Power requirement (kWh/kg)	34.4	111.1	34.6	34.5	65.4	1111.1	416.7
	CE (%)	25.5	7.2	45.3	27.6	24.6	1.7	5.6
	Selectivity (%)	95.8	59.2	74.2	82.6	77.6	4.6	27.9

After accumulating butyric acid in EC-2 catholyte, the CO_2 supply was interrupted (famine conditions) to maintain a high hydrogen partial pressure (pH_2 > 1.5 atm) at the cathode, which favours butanol production via solventogenesis. A butanol production rate of 2.2 g/(m^2·d) was obtained, with up to 28 % selectivity (Table 1). This confirmed that solventogenic pathways were favoured at low pH, low CO_2 concentration and high pH_2.

CONCLUSIONS

This study showed that alternating high pH_2 and pCO_2 promotes butyric acid production from CO_2 in MES cells. The microbial community dominated by *Megasphaera* sp. reached a remarkably high selectivity of 78%. The efficient cell design with low ohmic resistance contributed reducing the electric power requirement to 34.6 kWh/kg of butyric acid. This main compound can be upgraded to butanol by interrupting the CO_2 supply, keeping a high pH_2 and low pH.

AKNOWLEDGEMENTS

This research was carried out in the project "PANGEA – Process intensificAtioN for bioelectroCO2 recyclinG into carbon-nEutrAl products) funded by the Spanish Ministry of Innovation and Science (ref. PID2021-126240OB-I00). MR-C is grateful for the support of the Spanish Government (FPU20/01362). Abstract

This study explores a novel biological conversion of CO_2 and H_2 into fine chemicals produced at high salinity, hydroxyectoine and ectoine, that have an important value for the production of pharmaceuticals and cosmetics. Microbial pathways to produce ectoine and hydroxyectoine were investigated in several genomes of halophilic microbes able to use CO_2 (carbon source) and H_2 (energy source) through a novel methodology called genomic mining. A total of 11 species containing these genes were identified and selected for lab tests. Firstly, the species were exposed to H_2/CO_2 to verify their capacity to produce ectoines from CO_2. Further laboratory analyses in bioreactors showed that the most promising bacteria for this bioconversion were *Hydrogenovibrio marinus*, *Rhodococcus opacus* and *Hydrogenibacillus schlegelii*. Overall, these results constituted the first proof of this novel valorisation of CO_2 into pharmaceutical products with high economic and social value.

Keywords: Bio-economy, circular economy, CO_2 abatement, GHG bioconversion, novel cell platforms, pharmaceuticals.

INTRODUCTION

The industrial sector is one of the main sources of anthropogenic CO_2 emissions. Concomitantly, several of these industrial processes generate and store on-site green or blue hydrogen (H_2) with the aim of using it as an alternative energy source. In these scenarios, CO_2 is a perfect feedstock for its *in situ* transformation into chemicals where H_2 can be used as the energetic power to promote this valorization (Nisar et al., 2021). This is possible using biological dark gas fermentation that is based on the biocatalytic action of chemolithotrophic microorganisms able to grow with CO_2 as the only carbon source and valorize this GHG emissions thought out the production of interesting chemicals (Anand et al., 2020). However, current CO_2 bioconversion processes are still not profitable due to the utilization of a small number of model microorganisms and the production of low-price compounds. Therefore, the development of new technologies, which expand microbial catalysts and the portfolio of valuable products synthesized from the abatement of CO_2 is of great interest. Attractive compounds, due to their high market value, include ectoine and hydroxyectoine (1000-1200 € Kg^{-1}), which are small organic molecules that protect the cells under extreme halophilic conditions. Their exceptional properties are already being translated into health-promoting and therapeutic activities. In fact, (hydroxy)ectoines are already being manufactured in the bio-industry using sugars and sold to important pharmaceutical companies (Becker and Wittmann, 2020). However, the potential for generating ectoines from renewable or waste-based carbon sources has remained largely unexplored. Thus, this research aims to identify novel microorganisms capable to produce (hydroxy)ectoines from CO_2 and H_2. To this aim, halophilic chemolithotrophs were first determined through genomic mining and then, the transformation of CO_2 into ectoines was tested in the laboratory for proof-of-concept validation.

MATERIALS AND METHODS

Selection of chemolithoautotrophic organisms able to produce (hydroxy)ectoines

Target genomic mining was used to search for key genes that encode for specific enzymes necessary to produce the target chemicals (considered diagnostic enzymes). To perform these searches, we downloaded all the representative genomes of halophilic chemolithotrophs, able to use H_2 as energy source, from the National Center for Biotechnology Information (NCBI) using Datasets v.10.0.0. Their genomes were screened for genes encoding for enzymes involved in (hydroxy)ectoines synthesis pathways, specifically: *ectA, ectB*, *ectC* and *ectD*, *ectR*, and two genes involved in the production of precursors (*ask* and *asd*). Alignments or profile Hidden-Markov Models for each gene were also retrieved from public databases and searched against the downloaded proteomes using Interproscan. From those analysis, 7 strains were selected for laboratory validation. They were purchased from DSMZ (Brunswick, Germany). Growth tests with H_2/CO_2 were performed in quintuplicate using 100 mL ammonium mineral salt medium (AMS) supplemented with 3% NaCl in 200 mL gas-tight bottles with 10 CO_2: 40 H_2: 50 air (% v/v) in the headspace. 5% of actively grown bacteria was used as inoculum. The experiments lasted until H_2 complete depletion. The biomass dry weight, (hydroxy)ectoines content and gas concentration were monitored for all the strains. The bacteria with the highest productivities was selected for optimization in 1 L gas tight bioreactors.

Analytical methods

CO_2 and H_2 consumption were measured with a gas chromatograph with a TCD detector (Interscience, The Netherlands). Ectoine and hydroxyectoine were extracted following the method of Cantera et al. (2022) and concentrations were measured with a Shimadzu Prominence-i LC-2030C plus HPLC with a UV detector at 210 nm and equipped with a Polaris, NH2, 180Å, 3 µm, 4,6 x 150 mm. For biomass determination, optical absorbance at 600 nm (OD600) was measured using a UV/Vis spectrophotometer. Dry biomass concentration was measured as total suspended solids according to Standard Methods.

RESULTS AND DISCUSSION

Selection of potential chemolithoautotrophic ectoine-producing microorganisms

The genomic mining showed that eleven halophilic chemolithotrophs able to grow with CO_2 as sole carbon source and H_2 as the energy source had the genes to codify the enzymes for ectoine synthesis and six for hydroxyectoine synthesis (Figure 1). Among these, the following aerobic strains were tested for laboratory validation with CO_2 and H_2: *Alkalilimnicola (A.) ehrlichii, Hydrogenovibrio (H.) marinus, Hydrogenibacillus (H.) schlegelii, Pseudonocardia (P.) autotrophica, P. carboxydivorans, P. dioxanivorans, Rhodococcus (R.) opacus*.

Experimental screening for ectoine and hydroxyectoine producers

In our study, we detected chemolithotrophic growth (CO_2/H_2) of *P. autotrophica* and *P. dioxanivoran*s while *P. carboxydivorans* did not grow with these substrates. *P. dioxanivorans* accumulated the highest amounts of hydroxyectoine (41.4 ± 9.1 mg hydroxyectoine g $biomass^{-1}$) of all the tested strains, at the salinity range tested. However, the doubling times obtained for *Pseudonocardia* species in liquid phase were very long, thus process productivities would be low. *A. ehrlichii* did not show activity or growth on CO_2/H_2, despite viability when grown in rich medium. *H. schlegelii, H. marinus,* and *R. opacus* were able to use CO_2 with H_2 with doubling times inferior to 24 hours. The highest ectoine content at 3% NaCl was obtained with *H. marinus*. *R. opacus* and *H. schlegelii* accumulated hydroxyectoine in addition to ectoine. Thus, according to their fast growth and their high ectoines accumulation, these three species were selected for further optimization.

Continuous transformation of CO_2 into ectoines

The implementation of the selected strains in 1 L batch bioreactors was used to determine the optimal production and growth conditions. *H. marinus* accumulated the highest amount of ectoine among the three tested strains at 6% NaCl (79.6 ± 10.5 mg ectoine g $biomass^{-1}$) and had the fastest growth at 6% NaCl with the shortest lag phase. Hydroxyectoine was not detected, which was expected since *H. marinus* lacks the *ectD* gene. Interestingly, ectoine content was similar for *R. opacus* and *H. schlegelii* at all the salinities tested, but hydroxyectoine increased at higher salinities. *R. opacus* accumulated maximum hydroxyectoine values at 7% NaCl (52.1 ± 4.3 mg hydroxyectoine g $biomass^{-1}$) while *H. schlegelii* reached hydroxyectoine contents of 62.0 ± 7.9 mg of hydroxyectoine g $biomass^{-1}$ at 5% NaCl (Figure 2). These hydroxyectoine values are in the range of the hydroxyectoine yields obtained with rich carbon sources, such as glucose.

Our results demonstrate for the first time the feasibility of producing ectoine with CO_2 using relatively low salt concentrations. Additionally, we were able to produce hydroxyectoine using as an isolate osmolyte, which has higher economic value than ectoine and is rarely synthesized separately. Overall, this research set, by means of the use of an innovative genomic technique and laboratory validation, the possibility to find novel microorganisms able to transform CO_2 into fine chemicals with important value for the economy and society. This will impulse the future implementation of CO_2 biotransformation platforms capable of creating value out of CO_2 mitigation.

Abstract

This study explores the feasibility of applying MICP mediated by laboratory cultured *S. pasteurii* to precipitate copper (Cu) and zinc (Zn) from aqueous solutions with similar composition than anaerobic leachates. Solutions containing *S. pasteurii*, urea (20 g L^{-1}), volatile fatty acids (VFAs) (3 g O_2 L^{-1}) and varying concentrations of Cu and Zn (0, 0.5, 1, 5, 10 and 25 mg L^{-1}) at initial pH values adjusted to 5, 6 and 7, were incubated during seven days at 30 °C under aerobic conditions. Results showed that urea degradation led to an increase in NH_4^+ concentration and pH, despite the absence of bacterial growth, indicating urease activity. In the presence of biomass, Cu precipitation yields were higher than 50% for all concentrations tested although significantly lower urea hydrolysis yields were observed at pH=5 and 6, showing that urease activity may not be the only factor explaining Cu precipitation. Zn precipitation yields showed a clear decreasing trend at higher concentrations (i.e. from 100 % to 25 %) indicating a possible toxic effect on *S. pasteurii* activity. Furthermore, precipitation yields of Cu and Zn were lower in the presence of VFAs in all the conditions tested. These results aim to contribute with basic knowledge for next generation waste treatment facilities driven by bioprocesses focused on resource recovery applying technologies that mimic natural biogeochemical cycles

Keywords: Microbial induced carbonate precipitation; metals recovery; Sporosarcina pasteurii; volatile fatty acids; wastewater treatment

INTRODUCTION

There is a growing pressure on finding new sources for metals extraction to overcome a possible shortage of mineral resources in the near future. In this context, the application of biotechnologies for metals recovery can play a major role contributing to the ongoing transition to a circular economy. Among the different biotechnologies currently available for waste treatment and resource recovery, the integration of anaerobic digestion (AD) and microbial induced carbonate precipitation (MICP) pose many advantages.

AD is a well stablished technology commonly used for waste stabilization and biogas generation which can increase its resource exploitation capacity by promoting the formation of volatile fatty acids (VFAs) during anaerobic fermentation to leach metals from organic waste (Molaey et al., 2021)and limited information is available on migration and transformation behavior of potentially toxic metals during anaerobic digestion (AD. On the other hand, ureolysis driven MICP showed to be a novel sustainable alternative to remove metal ions from aqueous solutions via direct precipitation as metal carbonates (Kim et al., 2021; Qiao et al., 2021)four isolates which had the greatest urease production, calcite precipitation, and endurance to the heavy metals were obtained from contaminated areas during the screening steps. These isolates along with Sporosarcina pasteurii were used to bioprecipitate zinc (Zn. Among the extensive variety of microorganisms that hydrolyses urea, the non-pathogenic soil organism *Sporosarcina pasteurii* is widely considered for MICP applications since it has the potential to produce large quantities of active intracellular urease which leads to high yields of carbonate ions within a short time (Stocks-Fischer et al., 1999). The new approach proposed in this study is based on the integration of anaerobic fermentation and carbonate precipitation induced by *S. pasteurii* for metals bioleaching and recovery. To the best of our knowledge the effect of VFAs on MICP has not been studied yet. Therefore, the main objective of this study was to investigate the extent to which *S. pasteurii* can remove Cu and Zn from liquid solutions in the presence of acetate and propionate at acid to neutral pH values (i.e. similar conditions present in liquid anaerobic leachates).

MATERIALS AND METHODS

S. pasteurii culture and growth

S. pasteurii (DSM 33) cultured in an autoclaved growth medium which consisted of brain heart infusion (BHI) (37 g L^{-1}) and urea (20 g L^{-1}). The bacterial suspension was kept at room temperature until use for bacterial growth assays. 1 mL of this suspension was inoculated in a 500 mL liquid growth medium containing yeast extract (15 g L^{-1}) and urea (20 g L^{-1}) at pH=7.5 in a 1L Erlenmeyer. Incubation for growth assays was performed under aerobic conditions at 30 °C for three days before each bio-precipitation assay.

Bio-precipitation assays

After S. pasteurii growth, the complex medium was removed from the bacterial suspension to avoid any bias with metals precipitation. Bio-precipitation assays were performed in 50 mL Falcon tubes with a concentration of biomass of OD_{600} = 0.6 and 20 g L^{-1} of urea as suggested by Duarte-Nass et al (2020)the application of copper precipitation through microbe-induced carbonate precipitation (MICP to ensure maximum urease activity. All Falcon tubes contained varying concentrations of Cu and Zn (i.e. 0.5, 1, 5, 10 and 25 mg L^{-1}), at different initial pH values (i.e. 5, 6 and 7). To study the effect of VFAs on MICP, some samples were spiked with 3 g O_2 L^{-1} of acetic and propionic acid. Samples and controls, tested in triplicates, were **incubated during seven days under aerobic conditions at 30 °C in an incubator shaker at 180 rpm. samples were then centrifuged and filtered for determination of ammonia nitrogen (N-NH_3) and dissolved metals concentration in the supernatant. pH was measured immediately after centrifugation. The concentration of Cu and Zn in solution was analyzed by ICP-OES and the precipitation percentage was calculated from the original concentration of metals in the stock solutions. pH and N-NH_3 concentration were measured as indicators of urease activity. N-NH_3 in samples with S. pasteurii was determined colorimetrically by direct Nesslerization following the Standard test method for ammonia nitrogen in water. The percentage of urea hydrolysis was calculated based on the ammonium (NH_4^+) concentration derived from Nesslerization. Statistical analyses were carried out using one-way analysis of variance (ANOVA) to assess the significance of the results with a confidence level of 95%.**

RESULTS AND DISCUSSION

Urease activity

Final pH values were similar in all the conditions tested, varying between 7.0-9.2 in all the samples where *S. pasteurii* was inoculated except when the initial pH was adjusted to 5 and VFAs were spiked (Figure 1 (a)). These pH values fall into the optimum pH range for urease activity (Stocks-Fischer et al., 1999). A higher pH increase was observed at lower initial metals concentration indicating that urease activity might be affected by metals concentration in solution. A same decreasing trend in the final pH values at higher metals concentration was observed by (Mugwar and Harbottle, 2016)metal toxicity and availability limit the activity and remedial potential of bacteria. We report the ability of a bacterium, Sporosarcina pasteurii, to remove metals in aerobic aqueous systems through carbonate formation. Its ability to survive and grow in increasingly concentrated aqueous solutions of zinc, cadmium, lead and copper is explored, with and without a metal precipitation mechanism. In the presence of metal ions alone, bacterial growth was inhibited at a range of concentrations depending on the metal. Microbial activity in a urea-amended medium caused carbonate ion generation and pH elevation, providing conditions suitable for calcium carbonate bioprecipitation, and consequent removal of metal ions. Elevation of pH and calcium precipitation are shown to be strongly linked to removal of zinc and cadmium, but only partially linked to removal of lead and copper. The dependence of these effects on interactions between the respective metal and precipitated calcium carbonate are discussed. Finally, it is shown that the bacterium operates at higher metal concentrations in the presence of the urea-amended medium, suggesting that the metal removal mechanism offers a defence against metal toxicity.","author":[{"dropping-particle":"","family":"Mugwar","given":"Ahmed J.","non-dropping-particle":"","parse-names":false,"suffix":""},{"dropping-particle":"","family":"Harbottle","given":"Michael J.","non-dropping-particle":"","parse-names":false,"suffix":""}],"container-title":"Journal of Hazardous Materials","id":"ITEM-1","issued":{"date-parts":[["2016"]]},"page":"237-248","publisher":"Elsevier B.V.","title":"Toxicity effects on metal sequestration by microbially-induced carbonate precipitation","type":"article-journal","volume":"314"},"uris":["http://www.mendeley.com/documents/?uuid=7ca9b160-7bd6-4c98-97dd-4772cf809d4a"]}],"mendeley":{"formattedCitation":"(Mugwar and Harbottle, 2016 after seven days of incubation. Samples initially incubated at pH=5 and 6 also stabilized at pH≈7 indicating successful ureolysis driving production of alkalinity, thus implying encouraging results for the application of MICP to recover metals from acid effluents. Similar results were found by Proudfoot et al (2022) in mine waste with an average initial pH=4.4. Figure 1 (b) shows urea hydrolysis percentage of samples and controls after seven days of incubation. By the end of the experiment, ureolysis was observed in all the samples where *S. pasteurii* was inoculated, however, the maximum urea hydrolysis was only found in samples where the initial pH was adjusted to 7. Less than 4% of urea hydrolysis was observed in samples incubated at pH=5 and 6 at the highest metals concentration tested (i.e. 5, 10 and 25 mg L^{-1}) **suggesting a correlation between urease activity and metal tolerance, in agreement with several studies (Kang et al., 2016; Mugwar and Harbottle, 2016; Qiao et al., 2021)the efficiency of Microbially Carbonate Induced Precipitation (MICP.**

Metals precipitation

The precipitation yield of Cu was higher than 50% in all the conditions tested, except for samples spiked with VFAs (Figure 2 (a)). These results correlates well with pH final values found in samples after the incubation period, showing a high dependence of Cu precipitation on the pH of the solution as it was also observed by Duarte-Nass et al (2020)the application of copper precipitation through microbe-induced carbonate precipitation (MICP. In the presence of VFAs, Cu precipitation was significantly lower at the same initial pH, indicating that Cu-VFAs soluble complexes might be formed (Panina et al., 2002). Samples not spiked with VFAs showed significantly higher Zn precipitation yields at lower initial concentrations i.e. 0.5, 1 and 5 mg L^{-1}**, despite the set pH at the beginning of the bio-precipitation assays** (Figure 2 (b)). These results are in line with findings reported by Kim et al. (2021) and Mugwar and Harbottle (2016)metal toxicity and availability limit the activity and remedial potential of bacteria. We report the ability of a bacterium, Sporosarcina pasteurii, to remove metals in aerobic aqueous systems through carbonate formation. Abstract

High carbohydrate concentrations in mixed culture fermentation (MCF) result in higher products concentration, making the subsequent extraction process more cost-effective. However, this might also result in inhibition by undissociated acids (HA). A concentration threshold of HA inhibiting MCF is determined in this study. A lab-scale fermenter was continuously operated at constant experimental conditions and increasing influent glucose concentrations. The glucose conversion was found to be inhibited repeatedly with concentrations of undissociated acids above 24.9 mM, equivalent to 18.5 g COD L_{Feed}^{-1}. This limit concentration of undissociated acids appears to inhibit carbohydrate conversion. By raising pH to reduce the HA concentration, the inhibition was quickly reversed, and up to 34 g COD L_{Feed}^{-1} of glucose was fully consumed. Using granular biomass also allowed extending carbohydrate conversion above 18.5 g COD L_{Feed}^{-1}.

Inhibition; Organic acids; Resource recovery; Short-chain carboxylic acids; Substrate concentration; Undissociated acids.

INTRODUCTION

The application of mixed culture fermentation (MCF) represents an appealing resource recovery strategy to produce valuable chemicals from biowaste (e.g., food waste and industrial wastewater). In MCF, organic substrates are converted into a mixture of CO_2, H_2, solvents, and organic acids. The organic acid produced can be used in several downstream industrial processes: for biological nitrogen removal in sewage treatment; as a substrate for chain elongation processes; for biofuel production; to synthesize biodegradable polymers; and for applications in the pharmaceutical, food, textile and plastics industries The potential for sustainable and economically feasible production and recovery is currently limited at an industrial scale by the inhibition by products accumulation, amongst other challenges.

The suspected mechanism for inhibition by organic acids seems to be linked to the dissociation state. Undissociated acids can freely permeate the cell membrane and dissociate intracellularly at the higher cytosolic pH, which is maintained close to neutral. The uptake of protons lowers the cytosolic pH, increasing the maintenance energy required by the cell to create the transmembrane proton gradient to generate ATP (Booth 1985).

Most studies examining acidic product inhibition in MCF systems were conducted in batch assays, but there is still a lack of understanding about systems operated in continuous mode. In a previous study, we explored the limits and inhibition mechanisms of an MCF operated continuously (Rafay et al. 2022). The maximum concentration of undissociated acids compatible with full glucose conversion was 52 mM, at 38 g COD L_{Feed}^{-1}. However, this high substrate concentration was attained in presence of granules, which might provide protective internal microenvironments such that normal metabolic activities can be sustained even in bulk environments with high acidity. In the present study, the limits of carbohydrate conversion in a continuous MCF system were also explored, but in this case with the presence of only suspended biomass.

MATERIALS AND METHODS

A continuously stirred tank reactor (CSTR)s (Fermac 360, Electrolab), with a working and a headspace volume of 1.5 and 0.5 L, respectively (Figure 1), was operated in continuous mode. Operating parameters such as temperature (30°C), pH (5.4), and HRT (20 h) were kept constant throughout the operating period. pH was monitored and controlled. Glucose was used as the sole carbon source. To identify the limits of fermentation capacity, the feed glucose concentration was increased stepwise (3.8-33.8 g COD L_{Feed}^{-1}) until inhibition by undissociated acids was detected.

RESULTS AND DISCUSSION

The MCF was operated for 310 days with an influent flow rate of 1.81 ± 0.09 L^{-1} d^{-1} corresponding to an HRT of 20.0 ± 1.1 h. The COD balance errors were lower than 6.5 % in all the periods (Figure 2), but in Period XIII (10.3 %), indicating that the main fermentation products were successfully accounted for. Glucose was completely consumed at feed concentrations between 4 and 24 g COD L^{-1} (Figure 3), but with the presence of granular biomass inside the MCF (Periods I-V). In our previous study, using the same reactor configuration and experimental conditions, the accumulation of granular biomass was also observed inside the fermenter at high glucose feed concentrations (Rafay et al. 2022). The limit in the glucose fermentation capacity was found at 33 g COD L_{Feed}^{-1}, with 32 mM of undissociated acids. However, the development of granular biomass led to a significant increase in the fermentation capacity, and full glucose conversions were achieved even at undissociated acids concentrations up to 52 mM, with 38 g COD L_{Feed}^{-1}. Granular biomass is known to be less sensitive to environmental conditions compared to suspended biomass.

In the present study, to avoid granules accumulation, the effluent line was placed at the bottom of the reactor as shown in Figure 1. The vertically positioned effluent tube connected to the effluent pump was previously acting as an in-situ settler. After replacing the effluent line (day 76), a quick granules washout and a high reduction in the glucose conversion capacity were observed. From this moment onwards, granules accumulation was not detected anymore. Along with the washout, lactate started to accumulate in the fermenter, which might be considered a sign of saturation. Due to the lower conversions without granules, the glucose concentration had to be reduced from 24 to 4 g COD L_{Feed}^{-1} (day 100), and once the reactor stabilized, the feed concentration was raised first to 9 and then to 17 g COD L_{Feed}^{-1}, without observing glucose accumulation.

The activity of the suspended biomass was highly inhibited at 23 g COD L_{Feed}^{-1}. Unlike between days 21 and 76, with the same feed glucose concentration, granules were not available to protect the microbes from the high undissociated acids concentration, 29.1 mM (Figure 2). This suggests that the concentration of the acids inhibiting glucose conversion should be found between 17 and 23 g COD L_{Feed}^{-1}. To provide a more accurate inhibition value, the glucose concentration in the feed was raised again but in smaller increments. Glucose accumulated at 21 g COD L_{Feed}^{-1} (Period XII), but this inhibition was quickly reversed by increasing the pH from 5.4 to 6, as higher pH reduces undissociated acids concentration.

At pH 6, up to 33.8 g COD L_{Feed}^{-1} were fully fermented. Further concentration values were not evaluated. Overall, the results achieved strongly suggest that concentrations of undissociated acids above 24.9 mM must be avoided to prevent from possible inhibition events in mixed culture systems with only suspended biomass. Prolonged lactate accumulation could be used as a sign that carbohydrate fermentation is close to saturation, useful for possible full-scale applications. To extend carbohydrate conversion to higher substrate concentrations the formation of granular biomass and the impact of pH control on the accumulation of undissociated acids are determining factors to achieve full carbohydrate conversions in MCF at high acidic conditions.

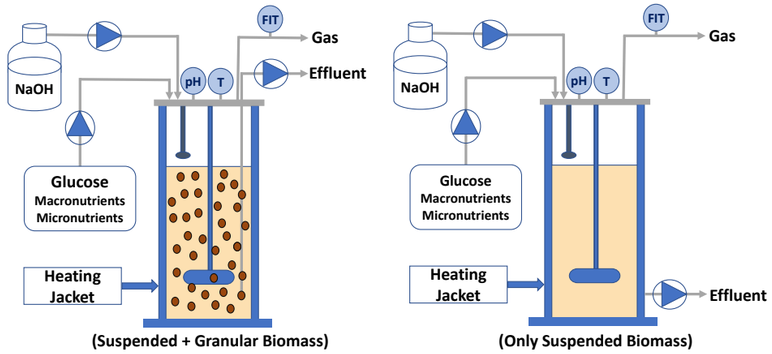

Figure 1. Schematic diagram of the open mixed-culture fermenter (MCF) (1.5 L) operated in continuous mode. Between days 0 and 76, the effluent was collected using a vertical pipeline (*left*), which enabled the accumulation of granular biomass. To promote the granular biomass washout, and keep only suspended biomass, the effluent's line location was shifted and placed at the bottom of the reactor (*right*).

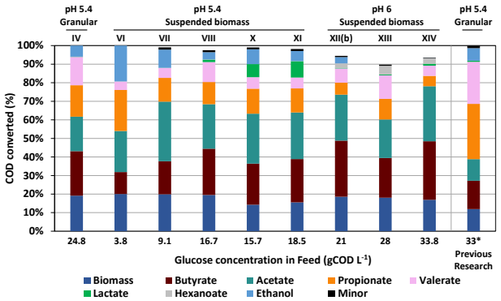

Figure 2. Representative product spectra (%CODproduct/CODglucose consumed), of the different operating periods for the mixed-culture fermenter. Only periods in which steady-state conditions were achieved are represented. The star (*) indicates the results achieved in previous research carried out by Rafay et al. (2022) in which the same reactor setup and operating conditions were used.

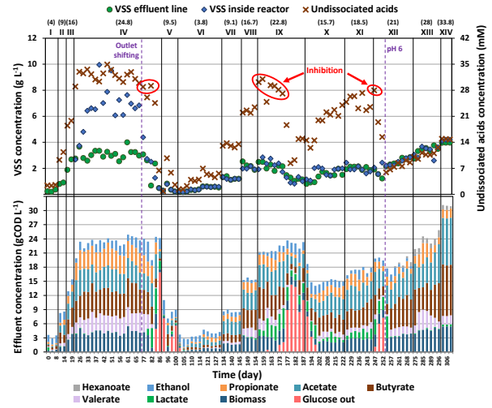

Figure 3. Evolution of the volatile suspended solids (VSS) concentration inside and in the effluent of the mixed culture fermenter (primary axis), and the concentration of the undissociated acid throughout the study (secondary axis) (*top*); and effluent's products concentration (*bottom*). The black vertical lines separate the different periods regarding the COD concentration in the feed. The feed glucose concentration value (gCOD L_{Feed}^{-1}) is indicated at the top part of the graph between (). The pH was increased from 5.4 to 6, from day 145 until the end of the study.

Abstract

Fermentation of sewage sludge to produce VFA appears as an alternative of greater value than generating biogas. In order to improve the hydrolytic stage rate, that has been identified as the limiting one, alternatives such as thermal hydrolysis pre-treatment (THP) have been proposed. This work studies the influence of THP on VFA production in batch and continuous operations. In batch mode, the impact of THP was detrimental (maximum VFA yields of about 0.4 g COD-VFA/COD versus 0.3 with raw sludge without pre-treatment). In continuous operation, THP had proved not exerting noticeable influence on the yield nor on the transformation rate of COD on VFA (0.15-0.17 g COD-VFA/g COD substrate). Microbial community analysis showed that phylum *Firmicutes* was the predominant in both reactors and that the enzymes involved in VFA production were very similar regardless of the substrate fed.

Keywords

Sewage sludge, volatile fatty acids, thermal hydrolysis pre-treatment, microbial populations

INTRODUCTION

Sewage sludge has been traditionally valorised by anaerobic digestion (AD) with biogas as the final product. As alternative, VFA are proposed as bioproducts with higher added-value and with an increasing demand in the chemical industry, whose current market is mainly supplied by the petrochemical route.

The most critical stage of fermentation process is the initial hydrolysis, thus affecting the subsequent steps of acidification. To speed-up the process, a wide variety of pre-treatment technologies, such as thermal hydrolysis pre-treatment (THP), have emerged aiming at solubilizing organic matter. Its effect on biogas production has been well documented, showing most authors a positive influence on methane generation; in contrast, the influence of this pre-treatment on VFA production has been less studied.

What has been consistently reported in literature is that biotransformation of organic matter on VFA results always in a much lower yield than the attained when methane is the target product (Liu et al., 2020). Moreover, yields reached in batch tests are normally lower than in continuous operation.

The objectives of this work are: i) to evaluate the effect of the THP on the VFA production from sewage sludge in batch and continuous mode; ii) to identify changes on microbiome after THP and the main key-players.

MATERIAL AND METHODS

The substrate used (raw and pre-treated sludge) was a mix of primary and biological sludge from a Galician WWTP (Table 1). The effect of THP on the higher proportion of soluble COD is clearly observed in pre-treated sludge. The inoculum used was one collected from the anaerobic digester of the same WWTP of the substrates.

Batch acidification experiments were carried out in an adapted AMPTS II device, using bottles with a working volume of 0.5 L (in triplicate) at a temperature of 37 ± 1 °C. Inoculum and substrate amounts were added inside the bottles to achieve a food/microorganism ratio of 2 g COD substrate/g VS inoculum. 2-Bromoethanesulphonic acid sodium salt (BES, 3 g L^{-1}) was also added as inhibitor of methanogenesis. pH was initially adjusted to 8 adding NaOH and blanks were used to study the endogenous VFA production from inocula.

Table 1 Characterization of substrate and inoculum used in the batch acidification experiment

	Raw sludge	Pre-treated sludge	Inoculum
pH	6.12 ± 0.00	6.31 ± 0.01	8.02 ± 0.00
tCOD (g/L)	200.8 ± 2.0	162.5 ± 1.1	58.6 ± 1.0
sCOD (g/L)	9.6 ± 0.2	24.9 ± 0.4	5.4 ± 0.2
TS (g/L)	114.2 ± 1.1	91.0 ± 1.5	46.7 ± 0.3
VS (g/L)	94.0 ± 1.3	73.4 ± 1.4	26.5 ± 0.1
TN (g/L)	14.8 ± 0.1	10.5 ± 0.2	5.4 ± 0.4
TP (g/L)	2.7 ± 0.0	1.9 ± 0.1	2.0 ± 0.2
TAN (g N/L)	0.68 ± 0.03	0.36 ± 0.02	1.52 ± 0.04
$P\text{-}PO_4^{3-}$ (g/L)	0.146 ± 0.001	0.133 ± 0.002	0.094 ± 0.002

Continuous operation was carried out in two CSTR with a working volume of 5 L, which were maintained at 37 °C ± 1 °C with continuous agitation at a speed of 170 rpm. The reactors were initially inoculated with 5 L of inoculum fed with raw (reactor RS) and pre-treated sludge (reactor PS) diluted to 60 g COD/L. Both reactors were operated at a controlled pH of 8.5 at a hydraulic retention time of 10 days during the whole operation period (80 days), with an OLR in the range of 4.8-6.4 g COD $L^{-1}d^{-1}$.

A Hach D43900 spectrophotometer and associated cuvette kits were utilized to monitor the batch test as well as lab-scale reactors and associated experiments. VFA were determined by gas chromatography (Agilent Technologies, model 6850 Series II), equipped with a flame ionization detector (FID). Total genomic DNA was extracted by triplicate using Nucleospin Microbial DNA extraction kit (Macherey Nagel) that were pulled together. The V3V4 hypervariable region for *Bacteria* was sequenced in AllGenetics & Biology SL using an Illumina PE150 platform. The bioinformatic analysis was performed using the Microbial Genomics module workflow (v21.1).

RESULTS AND CONCLUSION

In summary, the acidification test showed that pH 8 was more favorable in terms of VFA yield than pH 10 and that the raw sludge obtained better results. At both pH, acetic acid was predominant in the mix, always exceeding 60% of existence, since alkaline conditions favor the production of this VFA (Fang et al., 2020). Moreover, the addition of the BES salt has not been effective since working at pH 8 the lines begin to decrease once the maximum is reached instead of remaining stable (Figure 1), which indicates that the methanogenic stage took place.

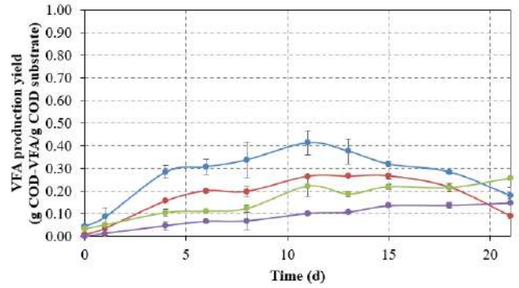

Fig. 1. Acidification yield of raw and pre-treated sludge at pH of 8 and 10. Raw sludge at pH 8 ( ), pre-treated sludge at pH 8 ( ), raw sludge at pH 10 ( ), pre-treated sludge at pH 10 ( ).

Additionally, two CSTR, reactor RS (fed with raw sludge) and reactor PS (fed with pre-treated sludge) were operated (Figure 2). In order to compare the VFA yield and acidification yield in both reactors, the Student's t-test (two independent samples with equal variances with an $\alpha = 0.05$) was used. The statistical analysis concluded that there was no significant difference between the VFA yield obtained with raw and pre-treated sludge (0.15-0.17 g COD-VFA/g COD substrate in both reactors). Therefore, working in continuous mode, THP has no influence on VFA production from sewage sludge. As in the batch tests, the VFA percent composition obtained was practically the same with the two substrates, with acetic acid always having a presence greater than 65% in terms of COD.

A microbiological study of the populations present in both the inlet and outlet streams of the continuous reactors has been carried out by taking samples on six different days. The alpha diversity measures suggest a specialization of the microbial communities present in both reactors converging towards similar hydrolytic and acidogenic populations which give rise to the same VFA yields in continuous operation, independently of the pre-treatment applied to the inlet. The most abundant phyla detected in both reactors was *Firmicutes*, being the enzymes involved in VFA production very similar in both reactors' outlets independently of the pre-treatment of the feeding. This reaffirms the equality both in the production yields and in the selectivity of the acidogenic process, being the same those key-players involved in the VFA production.

In conclusion, raw sludge was compared with thermally pre-treated sludge to see the effect of THP on VFA production in two modes, batch and continuous operation. In batch mode, THP resulted in lower VFA yields at both tested pH, being pH 8 the most favourable in terms of VFA yield. In continuous reactors, the negative effect of THP disappeared, obtaining the same VFA yields and distribution mix independently of the pre-treatment of fed sludge. Continuous mode microbiology analysis confirmed that both reactors converged into similar bacterial populations with *Firmicutes* phylum as the most abundant one.

Abstract

This study evaluated the effect of temperature (25, 35, 45 and 55 ºC) on waste activated sludge and food waste co-fermentation under continuous conditions. Temperatures had a significant influence on volatile fatty acids (VFA) yield and profile. The highest yield was achieved at 55 ºC followed by 45, and 35 °C. Temperature also had significant influence on VFA profile. High concentrations of acetic and butyric acids were obtained at 55 ºC, while the VFA profile at 35 °C was dominated by acetic, butyric, and propionic acids. At 45 ºC was facilitated the accumulation of caproic acid. Temperature had an influence on the fermenters' microbial community. Two different waste activated sludges were studied at 35 ºC from which different VFA concentration, yield and microbiome were obtained, possibly due to waste activated sludge inherent properties.

Keywords

Fermentation; microbiology; organic waste; sewage sludge; short chain fatty acids; temperature.

INTRODUCTION

Mixed-culture fermentation is an emerging biotechnology to transform organic wastes into easily assimilable organic compounds such as volatile fatty acids (VFAs), lactic acid and alcohols. At wastewater treatment plants, waste activated sludge (WAS) co-fermentation with food waste (FW) is an opportunity to boost VFA and alcohols (X-OH) yields with respect to WAS mono-fermentation. The synergy of this mixture relies on FW high biodegradability and WAS buffer capacity (Perez-Esteban, et al., 2022). Temperature is one of the most influencing parameters on fermentation due to its impact on carbon diversion. The highest fermentation yields have been reported at mesophilic conditions, although optimum performance have also been reported at psychrophilic and thermophilic conditions. However, most of these studies have been carried out in batch assays, which results could be strongly driven by the starting microbial community.

This research evaluates the impact of temperature (25, 35, 45 and 55 ºC) on WAS:FW co-fermentation performance under continuous conditions. The fermenters' microbial community was also assessed to establish links with the obtained VFA yield and profile.

MATERIAL AND METHODS

Substrates

WAS was collected from the secondary clarifier of a municipal WWTP. Synthetic FW was prepared to mimic the composition of household biowaste as for Vidal-Antich et al. (2021).

Experimental platform and methods

The experimental platform consisted of 4 L jacketed reactors equipped with mechanical stirrers. Each fermenter was manually fed once a day with a 70:30 WAS:FW mixture (%VS basis). The organic loading rate was 11 gVS/(L·d) (Hydraulic retention time of 3.3 days). The pH of the fermenters was not controlled. Two different runs (A and B) were carried out in this study. In Run A, the fermenters' temperatures were 25, 35 and 45 ºC, while in Run B, were 35 and 55 ºC. The following parameters were analysed three times per week following the Standard Methods procedures (APHA, 2017): VFA and X-OH, soluble chemical oxygen demand (sCOD), pH, total ammoniacal nitrogen (TAN) and alkalinity. DNA extraction was performed following the MiDAS field guide and the FastDNA® spin kit for soil. The V3-V4 region of 16S rRNA was sequenced by Novogene. Taxonomy was assigned to each amplicon sequencing variant (ASV) using MiDAS 4.8.1 database. Statistical and microbiology analysis were carried out with R studio.

RESULTS AND DISCUSSION

Fermenters' performance

Figure 1 shows significant differences in total VFA concentration depending on the working temperature. At 35 ºC, Runs A and B yielded VFA concentrations statistically different (336 ± 25 and 253 ± 11 mgCOD/gVS, respectively), showing that WAS characteristics had an important impact on fermentation yields (Figure 1a). The VFA concentration values recorded at 55 ºC were the highest (15291 ± 949 mgCOD/L) while at 25 ºC achieved the lowest concentration (8530 ± 398 mgCOD/L) (Figure 1b). These results indicate that thermophilic conditions enhance both the hydrolysis and the acidogenesis step since it showed the highest conversion of sCOD to VFA.

Figure 2 shows that each temperature had distinctive cluster based on the percentage of individual VFA, although the condition 25A, 35A and 35B were very close to each other. This fact indicates that each temperature had a statistically different VFA distribution. It is worth mentioning that 45 and 55 ºC did not enriched propionic acid, while 25 ºC and 35 ºC did. The VFA profile at 55 ºC is enriched in acetic and butyric acid, which is in accordance to Koupaie et al., (2021). 45 ºC led to the enrichment of caproic acid, which was not present in the other temperatures.

Figure 3 shows the monitored parameters of co-fermentation during Run A and B. The pH was slightly higher as the operating temperature increased (Figure 3a). This pH differences may be due to the higher buffering capacity of the fermentation medium at higher temperatures (Figure 3b). This could be partly explained by the higher concentration of ammoniacal nitrogen at higher temperature, indicative of higher organic matter ammonification at higher temperatures (Figure 3c) (Ariunbaatar, et al., 2015; Zhao, et al., 2018). Figure 1d shows that sCOD also increased with temperature, indicating an improvement of hydrolysis capacity at higher temperatures.

Microbial ecology

The indigenous microbial community of the WAS used in Run A and B was different (Figure 4). The genus *Ca.Microthrix,* well-known for causing filamentous bulking in WWTPs (Jiang, et al., 2021), was the most abundant in both WAS. However, the genus midas_g_6 (family *Saprospiracea*), *Amirococcus* and *midas_g_31* (family *midas_f_31*) was more abundant in WAS B than WAS A.

There were significant differences between the microbial community at each temperature (Figure 5). The clusters 35B, 35A and 45A are very close to each other in the PCA, indicating lower differences among their microbial community. At 25 °C predominated the genus *Prevotella*, related with acidogenesis (Shrestha, et al., 2022). At 55 ºC, the microbial community was dominated by the phylum *Firmicute*, including *Ruminococcaceae* (family), *Oscillospirales* (order), *Clostridium sense stricto* (genus). The phylum Firmicute is known to be able to hydrolyse and ferment carbohydrates (Qin, et al., 2021). The microbial community at 35 °C of the Run A and B was quite similar except for the presence of *Actinobacteriota* (phylum) in Run B (Figure 6). The phylum *Actinobacteriota* is reported to have an important role in hemicellulose and lignin degradation (Guo, et al., 2021).

At 35 °C (Run B), a consumption of VFA (mainly acetic acid) was observed, possibly cause by VFA-consuming microorganisms. Microbial ecology suggested that it is not consumed by methanogenic archea since its relative abundance is less than 0.1%. The genera found in the 35 ºC (Run B) were *Methanosphaera*, *Methanobrevibacter* and *Methanosarcina*. These genera stand out for being hydrogenotrophic methanogens.

Abstract

Availability of ammonia, coupled or uncoupled with carbon feeding, can impact the selection of PHA producing microorganisms in mixed cultures. This research studied this impact on the selection of a PHA accumulating phototrophic mixed culture operated under light-feast/dark-aerated-famine, winter-simulated outdoor conditions, fermented domestic wastewater as feedstock and selected under three ammonia settings: ammonia availability only in light-phase, constant presence, and ammonia availability during dark-aerated-famine phase. Results showed that ammonia presence was required to promote growth of PHA-accumulating bacteria in dark-aerated-famine phase, whereas ammonia absence in the light-period favoured cyanobacteria growth, resulting in decreased phototrophic PHA accumulation capacity. Constant presence of ammonia was the best selection strategy attaining a PHA content of 21.6 %gPHA/gVSS (0.6 gPHA/L.day). Furthermore, light-feast/dark-aerated-famine operation ensured total carbon depletion from wastewater and demonstrated being able to maintain the system PHA accumulation performance under winter conditions, suggesting it can contribute to overcoming the seasonal constraints of outdoor operation.

Feast and Famine selection; Polyhydroxyalkanoates; Phototrophic-chemotrophic consortium; Phototrophic Purple bacteria; Transient illumination; Wastewater treatment

INTRODUCTION

Polyhydroxyalkanoates (PHAs) are bio-based and biodegradable polymers that can be internally accumulated as carbon reserves by many bacteria and have similar properties to traditional plastics. Recently, phototrophic mixed cultures (PMC), composed of a consortium of microalgae (oxygen producers) and phototrophic purple bacteria (PPB) (PHA producers), have surged as a new technology in this field. PPB are versatile metabolic bacteria, that are able to remove organic carbon from waste streams using sunlight, as a free energy source, contributing to a reduction of the biopolymer production costs (Capson-Tojo et al. 2020).

Thus far, studies using the conventional selection strategy of carbon feast and famine (FF) on PHA-producing PMCs have achieved PHA storage levels of 30%, using fermented mixtures of wastewater with molasses as feedstock, under open operation, while simulating summer outdoor conditions (Almeida et al., 2021). Previous PMC research has also shown that extended carbon feast phases can improve PPB growth and PHA accumulation potential. However, the existence of an inactive dark phase, due to the absence of oxygen production by microalgae, limits further growth of PPB on accumulated PHA, thus confining both feast and famine phases to the light period. Therefore, it is important to investigate the potential of aerating the night-time to convert it into an active phase and thus enhancing the overall PHA productivity of the system.

Regarding to the organic waste streams used for PHA production, the existing variable nutrient concentrations can directly impact the system performance. In fact, studies with aerobic mixed cultures have shown that uncoupling the ammonia supply from the carbon feeding can promote the culture enrichment in PHA producers and improve PHA productivity (Matos et al. 2021). However, such impact of ammonia supply on PMC selection and PHA production efficiency has never been tested.

The current study aims to determine operational conditions that can improve PHA accumulation in PMCs under outdoor conditions and using real fermented feedstocks. It will be explored the potential of utilizing the full light period as a feast phase for PPB and transforming the dark phase into an active period through mechanical aeration, enabling PPB to consume PHA during a dark-aerated-famine phase, as well as the assessment of different ammonia settings (light-ammonia, constant presence of ammonia and dark-famine ammonia) on the PMC selection and respective PHA productivity.

MATERIALS AND METHODS

A sequencing batch reactor (SBR), with a working volume of 5.8L, was inoculated with sludge from a PMC operated under a FF regime (Almeida et al., 2021). The reactor was operated under simulated outdoor-winter conditions, registered in a paddle wheel high-rate algae pond from Chiclana wastewater treatment plant (Jerez de La Frontera, Spain). At a temperature of 15°C, the PMC was selected under a FF regime, trough a 24 hour light-transient cycle (12h light/12h dark) with a light intensity of 139.5 W/m^2 (0.82 W/L), and externally illuminated by a halogen lamp (60W). During the 12h dark period, the reactor was aerated using an air pump and disperser to ensure the total carbon depletion and guarantee PHA consumption. The air pump switched off when the oxygen concentration reached 2 mg/L. The reactor was fed with a fermented mixture of domestic pre-treated wastewater (de-sanding and degreasing) supplemented with 1% v/v of molasses provided by the Guadalete sugar plant. The evolution of the microbial culture regarding its photosynthetic pigments, such as bacteriochlorophyll *a+b* (absorbance at 775 nm) and chlorophyll *a* (absorbance at 665 nm) pigments was performed by ethanol extraction, as described in Almeida et al. (2021).

RESULTS AND DISCUSSION

A sequencing batch reactor was operated under light-feast/dark-aerated famine and winter outdoor simulated conditions. Along the operation, different settings on the ammonia availability along the SBR cycle were imposed (light-ammonia, constant presence of ammonia and dark-famine ammonia). Figure 1 presents the profile of the PMC selected under each of the three ammonia conditions tested.

In light-ammonia condition (Figure 1.A), ammonia was provided only during the light phase to promote the growth of PPB over other chemotrophic microorganisms by restricting growth during the dark-aerated phase. Results showed that despite the successful PPB growth, a low PHA content was attained (11.2% g PHA/g VSS) and a steady production throughout the cycle, with no accumulation or consumption patterns, was observed. This outcome likely occurred because the bacteria could not utilize the stored PHA for growth without the presence of ammonia during the famine phase.

The operation under constant presence of ammonia was implemented not only to promote PPB growth during the light phase but to allow them to grow on the accumulated PHA during the dark-famine aerated phase. The long-term operation of this condition, also allowed to assess the culture behavior through different feedstock compositions (Figure1.C and Figure 1.D). It was observed that during the light period, less reduce compounds (acetate and propionate) presented higher uptake rates and were preferable for PHA production by PPB. Overall, the microbial culture was able to maintain PHA accumulation efficiency under constant presence of ammonia, regardless of feedstock composition or the feast-phase length imposed by an unfavorable feedstock (higher content of reduced compounds, such as butyrate and valerate), since the dark-aerated phase ensured total carbon depletion and furthered PHA production by aerobic microorganisms.

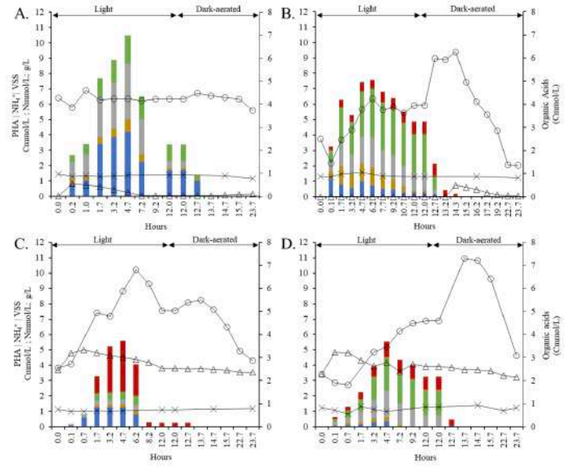

Figure 1. Photosynthetic mixed culture profile. **A.** Light-ammonia condition; **B.** Dark-famine ammonia condition; **C.** Constant presence of ammonia (feedstock with higher content of acetate and propionate); **D.** Constant presence of ammonia (feedstock with higher content of butyrate and valerate); (○) Polyhydroxyalkanoates (PHA) concentration; (×) Total Suspended Solids (VSS); (Δ) Ammonia (NH_4^+); (■) acetate; (■) propionate; (■) butyrate; (■) valerate; (■) ethanol; (■) lactate.

This condition registered the highest PHA content and production rates in both light and dark-aerated periods, indicating that both phototrophic and aerobic microorganisms were able to grow and accumulate PHA effectively in this condition. Under operation with favorable feedstocks the feast phase ended during the light period and a 21.6% g PHA/g VSS at a productivity rate of 0.6 g PHA/L·day was attained. While under unfavorable feedstock operation, carbon content passed to the dark period and the culture achieved a PHA level of 18.5% g PHA/g VSS at a production rate of 1.4 g PHA/L·day.

At last, dark-famine ammonia condition, aimed to study the separation of organic carbon from ammonia to promote the growth of photosynthetic microorganisms that accumulate PHA. During this condition, the selector reactor only achieved a PHA level of 10.4% g PHA/g VSS during the light period, and no further PHA accumulation was observed in parallel accumulation tests performed under increase light intensity (1.9 W/L) or synthetic acetate and propionate feeding. Overall, results show that the absence of ammonia during the light period, thrived the growth of other photosynthetic microorganisms, such as cyanobacteria. However, and despite cyanobacteria being able to accumulate PHA, a decrease in the culture's ability to accumulate PHA during the light period was observed, suggesting that these microorganisms were probably favoring growth through nitrogen fixation instead of PHA accumulation.

Overall, the proposed system operation with extended feast phases coupled to a dark aeration period, is able to ensure the well function of a photosynthetic system under winter conditions. Results showed that despite the existence of an aeration phase led to a drop in PPB pigment concentration (Bchl *a* + *b*), these were being produced, which was confirmed by DNA sequencing results that indicated the prevalence of PPB (Rhodobacter, Chromatiaceae and Rhodopseudomonas) over aerobic microorganisms (Paracoccus, Rhizobium, and Acidovorax). Additionally, and regarding to the system performance, similar PHA productivities were achieved compared to previous reports of PHA production with non-aerated PMC systems operated under the more favorable summer conditions (0.5 g PHA/L.day, Almeida et al. 2021). This suggests that the light-feast/dark-aerated famine system here presented could overcome winter conditions and may be able to ensure a continuous operation of PPB systems across seasons.

Abstract
The utilization of microbiomes for industrial biopolymer production is faced with significant obstacles. However, microbiomes have been observed to be both functionally robust and adaptable to changing environments. The use of cyanobacteria for biopolymer production has been identified as a promising approach as it helps to reduce greenhouse gas emissions and supports the formation of a closed-carbon loop for a circular economy based on polymers. The ultimate goal of this research is to devise a sustainable approach for producing bioplastics with phototrophic microbiomes through the utilization of nutrients present in wastewater. We have developed two strategies to enhance PHB production by utilizing field environmental microbiomes enriched with cyanobacteria. The first approach focuses on optimizing the culture conditions, resulting in a 14% of PHB production. The second strategy promotes the growth of PHB-producing cyanobacteria populations and has been shown to lead to a 22% increase in PHB production.

Carbon-based bioproducts; Photosynthethic Microbiome; Polyhydroxybutyrate

INTRODUCTION

Interest in microbial biopolymers is on the rise due to growing consumer demand for eco-friendly and sustainable products as an alternative to chemical-based polymers. One such biopolymer is polyhydroxybutyrate (PHB), a biodegradable polymer produced by various microorganisms for energy and carbon storage. It has potential applications in niche markets such as textiles, food, cosmetics, pharmaceuticals, and medicine (Li M, 2020). Cyanobacteria, a widespread group of photoautotrophic bacteria, can produce PHB using CO_2 and solar energy. The consumption of CO_2 for PHB production not only helps to mitigate greenhouse gases but also contributes to a closed-carbon-loop for a circular economy (Lee J et al., 2021). However, cyanobacterial PHB industrial production and commercialization remains a challenge due to lower productivity compared to PHB synthesis by heterotrophic bacteria (Ansari S, 2016), and high production costs resulting from the use of pure cultures, refined substrates, and sterile conditions, which limit its market potential (Tan D et al., 2020).

To bring PHB production to an industrial scale, phototrophic microbiomes have emerged as a viable alternative to pure-culture methods. Microbiomes have the advantage of not requiring reactor sterilization, having a wider metabolic potential, and expanding feedstock options (Scarborough MJ et al., 2022). A photosynthetic microbiome, which combines the benefits of working with a consortium with those of photosynthetic microorganisms, could use CO_2 and light for growth and bioproduct synthesis. However, research on biopolymer production by photosynthetic microbiomes is limited.

In this study, various photosynthetic microbiomes were evaluated for their ability to produce PHB. These cultures were obtained from environmental samples and enriched with cyanobacteria using low phosphorus concentration as a selective pressure. To boost biopolymer production, two approaches were employed: (1) altering operating parameters known to affect PHB synthesis, and (2) optimizing the culture to increase the presence of PHB-producing organisms. The ultimate goal of this study is to develop a sustainable method for producing PHB using phototrophic microbiomes, by recovering the nutrients present in wastewater. This approach aligns with the principles of circular economy, as it utilizes resources that would otherwise be considered waste, and transforms them into valuable bioproducts.

MATERIALS AND METHODS

Procurement of photosynthetic cultures

Seven samples were collected from four different locations (constructed wetland, river, canal and urban lake) in the metropolitan area of Barcelona, Spain. Samples were grown in laboratory conditions to obtain microbiomes enriched in cyanobacteria. Phosphorus (P) limitation was used to favor the growth of cyanobacteria against other phototrophic organisms (i.e. green algae). Most of the cultures were maintained with a P concentration in the flasks of 0.2 $mg \cdot L^{-1}$.

Microbial identification

The identification and classification of cyanobacteria present in the microbiomes were performed using a combination of morphological observation under a bright light microscope and molecular characterization via clone library analysis of the 16S rRNA gene.

Design of Experiments

The metabolic regime was evaluated by experiments combining three factors: (i) the presence of organic carbon (OC), (ii) inorganic carbon (IC) and (iii) light:dark photoperiods. Multivariable experimental design (DoE) and surface response methodology (SRM) were used to identify the optimal conditions and evaluate their effect on PHB production.

Enriching biomass in PHB-producing cyanobacteria

The Feast and Famine (FF) strategy, commonly used in PHB production by heterotrophic cultures, was implemented for the first time to enhance PHB production in cyanobacteria-enriched microbiomes. The study utilized a Sequencing Batch Reactor (SBR) for 209 days during which cycles of growth and starvation were systematically carried out to selectively enrich the microbiome with microorganisms capable of producing PHB.

RESULTS AND DISCUSSION

Effect of selective pressure on field environmental samples

The effectiveness of the selection pressure applied to favor cyanobacteria over other microorganisms was confirmed through a combination of microscopic observation using both a bright light and fluorescence microscope, as well as molecular analysis of the 16S rRNA gene. The microscopic observations revealed the presence of filamentous and punctate colony-forming cyanobacteria (Figure 1). The results of the 16S rRNA analysis further showed that this selection pressure (P limitation) resulted in a decrease in the number of (heterotrophic) bacterial populations in the environmental samples collected (Figure 2) and a significant increase in the presence of cyanobacteria in the microbiomes.

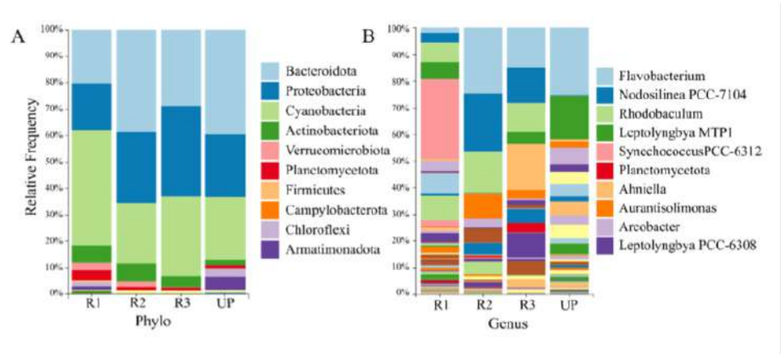

Figure 2. Relative abundance of microorganisms' populations identified in the microbial community at A) phyla level and B) genus level after 5 months of growth with P limitation. The legend shows only the top 10 most abundant taxonomies. Cyanobacteria are represented by light green in A) and dark blue, dark green, pink, and dark purple in B).

Figure 3. PHB evolution over the FF strategy for microbiome optimization on PHB-producer microorganisms for two different photobioreactors. Numbers correspond to the different FF cycles applied. Black arrow indicates the maximum PHB content achieved after 9 FF cycles.

Enhancing PHB production through the optimization of operating conditions

The study found that the optimal conditions for biopolymer synthesis were dependent on the specific microbiome being tested, however, the results from the Design of Experiment (DoE) revealed that higher PHB contents were obtained when the cultures were grown under heterotrophic or mixotrophic conditions. Additionally, the results showed that the addition of organic carbon was the sole factor that had a consistent impact on biopolymer production across all microbiomes tested. The highest PHB content, reaching 14% dry cell weight, was achieved for one specific microbiome by adding 0.6 g of acetate per liter and maintaining a light:dark photoperiod of seven days. Based on these results, the microbiome and the best conditions for bioproduct synthesis were selected for further scaling up.

Enhancing PHB production by enriching biomass in PHB-producer organisms

Glass photobioreactors (PBRs) were operated for 209 days with repeated FF cycles. In addition, the impact of three parameters (nutrient concentration, temperature, and light) on biomass growth and biopolymer synthesis was evaluated beforehand to establish optimal conditions for operating the PBRs. Organic carbon was added in the form of acetate (600 mg/L) at the beginning of the feast phase to stimulate PHB synthesis. Results showed an increase in PHB production from 2% dcw in the initial phase to 22% dcw after 209 days of operation (Figure 3), indicating the development of biopolymer-producing biomass.

Abstract

Single cell proteins (SCP) have emerged as an alternative protein source to partially alleviate the current problem of food scarcity. However, there is a need to produce SCP from renewable and pathogen-free sources, such as gaseous streams. This study evaluated, for the first time, the use of an enriched phototrophic purple bacteria consortium for SCP production using H_2 and CO_2. The influence of pH (6-8.5), temperature (15-50ºC) and light intensity (0-50 W m^{-2}) on the growth kinetics and biomass yields was investigated. Optimal conditions were found at a pH of 7, temperature of 25ºC and light intensities over 30 W·m^{-2}. High biomass (~ 1 g $COD_{biomass}$ □g^{-1} $COD_{consumed}$) and protein yields of ~4 g protein□g^{-1} H_2 were achieved, regardless of the environmental conditions. The resulted biomass exhibited high protein contents (51–64%w/w), showing its suitability as SCP. The biomass yields obtained herein are amongst the highest ones reported from gaseous streams.

INTRODUCTION

Sustainable food and feed production is nowadays a serious global concern. Ever-growing population, climate change and limited natural resources call for the development of new sustainable food/feed alternatives (Zha et al., 2021). Proteins play a key role in human and animal diet as a source of nitrogen and essential amino acids (Ritala et al., 2017). The use of microorganisms as a protein-rich feedstock, the so-called single cell protein (SCP), is a promising alternative to plant or animal-based proteins, since microorganisms provide higher nitrogen recovery during protein synthesis (Puyol et al., 2017). The production of SCP has many environmental benefits compared to plant/animal proteins, such as lower land requirements and greenhouse gases (GHGs) emissions, or a reduced water footprint (Alloul et al., 2022). Despite these advantages, SCP is currently produced from costly agricultural feedstock or from unsustainable raw materials such as molasses, sucrose, starch, n-alkanes, methanol or natural gas.

Phototrophic purple bacteria (PPB) grown on pathogen-free sources are a potential SCP source, thanks to their high yields and their high amino acids, pigments and vitamins contents. PPB exhibit a highly versatile metabolism, capable of performing anoxygenic photosynthesis, using solar light as energy source, and a wide range of electron/carbon donors such as organic compounds (photoheterotrophic growth), or H_2/H_2S with CO_2 as carbon source (litoautotrophic and photoautotrophic growth) (Capson-Tojo et al., 2020). The resulting H_2 from processes such as dark fermentation of organic waste, syngas, water electrolysis using surplus of electricity from renewable sources, as well as the CO_2 obtained from off-gases, represent promising electron and carbon sources for the sustainable and pathogen-free production of SCP. Spanoghe et al. (2021) proved, for the first time, the feasibility of SCP production from H_2 using pure PPB cultures. However, to the best of our knowledge, the potential of an enriched PPB community (without axenic conditions) growing photoautotrophically with H_2 as SCP source remains unexplored.

Here, the use of an enriched PPB consortium for the bioconversion of H_2 into SCP has been tested for the first time. The influence of environmental conditions (temperature, pH, light intensity) on microbial growth kinetics, protein contents, and microbial population, has been evaluated.

MATERIALS AND METHODS

An enriched photoheterotrophic PPB community grown in continuous photobioreactors treating wastewater was collected in Madrid (Spain) and used as a pre-inoculum. A series of batch enrichments (over 14) in 500 mL Schott flasks were performed to obtain a PPB consortium able to achieve a stable photoautotrophic growth. During each enrichment, aliquots of 20 mL from the previous culture were added to the Schott flasks, together with 230 mL of fresh medium. The medium was based on the mineral synthetic medium (MSM) proposed by Ormerod et al. (1961), modified to ensure photoautotrophic growth. The bottles were closed and the headspace was flushed with N_2 prior to H_2 addition to ensure anaerobic conditions. The initial headspace pressure was adjusted to 1.3 bar. The flasks were covered with UV/VIS filters (Capson-Tojo et al., 2021) and incubated under continuous illumination at ~50 W m^{-2} using infrared LED lights (850 nm) and a temperature of 22±2°C. The flasks pressure was monitored daily. Once the pressure dropped below 1.0 bar, hydrogen was added to reach 1.3 bar. Each enrichment lasted for around one week.

Once the enrichment was stable and showed a constant performance, batch tests at different environmental conditions were tested. Assays at initial pH values of 6, 7 and 8.5, temperatures of 15, 25, 38 and 50°C, and infrared light intensities of 0, 5, 15, 30 and 50 W·m^{-2} were carried out in triplicate, as described above for the enrichments (Figure 1). The gas composition and pressure were monitored 4-5 times per day. These data were used to calculate H_2 consumption rates. Liquid samples were also drawn at the beginning and at the end of each assay in order to determine biomass yields and productivities, crude protein contents, amino acid profiles and microbial communities.

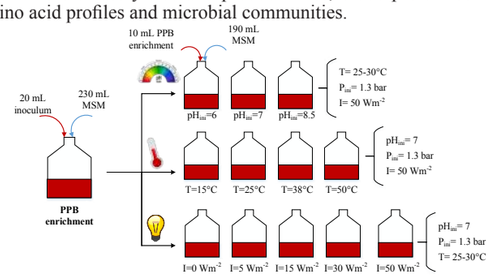

Figure 1. Simplified experimental procedure followed for the evaluation of the influence of environmental conditions (i.e. pH, temperature and light intensity) on the bioconversion of H_2 into SCP using an enriched PPB culture.

RESULTS

After 2-3 enrichments, H_2 consumption was observed, confirming the ability of the mixed PPB culture for growing photoautotrophically. Population analyses (16S r-RNA sequencing) of two enrichment samples after seven cycles confirmed that the consortium was dominated by PPB (> 80%), with *Rhodobacter* sp. and *Rhodopseudomonas* sp. as dominant genera. Consistent biomass yields of 0.9-1.0 g $COD_{biomass}$ □g^{-1} $COD_{consumed}$ were obtained during the last six enrichments.

Environmental conditions had a noticeable impact on H_2 consumption, affecting biomass growth, kinetics and protein production (Figure 2, Table 1). The highest H_2 consumption was observed at initial pH of 7 (with a final value of 8.4 due to CO_2 consumption). The most unfavourable initial pH was 8.5 with a final value of 9.0. The highest H_2 consumption was observed at 25ºC, with 38 and 50ºC decreasing the growth kinetics. Temperatures down to 15ºC also reduced H_2 consumption. Light limitation was observed at intensities lower than 30 W·m^{-2}, but similar results were obtained for both at 30 and 50 W·m^{-2}. Biomass yields close to 1 g $COD_{biomass}$ □g^{-1} $COD_{consumed}$ and protein yields over 4 g protein□g^{-1} H_2 were achieved in almost all the conditions tested (Table 1). These proteins yields were higher than those obtained using pure cultures (Spanoghe et al., 2021). High protein contents (> 50% w/w) were achieved, in agreement with PPB grown photoheterotrophically (Hülsen et al., 2022a, 2022b). Similar C and N contents in the biomass (42 and 9 %w/w) were obtained (Table 1).

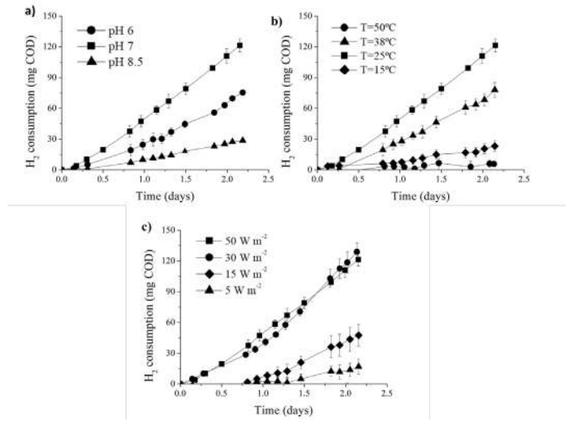

Figure 2. Time course of H_2 consumption by the enriched PPB culture at a) different pH values, b) different temperatures and c) different light intensities. Each data point shows the average and standard deviation (n=3).

Table 1. Main results obtained along with the corresponding standard deviation (n=3) during the batch tests.

	pH		Temperature (°C)		Intensity (W m^{-2})		
	6	8.5	15	38	15	30	50*
Biomass yield (g $COD_{biomass}$ □g^{-1} $COD_{consumed}$)	1.00±0.07	0.93±0.01	0.85±0.07	0.99±0.07	1.02±0.06	1.05±0.01	1.04±0.02
Biomass production rate (mgCOD□L^{-1}□d^{-1})	202±37	77±26	56±44	182±59	110 ±56	378±72	351±60
Protein content of biomass (%w/w)	-	56±5	54±2	51±3	48±7	64±2	51±2
Protein yield (g protein□g^{-1} H_2)	-	3.9±0.3	4.4±0.6	4.3±0.5	4.4±0.2	4.9±0.8	4.2±0.3
C content of biomass (%w/w)	42±1	41±2	41±1	41±1	44±0	43±3	41±2
N content of biomass (%w/w)	8±1	10±0	8±0	9±0	10±0	10±1	10±0

*These values also corresponded to the pH 7 and temperature 25°C tests.

CONCLUSIONS

This study demonstrated that PPB consortia can be efficiently used for production of SCP from H_2. Neutral pH, temperatures of ~25ºC and light intensities higher than 30 W·m^{-2} are the best conditions for biomass growth. **High biomass yields and protein contents were achieved. The high yields and rates achieved confirm the great potential of enriched PPB cultures for H_2 valorisation.**

Abstract

INTRODUCTION

High volumes of municipal sewage sludge (MSS) are produced worldwide each year (45 dry MT in 2017) (Gao et al., 2020), leading to high management costs for wastewater treatment plants (WWTPs) and serious environmental concerns. The pyrolysis of MSS allows not only its treatment and minimization, but also its conversion into feedstocks such as syngas, a gaseous mixture mainly composed by H_2, CO and CO_2, which could be further valorised into value-added products such as microbial protein (MP) (Sun et al., 2019). MP represents a proteinaceous material (up to 80% of protein content on a weight basis (w/w)) obtained from microbial biomass, and which is employable as alternative protein source for feed and food, as well as for biopolymers and slow-release fertilisers production (Areniello et al., 2022). Hydrogen-oxidizing bacteria (HOB) can ferment gaseous mixtures of H_2, O_2 and CO_2, while accumulating proteins in concentrations up to 75% w/w, and can thus play a key role in the development of a syngas-to-MP route (Matassa et al., 2020). Nevertheless, MSS-derived syngas is characterized by an extremely variable composition, with the H_2/CO_2 volumetric (v/v) ratio varying in the range 0.1-10.0 (Gao et al., 2014; Han et al., 2015), while HOB cultures are generally cultivated by using H_2/CO_2 ratios around 7.0 (Matassa et al., 2015). Potentially inhibitory gases such as H_2S and CO are also present in MSS-derived syngas with concentrations as high as 2000 parts per million by volume (ppmv) and up to 40 % on volume (v/v), respectively (Jaramillo-Arango et al., 2016; Xiong et al., 2013). The potential of HOB to ferment gaseous substrates containing high H_2S concentrations was never assessed before, while a few studies evaluated the performances of pure HOB cultures exposed to CO concentrations as high as 30% v/v (Jiang et al., 2022). In the present study, a mixed culture of HOB was enriched and investigated during the aerobic fermentation of gaseous mixtures simulating realistic MSS-derived syngas, containing H_2, CO_2, CO and H_2S in variable concentrations and ratios. The performance of the HOB culture was evaluated by monitoring gas consumption, biomass concentration as volatile suspended solids (VSS), biomass yield on chemical oxygen demand H_2 equivalents (COD-H_2), biomass volumetric productivity and biomass protein content. Furthermore, the evolution of the enriched HOB culture was evaluated by means of microbial community analysis.

MATERIALS AND METHODS

Active compost was used as source of microorganisms for the enrichment of HOB. The enrichment was performed within 306 mL serum bottles filled with 40 mL of mineral medium prepared according to Yu et al. (2013). The headspace of each bottle was filled with a mixture of $H_2/O_2/CO_2$ in a 65/20/15 volumetric ratio (Matassa et al., 2016), setting an initial pressure of 1.5 bar. The enrichment was incubated at 30 °C and agitated at 600 rotations per minute (rpm). After 5 weeks of enrichment, during which the culture medium and gas headspace were continuously refreshed, the culture showed stable and reproducible growth. The HOB enrichment was then used to perform two different series of batch aerobic fermentation tests, each one aiming to evaluate the effect of a specific syngas composition. In the first tests, a series of short (48 h) batch screening tests were performed to evaluate different syngas mixtures characterized by H_2/CO_2 ratios of 2.0, 4.3 and 10.0, H_2S concentrations from 2000 to 8000 ppmv, and CO concentrations from 10 to 40 % v/v. In the second series of batch tests, the effects of CO concentrations of 10 and 40 % v/v, and those of a mixed condition with CO at 10% v/v and H_2S at 2000 ppmv, were evaluated for a total duration of 30 days by refreshing the liquid and gas phase of each bottle every 48-96 h.

RESULTS AND DISCUSSION

Short-term batch tests

The short-term batch tests allowed to screen the performances of the HOB enrichment in the presence of variable syngas compositions (**Table 1**). No differences were observed for H_2/CO_2 ratios variable between 2 and 10 in terms of biomass concentration and yield (0.53-0.57 g VSS/L and 0.14-0.16 g VSS/g H_2-COD, respectively), as well as for biomass protein content (62-66 %VSS) and H_2 consumption (83-87%). Interestingly, for H_2/CO_2 = 10, a significatively higher CO_2 consumption (90%) was observed, suggesting that higher H_2/CO_2 ratios can lead to a more efficient CO_2 recovery as MP from syngas. Similar values were observed also with the addition of H_2S and CO, without significant differences for concentrations up to 4000 ppmv and 40 % v/v, respectively, thereby showing a remarkable resistance of the HOB enrichment towards these inhibitors. Biomass protein content was not affected by H_2S and CO as well, varying in the ranges of 39-56 %VSS and 53-59 %VSS in the H_2S and CO concentration tests, respectively.

Long-term batch tests

During the long-term batch test, no signs of inhibition were detected with CO as high as 10 and 40 % v/v (conditions CO10 and CO40, respectively) and with the simultaneous exposure to CO and H_2S in concentrations of 10 % v/v and 2000 ppmv, respectively (condition CO10+H_2S) (**Figure 1**). The protein content in biomass was similar in every condition for the entire duration of the test (45-65 %VSS). Biomass yield on H_2 for CO40 was significatively higher with respect to the other conditions, probably due to the H_2-limiting conditions established in the presence of a lower H_2 supply. The analysis of the microbiological composition of the HOB culture before and after the long-term test revealed the determinant role played by the presence of potentially carboxidotrophic HOB in the mixed culture. They might have provided a high degree of resistance to CO, as never shown before in literature for pure HOB cultures. The initial enrichment was mainly composed by representatives of the genus *Paracoccus* (relative abundance of 31.5 %), which were capable of resisting to CO concentrations up to 10 % v/v, but were inhibited by CO concentrations of 40 % v/v. Potentially CO-tolerant HOB, such as *Advenella Kashimrensis*, *Hydrogenophaga*, and *Xanthobacter Autotrophicus,* were instead favoured by the high presence of CO.
Overall, the obtained results suggest that mixed HOB community-driven aerobic syngas fermentation could be performed directly by using raw syngas, delivering high and stable process performances and allowing the production of MP biomass with a protein content of up to 65 % VSS. These findings could have remarkably positive implications in terms of cost and technical feasibility of the overall syngas-to-MP route applied to MSS treatment and valorisation.

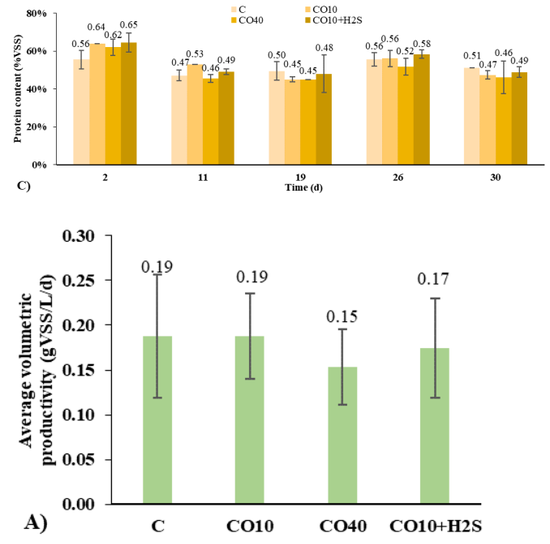

Figure 1. Performances of the HOB enrichment during the long-term batch test. The results are expressed in terms of: **A)** Average volumetric productivity; **B)** Average biomass yield on H_2; **C)** Protein content evolution during the test. *: Statistically different value (*p-value* <0.05).

Table 1. Main results of the short-term batch tests.

	H_2/CO_2		H_2S (ppmv)		CO (% v/v)	
	2, 4.3	10	0 - 4000	6000, 8000	0 - 30	40
H_2 consumption (%)	83 - 87		85 - 97	11* - 0*	82 - 94	
CO_2 consumption (%)	30 - 53	90*	47 - 62	0*	34 - 58	
Final biomass concentration (gVSS/L)	0.53 - 0.57		0.57 - 0.64	0.09* - 0.17*	0.54 - 0.59	
Biomass yield on H_2 (gVSS/gH_2-COD)	0.14 - 0.16		0.13 - 0.17	n.c.	0.13 - 0.20	
Protein content (%VSS)	62 - 66		39 - 56		53 - 59	

*: Statistically different value (*p-value* < 0.05); n.c.: not calculated due to negligible biomass growth.

Abstract

Finding new strategies to minimize carbon dioxide (CO_2) emissions impact is at the centre of society interests nowadays. The current fossil fuels crisis motivates both researchers and governments in finding alternative energy sources. Microbial electrosynthesis (MES) for bioelectroCO_2 recycling is an interesting and sustainable opportunity to exploit the spent off-gases from industrial facilities and convert them into valuable products. A novel setup for direct conversion of CO_2 is herein presented: a two-chamber BES coupled with a heterotrophic microalgae beads bioreactor (HMBB) was built and operated in recirculated batch mode. Acetic acid production from CO_2 and electricity was assessed and directly used as feedstock by the microalgae for biodiesel-compatible bio-oil and protein productions.

Keywords

Acetate production; *Auxenochlorella protothecoides*; biocathode; biodiesel; heterotrophic microalgae; microbial electrosynthesis.

INTRODUCTION

In just over a century, human activity significantly played a part in the constantly increasing greenhouse gas (GHG) emissions worldwide (Melillo et al., 2009). Researchers' interest in finding new strategies for GHG emissions mitigation increased sensibly and led governments to encourage to increase in the energy efficiency of productive processes, promote the use of non-fossil fuels, and enhance the capture and storage of carbon dioxide (CO_2) as well as its re-valorization. In this context, microbial electrosynthesis (MES) emerges as a promising technology for CO_2 conversion into multi-carbon products, such as added-value chemicals and biofuels. Being acetate the most abundant product, of scarce economic revenue and challenging downstream process. Further research for strategies to improve the economical sustainability of the process is essential, either by steering production to longer molecules or combining technologies (LaBelle and May, 2017; Dessì 2021). The coupling of MES systems with microalgae is an interesting option to enhance resource recovery by applying a biorefinery approach (Bolognesi et al., 2021; Sevda et al., 2019). Microalgae are considered a resource for GHG emissions mitigation, plus an essential feedstock for microalgal biorefinery products, such as biofuels and food and feed goods. Heterotrophic microalgae, though not directly exploiting CO_2, can use acetate and other short-chain fatty acids for their growth, accumulating lipids in their cells, with no need for light exposure. In the present study, a two-stage process based on coupling MES and a heterotrophic microalgae beads bioreactor (HMBB) is proposed to convert carbon dioxide into biodiesel-compatible oil and proteins. The overall process from CO_2 to bio-oils and proteins includes bioelectroCO_2 conversion into volatile fatty acids (VFAs) and their subsequent conversion into microalgae biorefinery products.

MATERIALS AND METHODS

A two-chambered methacrylate BES was built and operated in recirculated batch mode for 170 days. Cathodic and anodic chambers were separated by a cationic exchange membrane (Membranes International, USA). Carbon cloth (FuelCellsEtc., USA) was used as the cathode while a graphite rod was used as the anode. An Ag/AgCl reference electrode (+0.197 V vs. SHE) was also placed in the cathodic chamber, operating a three-electrode configuration with a potentiostat (Nanoelectra, Spain, E_{cat}=-0.8 V vs SHE). The net liquid volume for both anodic and cathodic chambers was 250 mL. The experiment was conducted at 25±3 °C. The biocathode was inoculated with 100 mL of inoculum from a parent BES (Bolognesi et al., 2022). Both anodic and cathodic chambers were filled with a modified ATCC1754 PETC medium adjusted to pH 6 (Blasco-Gómez et al., 2019). CO_2 (99.9%, Praxair, Spain) was the only carbon source, and it was supplied to the cathodic chamber every 3 days for 1 minute. Before feeding, gas and liquid samples were collected and analyzed to monitor the gas composition and the production of volatile fatty acids (VFAs) and alcohols, as reported in Bolognesi et al. (2022).

The HMBB was prepared by using a glass tube (d_{int}=1.8 cm, h=60 cm) and filled with a 5 cm layer of glass beads (d=0.8 cm) at the bottom, a 50 cm microalgae beads layer, and a 5 cm layer of glass beads to prevent overflow of algae and connected to the cathodic recirculation line (Figure 1). The HMBB was covered to maintain heterotrophic conditions. To prepare the microalgae beads, alginic acid was added to the microalgae solution (1g/100mL) and stirred continuously for one hour. Then, the solution was released drop by drop with a pipette in a $CaCl_2$ solution (0.5g/100 mL) to form the beads. Before the oil extraction, chlorophyll/protein analysis, microalgae beads were dissolved in a 0.1M EDTA solution, and then centrifuged to separate the pellet from the alginate.

Microalgae cultivation, Chlorophyll a analysis, and oil extraction from microalgae were performed as in Bolognesi et al. (2022). Protein extraction and quantification were performed at the beginning and end of each test, using the Bradford protein assay. Figure 2 schematizes the proposed process.

RESULTS AND DISCUSSION

Results obtained in terms of VFAs production and rates were in line with the previous works of our group (Bolognesi et al. 2022). Once the content of acetic acid was sufficient high to sustain the feed for the microalgae, the HMBB was connected to the recirculation line of the biocathode. A series of tests (Table 1) were performed. Table 1 reports initial and final values, but intermediate points for Chlorophyll a, optical density (OD_{540}) and acetate content were taken every second day. The first three tests (Test A, Test B and Test C) were performed with the HMBB disconnected from the MES reactor using a synthetic medium (1.5 g L^{-1} acetate solution) as feedstock. These preliminary tests were conceived to prove the switch from autotrophic to heterotrophic behaviour in algae beads and microalgae growth. All tests confirmed that heterotrophic conditions were reached (linked to the decrease of chlorophyll content) and that encapsulated microalgae were growing. Test B and Test C were performed with replicates algae beads/liquid microalgae to evaluate if using alginate to form the algae beads affected the performance. Test B confirmed that microalgae growth in microalgae beads and liquid microalgae was comparable (+2% for beads). Test C included oil extraction and the oil content detected was low (5%) due to problems with alginate removal compared to the liquid algae control (13%). During the test C, acetate consumption rate was compared between liquid algae and beads, resulting in higher rates for the liquid algae in the first 2 days (436 mg $L^{-1}d^{-1}$ against 371 mg $L^{-1}d^{-1}$), while increased during days 2-5 for the algae beads (168 mg $L^{-1}d^{-1}$ against 205 mg $L^{-1}d^{-1}$). Overall acetate consumption rate was comparable for both configurations.

All the following tests (D, E, F) were performed with the HMBB connected to the MES. During the last tests, both protein and oil contents were analyzed in the liquid algae and microalgae beads, confirming that the alginate does not significantly affect the performance. Oil extracted in test F was analyzed with NMR to compare its profile with other bio-oil compounds available in the literature. Both protein content and oil extracted from the microalgae increase over time using the acetate synthesized in an MES, making the process profitable for biofuel production and synthesis of proteins. The biorefinery potential of MES-HMBB system was assessed, further studies will be performed to test the system under continuous operation and to expand the portfolio of products.

Table 1. Global view of the tests performed with the HMBB. The increment or decrement over time in terms of microalgae growth, acetate content and chloropyll a is reported in parentheses.

	Day	Microalgae growth [g L^{-1}]	Acetate content [g L^{-1}]	Chlorophyll a [mg L^{-1}]	Oil extraction [%]	Protein content [protein/ biomass, %]	HMBB carbon source

Abstract

Co-treatment of urban wastewater together with pre-treated municipal solid waste for organic matter solubilization has proved to be an optimal environment for mixed phototrophic cultures of PPB. These cultures bacteria, working with an OLR of 0.94, an HRT of 3 days, an SRT of 6 days, 12:12h light cycles, and in a feast/famine regime, have been able to accumulate up to 12% PHA under continuous operation . This work has shown the possibility of co-treating two municipal wastes simultaneously to promote PHA accumulation under microaerophilic conditions.

Keywords

Co-treatment, OFMSW, PHA, Purple phototropic bacteria (PPB), urban wastewater.

INTRODUCCTION

There is increasing interest in looking for sustainable and competitive alternatives to petroleum-based plastics to mitigate the climate change caused by their production. One of the most promising options is bio-polymers of easy degradation, such as polyhydroxyalkanoates (PHA), where microbial biotechnology becomes indispensable for its production (Pilafidis et al., 2022). Several bacteria accumulate this biopolymer as a reservoir of energy. Some cultures capable of producing this bio-plastic include mixed phototrophic cultures of purple phototrophic bacteria (PPB) (Carvalho et al., 2014). However, the problem of extracting the PHA makes these processes very expensive and difficult to include in the commercial market. For this reason, it has been proposed to use waste to reuse it and generate added-value products while simultaneously adding value to these wastes (Carvalho et al., 2014). Several studies use organic wastes for the production of PHA, such as molasses, cheese whey, bio-oil, or industrial wastewater (Pokój et al., 2019), but in most cases, they are diluted to exceed the carbon requirements or supplemented with nutrients to reach the optimum ratio for the growth of PPB. However, co-treatment of wastewater with the organic fraction of municipal solid waste (OFMSW) favors an optimal COD:N:P mixture for growing mixed PPB cultures. In this case, the OFMSW is pre-treated by a steam explosion so that the organic matter is solubilised and can be easily disposed of to the crops, the conditions for which can be found in (Allegue et al., 2022).

In this work, we propose an alternative way of co-treatment of two urban wastes such as domestic wastewater and OFMSW, whose mixture gives rise to the optimal ratio of COD:N:P for the growth and accumulation of PHA by PPB cultures. It should be considered that the metabolic pathway of PHA accumulation in PPB cultures begins with volatile fatty acids (VFA) (Sali & Mackey, 2021), so fermenting the substrates favors this process, and even the presence of sugars in the medium can have a negative effect (Rangel et al., 2023). For this reason, two CSRT reactors are used simultaneously to observe the influence of fermenting LF (CSTR-2) or avoiding fermentation (CSTR-1) and mixing it with DWW. In addition, the inclusion of a hollow fiber membrane in each reactor means that the hydraulic and cell retention times can be separated. Therefore, the volumetric organic load can be optimized since carbon should be in excess, but there needs to be a deficit of one of the nutrients (N or P) (Hülsen et al., 2014). Another novel point of this work is to operate the reactors under microaerophilic conditions, where the ORP of both reactors has been monitored, as it is essential to keep it negative as they are anaerobic cultures (J. Fradinho et al., 2016).

MATERIALS AND METHODS

The co-treatment of the mixed urban wastes has been tested in two 2L cylindrical photobioreactors inoculated with 1% v/v of a mixed culture of PPB and operated in semi-continuous mode, fed during a light cycle of 12/12 h only. The reactors were continuously agitated with a shaker motor at 300 rpm. Two IR-LED lamps (emitting at 850 nm) illuminated the reactors from two sides. Each bioreactor's temperature and oxidation-reduction potential (ORP) were continuously monitored.

Both reactors had worked under microaerophilic conditions opened to the air, simulating the environmental conditions of a scaled-up process. The CSTR-1 was fed using the LF and DWW, and the CSTR-2 was fed using the fermented LF and de DWW (due to operative problems in the UASB, the Stage D was fed using DWW and mix of 50% of synthetic acids Hac:But:Prop and 50% of unfermented LF). The operational stages of both reactors are described in Table 1, where Stage 1 served as acclimatization to obtain a culture enriched in PPB working at an optimal COD:N ratio for its growth. Stage 2 increased the OLR without considering the optimal COD:N ratio for PHA accumulation. Stage 3 focused on PHA accumulation, where only SRT and HRT were fixed by varying OLR. This last stage is still in progress.

Table 1. Operating conditions of CSRT during the whole trial.

	STAGE 1		STAGE 2	STAGE 3		
Sub-Stage	A	B	C	D	E	F
HRT (d)	2,25	1,5	1,5	3	2,25	1,5
SRT (d)	3	2	2	6	6	6
OLR (gCOD/ L*d)	0,36	0,57	0,62	0.94 *Ongoing	*1.5* *To be made	*2 *To be made*
COD:N	100:5		*variable	100:3		
Time (d)	42	37	73	77		
Period (d)	1-42	43-80	81-153	253-330*		

Source of biowaste

The OFMSW came from a municipal waste processing plant in Madrid (Spain). The OFMSW had been thermally hydrolyzed according to previous results (Allegue et al., 2022). This treatment favors the solubilization of organic matter for its following acidification. The liquid fraction of the hydrolysate upon centrifugation was used in this work. *The DWW* came from the outlet of the primary settlers of two domestic wastewater treatment plants (WWTP) located in Estiviel, Toledo (Spain), and Valdebebas, Madrid (Spain).

RESULTS AND DISCUSSION

Values of 12% PHA were achieved in CSTR-2 with an HRT of 3d and an SRT of 6d, setting the OLR at 0.94 gCOD/L*d and, in addition, a more stable PHA production than in CSTR-1 was observed throughout Stage 3 compared to an average of 3.3% PHA in CSTR-1. It is observed that CSTR-2 has a more stable PHA production due to the influence of VFA in the medium and the lower concentration of nutrients in the mixture.

CSTR-1 does not maintain a stable PHA production even though the OLR in the reactor is increased and the solids concentration is similar to that of CSTR-2. A low assimilation of N and P by the PPB does not favor the accumulation of PHA. On the other hand, high organic loads may destabilize the system and promote the accumulation of glycogen instead of PHA, as described in a previous work (Allegue, et al., 2022).

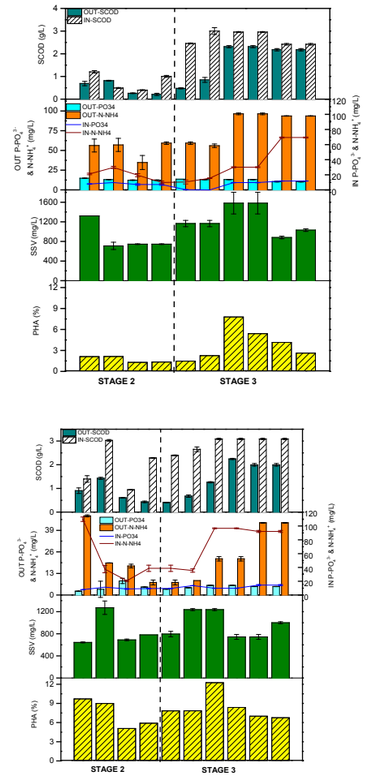

Figure 1. Time course of SCOD, nutrients, volatile solid suspension and PHA accumulation in both reactors at Stage 2 and 3. The graph on the left represents CSTR-1 and the graph on the right represents CSTR-2.

Although in the literature the data on PHA accumulation are higher using fermented DWW (up to 30%), these results are very promising as stability is observed in CSTR-2, which may lead us to believe that the mixed PPB culture developed in the reactor has a better resistance to changes in OLR than that of CSTR-1. In addition, working with the feast/famine strategy under continuous illumination together with external VFA feeding, 20% PHA is feasible (J. Fradinho et al., 2021). Therefore, variations of the HRT and SRT are fundamental, but establishing an optimal COD:N ratio for the operation of these reactors will be crucial for their scale-up. Thus, it is proposed in the following two Stages to decrease the COD:N ratio to 100:2 by fixing the OLR and varying the hydraulic and cell retention times. Increasing the SRT may stabilize more the phototrophic mixed consortia to allow a more positive reaction to carbon overload due to a lower specific loading rate, likely increasing PHA accumulation.

Abstract

Polyhydroxyalkanoates (PHA) are biodegradable polymers that can be produced by mixed microbial cultures (MMC) from different complex wastes for organic carbon recovery. PHA-accumulating microorganisms were selected in an enrichment sequencing batch reactor (SBR) inoculated with sewage sludge. The SBR was fed with volatile fatty acids and operated in five stages with different fed organic loads, from 2.50 g COD/(L·d) to 5 g COD/(L·d). It was enriched from the first week of operation and reached an average PHA accumulation of 51.9 ± 4.8 % at the end of the feast phase. The biomass concentration increased from 0.8 to 1.5 g VSS/L, which means increase the PHA productivity in the accumulation reactor. Thus, this study demonstrates the rapid MMC enrichment and its excellent performance at high loads, producing PHA with the target composition of 88% PHB and 12% PHV that provide propylene-like properties.

Keywords

Enrichment; fish cannery waste valorisation; mixed microbial culture; PHA; propylene.

INTRODUCTION

Polyhydroxyalkanoates (PHA) are natural, renewable and biocompatible biopolymers with properties similar to petrochemical plastics that can be produced by some microorganisms as energy storage. The PHA production by using pure cultures is expensive due to the need to use specific substrates and to maintain sterile conditions (Raza et al., 2018). These reasons have led to the search for more economic and environmentally sustainable production alternatives.

In this context, the use of mixed microbial cultures (MMC) stands out allowing the use of low-cost substrates (such as wastes from agri-food industries) and operation under non-sterile conditions (Raza et al., 2018). MMC is generally obtained from activated sludge systems from wastewater treatment plants because they contain a wide variety of microorganisms, including those that accumulate PHA (Tu et al., 2019). PHA production by MMC usually involves three steps: the acidogenic fermentation of the feedstock to obtain a stream rich in volatile fatty acids (VFA), the selection and enrichment of PHA-accumulating microorganisms, and the maximisation of PHA accumulation with the enriched biomass (Tu et al., 2019). The composition of the PHA obtained determines their properties and thus their potential applications (Raza et al., 2018).

The present study is part of the project BIOCENPLAS which aims to the production of PHA from acidified fish canning effluents to produce plastic packaging for this industrial sector. This research is focussed on the optimisation of the MMC enrichment step to maximize the productivity of the system on PHA which comply with the desired composition of 88 % PHB and 12 % PHV, that has properties like propylene, one of the most used petrochemical plastics in the agri-food industry.

MATERIALS AND METHODS

A 4-L Sequencing Batch Reactor (SBR) was operated under a dynamic aerobic feeding regime, at 30 ºC and without pH control, to select a MMC enriched in PHA-accumulating bacteria. The SBR operating cycles lasted 12 hours, and the hydraulic and solid retention times were 1 day. The dissolved oxygen (DO) concentration is measured over the cycle.

The SBR operational period lasted 231 days and was divided into five Stages (S) according to the fed organic load: I) 2.5 g COD/(L·d), II) 3.13 g COD/(L·d), III) 3.75 g COD/(L·d), IV) 4.38 g COD/(L·d) and V) 5 g COD/(L·d). The organic feeding consisted of a VFA mixture with a composition of 44% acetic acid, 44% butyric acid, 8% propionic acid and 4% valeric acid (% as COD). VFA and nutrient solutions (Palmeiro-Sánchez et al., 2016) were added simultaneously at the beginning of the cycle. The ammonium solution (165 mg NH4/L) was added uncoupled after 5 hours from the beginning of the cycle, to foster the nitrogen limitation during the feast phase. Nitrogen concentration also varied over Stages proportionally to the organic load increase.

RESULTS AND DISCUSSION

The selection of PHA-accumulating microorganisms was considered reached after 7 days of operation, when the duration of the feast phase (part of the cycle when the DO concentration remains low) was shorter than 20% of the total cycle duration (2.4 hours, Figure 1) according to Dionisi et al. (2007). The fed organic load was progressively increased up to 5 g COD/(L·d) without observing significant influence on the MMC enrichment performance (Figure 1). The values of the feast length that oscillate above the limit of 2.4 hours are ascribed to determination inaccuracies due to fouling of the DO electrode.

The MMC presented a high PHA-accumulation capacity at the end of the feast with average values of 52 ± 5 % (Figure 2), similar to the 51.30 % obtained by Palmeiro-Sánchez et al., (2016). No PHA accumulation data is available for Stage V yet. The targeted PHA composition (88% PHB and 12% PHB), able to potentially substitute the propylene, was obtained and remained stable (Figure 2).

The biomass concentration increased, because of the increase of the fed load, from 0.8 to 1.5 g VSS/L (Figure 3). Having a more concentrated sludge with high PHA-accumulating capacity will boost the productivity of the PHA accumulation reactor. This will allow to have a more compact resource recovery system decreasing not only the CAPEX but also downstream costs.

Abstract
Polyhydroxyalkanoates (PHA) are one of the main resources recoverable from various waste feedstocks such as sewage sludge. Despite the increasing number of papers, sewage sludge based PHA production is still far from the industrial application. The goal of this work, therefore, is to provide experimental data on PHA productivity in the light of a possible scaling up of the process. PHA producers were selected, and it was used to perform several accumulation tests by employing an own-designed software, reaching up to 60 % w/w of PHA contents in the biomass. Finally, an improved PHA extraction protocol was applied obtaining high recovery (78 ± 3 %) and purity (89 ± 2 %) yields.

Keywords Bioplastic production, Polyhydroxyalkanoates, Resource recovery, Sewage Sludge, Wastewater.

INTRODUCTION

Nowadays, despite of research in PHA resource recovery using municipal secondary sewage sludge from wastewater treatment is in the hot spot, still few works focus on improving the crucial stages of PHA accumulation and downstream process even though biopolymer content and quality are pivotal parameters to achieve the economic sustainability of the overall process (Moretto et al., 2020; Pesante and Frison, 2023). However, in the view of industrial PHA production process, other parameters such as the PHA productivity can be also prominent and should be monitored when pilot plant experiments towards scale-up are performed. In this sense, this work proposes a new advanced strategy to enhance the PHA accumulation from domestic wasted sewage sludge by fully automating the process using a newly homemade software. Moreover, the extraction protocol previously described by Mannina et al. (2019) was modified to improve recovery and purity yields.

MATERIALS AND METHODS

The pilot plant experiments were carried out at the Water Resource Recovery Laboratory at Palermo University (Mannina, et al., 2021). Three different selection sequencing batch reactors (S-SBR) were run at three volumetric organic-loading-rates (vOLR) to select PHA producers by adopting the aerobic dynamic feeding (ADF) strategy with a synthetic substrate. Once the selection reached the pseudo steady-state conditions, the biomass was harvested to perform two accumulation tests for each S-SBR at different food to microorganism (F/M) ratio (Table 1). The accumulation tests were run with an automatic pulsate feeding based on the feed-on-demand strategy controlled by a homemade software (Figure 1). Finally, the extraction protocol proposed by Mannina et al. (2019) was modified and applied.

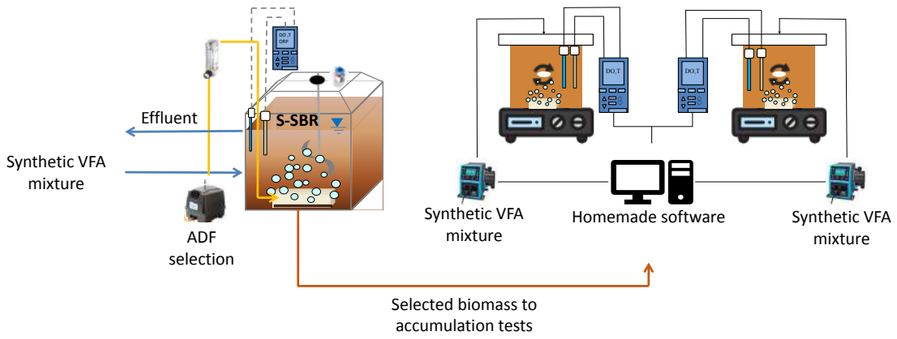

Figure 1. UNIPA pilot plant layout.

RESULTS AND DISCUSSION

Biomass enrichment and PHA accumulation

The highest vOLR applied (1.8 g COD L^{-1} d^{-1}) and feast-to-famine (F/F) ratio (0.28) allowed to obtain the better enrichment in PHA-storage microorganisms, reaching a PHA contents of 13.7 % w/w at the end of the feast phase. In table 1, the F/F ratio indicates that by decreasing the vOLR without changing the cycle length and other operational parameters, lower F/F rate can be achieved. Despite increasing the amount of PHA produced, the higher vOLR, the worse the removal efficiencies of the reactor are. This result suggests that an optimal trade-off for PHA production and reactor performance needs to be evaluated. Once the enrichment in PHA-storage microorganisms was achieved, the biomass was harvested to perform the accumulation tests.
Figure 2 shows the final PHA content achieved for each accumulation test and the PHB:PHV ratio calculated by analysing the lyophilized biomass. When comparing accumulation tests with similar Food-to-Microorganisms (F/M) ratio, it is clear that higher the vOLR during the selection step, the more effective is the enrichment in microorganisms' with PHA storage and production capability, which is mainly related to the PHV synthesis, as can be seen by the PHB:PHV ratio. The PHV:PHB ratio in T6 would suggest that this polymer might be a promising alternative to PHB homopolymers, especially when referring to its industrial applications (de Donno Novelli et al., 2021).
Figure 3 points out the correlation between productivity, PHA contents, vOLR applied in the selection step and F/M ratio used in the accumulation step. When the highest vOLR was used in the selection step, the biomass reaches a low productivity, but with a higher PHA content (Figure 3). On the other hand, there is a direct correlation between the F/M ratio and the enhance in the productivity. This shows that, like vOLR, a medium value of F/M ratio is the best condition to run an accumulation test in order to avoid substrate inhibition due to high F/M ratio while, on the other hand, low PHA content and productivity can be achieved with low F/M ratio (Palmeiro-Sánchez et al., 2019).
These results highlight pivotal parameters that should be taken into account when considering a pilot or full-scale implementation. Still few works focus on optimising the F/M ratio in the accumulation test while considering both PHA concentration and the productivity. These parameters could be used in an energy-mass balance to express, at an industrial level, where it is more convenient to stop the accumulation step and to extract the stored PHA.

PHA extraction

PHA content, purity and recovery were calculated by using a GC equipped with a FID. The protocol used is composed by a two-step solvent extraction: NaClO pre-treatment and non-polymeric cell material (NPCM) destruction by using an organic surfactant (ammonium laureate). The results in table 2 show an overall high purity (89±2%) and recovery (78±3%), proving that the protocol's efficiency is not influenced by the PHA content in the lyophilized samples, up to 32% w/w. The results consistency demonstrates the feasibility of applying this protocol for samples containing different amounts of PHA with different proportions between PHB and PHV monomers.

Abstract
Acidogenic fermentation is a known process to synthesize value added products such as Carboxylic Acids (CA) and ethanol. However, the impact of the substrate organic composition on the products obtained or process performance is still not clear. Thus, in this work, fermentation experiments were carried out in a sequencing-batch reactor (SBR) to assess the influence of using mixtures of whey protein isolate (as model protein (P)) and food-grade sugar (as model carbohydrate (C)) in different proportions (0% C/100% P; 25% C/75% P; 50% C/50% P; 75% C/25% P and 100% C/0% P) on the fermentation process performance and on the effluent composition. All the experiments were conducted under a volumetric organic loading rate (OLRv) of 6 g COD L^{-1} d^{-1} and a specific organic loading rate (OLRs) of 1.8 g COD g^{-1} VSS d^{-1} Acetic, propionic, butyric and isovaleric acid were present in all the experiments, but the effluent corresponding to a mixture of 75% C/25% P could be considered more convenient for polyhydroxyalkanoates (PHA) synthesis due to the large odd-to-even ratio, the high butyric acid concentration and the high acidified COD. Meanwhile, the effluent corresponding to a substrate of 100% C/0% P would be suitable for medium chain carboxylic acids (MCCA) production as it was the only one containing both CA and ethanol.

Keywords (maximum 6 in alphabetical order)
Acidogenic fermentation; carbohydrates; proteins; sequencing-batch reactor; Volatile Fatty Acids; Carboxylic Acids

INTRODUCTION

Acidogenic fermentation using mixed microbial cultures is a promising process able to produce value-added products such as CA or ethanol. These products can be used as final products or be transformed by subsequent biological processes in another value-added products such as PHA (Matos et al., 2021) or medium chain carboxylic acids (MCCA) (Sarkar et al., 2021). Many authors have performed experiments with numerous types of waste and wastewaters with a high content of organic matter. However, further knowledge about how to control the CA production yield and the effluent composition is needed to be able to scale up this process at the industrial level. In this study, process effectiveness parameters were defined and calculated to evaluate the acidogenic fermentation process performance. Moreover, fermentation experiments in a sequencing-batch reactor (SBR) employing synthetic wastewater containing different proportions of food-grade sugar and whey protein isolate as models compounds of carbohydrates and proteins, respectively, were conducted to analyze the effect of the organic composition of the substrate on the process effectiveness parameters and on the effluent composition.

MATERIALS AND METHODS

The experiments were carried in a SBR with an effective working volume of 2.7 L and a headspace of 1.7 L. The substrate used in the experiment was synthetic wastewater containing mineral salts essential for biomass growth and a total organic matter concentration of 14 g O_2 L^{-1}, in terms of chemical oxygen demand (COD). The substrate was composed by different ratios of food-grade sugar and whey protein isolate, depending on the experimental period (Table 1). The inoculum was acidogenic biomass previously acclimatized to both sucrose and whey protein isolate. The composition of the substrate was modified only after the steady state corresponding to the previous change was reached. The temperature was controlled at 37ºC while the pH was registered on-line. Soluble COD was determined by using COD kits (Lovibond) after filtering effluent samples with 0.45 µm pore filters. CAs (including acetic, propionic, isobutyric, butyric, isovaleric, valeric, isocaproic and caproic acids) and ethanol concentrations were analyzed by gas chromatography (GC, 7820A, Agilent Technologies). Food-grade sugar was measured as glucose and sucrose equivalents. Glucose and lactic acid were measured in a YSI 2950 Biochemistry Analyzer. Sucrose was analyzed by HPLC analysis (HPLC Dionex Ultimate3000). Whey protein isolate was determined using the Bradford method in a spectrophotometer at 595 nm (Bradford, 1976). OLRs and process effectiveness parameters (bioconversion, degree of acidification, acidified COD, CA yield and odd-to-even ratio) were defined and calculated according to the equations presented in Table 2. One-way ANOVA tests ($p<0.05$) were performed to evaluate if the different substrate compositions produced a significant impact on the process effectiveness parameters and the effluent composition.

RESULTS AND DISCUSSION

Figure 1 displays the steady-state effluent composition for the different substrate mixtures tested. The main products obtained for all the conditions were acetic, propionic, butyric and isovaleric acids. Acetic acid was 18%, 22% and 27% for 0% C/100% P, 25%C/ 75% P and 50%C/50% P in the substrate, respectively, showing a significant increase ($p<0.05$) when rising the % of C in the substrate up to the 50%. However, when increasing the C proportion to 75% and to 100%, the acetic acid remained at 20 and 28%, respectively. Propionic acid was 13%, 28%, 21%, 31% and 2% for 0% C/100% P, 25%C/ 75% P, 50% C/50% P, 75% C/25% P and 100% C/0% P in the substrate, respectively. Butyric acid was 15%, 11%, 17%, 34% and 47% for 0% C/100% P, 25% C/75% P, 50% C/50% P, 75% C/25% P and 100% C/0% P in the substrate, respectively, showing a significant increase when rising the % of C from 25% to 100% ($p<0.05$). Isovaleric acid was 17%, 13%, 9%, 5% and 0% for 0% C/100% P, 25% C/75% P, 50% C/50% P, 75% C/25% P and 100%C/0% P in the substrate, respectively, showing a significant decrease ($p<0.05$) as the % of C in the substrate increase. Isocaproic acid, which is considered a MCCA, was found when the substrate contained 0% C/100% P and 25% C/75% P, yielding a 7% and a 5% of the effluent COD, respectively. Ethanol was only detected when the composition of the substrate was 100% C/0% P resulting in an 8% of the effluent COD.

Table 3 shows the process effectiveness parameters obtained for the different substrate mixtures tested. Bioconversion was higher than 94% in all the experiments except for the experiment with 50% C/50% P since in that experiment, there was a significant amount of unconverted protein in the effluent. In relation to the degree of acidification, it was significantly higher ($p<0.05$) when the substrate was a mixture of C and P in different proportions in comparison to the use of a substrate only composed by C or by P or by C and P in equal proportions. The acidified COD was significantly higher ($p<0.05$) when the substrate was composed of 75%C/25% P compared to the rest of the conditions tested unless when the substrate contained 25%C/ 75% P. The CA yield was higher when the substrate was a mixture of C and P in comparison to a substrate composed only by C alone or P alone. Finally, the odd-to-even ratio was significantly higher when the substrate was a mixture of C and P in different proportions compared to the rest of the conditions. In descending order, the following conditions which lead to higher odd-to-even ratios were 50%C/50% P, 0% C/100% P and 100% C/0% P.

It is worth to mention that the effluents obtained when using a substrate with 25% C/75% P and 75% C/25% P are the more convenient ones for a subsequent PHA synthesis since they have the highest odd-to-even ratio (Gameiro et al., 2015) and acidified COD. Between these two, the effluent corresponding to the substrate with 75% C/25% P would be more appropriate as it is richer in butyric acid, which is one of the preferred precursors for PHA production (Matos et al., 2021). Additionally, for MCCA production, the effluent more suitable would be the one obtained with 100% C/0% P in the substrate since, besides CA, it contains ethanol which acts as electron donor in MCCA synthesis (de Groof et al., 2019).

Abstract

This work presents a new process for the recovery of energy from decentralised wastewater, based on the adsorption of urea from urine and its subsequent decomposition into ammonia and hydrogen. Herein, urea is recovered from urine through adsorption onto commercial activated carbon. Thermal urea desorption and decomposition into ammonia led to the regeneration of the carbon, keeping its adsorption capacity for at least 4 cycles. Finally, when the regeneration and urea decomposition steps are carried out in the presence of an ammonia decomposition catalyst, hydrogen is produced. Energy balances show that this energy recovery system would lead to a hydrogen production of 430 kg/d, with a net energy production of 2850 kWh/d in a city of 160000 inhabitants. In addition, it would cause energy savings of 4600 kWh/day at the wastewater treatment plant, reducing its energy consumption by 35%.

Keywords (maximum 6 in alphabetical order)
Adsorption, ammonia, hydrogen, urea, resource recovery.

INTRODUCTION

Decentralised systems are a novel approach to conventional wastewater treatment that consists of the separation and treatment of wastewater streams directly at their source. Specifically, urine source-separation can be achieved by utilizing urine-diversion toilets to collect undiluted or low diluted urine (Estévez et al., 2022). Despite accounting for less than 1% of the total volume of domestic wastewater, urine contributes to 80% of all the nitrogen, mainly in the form of urea ($(NH_2)_2CO$) (Egle et al., 2015). While urea is traditionally considered a pollutant in this context, it is also a hydrogen-rich compound and a potential source of green energy.

In this work, we present an innovative process for harvesting energy from human urine based on the integration of three different steps. Firstly, urea is recovered from aqueous solution by its adsorption on commercial activated carbon. Secondly, a thermal treatment is used to regenerate the carbon adsorbent leading to the simultaneous decomposition of urea into ammonia and carbon dioxide. And thirdly, hydrogen is produced through the catalytic decomposition of ammonia to be used as an energy fuel.

MATERIALS AND METHODS

Adsorption of urea was carried out in batch systems using commercial activated carbon (Vertex ROX 0.8). The concentration of urea urine was determined by a colorimetric method (With et al., 1961). Temperature programme desorption (TPD) was carried out in a Micromeritics Autochem II chemisorption analyser equipped with a MKS Cirrus 2 mass spectrometer. Decomposition of ammonia into hydrogen was carried out using a Ru (7% wt.) supported on carbon nanotubes catalyst (Hill & Torrente-Murciano, 2014) and measured with a gas chromatographer equipped with a thermo-conductivity detector.

RESULTS AND DISCUSSION

The adsorption capacity of urea in commercial activated carbon was studied by measuring the adsorption isotherm at 30°C using both, synthetic and real human urine samples. The lower adsorption capacity observed when using real urine shows that there are compounds competing for the adsorption sites, presumably proteins and other organic compounds. In both cases, monolayer adsorption dominates the process, following the Langmuir model (Figure 1A). Kinetic experiments show that adsorption was fast, reaching equilibrium in 7 minutes (Figure 1B), and fitting of the data to the Boyd model revealed that the adsorption limiting step was the intraparticle diffusion both using synthetic and real urine samples.

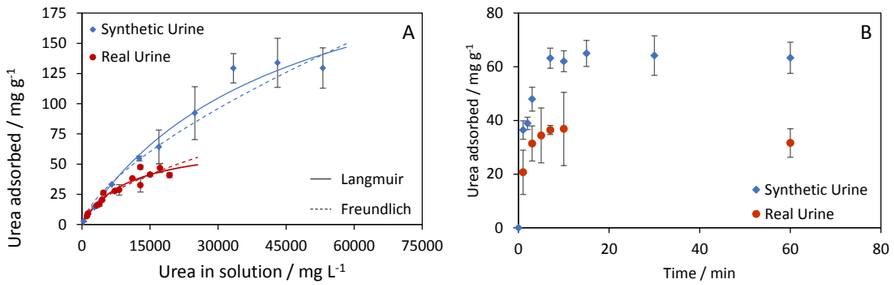

Figure 1. Adsorption of urea onto Vertex ROX 0.8 activated carbon using synthetic and real urine. A: Equilibrium isotherms. B: Kinetic study.

Continuous adsorption of urea was studied to evaluate the influence of different process parameters using synthetic and real urine. The volume of urine treated when the outlet concentration of urea is 50% of the inlet concentration (v_{50}, mL) and the amount of urea adsorbed in the carbon at that moment (q_{50}, mg g^{-1}) are used for comparison.

Firstly, an increase in the inlet concentration of urea presents a negative effect to the adsorption process, as the volume that can be treated is reduced. The urea adsorbed increases just a result of the equilibrium but does not imply a better performing of the system. Secondly, an increase in the mass of activated carbon presents a positive effect, as both the volume and the urea adsorbed raise due to the increase in the contact time between the urine and the adsorbent. Third, a higher flowrate shows a negative effect as can be observed by the lower volume and urea adsorbed, as the contact time is again reduced. Finally, the increase in the inner diameter of the column has a detrimental effect on the adsorption process, decreasing the volume and the urea adsorbed. Similar trends are observed for synthetic and real urine, while with real urine the adsorbed urea is generally lower due to competing adsorption as observed in batch experiments (Figure 2).

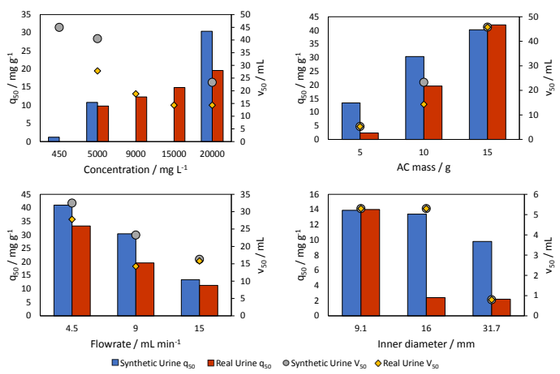

Figure 2. Effect of process parameters on continuous adsorption of urea from synthetic and real urine.

Thermal treatment at 250°C successfully regenerates the saturated activated carbon. The adsorption capacity keeps constant during at least 4 adsorption/desorption cycles when working with synthetic urine (Figure 3A). In the case of real urine samples, the capacity is decreased by 20% in the first cycle, while maintaining a constant value in the next 3 cycles. Temperature programme desorption experiments show adsorbed urea decomposes into NH_3 and HNCO, the latter undergoing further reactions, mainly hydrolysis into more NH_3 and CO_2 (Figure 3B). When the regeneration step is carried out in the presence of an ammonia decomposition catalysts (Ru/CNT), hydrogen is produced. (Figure 3C) (Asiain-Mira et al., 2022).

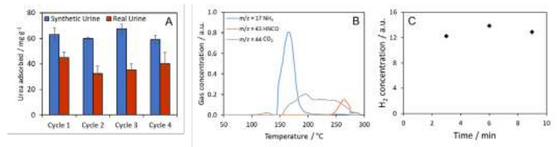

Figure 3. Desorption of urea and regeneration of the carbon. A: Adsorption capacity of activated carbon during 5 adsorption/desorption cycles. B: TPD profile of the activated carbon after adsorption. C: Hydrogen production from adsorbed urea.

An energy balance demonstrates the feasibility of the process for energy recovery. For the analysis, it was assumed that the process is installed in the city of Lleida in Spain, with 160000 inhabitants. Considering a urine production of 1.5 L/person day, the process would produce 430 kg/day of hydrogen, which represent 14225 kWh/day (Figure 4A). Considering the energy requirements of the process (Figure 4B), and the efficiency losses associated to the use of the hydrogen in a PEM fuel cell, the system results in a net electrical production of 2850 kWh/day. Additionally, savings of 4575 kWh/day would be achieved at Lleida's wastewater treatment plant, associated to the reduction on the nitrogen income, which represents more than 35% of its electrical consumption (Asiain-Mira et al., 2022), (Palatsi et al., 2021).

Abstract
Sustainable supply of clean water and energy has become a global challenge due to population increase. In this study, we demonstrated a photovoltaic powered novel hybrid biotechnology at pilot scale (36 L) to treat domestic wastewater with recovery of resources (reclaimed water for non-potable reuse and energy). In this hybrid system, microbial electrolysis cell (MEC) was integrated with gravity-driven fluidized membrane bioreactor (FMBR) to harness resources from wastewater and mitigate membrane biofouling with minimal energy input. The MEC was coupled with photovoltaic solar panel to improve energy efficiency.

Keywords
MEC; MBR; Resource recovery

INTRODUCTION

Anaerobic microbial technologies hold great promise for resource recovery (energy and nutrients) from wastewater. As such, microbial electrolysis cell (MEC) offers an opportunity to anaerobically treat wastewater with concomitant recovery of energy as methane (double chamber) or hydrogen (single chamber) (Katuri et al., 2019). However, MEC alone cannot generate an effluent suitable for reuse due to the abundance of microbes in the effluents. Therefore, they have to be coupled with micro- or ultra-filtration membranes to effectively block the passage of bacteria and produce high- quality effluent suitable for reuse. Currently, the aerobic membrane bioreactor (AeMBR) technology is the standard technology for wastewater treatment and reuse. However, AeMBR is energy intensive, consumes on average 1–2 kWh/m3, where a large fraction of this energy is used for aeration, filtration process, and scouring of the membranes to minimize fouling. To transform wastewater treatment from an energy-intensive process to an energy-efficient process, we developed a hybrid biotechnology by integrating MEC with gravity-driven FMBR to treat domestic wastewater and recover resources (reclaimed water for reuse and energy).

MATERIALS AND METHODS

The pilot-scale hybrid MEC-FMBR reactor (Figure 1.1) was installed next to the King Abdullah University of Science and Technology (KAUST) AeMBR to treat real wastewater. The primary treated raw wastewater received at the inlet of the KAUST AeMBR has a COD concentration < 200 mg/L. To maintain an influent COD concentration of 450 mg/L, starch and peptone were added to the primary treated wastewater. Four electrode modules were packed in the MEC. Each electrode module contains a carbon-fiber brush anode and nickel mesh cathode, and each module operates independently with a separate power source (powered by a PV cell). The influent wastewater was pumped into the MEC from the bottom the reactor, and the effluent from the top of the MEC flows into the FMBR (through a connection port on the top of the FMBR) for further polishing and water reclamation. The FMBR is equipped with customized hollow fiber microfiltration (pore size 0.1 µm) membrane module with 0.5 m^2 effective membrane surface area (KOLON Industries, Inc., Korea). The water in the FMBR is filtered by gravity. The membrane module was connected to a mass-flow controller (Alicat Scientific) and digital pressure transmitter (LEO3, Keller) to measure flux and FMBR head pressure. Granular activated carbon (GAC, ~1.5 mm) particles pre-enriched with biofilm (with MEC effluent) was added to the FMBR to minimize membrane fouling and promote CH_4 production through methanogens. Microbial community analysis was performed using gene amplicon sequencing targeting the Archaea/Bacteria/Eukarya 16S/18S rRNA gene variable regions 4-8 (abeV48-A). Biogas was analyzed using gas chromatography (SRI Instruments, USA).

RESULTS AND DISCUSSION

The MEC reactor was inoculated with a co-culture of acetoclastic electroactive bacteria (EAB, *Geobacter sulfurreducens* and *Desulfuromonas acetexigens*) and operated in a fed-batch mode of operation at an applied voltage of 1 V for the anodic biofilm development. A synthetic medium containing acetate (10 mM) as a carbon and energy source was used at the beginning of operation to enrich for EAB. A stable current response from each module was observed after few batches of operation. After achieving stable current, the feed was switched to primary treated raw wastewater supplemented with starch and peptone on day 120, and the MEC reactor was operated in batch mode for 40 days (120-160 days) until the reactor produced a reproducible current (Figure 1.2A). A stable current generation from the modules was observed after switching the operation of the MEC to continuous mode (on day 160, Figure 1.2B) with a hydraulic retention time (HRT) of ~14 h and organic loading rate (OLR) of 0.73 ± 0.05 kg COD/m^3/day. During this phase of MEC operation (160-220 days), the COD removal in the reactor was 79 ± 4%, and high purity CH_4 (no CO_2) was produced at a rate of ~0.21 ± 0.002 L CH_4/g COD removed. The H_2 gas concentration in the biogas was below the detection limit. The low CO_2 and H_2 in the biogas are due to hydrogenotrophic methanogens' activity at the cathode of the wastewater-fed MECs. After observing stable reactor performance at OLR of 0.73 ± 0.05 kg COD/m^3/day, the OLR was increased to 1.47 ± 0.07 kg COD/m^3/day (HRT ~7 h, 220-335 days). An increase in current response from the modules (except module 2) was observed after increasing the OLR (Figure 1.2B). However, fluctuations in current generation (240-280 days) occurred due to changes in influent chemical composition (shock-load) associated with repairing and cleaning a central sewer line on campus. Followed by this perturbation phase, the reactor showed a stable performance in terms of CH_4 production (~0.3 ± 0.01 L CH_4/g COD removed) and COD removal (67 ± 6%) and with only ~10% CO_2 gas detected in the biogas.

Further polishing of COD was attained by integrating the MEC with FMBR. The performance of the virgin membrane was assessed at a fixed flux (6 LMH) with clean water (Figure 1.3A) and with effluent from the MEC reactor at 1.47 OLR (Figure 1.3B) without GAC fluidization. A stable water flux was observed with clean water. However, with MEC effluent (i.e., FMBR influent), the flux was dropped by half after one day of reactor operation. Membrane scouring with N_2 gas quickly recovered the desired flux. However, the flux was only sustained for a short time.

The FMBR performance was assessed under GAC fluidization mode (10 min for every two hours interval) with effluent from MEC reactor. Membrane fouling was not noticeable for two months at OLR of 0.73 ± 0.05 kg COD/m^3/day (Figure 1.3C). Constant membrane flux and head pressure were sustained for a prolonged period. Also, the reactor produced clear (zero turbidity) and odorless permeate with <30 mg/L COD at a flux of 6 LMH. More than > 94 ± 2% of bacterial cell removal (i.e., total live cells difference between permeate and MEC effluent) was achieved due to filtration. These results are the first to demonstrate the impact of GAC fluidization on GDM process. When the operation of the MECs was shifted to OLR of 1.47 ± 0.07 kg COD/m^3/day, a stable flux was observed for ten days (Figure 1.3D), and then a gradual drop in flux was observed due to the reactor-head pressure drop, which was associated with the membrane fouling. After subtracting the electrical energy demand from the recovered energy, the energy required to operate the hybrid system was positive (~ 0.1 kWh/m^3). Recovery of reclaimed water for reuse from real wastewater with net positive energy offers a potential advantage of this hybrid configuration over other anaerobic and aerobic MBR systems.

The microbial community analysis of the biomass collected from different components of both reactors confirms the existence of key functional microbiomes responsible for improved reactor performance (Figure 1.4). High relative abundance of the EAB *Geobacter sp.* was observed on the anodic biofilm. The presence of *Methanobacterium sp*. on the cathode (at high abundance) and other locations (anode and suspension) supports hydrogenotrophic methanogenesis in MEC. The presence of *Methanosaeta sp.* supports direct interspecies electron transfer (DIET) or/and acetoclastic methanogenesis at low acetate conditions. The abundance of *Geobacter sp., Methanobacterium sp.,* and *Methanosaeta sp.* on GAC particles in the FMBR may play a crucial role in CH_4 production (via DIET or/and methanogenesis).

Abstract

In order to increase the energy recovery potential of the anaerobic digesters (ADs), most UK water utilities have implemented pre-treatment technologies that can aid biological degradation of the sludge with the resulting process being referred to as advanced AD. The predominant technology implemented thus far is thermal hydrolysis process (THP). While plenty of advancements have been made over the past decade, the operational envelopes for THP-ADs are still defined by the feed type, rather than their biochemical composition and fate after pre-treatment and in the digester, which limits optimisation opportunities. Apart from this, Trace elements (TE) also play a significant role in influencing digester performance, especially since THP induces high ammonia concentrations in the digester. This results in very different TE needs for THP-AD compared to conventional digesters to maintain stable conditions. However, the impact of THP on their bioavailability remains underexplored. This paper aims to set a precedent in THP-AD process optimization by profiling sludge composition and TE bioavailability in a full-scale site and informing possible synergistic effects of cost-effective options like enzyme and TE dosing.

Keywords (maximum 6 in alphabetical order)

Augmented treatments; Enzyme dosing; Macromolecules and fate, Thermal hydrolysis; Trace Elements.

INTRODUCTION

In UK, thermal hydrolysis process (THP) is a widely adopted pre-treatment technology in implementing advanced anaerobic digestion (AAD). This is usually done to increase energy recovery potential of the sludge, as well as significantly increasing throughput by enhancing the rate limiting hydrolysis step. THP comprises subjecting the feed sludge to high pressure and temperature to enable solubilization and hydrolysis, while simultaneously overcoming the various constraints imposed by the high sludge bulk viscosity and limited suspended solids (SS) solubility.

While optimization of AAD is usually carried out from an engineering standpoint, their influence on macromolecular composition and fate that predominantly govern the digester's performance is largely unknown, which limits true optimization. This is especially true for THP pre-treatment as it involves the destruction of extracellular polymeric substances (EPS), and enhanced solubilization of suspended matter, rendering substrates with low accessibility for hydrolysis enzymes more accessible. There is also a lack of understanding on how THP pre-treatment impacts the need for trace-element addition in ADs. Moreover, to date, there has not been an integrated approach in understanding the synergistic effects of THP with strategic in-situ options like enzyme and trace element (TE) dosing to enhance digester performance.

Hence, the aim of this study is to set a precedent for THP optimisation, by profiling organics solubilization, macromolecular composition and TE bioavailability throughout a full-scale treatment chain of AADs. Furthermore, this study will inform on optimizing the process through the dosing enzymes and TE to maximise the performance of THP through batch solubilization and BMP tests.

MATERIALS AND METHODS

Macromolecular composition across THP-AD treatment

Sludge was collected before THP pre-treatment, after pre-treatment and after anaerobic digestion from a sludge treatment site processing 21,000 Tons Dry Solids (TDS)/ annum. The sludge is a mixture of primary sludge (PS) and waste activated sludge (WAS) with a combined ratio of 1.5. Protein, lipid and fibre content, as well as trace elements were quantified. Trace element bioavailability was profiled in decreasing order by soluble, exchangeable, carbonates, oxidisable and residual fraction, as described by (Ortner et al., 2014) .

Effect of hydrolysic enzymes on soluble COD release and biogas potential

Five enzymes- Protease 1000 (UB/g)**, Cellulase** (1000 U/g)**, Alpha amylase** (4000 U/g)**, Subtilisin** (2.5 AU-A/g) **and Lipase** (10,000 FIP/g) **were selected to study their effect on solubilization of the pre-treated sludge through batch solubilization tests. The enzymes were dosed at 0.5%,1%,2% and 4% TS (w/w). Best performing enzyme (protease) was then tested in biomethane potential (BMP) tests with sludge collected form the same full-scale site, and its performance compared with control and blank reactors. At present, continuous reactors are running with best conditions from BMP testing.**

RESULTS AND DISCUSSION

Solubilization of macromolecules across full-scale THP-AD

Full-scale profiling evidenced that THP pre-treatment enhances the solubilization of proteins and fibres by 29% and 20% respectively, while not having an impact on lipids (Figure 1). The ineffectiveness of THP at solubilizing lipids has been previously reported (Barber, 2016). Post THP however, the digester achieves the most reduction of volatile suspended solids belonging to lipids at 61% followed by fibres at 47% and proteins at a close 43%. It has been reported that for conventional mesophilic AD treating combined primary and secondary sludge, AD has the least impact on lipids degradation at 25% followed by fibres (Villa et al., 2022). Based on these results, our study suggests that THP pre-treatment, while not necessarily enhancing solubilization of recalcitrant compounds like lipids in the digester feed, may alter their innate composition and biodegradability, making them more amenable to degradation in advanced anaerobic digesters.

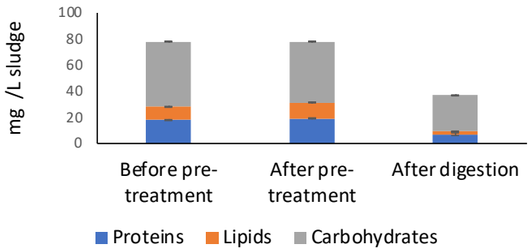

Figure 1. Fate of macromolecule solubilization throughout the THP-AD treatment chain.

Fate of trace element speciation across THP-AD

TE speciation yielded unique distribution patterns for each trace metal (Figure 2a-d). While Se, Co and Ni showed greater mobility towards bioavailable fractions (F1 and F2) after pre-treatment, Zn and Fe showed minimal improvement in bioavailable fractions, while those of Mo were further reduced after pre-treatment. Among all trace elements, THP pre-treatment had the maximum influence on increasing the bioavailable fraction of Se from 1% to 19%.

TE bioavailable concentrations (sum of F1 and F2) were then compared with the minimum free TE requirements for ADs. In general, the required concentration for the micronutrients is very low and in the range between 0.05 and 0.06 mg/l (Weiland, 2010). Only iron is necessary in higher concentration between 1 and 10 mg/l (Weiland, 2010). However, in high-ammonia digesters, like the ones achieved in THP-ADs, sufficient bioavailability of cobalt (0.5 mg/L) and nickel (0.2 mg/L) has been proven to be highly important for good performance of the processes (Westerholm et al., 2016). The study reveals that THP increases Se towards bioavailable limit after pre-treatment while indicating a minor deficiency in the digester (Figure 3a-f). It also shows obvious signs of deficiency in Co and Mo, challenging the general thought that sewage sludge digesters are self-sufficient in meeting their trace element requirements. Our study thus brings into context the bioavailable versus the total concentration of TE in the digesters and the importance of fractionating them to better understand their trace element requirements, especially at high loading rates and high digester ammonia concentrations brought about by THP pre-treatment. The full-scale profiling has informed Co and Mo as possible TE supplements in THP-ADs, with continuous reactors currently in operation.

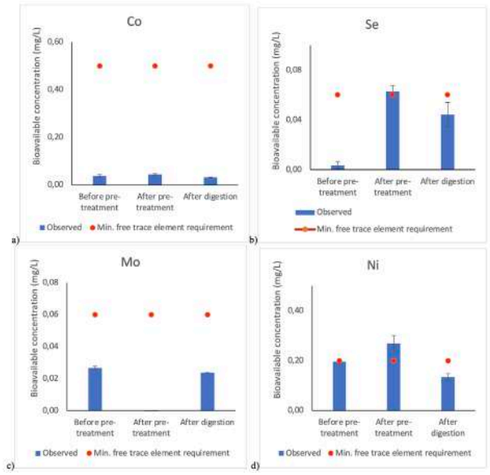

Figure 3a-f. Some important examples of bioavailable trace elements on an indicative basis with data for Fe and Ni available.

Effect of hydrolysis enzymes on soluble COD release

Dosing of different enzymes showed variability in terms of their performance for sCOD release with Cellulase, Alcalase and Lipase restricted to increasing the solubility of organic fraction to within 10% of control. Protease had the highest sCOD release compared to control between 17% and 19% even at low doses, suggesting an opportunity for a synergistic enhancement of AAD performance with the addition of protease. This was further investigated by conducting BMP tests with protease enzyme. Alpha amylase showed a negative performance compared to control , which can be attributed to the flocculation of sludge particles by the enzyme itself (Bonilla et al., 2015).

BMP tests with protease enzyme

The addition of protease in batch THP-AD reactors had a profound impact on enhancing the cumulative methane production, even at the lowest dose (Figure 3). The BMP of control was 431 NmlCH_4/g VS fed or 419 NmL biogas/g TS fed, which is within the range for THP pre-treated digester feed having mixed primary and secondary sludge (400-450 mL biogas/g TS fed) (Barber, 2020). The addition of protease at 0.5%, 1%, 2% and 4% TS (w/w) resulted in an increase in BMP by 22%, 27%, 35% and 36% respectively, indicating that at 2%, the enzyme will no longer be a limiting factor in the reaction. Our results so far show a potential window of opportunity at further enhancing the energy recovery potential of advanced anaerobic digesters at a cost-effective manner and without much investment in infrastructure

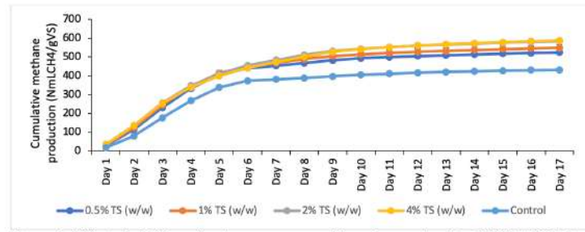

Figure 4. Effect of addition of protease enzyme on biomethane potential of THP-AD sludge.

CONCLUSION

Our study thus far reveals that THP can impact the innate biochemistry of recalcitrant macromolecules like lipids, even if does not lead to solubilization and subsequent hydrolysis but resulting in their enhanced degradation in digesters instead. The unique impact that THP imparts on feed and digester composition is also reflected on trace element speciation and bioavailability. Our study is the first of its kind profiling the influence of THP pre-treatment on bioavailability across a full-scale treatment chain. Results evidence a positive effect of THP on selenium bioavailability and a negative impact on molybdenum and zinc. A deficit of Co and Mo on the full-scale site has informed currently operating continuous AD trials. The BMP tests with protease addition shows that the margin for energy recovery can be pushed further, opening up avenues for augmented treatment with enzyme dosing, with further investigation ongoing for TE supplements as well. Overall, the implementation of THP pretreatment, while greatly enhancing the energy recovery and throughput of sludge treatment sites, could impart a greater benefit to utilities by augmenting with cost effective measures like enzyme and TE dosing to fully realize the potential of advanced anaerobic digesters in achieving higher energy recovery or treatment capacity.

Abstract: In high-rate activated sludge (HRAS) processes, reducing the solid retention time (SRT) minimizes COD oxidation and allows to obtain the maximum energy recovery. The aim of this research was to operate a pilot plant (35 m3·d-1) with an automatic control strategy to assure the HRAS process stability and high COD fractions removal efficiency at very low SRT (0.2 d), HRT (0.6h) and DO (0.5 mg·L-1) treating high-strength raw wastewater, at 18-26ºC and at variable influent flow rate. The research includes the effects of temperature, influent concentration and MLSS reactor concentration over the sCOD, cCOD and pCOD removal. The study points out that operating at 2,000±200mg·L-1 assured a stable process despite the large influent variation. Low SVI values of 50-70ml·g-1 indicated the good settling properties of the biomass. With only a 6,9% COD oxidation, a high organic matter removal (57±9% for COD and 56±10% for BOD5), was reached. The high removal efficiencies for pCOD, 74%, compared to the 29% for sCOD and 12% for cCOD also confirmed the importance of settling efficiency and stability in the HRAS.

Keywords: COD fractions removal; HRAS process stability; HRAS pilot plant.

INTRODUCTION

The High rate activated sludge (HRAS) process enhances the removal of particulate and colloidal COD (pCOD, cCOD), and even some of the soluble COD (sCOD) from urban wastewater, with a minimum energy consumption (Carrera et al 2022) by 1) Carbon redirection, where particulate and colloidal fractions are removed by bioadsorption and bioflocculation, and redirected into the sludge matrix, while soluble biodegradable COD is removed by intercellular storage (bioaccumulation), microbial growth and carbon oxidation; and 2) Carbon harvesting, where redirected organic carbon is recovered through settling without having been metabolized by bacteria and sent to anaerobic digestion. One factor that limits carbon harvesting is the settling capability of the biological sludge. Low oxidation of organic matter due to the low sludge retention time (SRT) maximizes the organic matter redirection but decreases the settling of biomass and consequently worsens the harvesting.

The main objective of this study was to evaluate the carbon redirection and the carbon harvesting in a stable operation of a HRAS (SRT< 0.5d, HRT<1h and DO<0.5 mg·L^{-1}) by: i) Evaluating the removal efficiency of each COD fraction and BOD_5 and their correlations with key operational process parameters; ii) Monitoring the influent and effluent COD fractions and BOD_5 in long-term operation; iii) Evaluating the COD oxidation; iv) Comparing the simulated COD fractions removal efficiency with the pilot plant results.

MATERIALS AND METHODS

A HRAS pilot plant was operated during 497 days, running over nine different operational periods treating, the main parameters and conditions of which are summarized in Table 1. The COD mass balance was calculated for each experimental period in order to investigate the efficiency of the process in terms of COD sent to digestion and COD oxidized.

RESULTS AND DISCUSSION

Figure 1 shows the fractions of soluble (sCOD), particulated (pCOD), total COD concentration and BOD_5 at the influent and at the effluent during the HRAS pilot plant operation.

Figure 2 shows the results of the mass balance for each period. The HRAS working at low SRT and high variations in the influent load, permitted to send to digestion an average 55% of the influent COD, with a low average oxidation of 6.9±3.6% and maintaining the COD_{OUT} around 40% for almost every period. Reducing SRT up to 0.2 days and HRT up to 0.6 hours, corresponding to one third of the usual values reported in HRAS operation, allows a high redirection and harvesting of organic matter 57±9% for COD and 56±10% for BOD_5. The different COD fraction removal: 29±12% sCOD, 12±35% cCOD and 74±10% pCOD, highlighted the importance of settling efficiency and stability in the HRAS removal efficiencies.

In order to investigate the sCOD influent concentration effect over the sCOD removal efficiency, Figure 3 shows the relation between COD_{in} fractions and the COD removal at 20 °C corrected temperature (Θ=1.045) (Seeley, 1992) along the nine experimental periods considered. The good correlation indicated that the sCOD removal was controlled by a biological oxidation-storage process according to Hauduc et al. (2019).

Maintaining the biomass concentration in the reactor at 2000±200 mg·L^{-1} as process control strategy assured a very stable process even with the large variations in the influent. So, both in short- and long-term performance the best control parameter at very low SRT to ensure the process stability and minimize COD oxidation was not strictly the SRT but rather the MLSS concentration (Figure 4). The biomass concentration was directly correlated with sCOD and pCOD removal, while the reactor temperature hampered the pCOD removal but increased the sCOD.

The direct relation between influent COD concentration and COD removal makes it advisable to use the HRAS process as a replacement of the PC stage and not as a downstream treatment afterward. Settling efficiency and stability showed a great importance in the HRAS performance. The low SVI30 values of 50-70 mL·g^{-1} showed the exceptional biomass settling properties, while the relatively low SS effluent concentration 50-120 mg·L-1 indicated correct flocculation. HRAS process acts as a filter for the influent COD and pCOD peak loads and, albeit to a lesser extent, for BOD_5, buffering the influent load to the subsequent CAS process. The HRAS-AS process, on the other hand, does not act as a filter for sCOD peak loads, which is important regarding the likely subsequent denitrification process.

Abstract

The generation of bioproducts and biogas from sewage sludge is a way to manage it correctly. Specifically, volatile fatty acids (VFA) can be produced through fermentation process when methanogenesis is inhibited. However, the lower yields of the process compared to those from the anaerobic digestion (AD) make necessary to valorise the solid fraction obtained after solid-liquid separation of fermented sludge. In this work, it was proved that it is not feasible to ferment this stream in a second fermentation to produce VFA but it can be converted into biogas, since its biomethane potential is still relevant (184 L (N) CH_4/kg VS). The overall mass balance shows that this process (VFA+AD) achieves the same organic matter conversion as the conventional AD alone. However, the main bottleneck is the VFA concentration; membrane separation and liquid-liquid extraction+distillation are being tested and the overall techno-economic and environmental analysis of the process will be presented.

Keywords

Biogas, hydrolysed sewage sludge, volatile fatty acids

INTRODUCTION

Sewage sludge has been traditionally valorised as biogas through the anaerobic digestion (AD) process. However, if last step of the process (methanogenesis) is inhibited, it can be valorised as volatile fatty acids (VFA), a highly demanded product in several chemical and petrochemical industries that can replace those produced from fossil fuels.

Moreover, in last decades some pre-treatment technologies such as the Cambi™ process prior the AD stage have been developed in order to increase biogas production and to obtain a pathogens free sludge. This technology is currently fully implemented worldwide with more than 70 installations. However, the number of works studying the impact of thermal hydrolysis sludge on VFA production is more limited.

Independently of whether pre-treatment technologies are included in the VFA production or not, the reported conversion yields of sludge into VFA are commonly much lower (20-30% in COD basis) than those of the AD process (50-60%) and reasons for these results are still unclear since VFA are an intermediate of the AD process and a similar yield in both processes could be expected. Therefore, it is essential to post-treat the solid fraction obtained after the VFA production step, since this subproduct still has high proportion of biodegradable organic matter that would damage the soil if used in agriculture.

Moreover, a second bottleneck of the process is the purification and concentration of VFA from the aqueous phase. Several technologies have been or are being developed such as gas stripping with absorption, adsorption, solvent extraction, electrodialysis and membrane separation, but the challenge now is the selection of cost-effective recovery methods which lead to maximum VFA recovery at a minimal cost (Atasoy et al., 2018), since for some applications the VFA must have a very high purity, even above 90%.

Therefore, this work seeks to optimize a fermentative process for the production of VFA on a pilot scale prototype for the obtention of a VFA-rich stream capable of being concentrated, and also a solid cake, whose potential for VFA production was evaluated in a subsequent acidic/alkaline fermentation, as well as its biomethane potential (BMP).

MATERIAL AND METHODS

The work has been carried out in a pilot plant located in Ourense WWTP (Spain), that has the Cambi™ thermal hydrolysis process in its sludge line.

The pilot plant (Figure 1) mainly consists of a 1.5 m^3 volume CSTR fermenter (operated at HRT of 10 days and pH of 8.5), which is fed with thermally hydrolysed sewage sludge stored in a buffer tank. The fermented effluent is fed to a coagulation-flocculation tank and to a subsequent press filter for solid-liquid separation, obtaining a VFA-rich supernatant and a solid residue. The liquid fraction is first purified with the ultrafiltration membrane and then concentrated thanks to the reverse osmosis one, before being subjected to liquid-liquid extraction and distillation.

Figure 1. Pilot plant for the production of VFA operated in the project.

To valorise the solid fraction, it was rehydrated and fed into two acidogenic reactors working at different conditions to determine its potential to be converted to VFA in a second fermentation (at HRT of 6 days and pH of 6 and 8.5). Alternatively, this solid residue was also valorised as biogas in a biomethane potential batch test. To execute this, two semi-continuous 5-L reactors at lab scale and the AMPTS II equipment of the Bioprocess Control brand were used.

The Hach D43900 spectrophotometer and associated cuvette kits were utilized to monitor the pilot plant fermenter, as well as lab-scale reactors and associated experiments. VFA were determined using a gas chromatograph Agilent Technologies (model 6850 Series II), equipped with a flame ionization detector (FID).

Figure 2 shows the proposed technology, a several-stage system which integrates a pilot scale fermentation for the production of VFA with a following valorisation of the press filter cake.

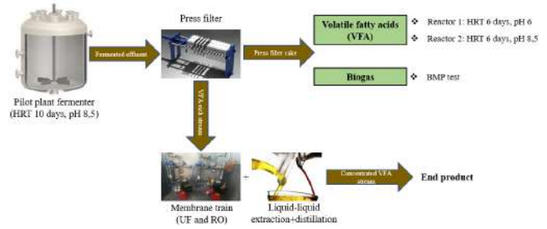

Figure 2. Scheme of the complete proposed system with the applied operating conditions.

RESULTS

Figure 3 exhibits the results obtained in the operation of the pilot plant fermenter. The average production yield of VFA was in the range 0.15-0.20 g COD-VFA/g COD influent, being the VFA mix composed of almost 70% acetic acid (COD-basis), followed by propionic (15%) and butyric acids (10%), in accordance with other authors (Morgan-Sagastume et al., 2011).

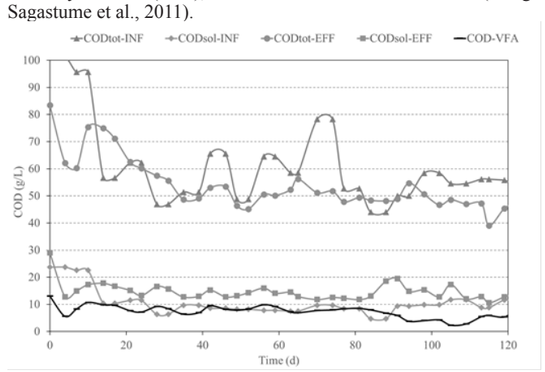

Figure 3. Influent and effluent COD in the fermenter and VFA concentration in the effluent.

As a consequence of the lower yields compared to the conventional AD process, it is necessary to value the solid fraction of the solid-liquid separation due to its still high presence of biodegradable COD. The experiments carried out for the fermentation of the rehydrated solid cake obtained after the first fermentation at alkaline and acidic pH showed negligible transformation, proving that it was not feasible to produce VFA in a second fermentation stage.

However, the BMP test showed that this solid cake has a BMP of 184 L (N) CH_4/kg VS (Figure 4), equivalent to 34% of anaerobic biodegradability, which can be used to partially or totally cover the energetic demand of the whole process.

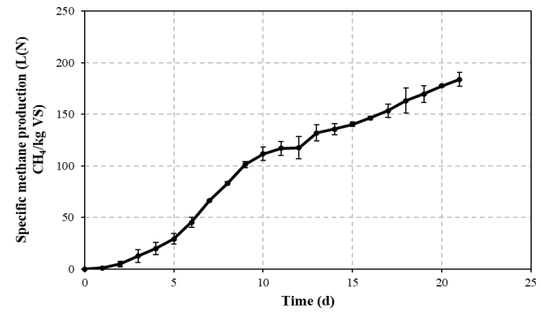

Figure 4. Graph of the BMP test of the solid cake.

The mass balance comparison of the two stages VFA production+AD vs conventional AD shows that per 1 kg of COD of sewage sludge fed into the system, in both cases 0.6 kg of COD as digestate are obtained. However, while conventional AD generates only biogas, with this technological proposal around 0.15-0.20 kg COD-VFA+0.4 kg COD-CH_4 are obtained, being the market value of VFA up to 10 times higher than biogas (Zhou et al., 2018).

CONCLUSIONS

The results show that pilot-scale fermentation can produce an effluent that, after being separated into its solid and liquid fractions, gives rise to a VFA-rich stream and a solid residue that can be converted into biogas. The liquid stream still has to be concentrated to fulfil the requirements of the chemical industry to be used as raw material in biorefineries (purity>90%). Currently, two technologies such as membranes and liquid-liquid extraction+distillation are being tested and the overall technoeconomic and environmental analysis of the process will be presented at the conference, from which the selling price of the obtained bioproducts will be estimated.

The project was financed by the Xunta de Galicia within the framework of the CIGAT CIRCULAR project and also by INTERREG SUDOE ECOVAL and HOOP (EU's Horizon 2020 Nº101000836).

Abstract

The present work investigated the influence of the concentration of carbon-coated zero-valent iron-based nanoparticles (70, 140 and 280 mg L^{-1}) on the continuous biogas upgrading in an algal-bacterial photobioreactor. In addition, the influence of nanoparticle concentrations on the CO_2 liquid-gas mass transfer in the absorption column was investigated. A nanoparticle concentration of 140 mg L^{-1} was the optimal among the concentrations tested, improving almost by 50 % the microalgae productivity compared to the concentration of 70 mg L^{-1}. Concentrations of 280 mg L^{-1} did not entail higher microalgae productivities. The biomethane obtained complied with the European biomethane standard only when nanoparticles were added. Interestingly, none of the nanoparticle concentrations influenced the CO_2 liquid-gas mass transfer in the absorption column.

Algal-bacterial photobioreactor; CO_2 liquid-gas mass transfer; microalgae productivity; nanoparticle concentrations; optimization; photosynthetic biogas upgrading

INTRODUCTION

Microalgae are photosynthetic microscopic organisms with a wide variety of applications that contribute to the development of a bioeconomic worldwide. A very interesting application of microalgae that has emerged in recent years is photosynthetic biogas upgrading, where CO_2 is fixed by microalgae via photosynthesis and the O_2 released supports the bacterial oxidation of H_2S (Posadas et al., 2017; Toledo-Cervantes et al., 2016). Nanoparticles can be an effective and promising strategy to enhance photosynthetic biogas upgrading as well as microalgae growth (Vargas-Estrada et al., 2022). The work carried out by Vargas-Estrada et al. (2023) was a preliminary study to evaluate the influence of the addition of carbon-coated zero-valent iron nanoparticles at 70 mg L^{-1} to algal-bacterial cultures devoted to photosynthetic biogas upgrading under continuous operation. The results showed that the addition of nanoparticles significantly boosted the performance of photosynthetic biogas upgrading and microalgae growth. This work aimed at evaluating the effect of nanoparticle concentrations on photosynthetic biogas upgrading under continuous operation. In addition, the influence of nanoparticle concentrations on the CO_2 gas-liquid mass transfer in the absorption column was investigated.

MATERIALS AND METHOD

Figure 1 shows the main experimental set-up, which consisted of a High Rate Algal Pond (HRAP) configuration interconnected to an external CO_2 absorption column (AC) via external liquid recirculation of the supernatant from a settler. Synthetic biogas was used with a composition (% v/v) of 70 % CH_4, 29.5 % CO_2 and 0.5 % H_2S. Centrate was obtained from the wastewater treatment plant of Valladolid, Spain. The carbon-coated zero-valent iron nanoparticles (NPs) (kindly provided by CALPECH) were added to the system and daily to the centrate at the concentrations studied. The operating conditions were: ambient temperature = 26.3 ± 1.6 ºC, HRAP liquid temperature = 31.1 ± 1.2 ºC, photosynthetic active radiation (PAR) = 1405 ± 45 µmol m^{-2} s^{-1}, gas flowrate = 60 L d^{-1}, L/G (external liquid recirculation/gas flowrate) ratio = 2, and centrate feed = 4.3 L d^{-1}. The parameters monitored were: pH, dissolved oxygen, total organic carbon, inorganic carbon, total nitrogen, NH_4^+, NO_2^-, NO_3^-, PO_4^{3-}, SO_4^{2-}, total suspended solids, volatile suspended solids (VSS), gas composition (CH_4, CO_2, H_2S, N_2 and O_2) at the inlet and outlet of the AC, and microalgae population. The influence of NPs concentration on the CO_2 gas-liquid mass transfer in the AC under abiotic conditions was assessed using synthetic centrate mimicking the characteristics of HRAP cultivation broth without biomass at pH = 8 (Figure 2). The composition of the synthetic biogas and the operating conditions were as above described. Four different concentrations of NPs were tested: 0, 70, 150 and 300 mg L^{-1}. Both the gas composition and the pH of the liquid at the outlet of the AC were measured under steady state conditions.

RESULTS AND DISCUSSION

From an initial NPs concentration in the system of 70 mg L^{-1} (stage I), the concentration was increased to 140 and later to 280 mg L^{-1} (stage II and III, respectively) (Figure 3). An increase in the NPs concentration from 70 to 140 mg L^{-1} entailed a rapid increase in pH and VSS in the HRAP (Figure 3a, b), which was mediated by an increase in photosynthetic activity and therefore in algal growth. This phenomenon induced a significant increase in productivity of almost 50 % (from 33 to 48.2 g m^{-2} d^{-1}). During stage II, the CO_2 removal efficiency (RE-CO_2) increased from 90.2 ± 1.8 up to 95.8 ± 1.9 % and thus the CO_2 concentration decreased from 3.6 ± 0.6 to 1.7 ± 0.7 % (Figure 3c), and the CH_4 concentration increased from 91.8 ± 0.8 to 94.2 ± 0.8 % (Figure 3d). The biomethane obtained in stage II complied with the recently enforced European biomethane standard ($CH_4 \geq 90\%$, $CO_2 \leq 2\%$, $O_2 \leq 1\%$ and negligible amounts of H_2S) (Vargas-Estrada et al., 2023). The increase in NPs concentration from 140 to 280 mg L^{-1} led to an initial decrease in algal growth since pH and VSS decreased. However, microalgae activity recovered. This change in conditions did not imply an improvement in microalgae productivity but a change in microalgae population (from *Chlorella sp.* to *Chloroidium saccharophilum*). Due to the increase in pH from 9.2 (stage II) to 9.5 (stage III), the RE-CO_2 increased to 98.1 ± 0.8 % and therefore the CO_2 content decreased to 0.8 ± 0.3 %. Therefore, the CH_4 content slightly increased to 94.4 ± 0.7 %.

Table 1 shows the results of the study of the influence of NPs on the CO_2 gas-liquid mass transfer in the AC. According to the results, the studied nanoparticles at the concentrations tested had no influence on the CO_2 mass transfer in the AC, contrary to the study performed by Jeon et al. (2017) using SiO_2 nanoparticles, which enhanced the CO_2 gas-liquid mass transfer. This finding suggests that the improvement in process performance recorded by the addition of nanoparticles does not rely on an improvement of CO_2 capture in the AC but in the enhancement in photosynthesis.

Abstract

The present study aims to maximize biohydrogen production from food waste in a two-stage process coupling dark fermentation (DF) and microbial electrolysis cells (MECs). Firstly, the effect of stepwise increases (30, 45, and 60 gVS/Ld) was evaluated in a continuous DF reactor at 37°C and pH 7. Afterwards, the DF effluent was filtered and fed in four two-chamber MECs (Two enriched with *Geobacter sulfurreducens* and two with a mixed consortium). The effluent profile in DF was dominated by acetate (26-30% COD-acetate/COD-metabolites). Interestingly, the butyrate fraction, not easily metabolized by electroactive bacteria, was reduced when increasing the OLR from 25 to 10% COD-butyrate/COD-metabolites. The high acetate content impacted the current densities obtained for both *G. sulfurreducens* and mixed culture-based MECs (7 and 11 A/m², respectively). Overall, the biohydrogen yield in the MEC achieved values of 0.56-0.64 LH_2/ g CODin, whereas considering the coupling the yield was 0.16 LH_2/ g CODin.

Biohydrogen; dark fermentation; *G. sulfurreducens*; microbial electrolysis cells; mixed culture; process coupling

INTRODUCTION

Renewable bioprocesses to produce biohydrogen such as dark fermentation (DF) might contribute to the energetic change of paradigm. Nonetheless, the limited hydrogen yields obtained so far still prevent further commercialization of this technology, as most of the organic matter degraded remains in form of volatile fatty acids. A possible strategy to improve the hydrogen yield is to couple the DF process with microbial electrolysis cells (MECs). In this context, the VFAs accumulated during DF can be further metabolized in the MEC to produce biohydrogen at high purity. The abundance of each VFA composing the effluent has a crucial impact on the biohydrogen yields obtained in MECs since some acids are more easily degradable than others. For instance, lactate and acetate showed higher performances in terms of current densities than propionate and butyrate (Flayac, Trably, et al., 2018). Therefore, the increase of the acetate fraction in the digestate, and the reduction of other compounds such as butyrate might enhance the biohydrogen production in MECs. The novelty of this study lies in employing increasing organic loading rates (OLRs) and neutral pH in DF as a tool to promote acetate in DF. Additionally, the effluent was evaluated in MECs with a pure culture of *G. sulfurreducens* and a mixed culture for hydrogen production.

MATERIALS AND METHODS

The aerobic inoculum was subjected to a freeze-drying process. The VS/TS ratio was of 0.97. The FW substrate was stored frozen at -20 °C to avoid changes in its composition over time as described in previous research (Noguer, Magdalena, et al., 2022). FW was thermally pretreated at 70 °C for 1 h and sieved through 2 mm mesh before fermentation. 2 L Fermenters were fed continuously with the FW at controlled pH and temperature (7 and 37.0°C, respectively). Three different stages were distinguished depending on the organic loading rate (OLR) and hydraulic retention times (HRT), namely Stages I, II, and III (30, 45, and 60 g VS/Ld and 1, 1, and 0.75 days, respectively). Effluent from the reactor was recovered and filtered in an ultrafiltration unit (50 nm mesh) composed of a ceramic membrane. Prior to MEC operation, filtered effluents were diluted with distillate water to reach a final acetate concentration of 1 g/L to avoid inhibition of the electroactive bacteria in the MEC (Table 1). MECs consisted of two chambers separated by a cation exchange membrane. MECs were operated using a three-electrode set-up with an anode potential of 0.444 V vs SHE, using a VMP3 potentiostat. An enrichment step with a synthetic medium was conducted in the MEC to create a biofilm using acetate (1 g/L) as a carbon source with the same type of aerobic inoculum used for DF. Concerning *G. sulfurreducens*, the strain was inoculated in 2 MEC reactors using a phosphate-buffered (pH 7) mineral medium with acetate (1 g/L) as a carbon source. Afterward, effluents were adjusted to pH 7 and bubbled with N_2 gas to remove all oxygen and fed into the MEC reactors. MECs were operated at 30 °C and constant stirring of 180 rpm.

RESULTS AND DISCUSSION

The OLRs assessed (30, 45 and 60 g COD/Ld) resulted in average sCOD/tCOD values ranging from 0.51-0.61 corresponding with a COD removal lower than 25%. Hydrogen production was around 0.1 L H_2/Ld regardless of the OLR with increasing hydrogen concentrations in the biogas (from 47±10 to 65±10 %v/v H_2). Nonetheless, hydrogen production was not promoted in this step due to the neutral pH selected, which was set to improve the acidogenic selectivity towards acetate. As a matter of fact, the system showed high robustness to transform organic matter into metabolites at high OLRs maintaining conversion values as high as 41-45% COD-met/CODin (Figure 1) during the experimental time (51 days). Acetate appeared as the most abundant product during the investigation (26 to 30% COD-acetate/COD-metabolites), whereas butyrate was reduced (25 to 10% COD-butyrate/COD-metabolites from Stage I to III).

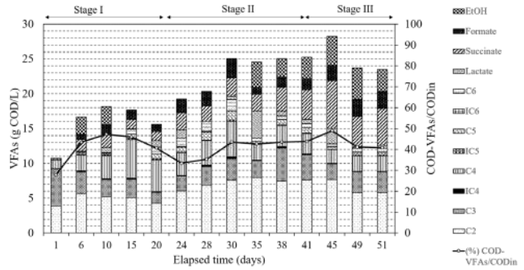

Figure 1. Metabolite analysis at selected experimental points during reactor operation

In the case of *G. sulfurreducens* (R1 and R2_GS, Figure 2) acetate was almost completely consumed by day 4, however high current densities (5 A/m²) were maintained almost until day 5, indicating that other substrates were as well easily consumed. On top of acetate; lactate and formate were completely consumed; while butyrate, valerate and caproate remained unconsumed. On the other hand, succinate was most likely converted into propionate via the succinate pathway, which caused its accumulation. H_2 production in both R1_GS and R2_GS was similar until day 4. Differences from this point were attributed to gas leakage since the CE was similar in both reactors (Table 2). As for the MECs enriched with a mixed culture (R1 and R2_Mixed, Figure 2), the current densities were surprisingly high as well as r_{cat} and r_{H2} (Table 2). Nonetheless, the substrate consumption profile was quite similar than with the pure culture. Differences in current densities were observed between both systems and were attributed to the different ages of the anodic biofilms (15 days and 47 days for the mixed and *G. sulfurreducens* biofilms respectively). The main difference was on valerate formation, while for *G. sulfurreducens* increased only by 0.1 mM for both reactors, in the case of the mixed culture MECs the increases were 0.4 and 0.7 mM. Microbial analysis of the anodic biofilm will be performed to better understand this result.

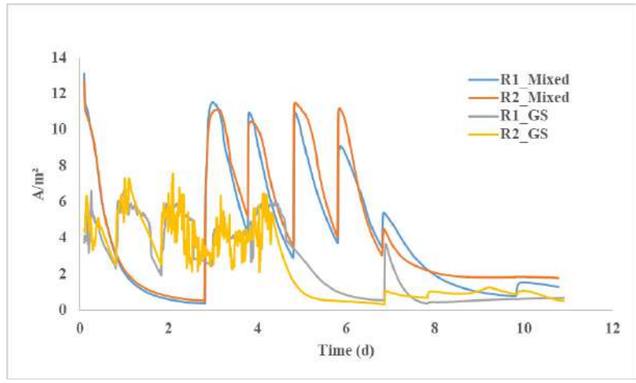

Figure 2. Current density obtained by duplicate in the pure and mixed cultures in the MEC step along the 11 days of experimental time. Pics correspondent to pH adjustment to 7.

CONCLUSION

The OLR was successfully employed as a tool to favor the acetate production as well as a reduction of the butyrate fraction in DF. The subsequent MEC stage benefited due to the acetate-rich DF effluents employed. The enrichment performed with the mixed culture was most likely a key factor for the high process efficiencies obtained in the MEC. Both pure and mixed cultures achieved high VFAs removal and r_{cat}. H_2 production in the MEC step through this strategy contributes to obtaining a highly pure H_2.

Table 1. Initial VFAs concentration fed in the MEC

	Succinate	Lactate	Formate	C2	C3	IC4	C4	IC5	C5	C6
MECs Mixed	7.5	1.8	5.4	16.8	3.8	0.1	3.0	0.1	0.3	0.3
MECs G. sulf	6.9	1.9	4.9	16.0	4.0	0.0	3.8	0.0	0.3	0.1

Table 2. Performance indicators evaluating hydrogen production and VFAs consumption in MECs

	CE	r_{Cat}	r_{H2}	*% e⁻ consumed*
R1_Mixed inoculum	105	89	93	48
R2_Mixed inoculum	88	90	79	44
R1_G. sulfurreducens	88	58*	51	47
R2_G. sulfurreducens	85	94	80	42

CE = Coulombic efficiency (amount of degraded substrate that is converted into current), r_{Cat} = cathode recovery (ratio between the H_2 recovered and the theoretical amount based on the current measured), rH_2 = global H_2 yield (CE*r_{Cat}), *No H_2 recovery after day 6. Electrons for balances were calculated by multiplying the molar amounts of each compound by their electron (Eeq) molar equivalents: Succinate (Eeq = 14), Lactate (Eeq = 12), Formate (Eeq = 2), Acetate (Eeq = 8), Propionate (Eeq = 14), Butyrate and iso-form (Eeq = 20), Valerate and iso-form (Eeq = 26), Caproate (Eeq = 32), H_2 (Eeq = 2).

Aerobic granulation

Unravelling the alpha factor for aerobic granular sludge reactors

Abstract

The alpha factor is an important factor influencing the oxygen transfer efficiency and thus the aeration energy costs of water resource recovery facilities. Nevertheless, the dynamic behaviour of the alpha factor has never been studied for aerobic granular sludge reactors. This study showed that the alpha factor increases during the aeration phase of a batch cycle of an aerobic granular sludge plant due to the influence of different process variables. Through a data analysis study of 175 batch cycles of the Prototype Nereda® installation in Utrecht over the summer and winter period of 2020-2021, the exchange ratio and temperature were identified as the main influencing factors on the rate of increase of alpha in a batch cycle. A higher exchange ratio was related to a slower increase in alpha over the aeration phase, while a higher temperature was related to a faster increase in alpha. Moreover, alpha was characterized by a same minimal value at the beginning of every aeration phase, which could be explained by the adsorption of soluble biodegradable organic carbon described by a Langmuir adsorption model. The dynamic behaviour of the alpha factor could be described by a decreasing exponential model as well as by a first order model.. The practical implications of these models are discussed in view of the design and performance optimization of aerobic granular sludge reactors and other batch-wisely operated aerobic wastewater treatment systems.

Keywords

Aeration; aerobic granular sludge (AGS); alpha factor; batch-wise operation; oxygen transfer efficiency; wastewater resource recovery

INTRODUCTION

Water resource recovery facilities (WRRFs) nowadays are not only focusing on wastewater treatment but increasingly aim at recovering resources such as energy. To reach this goal, reducing the energy consumption is paramount. Aerobic granular sludge (AGS) reactors are a most promising technology with low energy consumption (Pronk et al., 2015), but still a relatively high fraction of energy consumption is spent on aeration, which thus holds a strong saving potential. It is known that the alpha factor is an important factor influencing the oxygen transfer efficiency, however its dynamic behaviour has hardly been researched in a batch reactor and never in an AGS reactor.

The alpha factor, αF , lumps the effect of contaminants, biomass and diffuser fouling on the gas-liquid mass transfer coefficient of oxygen, $k_La_{O_2}/k_La_{O_2}$. Cycles of batch reactors show a gradual increase in the $k_La_{O_2}/k_La_{O_2}$ (e.g. Baeten et al., 2021). This is likely due to a slow degradation of surface-active compounds present in the wastewater (Rosso et al., 2006). Because of their amphiphilic nature, they accumulate at the air-liquid interface of bubbles, reducing the mass transfer of oxygen to the liquid.

A lot of research used the influent organics as a proxy for surface-active compounds to express the impact on the alpha factor (e.g. Bencsik et al., 2022; Jiang et al., 2017). Ahmed et al. (2021) were the first to investigate the real-time impact of the degradation of soluble organics on the increase of the alpha factor for an activated sludge batch plant. For the AGS process such an assessment has not yet been performed. Moreover, the influence of process conditions on the observed dynamic behaviour of the alpha factor is still unclear.

MATERIALS AND METHODS

This research was done using the Prototype Nereda® in Utrecht, the Netherlands, which is a full-scale AGS research facility (1050 m^3), operated by Royal HaskoningDHV. The reactor was monitored for liquid and gas phase concentrations during the summer and winter period of 2020-2021. The 175 batch cycles in which the off-gas analyser was active and the exchange ratio met the predefined value were used to calculate the alpha factor over the aeration phase of every cycle.

Soluble organic carbon (estimated through a COD_S measurement) was measured during the aeration phase of one specific cycle on 18 December 2020 at an exchange ratio of 50%. The biodegradable COD_S fraction ($bCOD_S$) at each time instant was determined by subtracting the effluent concentration of COD_S (assumed to be the inert COD_S concentration) from measured total COD_S concentration at that time. This implicitly assumes that the effluent concentration of COD_S is inert, which is reasonable given the long SRT, the plug flow regime in the reactor and full ammonium oxidation.

RESULTS AND DISCUSSION

The oxygen transfer efficiency in a batch-wise operated AGS reactor was scrutinized through the study of the alpha factor during the aeration phase.

The alpha factor increased over the aeration phase length, analogous to the increase along the length of the aeration tank of a continuous fed plug flow reactor (Fig. 1). All aeration cycles had the same value of alpha at the beginning of the aeration phase and the same value of alpha at the end of the aeration phase cycle, independent of the influent load, exchange ratio and temperature. However, a higher exchange ratio was related to a slower increase in alpha over the aeration phase, while a higher temperature was related to a faster increase in alpha (results not shown).

The alpha factor was related to the removal of $bCOD_S$. The relation between αF and the $bCOD_S$ concentration could be described by a decreasing exponential function (Fig 2a). Alternatively, the inverse relation between $bCOD_S$ and the alpha factor could be described by a Langmuir adsorption isotherm for the adsorption of $bCOD_S$ at the air-liquid interface (Fig 2b). The constant initial alpha value is in agreement with the associated concept of a maximum adsorption capacity. Besides, the lower the $bCOD_S$ concentration at the start of the aeration phase, the faster the increase in αF (Fig. 2) and thus the higher the oxygen transfer efficiency over the cycle. It follows that a possible optimization strategy include the trade-off between the exchange ratio and cycle time to influence the $bCOD_S$ concentration at the start of the aeration phase.

Another way to describe the dynamic behaviour of the alpha factor is through a first order relation (Fig. 3), with a fixed gain for all cycles under study and a time constant depending on several factors, such as the initial $bCOD_S$ concentration (in its turn determined by the exchange ratio) and the temperature. The potential of proxies for the initial $bCOD_S$ concentration (e.g. NH_4^+, PO_4^{3-} at the start of the aeration phase) was further investigated to predict the dynamics of alpha over the aeration phase. In contrast to the relation between αF and $bCOD_S$, the first order relation can only be established by first studying the dynamic behaviour of αF over a longer period of time to find a proxy for the $bCOD_S$ concentration. Afterwards, the first order relation could be part of a control strategy to select for the most optimal process performance depending on the incoming load of the specific AGS plant.

CONCLUSION

In light of the growing awareness on energy efficiency, research efforts are underway globally to reduce the energy consumption of WRRFs. However, it is remarkable that an important aspect as the alpha factor is hardly researched while it is well known to affect the aeration energy significantly. In this study, we scrutinized the oxygen transfer efficiency in a batch-wise operated aerobic granular sludge reactor through the study of the alpha factor during the aeration phase. The insights from this study can be used to further optimise the energy efficiency and operation of aerobic granular sludge reactors and other batch-wise operated aerobic wastewater treatment systems.

Abstract
The application of the aerobic granular sludge technology in continuous flow systems is still a challenge. In this work, a continuous reactor of 25 L, with six baffles to promote a feast/famine regime, was inoculated with mature granules. When the upflow velocity of 2.9 m/h was imposed in the settler, the flocculent biomass ended up predominating in the system while, when this upflow velocity was increased up to 6.0 m/h, granular biomass maintained its predominance, but its sludge volume index (SVI) worsened along the operation time. This fact could be related to the low substrate concentration present during the feast period. A model to explain the competition between the granular and flocculent biomass was developed. According to this model, the ratio between the solids retention time of granular and flocculent biomass, obtained in each experiment, defines the predominant type of biomass inside the reactor.

Keywords
Continuous flow; feast/HRT ratio; granular biomass; solids retention time; substrate concentration.

INTRODUCTION

The constant increase of the urban population brings with it the need to increase the capacity of the existing wastewater treatment plants (WWTPs). Since, in large cities, the available area to expand the WWTPs is limited, the most suitable alternative to increase their treatment capacity seems to be the change of the conventional activated sludge systems (CAS) by other higher-rate technologies. In this context, a successful alternative technology developed during the last two decades corresponds to the aerobic granular sludge (AGS) (Hamza et al., 2022). AGS offers improved settling properties in comparison to CAS, which allow increasing the suspended solids concentration in aeration tanks and, therefore, increasing the treatment capacity of the system. Although specific conditions to promote aerobic granule formation are well known in sequencing batch reactors (SBR), the conditions to achieve a rapid and stable granulation in continuous flow systems are still under investigation and have been the focus of many AGS studies (Xu et al., 2022). On basis of these observations, the aim of the present work is to define the operating conditions of a continuous flow system that allow maintaining the physical stability of aerobic granules such as in an SBR.

MATERIALS AND METHODS

A continuous reactor of 25 L with six baffles was operated to determine the suitable operational conditions to maintain the long-term stability of granular biomass. Granular biomass taken from a 25 L SBR reactor operated in parallel to the continuous flow reactor was used as inoculum. Both systems were fed with a synthetic medium simulating the composition of domestic wastewater (Jungles et al., 2011). The operating conditions imposed in the continuous flow reactor and the inoculum characteristics of the 3 experiments carried out are detailed in Table 1.

Table 1. Operating conditions and inoculum characteristics of the experiments.

Experiment	Operating conditions			Inoculum	
	Flow rate (L/d)	Upflow velocity in the settler (m/h)	HRT (h)	Initial concentration (TSS/L)	SVI (mL/g TSS)
1	100	2.9	6.0	3.2	26
2	200	6.0	3.0	1.9	56
3	200	6.0	3.5*	1.5	60

*An anaerobic chamber of 4 L was added to the system before the aerobic reactor.

RESULTS

In all the experiments, the system was able to remove more than 95% of the organic matter while nitrogen removal efficiency was around 34% and was due to assimilation, since neither nitrate nor nitrite was detected. None of the operating conditions tested were suitable to maintain the physical stability of the granules for a period longer than 22 days. In the first experiment, the hydraulic selection pressure imposed in the settler was not able to promote the wash-out of the flocculent biomass. Also, since flocs grow faster than granular biomass, its overgrowth probably limited the availability of substrate for granular biomass development. In the case of the second and third experiments, the hydraulic selection pressure imposed was increased and flocculent biomass was successfully washed-out. This promoted the growth of aerobic granules (Figure 1). In the second experiment the average diameter of granular biomass increased from 0.5 up to more than 2.0 mm. Nevertheless, their appearance was fluffy, with an SVI of 109 mL/g TSS. A similar behavior was observed during the third experiment but, in this case, the average diameter and the SVI were lower (1.80 mm and 82 mL/g TSS, respectively) than in the previous experiment. This difference could be attributed to the implementation of an anerobic contact tank during the third experiment.

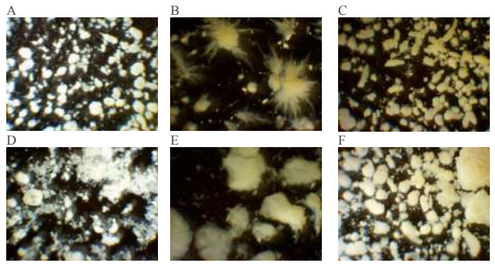

Figure 1. Aspect of biomass. Inoculum: A) Experiment 1; B) Experiment 2; C) Experiment 3. End of the experiment: D) Experiment 1; E) Experiment 2; F) Experiment 3.

In addition to the hydraulic selection pressure, maintaining a suitable feast/famine regime by means of the hydraulic retention time (HRT) is a key operational condition to promote the formation of stable granular biomass. In order to determine if the values of the feast/HRT ratio during the different experiments were suitable to favor the growth of granular biomass over the flocculent one, a conceptual model was developed based on the growth rate of both kinds of biomass. This model allowed calculating the solids retention time (SRT) required by each type of biomass to grow under certain feast/HRT value. The ratio between the SRT values calculated for granular and flocculent biomass (SRT_g/SRT_f) would define the conditions in which the granular biomass would begin to predominate over flocs for a certain value of the feast/HRT ratio (Figure 2). From the COD concentration profile measured along the reactor, a feast/HRT value of 0.14 was determined during the first experiment and of 0.29 during the second and third experiments. Considering the SRT calculated for each type of biomass during the experiments, the model results suggest that the selective hydraulic pressure imposed during the first experiment was not strict enough to achieve the predominance of the granular biomass, while the up-flow velocity imposed in the settler in both experiments 2 and 3 allowed a suitable uncoupling of the SRT of granular and flocculent biomass (Figure 2). However, even though the operating conditions of the two last experiments seemed suitable for the development of the granular biomass, the physical characteristics of the granules generated were not the desired ones (i.e. high SVI, long-term instability). This suggests that the selective hydraulic pressure and the feast/famine regime were suitable for granulation, but not enough to generate granular biomass with good physical characteristics.

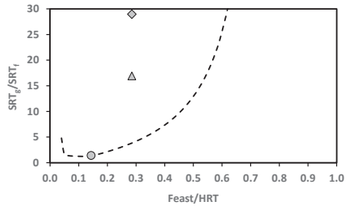

Figure 2. Minimum solid retention time of granular and flocculent biomass ratio required for the predominance of the granular biomass (dashed line); solid retention time of granular and flocculent biomass ratio obtained in: Experiment 1 (◆); Experiment 2 (▲); and Experiment 3 (◆).

Since the deterioration of the physical properties of granules observed during experiments 2 and 3 could be related with the growth of ordinary heterotrophic biomass (X_H) over accumulating heterotrophic biomass (X_{STO}), a simulation based on a diffusion-reaction model was carried to determine how the substrate is consumed inside the granule. The simulation done under the feast phase conditions of both experiments (65 mg COD/L and HRT of 20 minutes) shows that the generation of X_H is 1.46 times higher than that of X_{STO} and, therefore, the granulation process would not be favored. In order to determine the influence of the substrate concentration on the granulation process, a new simulation was performed including the granule size range observed in the experiments (Figure 3). This simulation showed that for a granule diameter of 1.7 and of 3.1 mm substrate concentrations lower than 100 mg COD/L promote the growth of the ordinary heterotrophic biomass over the accumulating heterotrophic biomass (X_H/X_{STO} higher than 1). Also, for these given sizes the X_H/X_{STO} is lower than 1 at substrate concentrations higher than 250 mg COD/L. At higher concentrations the substrate gradient may not limit the growth of accumulating heterotrophs inside the granules. Thus, the configuration of a continuous flow reactor used to generate granular biomass not only should have a suitable feast/famine regime, but also maintain an adequate substrate concentration during the feast period in order to promote the growth of the accumulating heterotrophic biomass.

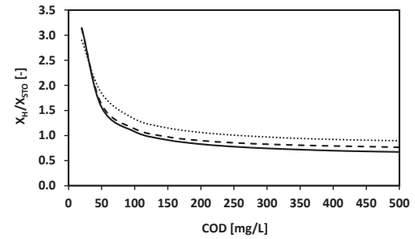

Figure 3. Influence of substrate concentration on the biomass concentration ratio between ordinary heterotrophs and accumulating heterotrophs (granule diameter: 3.1 mm (continuous line); 1.7 mm (dashed line); 0.5 mm (dotted line)).

Abstract

This study quantifies the hydraulic performance of pilot-scale ultrafiltration integrated in a full scale industrial aerobic granular sludge (AGS) plant. The treatment plant consisted of parallel AGS reactors, Bio1 and Bio2, with similar initial granular sludge properties. During the 3-month filtration test, a COD overloading episode took place, affecting the settling properties, morphology and microbial community composition in both reactors. The impact on Bio2 was more severe than on Bio1, with higher maximal sludge volume index values, a complete loss of granulation, and the excessive appearance of filamentous bacteria extending from the flocs. The membrane filtration properties of both sludges, with these different sludge qualities, were compared. The permeability in Bio1 varied between 190.8±23.3 and 158.9±19.2 $L.m^{-2}.h^{-1}.bar^{-1}$, which was 50% higher than in Bio2 (89.9±5.8 $L.m^{-2}.h^{-1}.bar^{-1}$). A lab scale filtration experiment using a flux-step protocol showed that the fouling rate remained below 0.5 $mbar.min^{-1}$ for Bio1, but increased in Bio2 resulting in a critical flux of 30-35 $L.m^{-2}.h^{-1}$. The membrane resistance due to pore blocking was three times higher in Bio2 vs. Bio1. This study show the positive impact of granular biomass on the long-term membrane filtration properties, and stresses the importance of granular sludge stability during reactor operation.

Feast/famine regime; glycogen accumulating organisms (GAO); nutrient deficient industrial wastewater; sequencing batch reactor; side stream membrane bioreactor (MBR); ultrafiltration

INTRODUCTION

Membrane bioreactors (MBR) combine the biological treatment process with excellent sludge separation. As a result the obtained effluent represents a high potential for reuse, e.g. if followed by reverse osmosis. In addition, MBRs occupy limited space. Despite these advantages, MBR application is limited, because the investment and operating costs are quite high. The main cause of the high operating costs is the mitigation of membrane fouling, leading to loss of permeability and/or increase of transmembrane pressure (TMP) (Le-Clech et al. 2006). An innovative fouling mitigation strategy, related with the morphology and the microbial community of the biomass, is the coupling of aerobic granular sludge (AGS) with a MBR. The dense and compact structure of the more hydrophobic aerobic granules, in comparison to conventional activated sludge, enhances the filtration performance (e.g. Liebana et al. 2018, Campo et al. 2021, Stes et al 2021). To the best of our knowledge there are no studies that evaluate the membrane filtration performance of full scale AGS systems. The first goal of this study was therefore the quantification of the filtration performance of a pilot-scale ultrafiltration unit coupled to a full-scale AGS reactor treating industrial wastewater. The second goal was the evaluation of the effect of the long-term ultrafiltration on the characteristics of the granular sludge.

MATERIALS AND METHODS

Full-scale industrial AGS plant and pilot-scale side-stream ultrafiltration

The biological treatment step in the full-scale installation consists of two parallel AGS SBRs, Bio1 and Bio2 (Caluwé et al. 2022). The nutrient-deficient wastewater originates from a tank truck cleaning (TTC) company, mainly cleaning trucks transporting chocolate and beer. The SBR cycles consisted of 4 h anaerobic feeding, 16 h aerobic reaction, 2 h settling and 2 h discharge.
A pilot ultrafiltration (UF) installation was connected with Bio1 which presented more stable performance. The feed stream for the membranes was mixed liquor pumped for 10h per day during the aerobic reaction phase, hereby producing approximately 50 m^3 permeate. The UF filtration test consisted of three stages. In stage I (approx. 2 months), the membrane unit was connected to Bio1. Then, in stage II (approx. 1 week), it was connected to Bio2 to compare the two sludge systems. After switching back to Bio1, filtration was continued for 11 more days (stage III).

Analyses

Sludge samples derived from both SBRs were delivered frequently and analyzed in the lab. We analyzed the sludge concentration (mixed liquor suspended (volatile) solids, MLSS and MLVSS), morphology (using light microscopy), settleability (sludge volume index, SVI), particle size distribution (using a Malvern Mastersizer), microbial community composition (using 16S rRNA amplicon sequencing), the anaerobic substrate storage capability (as described by Tsertou et al., 2022), and the sludge filterability (using a flux step protocol as described by Stes et al., 2021).

RESULTS AND DISCUSSION

AGS properties at start and overloading episode during the experiment

The granular sludge in the full scale SBRs was formed by introducing an anaerobic mixed feeding step followed by an extended aerated step, without selective discharge, to select for granule-forming slow-growing organisms, as described previously by Caluwé (2022).

Initially, the granular sludge presented a compact structure with excellent settleability, high anaerobic substrate uptake and a high abundancy of glycogen accumulating microorganisms (GAO) (29.8 % and 18.9% for Bio1 and Bio2 respectively). The stability of the granular sludge was however significantly affected by an overloading episode during the experiment. The COD in the influent wastewater on DAY 34 was 7736 $mg.L^{-1}$, and remained high for the next 20 days, whereas the average COD before and after the overloading episode was 4303 ± 160 $mg.L^{-1}$ and 3869 ± 355 $mg.L^{-1}$ respectively. Figure 1 shows the SVI values for both SBRs.

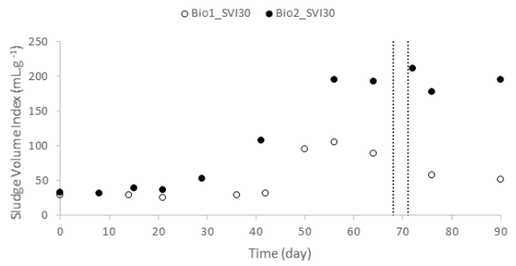

Figure 1. Evolution of the SVI for Bio1 and Bio2 (dashed lines separate the 3 experimental stages).

The SVI value was approximately 33mL.g-1 for both on DAY 0. An increase of SVI30 close to 100 $mL.g^{-1}$ was observed due to the overloading of the two reactors. Bio1 seemed to withstand better the overloading episode. The highest SVI30 value was 105 $mL.g^{-1}$ for Bio1 and 211 $mL.g^{-1}$ for Bio2. Furthermore, Bio1 presented an improvement after DAY 88 but no change was observed for Bio2. Similar observation were done with respect to the anaerobic substrate uptake, particle size distribution, sludge morphology and GAO read abundancies (results available, but not shown, given the page limitation of the abstract).

Pilot-scale filtration performance and lab-scale filterability

Figure 2.a shows the permeability profile obtained from the operation of the pilot ultrafiltration installation.

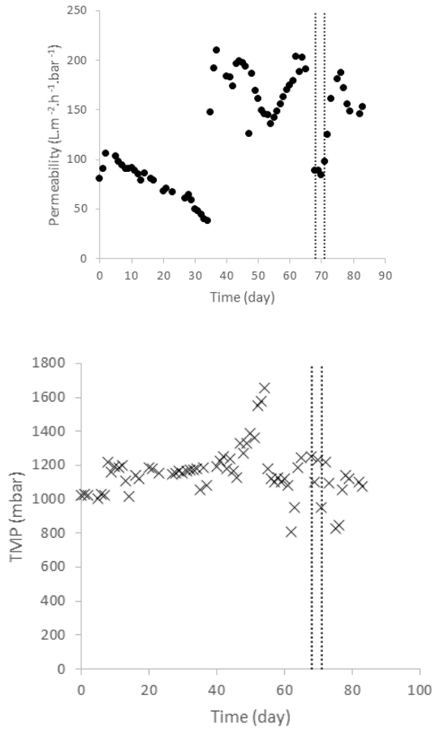

Figure 2. Average permeability profile (a, left), and evolution of the transmembrane pressure TMP (b, right) during the pilot operation (dashed lines separate the 3 experimental stages).

High permeability values (above 80 $L.m^{-2}.h^{-1}.bar^{-1}$) were measured during the start-up of filtration for Bio1. However the permeability continuously declined from DAY 17 until DAY 35, due to an inoperative backwashing. Despite the decreasing trend of permeability, the overall values remained satisfactory since the lowest permeability recorded was 38 $L.m^{-2}.h^{-1}.bar^{-1}$. On DAY 35 cleaning in place (CIP) was performed to restore the membrane permeability. The average permeability was 172.82 ± 23.25 $L.m^{-2}.h^{-1}.bar^{-1}$ for the period after the first CIP, and before switching to Bio2. During the filtration of sludge of Bio2 (stage II), the permeability decreased by almost 50% to an average value of 89.95 ± 5.84 $L.m^{-2}.h^{-1}.bar^{-1}$. Recovery of the permeability was observed when the filtration was switched back to Bio1 (stage III), reaching an average permeability of 158.96 ± 19.21 $L.m^{-2}.h^{-1}.bar^{-1}$. Figure 2.b shows the transmembrane pressure (TMP) profile during the whole operation. Although no backwashing/chemical backwashing was performed in the beginning, the TMP remained almost stable. The TMP stability was interrupted in the period between DAY 45 and DAY 54. Then, elevated TMPs were observed. The increase of TMP was almost linear (R^2= 0.9079). On DAY 55, the membranes were cleaned (CIP). Afterwards, the TMP decreased again.

The lab scale filtration experiment using a flux-step protocol showed that the fouling rate (= slope of the TMP profile as a function of time) remained below 0.5 $mbar.min^{-1}$ for Bio1, but increased in Bio2 resulting in a critical flux of 30-35 $L.m^{-2}.h^{-1}$. The membrane resistance due to pore blocking was three times higher in Bio2 vs. Bio1 (results available, but not shown here).

Discussion

Several studies investigated the filtration performance of conventional activated sludge and aerobic granular sludge, showing the superiority of aerobic granular sludge (Liebana et al. 2018, Stes et al. 2021). Most of these studies attribute the better filtration performance of aerobic granular sludge to their dense structure. In this study, the filtration performance can be related to the sludge morphology. Bio 1 consisted of well-shaped granules, while Bio 2 consisted of more irregular granules with more filaments present. Differences in filtration between Bio1 and Bio2 were observed both in pilot (Figure 2) and lab scale (not shown). In pilot scale, the permeability was more than double in Bio1 vs. Bio2. This confirmed that Bio1 consisted of better quality of granules compared to Bio2.

The maintenance of granular stability is one of the biggest challenges in AGS reactors. The shock load, during stage I, had clearly an impact on sludge settleability, morphology, the ability for anaerobic uptake and the microbial community both in Bio1 and Bio2. Industrial wastewaters present more variable composition compared to municipal wastewater, potentially leading to overloading episodes. This may unsettle the feast (anaerobic)/ famine (aerobic) system that is key to granulation (Tsertou et al. 2022, van Dijk et al. 2022).

Conclusions

The reuse of treated water is imperative because the supply-demand relationship of water has been disrupted. Furthermore, the future solutions should have a limited footprint. The AGS-MBR technology can address both and presents extra advantages compared to conventional MBR such as less fouling. The critical fluxes for aerobic granular sludge were lower in comparison with conventional activated sludge, indicating the possibility of higher applied fluxes and by extension less membrane surface area is required. Further research about long-term filtration operation in full scale and the stability of AGS in overloading episodes is recommended.

Abstract

By 2030, the global demand for energy and freshwater is expected to increase by 40% and 50%, respectively (UN-Habitat, 2016). To augment these depleting resources, municipal wastewater cannot be regarded merely as a "waste," but as a valuable resource of energy, material/mineral, and water for reuse (McCarty et al., 2011). The conventional activated sludge (CAS) process has been employed in most wastewater treatment plants (WWTPs) for over a century, where organic matter in municipal wastewater is aerobically converted to biomass and carbon dioxide. Although the CAS process is widely used, it has several significant drawbacks, like poor settling sludge characteristics, limitation to low mixed liquor suspended solids (MLSS) concentrations, and the tendency to develop floating sludge. Additionally, the CAS process is energy-intensive and usually requires 0.3 to 0.6 (typically 0.45) kWh per m^3 of wastewater treated, equivalent to 1620 kJ m^{-3} (US-EPA, 2014). This can be expressed as 324 kJ p^{-1} d^{-1}, assuming a person living in a sewer catchment produces 0.2 m^3 wastewater per day (Chen et al., 2020).

Aerobic granular sludge (AGS) technology can outcompete existing biological wastewater treatment technologies based on CAS, and it can become the standard for biological wastewater treatment in the future because of its small footprint, simultaneous removal of carbon and nutrients (P & N) in a single reactor tank, and ability to withstand toxic shock loading (Ali et al., 2019). The AGS-based system was estimated to have a 40–50% smaller footprint and 23% less electricity requirement than CAS (Bengtsson et al., 2019; Pronk et al., 2015). Currently, there are more than 70 full-scale AGS installations worldwide, and the number is multiplying rapidly (https://www.royalhaskoningdhv.com accessed on 12 May 2022). Nevertheless, to achieve microbiologically safe effluent, further polishing would be required for AGS-treated effluent (van Dijk et al., 2018; 2020). Aerobic membrane bioreactor (AeMBR) technology is currently being used for wastewater treatment and reuse. However, AeMBR process is a highly energy-intensive (energy-driven membrane process) process and on average requires more than 0.6 kWh per m^3 of wastewater treated, equivalent to 2232 kJ m^{-3} (Bengtsson et al., 2019). Here, gravity-driven membrane (GDM) was integrated with AGS system **(Fig. 1)** to reclaim microbiology and chemically safe water for non-potable uses. The GDM filtration is compatible with AGS reactor due to its natural height (tubular shape design). The height of the AGS tank would provide a sufficient water pressure head to drive the GDM filtration process through gravity (without energy input). The GDM-coupled AGS process (AGS-GDM) could easily replace conventional AeMBR technology in the wastewater treatment and reuse market.

The AGS-GDM unit was operated in a sequential batch mode with 2 hours of filling, 1.5 hours of aeration, 10 minutes of settling, and 20 minutes of effluent draw. The AGS tank has a volume of 35 L, and draw and filling were performed with a 50% exchange ratio. Primary treated raw wastewater received at the inlet of the KAUST wastewater treatment plant (GPS coordinates: 22°17′54.3″N 39°07′09.8″E) is diluted, having low concentrations of COD (229±59 mg/L), NH_4^+-N (17±4 mg/L) and PO_4^{3-}P (9±2 mg/L). The raw wastewater was supplemented with synthetic wastewater to make the concentration of COD (450 mg/L), NH_4^+-N (35 mg/L), and PO_4^{3-}P (20 mg/L) more representative of domestic wastewater. The influent wastewater was fed to the AGS tank from the bottom during the filling phase. Then AGS treated effluent was introduced to the GDM tank equipped with customized hollow fiber microfiltration (nominal pore size 0.1 µm) membrane module with a 3.5 m^2 effective membrane surface area (KOLON Industries, Inc., Korea). The AGS-GDM system showed excellent removal performance as the treated effluent has lower residual concentrations of COD (32.6±10.1 mg/L), NH_4^+-N (0.6±1.9 mg/L), NO_2^--N (0.2±0.04 mg/L), NO_3^--N (0.7±0.4 mg/L), and PO_4^{3-}P (1.3±2.6 mg/L) **(Fig. 2)**. The effluent quality of the AGS-GDM system was superior to neighbouring full-scale AeMBR, which generated an effluent with higher concentrations of NO_3^--N (5.6±3 mg/L) and PO_4^{3-}P (7.8±1.5 mg/L). Also, the GDM unit in AGS-GDM showed consistent flux (10 LMH per m hydraulic head) for 50 days without any cleaning **(Fig. 3)**, whereas the AeMBR required constant physical cleaning through aeration blowers and backwashing to control fouling. The AGS-GDM unit consumed significantly lower energy (0.35 kWh/m^3 for pumping and aeration) than the neighbouring full-scale AeMBR (0.82 kWh/m^3 for aeration alone). Taken together, these results demonstrate that the AGS-GDM technology could be a promising viable alternative to AeMBR for energy-efficient wastewater treatment and reuse in water-scarce regions like Saudi Arabia.

Abstract

The ongoing transition in the water sector from wastewater treatment plants to resource recovery facilities is driving change in water management. Biofilm-based technologies are being developed to intensify treatment and reduce environmental impact. The LIFE program project RESEAU is retrofitting two demo sites in Spain and Denmark with MABR (membrane-aerated biofilm reactors) and AGS (aerobic granular sludge) technology to reduce untreated stormwater overflows. The Spanish demo site in Moaña will be retrofitted with AGS reactors to increase capacity by 400%. The Danish demo site in Søndersø will be retrofitted with seven full-scale MABR units, becoming one of the largest MABR installations to date. The implementation will allow a comparison of performance, including capex, opex, capacity increase, energy consumption, and N_2O emissions.

Keywords (maximum 6 in alphabetical order)

INTRODUCTION

The water sector is currently undergoing a revolution, which involves the ongoing transition from the concept of wastewater treatment plants into resource recovery facilities (WRRF), where wastewater is now seen as a matrix containing many resources useful for society: clean water, chemicals, energy, and heat (Garrido-Baserba et al., 2020). Water management is expected to change more in the next twenty years than in the past century (Biswas and Tortajada, 2018) as rapid urbanization, population growth and aging infrastructure will increasingly put pressure on wastewater treatment management (Larsen et al., 2016). The greater frequency of heavy precipitation events due to climate change and stricter effluent requirements increases the need for capacity increase in urban wastewater infrastructure.

On the other hand, utilities around the world are moving toward de-carbonizing their activities. It is therefore of the utmost importance to develop technologies that allow utilities to both intensify treatment and reduce their environmental footprint. More intensive technologies, tend to produce higher N_2O emissions (Figure 1).

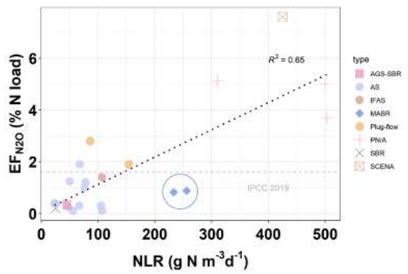

Figure 1. Benchmark of different types of biological N removal technologies according to the % of N load emitted as N_2O-N (y-axis) and the nitrogen loading rate (g N m^{-3} d^{-1}) (x-axis). (Uri-Carreño et al., 2023).

The LIFE program project RESEAU (Retrofitting solution for increasing the resilience of urban wastewater infrastructures in heavy precipitation areas) seeks to reduce by up to 100% the discharge of untreated stormwater overflows from WWTPs in heavy precipitation areas using advanced biofilm technology. Biofilm-based technologies are based on bacteria aggregation either on a carrier material or auto aggregation to form granules. The main benefits include higher nutrient removal rates per reactor volume and a higher level of treatment during loading peaks. Therefore, they will be able to increase the capacity of the WWTPs during high-flow events. Moreover, recent studies have demonstrated the potential of MABR technology to provide nutrient removal intensification with high energy efficiency and maintain low N_2O emissions (Uri-Carreño et al, 2023).

Two demo sites located in Spain in Denmark are being retrofitted with novel biofilm technology, namely MABR (membrane-aerated biofilm reactors) and AGS (aerobic granular sludge). The full-scale implementation of these technologies will allow the comparison of performance in terms of capex, opex, capacity increase, energy consumption and N_2O emissions.

Spanish Demo Site: Moaña WWTP

Located in a coastal region in north-western Spain, close to the Atlantic Ocean. A WWTP of 35,000 population equivalent (P.E.) was built in Moaña in 2001 to improve the wastewater treatment and the effluent quality to Vigo's Estuary, the greatest fishing ground in Galicia (Figure 1). There are currently between 15 and 20 heavy precipitation events per year, causing infiltration/inflow rates of over 80% in the sewer network and stressing the limited hydraulic capacity of the WWTP, which is determined by its unique secondary settler, driving to an estimated discharge of 15,000 m³ of untreated SWOs/year.
The demonstration actions include a retrofit of the existing treatment plant with two AGS reactors of 500 m³ each and liberation of the existing volume of Activated Sludge basins, providing 2,500 m³ to be used as storm tanks. This will increase the WWTP capacity up to 400% (2,000 m³/d).

Danish Demo Site: Søndersø WWTP

Located in Denmark, close to the Baltic Sea. The Søndersø WWTP of 20,000 P.E was built in 1990 and it is heavily loaded with rainwater and infiltration, accounting for two-thirds of the hydraulic loading to the plant (Figure 2). It receives a large quantity of industrial organic load, increasing the aeration/nutrient removal need. During heavy precipitation events, the maximum incoming flow (550 m^3/h) is more than four times the yearly average incoming flow, when the facility is under stress and its performance worsens, resulting in ammonia peaks discharged in the effluent.

The nutrient removal treatment at Søndersø WWTP is configured with two lanes running in parallel, each consisting in two oxidation ditches operated under alternate aerobic/anoxic conditions, as per the so-called BioDenitro process. The MABR upgrade is planned to be installed in one of the two lanes (Figure 3). This will allow for the comparison between the conventional activated sludge lane and the MABR lane.

The demonstration actions include a retrofit of the existing bioreactors with seven units of full-scale MABR technology, therefore becoming one of the largest MABR installations up to date.

Abstract

Antibiotic-resistance is a growing emergence worldwide promoted by improperly managed wastewater (WW) that results in the dissemination of antibiotic-resistant genes (ARGs) to the environment. Aerobic granular systems in sequential batch reactors (AGS-SBRs) are a promising alternative in WW treatment; however, the removal rates of ARG by these systems are not well known. Hence, the abundances of different ARGs were determined by qPCR in influent, granular biomass, and effluents of a lab-scale AGS-SBR treating real WW for 60 days. Generally considered, high abundances of the different ARGs were found in the biomass, particularly during the granulation period of the operation, highlighting its potential role as antibiotic-resistance hotspots, mainly for *aadA*, *aadB*, and *tetA* genes. Also, generally considered, the average removal rate of ARGs of the bioreactor was very scarce, suggesting that the removal efficiency of ARGs in AGS-SBRs must be optimized to improve the advantages of this technology in WW treatment.

Keywords (maximum 6 in alphabetical order)

AGS-SBR; antibiotic-resistant genes; environmental pollution, qPCR, water bodies, WWTPs

INTRODUCTION

The overuse and improper use of antibiotic substances have led to an increase in the appearance of antibiotic-resistant bacteria (ARBs), resulting in a reduction in the effectiveness of medical treatment against contagious diseases. Particularly, wastewater treatment plants (WWTPs) play potential roles as a transmission route of ARBs via improperly management or treatment of the highly antibiotic-concentrated wastewater (WW), constituting an important antibiotic-resistant genes (ARGs) reservoir (Schages et al., 2021). In addition, the inefficient removal of antibiotics by WWTPs contributes to disseminating ARBs and ARGs to receiving water bodies.

Nowadays, aerobic granular systems in sequential batch reactors (AGS-SBRs) have multiple advantages over conventional WW treatment systems (Cui et al., 2021); however, the effectiveness of AGS-SBRs for the removals of antibiotics, ARBs, and ARGs are largely unknown. Therefore, it is necessary to evaluate the dynamics of the predominant genetic mechanisms that contribute to the antibiotic-resistance phenomenon within the AGS-SBR to prevent the dissemination of ARGs from the effluents generated in these novel engineering systems to the receiving environments.

The general aim of the present research was to determine the absolute abundances of several ARGs in the influent, biomass, and effluent of a lab-scale AGS-SBR fed with real urban WW by qPCR, using a newly developed set of primers covering a higher ARG diversity than the currently available molecular tools.

MATERIAL AND METHODS

A lab-scale AGS-SBR was operated for 60 days to treat real WW sampled from a municipal WWTP (Granada, Spain). The bioreactor was inoculated with activated sludge from the same WWTPs for granule formation. The detailed operational conditions were described in Rosa-Masegosa et al. (2022). Quantification of total abundances of 11 different ARGs was performed by quantitative PCR (qPCR) on a QuantStudio-3 Real-Time PCR system (Applied Biosystems). The different ARG (*aadA*, *aadB*, *ampC*, *blaSHV*, *blaTEM*, *dfrA1*, *ermB*, *fosA*, *mecA*, *qnrS*, and *tetA* genes) analyzed in the influents, granular biomass, and generated effluents are listed in Table 1. In addition, the bacterial 16S rRNA gene was used as a proxy for total *Bacteria* quantification. All reactions were made in triplicate, according to Correa-Galeote et al. (2021). The statistical differences among samples were analyzed using the non-parametric Kruskal–Wallis and Conover–Iman tests (p<0.05 significance level) in XLSTAT v2020 (Addinsoft).

RESULTS AND DISCUSSION

The gene copies of bacterial 16S rRNA genes varied between 1.15×10^5 to 1.87×10^7 gene copies g^{-1} in the influent, 1.42×10^{10} to 2.47×10^{11} g^{-1} in the granular biomass, and 4.98×10^5 to 8.82×10^7 gene copies g^{-1} in the effluents (Fig. 1). These results agree with those of previous work (Rosa-Masegosa et al., 2022). On the other hand, all of the investigated ARGs were detected in the samples except *mecA*, which was removed from further analyses. The abundances of the remaining ARGs oscillated from being below the detection limit (< 0.5×10^3 copies g^{-1}) to 4.55×10^9 gene copies g^{-1} (Fig. 1).

Regarding the influent samples, the average abundance of *tetA* was 2.74×10^6 copies g^{-1}, which was higher than *aadA* (2.05×10^6 copies g^{-1}), *aadB* (1.55×10^6 copies g^{-1}), *blaTEM* (1.11×10^6 copies g^{-1}), *ampC* (4.59×10^5 copies g^{-1}), *qnrS* (1.37×10^5 copies g^{-1}), *drfA1* (1.10×10^5 copies g^{-1}), and *ermB* (9.65×10^4 copies g^{-1}). The *blaSHV* gene was not detected. Hence, the urban WW used in this study presented a high level of ARGs, reinforcing previous reports of its potential to strongly contribute to the phenomenon of antibiotic resistance dissemination (Pantanella et al., 2020).

All the ARGs analyzed in this study were found in the inoculum sample (range 3.76×10^5 - 1.82×10^9 gene copies g^{-1}). On the other hand, the granular biomass harboured a wide variety of ARGs. In this sense, the higher average abundances were found for *aadA* (2.57×10^9 copies g^{-1}), followed by *aadB* (5.88×10^8 copies g^{-1}), *tetA* (2.28×10^8 copies g^{-1}), *drfA1* (9.93×10^7 copies g^{-1}), *blaTEM* (8.34×10^7 copies g^{-1}), *ermB* (6.96×10^7 copies g^{-1}), *qnrS* (4.09×10^7 copies g^{-1}), *blaSHV* (3.97×10^7 copies g^{-1}), and, finally, *ampC* (1.61×10^6 copies g^{-1}). Consequently, great differences in the contribution of the different genes to the total resistome were observed in the granular biomass of the ASG-SBR, being *aadA*, *aadB*, and *tetA* the dominant ARGs. The abundances of the ARGs here analyzed were in the same range than those reported in other WW technologies (Nõlvak et al., 2018; Leroy-Freitas et al., 2022). Also, it is worth mentioning that higher abundances of all the ARGs were found at the beginning of the experiment (day 7) compared to those of days 30 and 60, highlighting the particular extensive potential contribution to the dissemination of ARGs during the start-up periods of AGS-SBRs.

Similarly, higher concentrations of ARGs were present in the final effluents, particularly for *tetA* (4.23×10^6 copies g^{-1}), *blaTEM* (3.72×10^6 copies g^{-1}), *aadA* (1.88×10^6 copies g^{-1}), *aadB* (1.69×10^6 copies g^{-1}), and *ampC* (3.67×10^5 copies g^{-1}). These ARGs were detected in most sampling times. The high prevalence of the ARGs in the effluents is in agreement with Calderón-Franco et al. (2020), which studied the dynamic of ARGs in a full-scale granular sludge WWTP.

Finally, it should be noted that for all the ARGs, except *ermB* and *qnrS*, scarce removal rates in the ARGs were observed when comparing the abundance of ARGs in the influents and those of the effluents. Despite the advantages of AGS-SBR over other technologies in several aspects, the final effluent generated in AGS-SBR could act as an important hotspot in the dissemination of antibiotic-resistances to the receiving water bodies. Therefore, an optimization in the removal of ARG through this promising technology must be addressed.

ACKNOWLEDGMENTS: This research was supported by the Andalusian Government through ECORESISTOME project (A-RNM-62-UGR20).

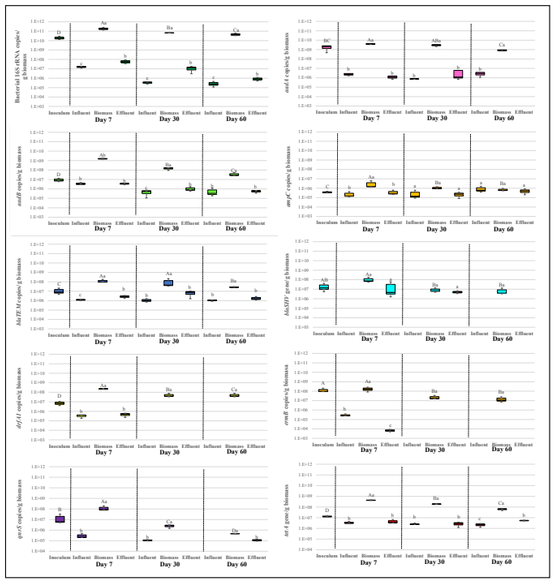

Figure 1. Bacterial 16S rRNA and ARGs genes copies per gram of samples retrieved from a lab-scale AGS-SBR treating real urban WW, determined by quantitative PCR (n = 3). According to Kruskal–Wallis and Conover–Iman tests ($p < 0.05$), different capital letters indicate significant differences among biomass samples (inoculum and granular biomass samples) and different lowercase letters indicate significant differences among samples (influent, biomass, and effluent) for a given sampling time.

Table 1. Antibiotic-resistant genes determined by qPCR in this study, their KEGG orthology numbers, the resistance proteins encoded, and the related antibiotics they confer resistance to.

Gene	KEGG orthology number	Resistance protein encoded	Antibiotics to which the gene confers resistance

Abstract

In this study, carbon (C) and nitrogen (N) removal from a synthetic urban wastewater was investigated in a continuous double-column upflow aerobic granular sludge blanket (UAGSB) system. The UAGSB reactor was operated under different dissolved oxygen (DO) ranges (0.01-6.00 $mg \cdot L^{-1}$), feed C/N ratios (4.7-13.6), and hydraulic retention times (HRT) (6-24 h). This work shows that at a DO range of 0.01-0.30 $mg \cdot L^{-1}$, a feed C/N ratio of 13.6 and an HRT of 24 h, the UAGSB system achieved the highest chemical oxygen demand, $N\text{-}NH_4^+$ and total inorganic nitrogen removal efficiencies of 86, 99 and 84 %, respectively, representing a potentially valuable and economic alternative to the conventional activated sludge systems for the treatment of municipal or industrial wastewaters.

Keywords

Aerobic granular sludge, carbon and nitrogen removal, denitrification, nitrification, urban wastewater

INTRODUCTION

The biological treatment in municipal wastewater treatment plants (WWTPs) is often accomplished by means of the conventional activated sludge (CAS) process for the removal of organic matter and the modified Modified Ludzack-Ettinger (MLE) process, consisting of separate denitrification and nitrification steps, for combined carbon (C) and nitrogen (N) removal. The simultaneous nitrification and denitrification process (SND) is a promising alternative to the MLE cycle in WWTPs for the concomitant C and N removal from municipal wastewater due to lower carbon demand in denitrification process and sludge production [1], lower energy for aeration [2] and smaller footprint [3]. Generally, the use of biofilm-based systems promotes the coexistence of different microbial communities and allows higher concentration of active biomass, while reducing space requirements and sludge production compared to suspended-cell systems such as CAS and MLE [4]. Aerobic granular sludge (AGS) integrates the characteristics of suspended-growth and biofilm systems, as it leads to the formation of microbial aggregates without any support and having a structure similar to biofilms [5]. Nevertheless, AGS systems have been poorly applied under continuous flow conditions due to system instability and reduced performance [6]. In this study, a continuous double-column upflow aerobic granular sludge blanket (UAGSB) reactor was studied for 306 days for the treatment of synthetic urban wastewater. The effect of different DO concentrations, feed C/N ratios and HRT was mainly assessed in terms of chemical oxygen demand (COD), ammonium nitrogen ($N\text{-}NH_4^+$) and total inorganic nitrogen (TIN) removal as well as the evolution of the different N species.

MATERIALS AND METHODS

The synthetic wastewater used as influent for the UAGSB reactor was prepared as reported by Beun et al. [7]. The influent concentrations are shown in **Table 1**. The inoculum used for the start-up of the bioreactor was an AGS collected from a 1 L lab-scale sequencing batch reactor previously run by Sguanci et al.[8]. The experimental set-up included two laboratory-scale glass columns (0.6 L), one used as the main bioreactor and the other as an aeration column to avoid the loss of biomass from the top of the reactor and prevent damaging of the granules due to impact with air bubbles [9]. A 205S peristaltic pump (Watson-Marlow, UK) was used for influent feeding and effluent suction from the bioreactor. The effluent from the bioreactor was oxygenated in the aeration column and recirculated at the bottom of the bioreactor with a 505U peristaltic pump (Watson-Marlow, UK) at a flow rate between 20 and 40 $mL \cdot min^{-1}$. Air was transferred to the aeration column at a flow rate ranging from 0 to 4.5 L min^{-1} using an aquarium air pump equipped with tubing and a porous stone. DO concentration was continuously monitored using a FDO 925 optical probe (WTW, Germany) connected to a multiparameter benchtop meter inoLab® Multi 9620 IDS (WTW, Germany). A Raspberry PI 3 Model B+ single board computer (Raspberry Pi Foundation, UK) coupled with Python software 3.0 (Python Software Foundation, USA) was used to control and automate aeration in the reactor, as described by Iannacone et al.[10].

RESULTS AND DISCUSSION

The first four periods were aimed at evaluating the effect of different DO concentrations on the removal efficiencies (REs) of COD, $N\text{-}NH_4^+$ and TIN at feed C/N ratios in the range of 12.1-13.5 (**Table 1**). The decrease of DO concentration from period I (4.0-6.0 mg L^{-1}) to period IV (0.02-1.60 mg L^{-1}) resulted in stable (p>0.05) $N\text{-}NH_4^+$, TIN and COD REs of 95 ± 9, 85 ± 8 and 84 ± 5 % (**Fig. 1**), respectively, with a maximum effluent $N\text{-}NO_3^-$ concentration of 10.6 $mg \cdot L^{-1}$. This indicates that the UAGSB reactor could be efficiently operated at low DO conditions, thus entailing low aeration costs for the treatment of municipal wastewater. Periods V and VI were characterized by a similar DO range (**Table 1**) and a decrease of the feed C/N ratio from 13.5 (period IV) to 7.0 and 4.7, respectively. The decrease of the C/N ratio did not negatively affect $N\text{-}NH_4^+$ RE, which remained in the range of 97-99 % (p>0.05) (**Fig. 1**). Nitrification was stimulated as $N\text{-}NO_3^-$ concentration increased from 4.5 ± 2.3 (period IV) to 11.9 ± 5.2 (period V) and 31.1 ± 4.1 mg $N \cdot L^{-1}$ (period VI). The reduction in the feed C/N ratio led to insufficient organic carbon to support denitrification. Consequently, the TIN RE reached a minimum value of 28 ± 8% in period VI (**Fig. 1**) because of the higher effluent $N\text{-}NO_3^-$ concentrations. The COD RE decreased from 84 ± 5% (periods I- IV) to 62 ± 13% (periods V-VI) (**Fig. 1**), while the effluent COD concentration did not change significantly (p>0.05) and averagely remained at 94.7 ± 55.6 $mg \cdot L^{-1}$. Periods VII and VIII were characterized by an increase of the feed COD concentration and, therefore, of the C/N ratio from 4.7 (period VI) to 8.0 and 13.6, respectively, resulting in lower DO concentrations in the bioreactor (below 1 $mg \cdot L^{-1}$ in period VIII), even though the inlet air flow was increased. Interestingly, despite the low DO conditions, $N\text{-}NH_4^+$ RE was not affected (p>0.05) and remained stable at 98 ± 5%. The feed C/N increase resulted in a gradual reduction of the effluent NO_3^- concentration, suggesting an increase in the denitrifying efficiency of the system that could be favoured by the low DO levels in the bioreactor. The results obtained in this stage confirm that the UAGSB reactor works more efficiently at higher C/N ratios, which should be considered in view of future real-scale applications of this system. During the periods IX (day 221) and X (day 259), the HRT was set at 12 and 6 h with the objective to evaluate the COD, $N\text{-}NH_4^+$, and TIN REs at increased organic and nitrogen loading rates. The HRT reduction from 24 to 12 and to 6 h resulted in a significant decrease of $N\text{-}NH_4^+$, TIN and COD REs to 71, 63 and 64 %, respectively (period X). This suggests that the significant increase in the influent organic and nitrogen loads, coupled with the low DO concentrations in the bioreactor, negatively affected nitrification.

Table 1. Operating conditions and duration of each experimental period during the continuous-flow operation of the UAGSB reactor.

Abstract

This study aims to investigate the anaerobic kinetic parameters and competition between phosphorus and glycogen accumulating organisms in aerobic granular sludge under different substrate concentrations. Several tests were conducted monitoring the concentrations of COD and phosphates, to model the process according to a Monod curve and to evaluate the activities of the accumulating organisms under the different conditions. Results show that the half-saturation constant tends to increase with the maximum specific removal rate, and that a higher GAO activity didn't compromise the biological phosphorus removal process.

Keywords (maximum 6 in alphabetical order)

Aerobic Granular Sludge, Anaerobic metabolism, Enhanced Biological Phosphorus Removal, Phosphorus/Glycogen Accumulating Organisms, Wastewater treatment.

INTRODUCTION

Aerobic Granular Sludge (AGS) is a technological application of biofilm in which microorganisms are aggregated into dense pseudo-spherical shapes. AGS can host different microenvironments with different redox potentials which allows for the simultaneous removal of COD, nitrogen and phosphorus all within a single unit (Pronk et al., 2015). AGS are enriched of Phosphorus Accumulating Organism (PAOs) and Glycogen Accumulating Organisms (GAOs), non-ordinary heterotrophs capable of removing rapidly biodegradable COD anaerobically and storing it in the form of PHA, which can be used as electron donor in the aerobic phase of the cycle. These organisms have a very complex metabolism as it involves the production/consumption of intracellular storage compounds (PHA, polyphosphate and glycogen), which play an essential role in the Enhanced Biological Phosphorus Removal (EPBR) process. The aim of this study is to characterize the anaerobic kinetics of PAOs and GAOs in an AGS reactor fed at different level of COD evaluating the effect on the competition for the common substrate and on the phosphorus removal efficiency.

MATERIALS AND METHODS

The experiments were conducted within a laboratory scale Granular Sequencing Batch Reactor (GSBR) with a useful volume of 5L, operated for seven months as follows: cycle time 6h, HRT=15h, SRT=176±20d, OLR=640mgCOD/Ld, ORE=81%, NLR=80mgN/Ld, NRE=99.5%, PLR=22.4mgP/Ld, PRE=97.5%, T=20±0.5°C and pH=7.5±0.3. The cultivated biomass was mainly granular, with a floccular fraction of about 3% on volatile basis and have been characterized by gravimetric and granulometric analysis: 9.6%gTS/gWW, 6.56gTS/L, 80.1%gVS/gTS, D10=226.4µm, D50=776.9µm and D90=2144.7µm.

The tests were conducted operating the reactor in batch mode after the end of the conventional cycle and all necessary substrates have been supplied through a concentrated solution spike once the Oxidation Reduction Potential (ORP) fell below -200mV, in order to guarantee strict anaerobic conditions. Sodium acetate (HAc) has been used as the sole organic carbon source, with concentrations ranging from 160 to 800 mgCOD/L.

COD and PO_4-P concentrations have been monitored intensively to determine anaerobic kinetics such as the maximum biomass specific COD removal rate (q_{COD}^{max}, [mgCOD/gVSS/h]) and the half-saturation constant (Ks, [mgCOD/L]) to model the process with Monod equation according to the procedure proposed by Smith et al. (1998).

To evaluate PAOs activity a molar ratio of 0.5 Pmol-rel/Cmol-sto (Smolders et al., 1994) has been considered while GAOs activity have been calculated by difference through mass balance on the acetate. Their activity was estimated during the course of the experiments, to evaluate the influence of consumption of internal substrates, and over the whole test time.

RESULTS AND DISCUSSION

Results showed that the removal rates increase with the initial COD concentration, until a plateau is reached for concentrations above 600mgCOD/L (data not shown) when the concentration profile within the biofilm allows for non-limiting conditions even for inner layers. The q_{COD}^{max} recorded for initial concentration of 800mgCOD/L is 157mgHAc/gVSS/h, which is in line with literature values (166mgHAc/gVSS/h, reported by Lopez-Vázquez (2009)) obtained in a flocculent system, showing the high level of PAOs/GAOs enrichment of the GSBR system. The half-saturation constant (Ks), to be considered as "apparent" since bacteria are not in the planktonic state, also increases with increasing initial COD levels (Fig.1).

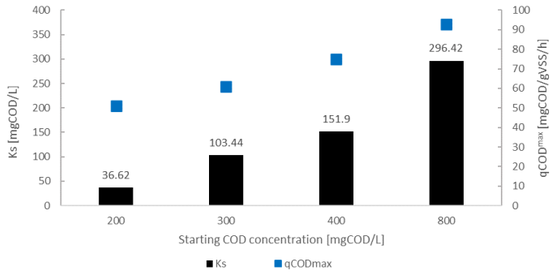

Figure 1. Anaerobic kinetic parameters under different starting COD concentrations.

This is likely due to increasing diffusion limitation inside the biofilm due to higher consumption rate, as proposed by Shaw et al. (2013). Nevertheless, the contribution of limiting availability of internal substrates progressively interesting the microorganisms from the external to the internal layers cannot be excluded.

Regarding the competition between PAOs and GAOs, an increase in phosphates released in the bulk was observed (Fig.2) for increasing COD starting levels, indicating a raising PAO activity. At lower COD concentrations PAOs outcompeted GAOs, but for higher COD levels an increase in GAO activity was registered (Fig.3). Nevertheless, the subsequent aerobic P-removal efficiency was not compromised (data not shown) indicating that GAOs exerted the positive effect of contributing to COD depletion without hampering P-removal efficiency, as stated by Nielsen et al., (2019) for a flocculent system. In Fig.2 the acetate left over at the end of the 800 test shows that the maximum anaerobic uptake capacity of the system was exceeded, which allowed the estimation of the overcapacity of the consortium of 450%, calculated in comparison to a standard cycle.

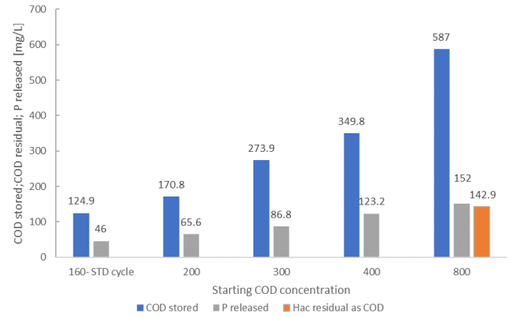

Figure 2. Volumetric concentrations of the stored COD, the residual COD at the end of each test and the PO4_P released with different starting COD concentrations. In the last test the residual HAc as COD is highlighted.

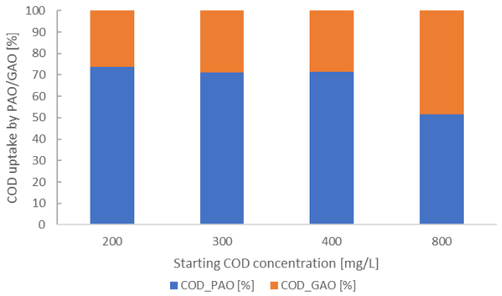

Figure 3. Percentage of activity by PAOs/GAOs over the entire experiment.

During the course of the individual tests, a trend was observed indicating the progressive decrease in PAO activity as the concentrations of COD in the bulk decrease from the starting point, being compensated by higher GAO activity (example reported in Fig.4). As reported by Lopez-Vázquez et al. (2009), the conditions under which the tests took place (T=20°C, pH=7.5 and HAc as sole carbon source) favour PAOs metabolism, which explains the higher activity at the start of the test. To explain the switch from the dominance of PAOs metabolism to GAOs several things need to be taken into account. First, the spatial distribution is important within a biofilm, the species found in the outer layer of the granule detect higher concentrations allowing higher activity and limiting the diffusion of substrate in the inner layers. Then, this initial high PAOs activity is related to a rapid consumption of the internal substrates, which will lead to a progressive slowdown of the metabolism allowing a greater activity of either the microorganisms with lower affinity with the substrate or located in the inside of the granule. In fact, as reported by Lemaire et al. (2008), in AGS PAO Accumulibacter are most likely to be found in the layers penetrated by oxygen in the aerobic period of the SBR operations, corresponding to the external part of the granule.

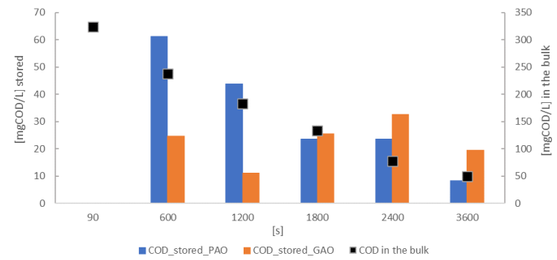

Figure 4. COD concentration in the bulk and its volumetric uptake by PAOs and GAOs in each time interval of the single test.

In summary, the Monod curve turned out to be a good approximation for the modelling of the single tests, but the absence of a constant half-saturation parameter impedes its generalized application to estimate the minimum anaerobic time required in function of the COD fed. Moreover, results show that the enrichment of GAOs in EBPR systems is not necessarily negative since, especially for layered microbial consortium as biofilms, they contribute to face fluctuating COD loads without compromising bio-P removal.

Abstract
Implementation of mainstream partial nitritation/anammox for resource-efficient nitrogen removal is important to transition towards energy-autonomous sewage treatment. Its development is challenged by the competitiveness of nitrite-oxidizing bacteria (NOB) scavenging nitrite from anammox bacteria (AnAOB). A unique multi-stressor floc treatment (sulphide-spiked deoxygenated starvation and free ammonia shock) was therefore validated for the first time under lab-scale conditions. A good microbial activity balance was achieved with high AnAOB (71±21 mg N L-1 d-1) and low NOB (4±17% of total nitrite consumption) activity. Recurrent floc treatment was revealed to be an essential strategy. In addition, NOB growth on the biofilm was avoided despite only treating the flocs to safeguard AnAOB activity. Overall, the multi-stressor treatment concept was validated as a useful NOB growth control strategy.

Keywords (maximum 6 in alphabetical order)
Biological nitrogen removal; cold anammox; deammonification; sewage treatment

Introduction
Partial nitritation/anammox (PN/A) is a resource-efficient nitrogen removal pathway. Compared to the conventional nitrification/denitrification process, it offers a 60% reduction in aeration demands (energy consuming) and 100% reduction in COD demands (could be used to produce energy via anaerobic digestion) (Jetten *et al.* 1997). The major challenge for mainstream PN/A implementation is the selective suppression of nitrite-oxidizing bacteria (NOB) over aerobic and anoxic ammonium-oxidizing bacteria (AerAOB and AnAOB). A combination of multiple dedicated control strategies hereby essential (Van Tendeloo *et al.* ; Agrawal *et al.* 2018).

Exposing the sludge to a single biocidal agent or stressor is often applied to selectively suppress NOB activity with for example free ammonia (FA) (Wang *et al.* 2021), sulphide (Erguder *et al.* 2008), or a short substrate starvation (Ye *et al.* 2019). Typically, the concentrated return-sludge stream is periodically treated rather than a continuous exposure in the main tank to reduce the operational cost. Despite promising performance achieved in the lab, long-term and large-scale successes remain scarce. The ability of NOB to adapt to certain control strategies, such as these single-stressor treatments, threatens the implementation of mainstream PN/A (Wang *et al.* 2021). The development of multi-stressor treatments could help to overcome this challenge as they are potentially less susceptible to NOB adaptation (Seuntjens *et al.* 2018).
In this study, the unique multi-stressor treatment concept formulated by Seuntjens *et al.* (2018) was validated under lab-scale conditions, implemented as foreseen in a possible full-scale application. The treatment consisted of sulphide-spiked deoxygenated starvation (2 d) followed by an FA shock (1 h). The main objective was to achieve nitrogen removal via AnAOB with minimal NOB contribution.

Material and Methods
A 4.7L fixed-film activated sludge (IFAS) reactor was operated under mainstream conditions (20±1°C; influent: 49±6 mg NH_4^+-N L^{-1} and 75 mg COD L^{-1}, among others), continuously fed and equipped with a settler (1.0L), pH and DO control. A combination of pre-colonised PN/A carriers (1.3L, from a mainstream lab reactor) and PN/A flocs (< 200µm, from a sidestream DEMON® reactor) was used as inoculum. Floc age was controlled at 8.5 days while the biofilm was not actively wasted. Intermittent aeration (4/8 min on/off at 0.9 mg O_2 L^{-1}) was applied and ammonium limitations (< 5 mg N L^{-1}) were avoided.

Flocs were recurrently exposed to the multi-stressor treatment at a frequency of 0.095 d^{-1} by treating 33% of the flocs every 3.5 days. Deoxygenated conditions were applied by sparging with N_2 gas, and sulphide (157±16 or 305±12 mg S^{2-}-S L^{-1}) was added by a needle. After a 2-day starvation, a short 1-h FA shock was conducted (34±2 mg NH_3-N L^{-1} at pH 8.1).
The performance was evaluated by making a so-called microbial activity balance: all total nitrogen (TN) removal was assumed to originate from AnAOB activity, and subsequently the AerAOB and NOB activity was calculated according to the average stoichiometry(Strous *et al.* 1998; Lotti *et al.* 2014). TN removal by denitrification was assumed to remain limited as oxygen was present for > 81% of the time.

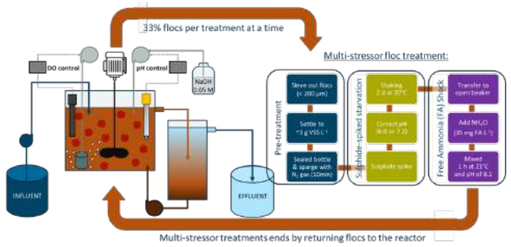

Figure 1 Schematic overview of the reactor and experimental design. Multi-stressor floc treatments were conducted twice a week, treating about 33% of the total flocs, resulting in an overall frequency of 0.095 d^{-1}. Biofilm (both attached and suspended) were excluded from the treatment.

Results and Conclusions
The initially applied operational conditions in Phase Ia were insufficient to maintain a good microbial activity balance with low NOB activity (Figure 2). After doubling the sulphide dose in the floc treatment to 307±15 mg S^{2-} L^{-1} (Phase IIa onwards), a temporal reduction in oxygen levels due to technical difficulties (Phase IIb-IIc), and the addition of extra PN/A carriers in combination with fixing the oxygen control (Phase IIIa), a desired performance was achieved again in Phase IIIa. In the final two phases, the balance deteriorated after removing 57% of the carriers (Phase IIIb), highlighting the importance of sufficient AnAOB activity as nitrite sink(Seuntjens *et al.* 2020; Wang *et al.* 2021), and stopping the recurrent floc treatments, showing the importance of the floc treatment.

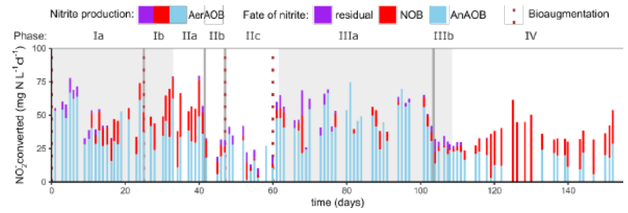

Figure 2 Microbial activity balance in the IFAS reactor during process operation. The nitrite production by AerAOB is visualised as well as the fate of this nitrite: consumed by AnAOB, NOB or remained residual.

This study demonstrated that a clever combination of the recurrent multi-stressor floc treatment and other operational strategies (oxygen availability control, short floc age, and residual ammonium) can result in a good microbial activity balance with high AnAOB (71±21 mg N L^{-1} d^{-1}) and low NOB activity (4±17% of AerAOB) (Figure 2, Phase IIIa). The floc treatment was hereby essential and should be continuously applied to avoid NOB growth. No signs of NOB adaptation were observed over 104 days. Interestingly, NOB growth on the biofilm could successfully be avoided despite solely treating the flocs to safeguard AnAOB activity. The presence of sufficient AnAOB activity was hereby essential. These obtained results ease the implementation of mainstream PN/A, thus advancing the concept of energy neutrality in sewage treatment plants.

Table 1 Summary of the main performance indicators: TN removal rate and efficiency, effluent nitrite concentration, and estimated NOB activity.

Abstract

The partial nitritation and anammox (PN/A) process has gained popularity for the treatment of nitrogen removal in wastewater due to significant energy savings and its potentially much lower CO_2 footprint. However, the treatment of mainstream wastewater by PN/A has been limited mainly due to its unsuitable composition. In this research, we apply ion exchange (IX) using a zeolite column to selectively remove and concentrate ammonium from mainstream wastewater. After an absorption phase, the IX column is regenerated using a brine solution. The ammonium rich brine is "bioregenerated" in a PN/A reactor where the ammonium is converted to nitrogen gas allowing the brine to be reused in another cycle of IX regeneration. To successfully remove ammonium from the spent brine, anammox and ammonia oxidizing bacteria (AOB) were first cultivated in separate reactors under saline conditions (4.0%) and later combined in a single PN/A reactor. After continuous operation with sea water, the PN/A reactor treated recirculating brine from the IX column for 48 cycles of ammonium absorption and bioregeneration with minimal blowdown. The various cations of the regenerant solution were stable except for calcium that reached very high values upwards of 3,000 mg/L as Ca^{+2} and finally caused PN/A reactor failure due to mineral precipitation. The build-up of high concentrations of calcium in the regenerant was addressed in two ways: 1) 20% regenerate replacement per cycle, and 2) precipitation of $CaCO_3$ via the addition of sodium carbonate. Both methods were applied to 30 absorption and bioregeneration cycles each and shown to be effective in keeping calcium concentrations from accumulating in the regenerant allowing for stable PN/A reactor operation.

Keywords

INTRODUCTION

While partial nitritation and anammox (PN/A) has been proven as an effective technology for nitrogen removal in municipal wastewater (MWW) side-stream treatment, the technology has not been effectively applied to the much larger market of mainstream MWW treatment. The main reasons for the limited implementation of the PN/A process for mainstream MWW are: 1) high COD/N ratio that encourages heterotrophic microbial growth with the accompanied short sludge age and washout of slow growing autotrophic bacteria, and also competition by denitrifying bacteria for nitrite; 2) lower temperatures with the resulting low conversion rates, and 3) low and fluctuating ammonium concentrations prevalent in mainstream MWW that further limit the extremely slow growing anammox bacteria. On the other side, PN/A offers an enormous potential towards reducing the CO_2 footprint through 1) energy savings for nitrogen removal, 2) better usage of the organic carbon, and 3) reduction of greenhouse gas emissions.

The strategy presented here to overcome the limitations of PN/A is based on an ion exchange (IX) and bioregeneration process for the selective removal and treatment of ammonium from mainstream MWW either before or after carbonaceous removal (see Fig. 1). MWW is passed through an IX column filled with natural zeolite that absorbs ammonium until exhaustion. The IX column is regenerated by passing a cation rich regenerant solution through the column desorbing the ammonium. The ammonium rich regenerant solution is treated in a PN/A biofilm reactor where ammonium is converted to nitrogen gas enabling the reuse and recycling of the regenerant. The premise for this strategy is that selective removal of ammonium from mainstream by IX eliminates competition from carbon removal and provides a desired ratio of COD:N for stable PN/A operation. Moreover, heating a smaller volume of brine to be treated and continually recycled is economically feasible and the much higher ammonium concentration obtained after IX can be used to control nitrite oxidizing bacteria (NOB). In this study, we present results from the operation of a lab scale combined ion exchange and bioregeneration process for ammonia removal from mainstream using partial nitritation/anammox.

Figure 1. Schematic diagram of the ion exchange – bioregeneration process for nitrogen removal. After organic carbon removal, wastewater first passes through the IX column and ammonium is absorbed (left side). After the absorption cycle, the IX column is regenerated with brine (right side). The brine is subsequently treated in a PN/A reactor for ammonium removal and is reused again for another cycle of IX column regeneration.

MATERIALS AND METHODS

Anammox bacteria and AOB biomasses were first enriched separately for treatment of the ammonium rich regenerant solution. Anammox bacteria were enriched under saline conditions (East Mediterranean Sea water, 4.0%) in 6 L continuous flow reactors filled with volcanic scoria and fed with a 1:1 ratio of nitrite to ammonium. Initial inoculum was sludge taken from a denitrification filter treating sea water aquaculture effluent. Growth of AOB for nitritation under saline conditions was carried out in similar reactors with pH control (pH 8.2) and free ammonia concentrations between 5 and 10 mg/L to selectively inhibit NOB. After biomass enrichment, AOB were harvested and added to a 20 L anammox reactor filled with 15 L of volcanic scoria receiving sea water amended with nitrite and ammonium. The feed solution was changed to ammonium only and a mixture of 2.5%/97.5% oxygen/nitrogen gas was sparged to the PN/A reactor to ensure low dissolved oxygen (DO) concentrations. The PN/A reactor temperature was 32°C.

Ion Exchange - Bioregeneration Experimental Setup. IX absorption and regeneration parameters were carried out for a natural zeolite (chabazite) with an IX capacity 2.5 to 3 meq/g (Lahav & Green, 1998). Simulated wastewater with a typical Israeli cation composition was used in the absorption experiments (see Table 1). Regeneration experiments were carried out with same sea water as above. A bench scale IX and bioregeneration system was constructed consisting of an IX column filled with 1 L of chabazite and the PN/A reactor mentioned above. The IX absorption cycle treated 200 L wastewater per cycle (200 bed volumes, BV) and run to maximize NH_4^+ absorption capacity, i.e. complete IX column breakthrough where influent N-NH_4^+=effluent NH_4^+ (higher quality effluent is obtained by running multiple IX columns in series). The IX regeneration cycle used 24 L (24 BV) brine (starting with sea water) per cycle with no blowdown except for the brine remaining in the column at field capacity at the completion of regeneration. Sodium lost during the absorption phase was replaced by adding NaCl to the regenerant and NaOH to the PN/A reactor for nitritation requirements. The IX regenerant was collected and treated batchwise to ensure a constant ammonium concentration. The PN/A reactor was continuously fed with regenerant brine at a flowrate of 10 L/day. Three (3) absorption/regeneration cycles were performed per week.

RESULTS AND DISCUSSION

Table 1 shows the average concentration of IX effluent for 48 absorption cycles of synthetic wastewater after 200 BV. 46.6% of the N-NH_4^+ and 52.5% calcium were removed from the wastewater, resulting in a concurrent rise in sodium by 100 mg/L in the effluent wastewater. This demonstrates the similar affinity ammonium and calcium have for chabazite (1.67 meq NH_4^+ absorbed vs 1.34 meq/L Ca^{+2} absorbed). Wastewater influent and effluent magnesium and potassium concentrations during ion exchange remained largely unchanged.

Fig. 2 shows the ammonium concentration of the ion exchange regenerant before and after treatment in the PN/A reactor throughout the 48 absorption cycles of synthetic wastewater. The average regenerant brine ammonium concentration for synthetic WW was 207.5 ± 12.7 mg/L. The brine regenerant was fed to the PN/A reactor and more than 90% of ammonium was successfully removed (average effluent of 12.7 ± 4.5 mg/L N-NH_4^+) at a removal rate of 0.13 gN/L-reactor/day. The nitrate build up in the recycled regenerant was a result of anammox activity. Microbial community analysis of the PN/A reactor by next generation sequencing (NGS) revealed an obligately halophilic anammox bacteria from the genus *Candidatus Scalindua* and AOB from the halotolerant genus of *Nitrosomonas*. No significant amount of NOB was observed as the ammonium concentration in the PN/A reactor was high enough and DO low enough to maintain inhibitory conditions for their growth. The constant and relatively high influent ammonium concentration allowed for stable PN/A operation for nearly all the experimental period along with stable potassium and magnesium concentrations in the regenerant. However, the build-up of calcium in the recycling regenerant (Fig. 3) to very high concentrations (3000 mg/L as Ca^{+2}) due to its high affinity for chabazite and minimal regenerant blowdown (approximately 1%) led to excessive mineral precipitation in the PN/A reactor and eventually impaired performance as evidenced by the appearance of N-NO_2^- concentrations. Reducing flow to the reactor did not improve reactor performance and the PN/A reactor had to be taken offline for recovery.

Table 1. Chemical composition (average) after 48 cycles of absorption/regeneration using synthetic wastewater and 30 cycles of actual secondary treated wastewater amended with ammonium.

Component	IN synthetic WW	OUT synthetic WW	IN real WW	OUT real WW
N-NH_4 mg/L	50.4 ± 1.9	26.9 ± 2.0	50.2 ± 1.4	30.9 ± 1.5
Ca mg/L as Ca^{+2}	51.0 ± 3.8	24.2 ± 6.9	90.2 ± 3.1	59.6 ± 3.7
Mg mg/L as Mg^{+2}	32.9 ± 4.1	33.4 ± 4.6	30.0 ± 0.7	30.3 ± 0.8
K^+ mg/L	26.7 ± 2.9	25.9 ± 3.5	36.6 ± 0.8	31.2 ± 0.5
Na^+ mg/L	116.4 ± 17.2	213.9 ± 18.0	148.9 ± 2.2	244.7 ± 4.7

The PN/A reactor was reseeded with AOB and anammox bacteria and after a period of continuous operation on sea water, the reactor was again ready to treat the regenerant brine. In this reactor run actual secondary treated wastewater amended with ammonium was used for 30 cycles (Table 1). The average regenerant brine ammonium concentration for real wastewater was 157.8±10.6 mg/L, lower than for synthetic wastewater due to the higher calcium content depressing ammonium absorption. The zeolite showed no reduction in absorption capacity due to potential fouling.

Stabilizing regenerant calcium concentration. Two methods were tested to arrest the increase of calcium in the recirculating regenerant. The first was regenerant replacement, i.e. 20% of the recycling regenerant solution was replaced after treatment in the PN/A reactor with fresh sea water. In this method there was no need to add NaCl to replace sodium lost during IX. The method was run for the 30 cycles when actual wastewater was used. Using regenerant replacement it took 15 cycles for the calcium concentration to increase from 490 mg/L (sea water) and then stabilize at 1879±39 mg/L as Ca^{+2}. The system was run for a further 15 cycles with no problem.

In the second method, calcium removal was carried out by precipitation using sodium carbonate (Zhou *et al.*, 2021). Here a dose of between 0.8 and 1 gram of sodium carbonate per liter of regenerant was given after IX column regeneration just before entering the reactor. The method was run for a further 30 cycles using synthetic wastewater based on the higher Ca^{+2} concentration of actual secondary wastewater used earlier during regenerant replacement. The average Ca^{+2} concentration before IX column regeneration was 1838±42 mg/L and 2130±33 mg/L after regeneration. The average Ca^{+2} after adding Na_2CO_3 was 1858±50 mg/L for an average precipitation of 280±50 mg/L Ca^{+2} per liter regenerant. Excess alkalinity remaining after the addition of sodium carbonate was neutralized to between 40 and 60 mg/L to prevent any further $CaCO_3$ precipitation in the reactor and leave enough inorganic carbon for the autotrophic bacteria. Both methods were shown to be effective in keeping calcium concentrations from accumulating in the regenerant and allowed for stable PN/A reactor performance and continued process operation.

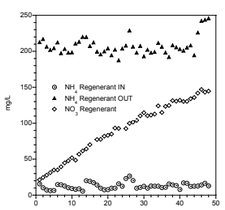

Figure 2. Regenerant N-NH_4 concentration before and after PN/A reactor. Increase in N-NO_3 was due to the anammox activity.

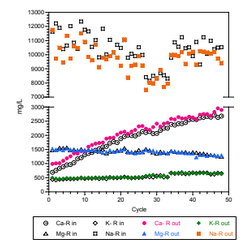

Figure 3. Cation composition of regenerate before and after PN/A reactor treatment.

Abstract

Energy efficiency in WWTP can be significantly improved by maximising biogas production while minimising energy demand. One suitable option is a first organic matter redirection to anaerobic digestion followed by autotrophic nitrogen removal using granular biomass. In this paper, the results obtained during the start-up of an AGS reactor fed with a HRAS effluent are presented. Aerobic granulation targeting partial nitritation is addressed by elucidating key operational parameters. The study shows that solids wasting strategy is the key point in aerobic granulation, being a selective purge from the top of the settled sludge bed the best option. Partial nitritation with no nitrate formation is reported, being FNA the main responsible for NOB inhibition.

INTRODUCTION

Currently, urban wastewater treatment plants (WWTP) are net energy-consumption systems that represent 3% of the global electricity consumption (Li et al. 2015). In the quest to achieve operational self-sufficiency and sustainability, technologies based on a first organic matter redirection to anaerobic digestion (i.e high-rate activated sludge systems, HRAS) followed by autotrophic nitrogen removal using granular biomass have been proposed to maximise biogas production while minimising energy demand (Coma et al., 2011; Cao et al., 2017; Canals et al., 2023). Kosar et al. (2023) coupled HRAS effluent with AGS at lab scale with a good settling property (SVI_{30}=45 mL/gr) but not granular sludge (SVI_5/SVI_{30}=1.44) and focused to achieve full nitrification with nitrogen removal. Efforts have been conducted to achieve autotrophic nitrogen removal in mainstream, where the two-stage process seems to be a more promising option to achieve a successful autotrophic nitrogen removal (Akaboci et al., 2020; Hoekstra et al., 2019)which results in an excess of IC for full nitritation, the oxidized ammonium fully nitrified, and nitrite accumulation was not reached. Limiting influent IC (influent NH4+-N/IC of 0.73 ± 0.03 mg N·mg C−1. The first stage should be devoted to obtain a partial nitritation with a suitable nitrite to ammonia ratio (close to 1.32 $N\text{-}NO_2^-$:$N\text{-}NH_4^+$) while removing the biodegradable organic matter. The second stage should focus on anaerobic autotrophic deamonification (Anammox process). In this paper we present the results obtained during the start-up of an Aerobic Granular Sludge (AGS) fed with the effluent of a HRAS reactor operation at full scale conditions (hourly variation of wastewater quality and temperature for 620 days). First, we address the aerobic granulation process from CAS seeding and secondly the partial nitritation to achieve a suitable anammox reactor influent.

MATERIALS AND METHODS

An 880 L sequencing batch reactor was operated 620 d for AGS development treating the effluent of a HRAS reactor working at real conditions (location: La Garriga WWTP, Catalonia, Spain). Cycle phases comprised i) simultaneous fill/draw (F/D), ii) anaerobic and aerobic reaction and iii) settling. The applied volumetric exchange ratio (VER) was 50%, dissolved oxygen (DO) concentration in aerobic phases was maintained over 2.0 mg/L and total cycle length ranged from 160 to 360 minutes. The SBR was inoculated at day 0 with floccular sludge from a conventional activated sludge system. COD removal efficiency in the HRAS system was 43 ± 15 %. HRAS effluent composition was COD: 406 ± 82 mg/L, NH_4^+-N: 40 ± 14 mg/L, PO_4^{3-}-P: 4.5 ± 1.6 mg/L and alkalinity: 340 ± 56 mg $CaCO_3$/L. No temperature control was applied, ranging from 13 to 26ºC during the whole operation.

RESULTS AND DISCUSSION

To develop AGS, the operation was divided in 3 periods (Table 1). In Period I, granulation strategy was focused in flocs washout during F/D phase by providing an increasing upflow ascensional velocity (v_{asc}) from 2.3 to 4.5 m/h while reducing settling phase from 30 to 5 minutes. Total suspended solids (TSS) in the reactor remained stable around 3 g/L (SRT=4 d) and the sludge volume index (SVI) ranged from 100 to 150 mL/g until day 170, when first granules appeared. Afterwards, TSS increased up to 8 g/L and SVI decreased up to 40 mL/g. First granules were big and had finger-type outgrowth (Figures 1, 2.A and 4). Decreased temperatures due to winter conditions reduced the whole biomass settleability at the end of Period I, which lead to biomass washout (Figures 1 and 4). In order to remove floccular biomass, a once a day manual purge at the end of a settling phase was introduced in Period II. At this time, TSS were low (<2 g/L) while SVI ranged from 50 to 100 mL/g. SRT was as low as 1.1 days. AGS could not develop under these conditions (Figures 2.B and 4) since biomass washout was too severe and unselective. In this context, Period III was characterised by the implementation of an automatic selective purge from the top of the settled sludge bed at the end of every settling phase. At that point, granulation process started and perfect granules were formed (Figure 2.C). TSS reached values of 6 g/L and SVI 20 mL/g. SRT increased to 15-18 d. Moreover, the ratio SVI_5/SVI_{30} reached values of 1.0, being indicative of the high predominance of AGS (Figure 4).

Regarding nitrification, partial nitritation with no nitrate formation was observed in Period I and III. It has been reported the important role and the sensibility of microorganisms to FNA in biological nutrient removal processes (Pijuan et al. 2010)phosphorus removal typically occurs together with nitrogen removal. Nitrite, an intermediate of both the nitrification and denitrification processes, can accumulate in the reactor. The inhibitory effect of nitrite/free nitrous acid (FNA. FNA values of 0.030 mg N/L can lead to a 50% inhibition in nitrite oxidation, according to Blackburne et al. (2007). High FNA concentrations up to 0.075 mg N/L were obtained in the reactor during aerobic phases (Figure 3) and could be responsible for the inhibition of nitrite oxidizing bacteria (NOB) growth in the AGS reactor. Thus, in Period I and III, FNA inhibition to NOB could have prevented nitrate formation in the reactor.

The main outcomes from this paper are: i) selective biomass washout from the top of the sludge bed rather than F/D biomass washout is responsible for a successful aerobic granular formation and ii) partial nitritation can be achieved during aerobic phase if a suitable FNA concentration is achieved to avoid NOB development.

Abstract
The anammox bacteria (AMX) sensitivity, especially at low temperatures, hinders its application. In this research work the effects of pH and concentrations of ammonium, free ammonia, nitrite and free nitrous acid (FNA) on the specific anammox activity (SAA), at different temperatures were investigated. Results showed a decrease of SAA by 30% per every 5 °C. AMX are particularly sensitive to low pH. At a pH of 6.5, SAA decrease to 50% and 65% at 20 and 30 °C, respectively. FNA plays an important role in the inhibition of SAA, since SAA drops to 65%, at 30 °C and pH 6.5, when using 30 mg N/L as substrate (FNA=18 µg N/L) and to 15% with 70 mg N/L (FNA=54 µg N/L). Therefore, for process robustness, operational strategies should be adapted to avoid feeding acidic nitrified waters into AMX reactors.

INTRODUCTION

The combined use of partial nitritation (PN) and anammox (AMX) processes has attracted interest in the search for more energy-efficient nitrogen removal in wastewater treatment plants (WWTPs). Although intensive research has been conducted to implement PN/AMX processes in the mainstream of WWTPs, several issues still need to be addressed. For example, AMX are known to be sensitive and slow growing, especially at low temperatures (Wang et al., 2022).

The two-stage configuration allows the PN and AMX processes to be optimised separately. pH and temperature are two key parameters for the AMX process, as they control the equilibria between ammonium-free ammonia (FA) and nitrite-free nitrous acid (FNA). The effects of FA and FNA on AMX activity have been extensively studied (Carvajal-Arroyo et al., 2014, Fernandez et al. 2012). However, these values vary greatly between studies and have been determined mainly at higher temperatures than those prevailing in the mainstream of a WWTP.

This study aims to research the sensitivity of AMX bacteria to environmental conditions. In particular, this research investigates the effects of pH and ammonium, nitrite, FA and FNA on specific anammox activity (SAA) at different temperatures.

MATERIALS AND METHODS

The SAA, expressed as g N/(g VSS·d), was determined in batch tests, performed in triplicate, in 38 mL-vials with a working volume of 25 mL. The maximum SAA was measured at 30 ºC, pH 7.8 and 70 mg N/L (of each nitrite and ammonium) (Dapena-Mora et al. 2007). First, three temperatures (20, 30 and 35 °C) were tested varying ammonium and nitrite concentrations (30 - 140 mg N/L of each) at pH 7.8 (Table 1). Later, different pH values (6.5 - 8.0; adjusted with phosphate buffer) were tested at 20 and 30 °C and two substrate concentrations (30 and 70 mg N/L of each) (Table 1). AMX-enriched biomass was taken from a lab-scale reactor operated at 30 °C and treating a nitrogen loading rate of 1.13 g N/(L·d). The percentage of activity remaining in the inhibition tests was calculated as %SAA= SAA/SAA_0*100 (where SAA_0 is the maximum SAA measured in a set).

RESULTS AND DISCUSSION

SAA is strongly temperature dependent, with a 33% increase measured from 30 °C (the temperature at which biomass was grown) to 35 °C (Fig. 1). SAA decreased by 61% from 30 to 20 °C. Substrate concentration (30 -140 mg N/L, each) did not significantly affect SAA (Fig. 1). The lowest reported inhibition values, at 30 °C, were 38 mg FA-N/L (50% of SAA loss) and 4.4 µg FNA -N/L (70% of SAA loss) (Fernandez et al. 2012). In these tests, FA concentrations ranged from 0.7 – 9.4 mg N/L and FNA from 0.8 to 5.7 µg N/L (Table 1). Thus, FA is below the inhibition thresholds, but FNA could have negative effects that do not appear to be temperature dependent.

In assays with different pH values performed at 20 and 30 °C, the maximum SAA was measured at pH 7.5 (Fig. 2A). While the loss of SAA at a pH of 8.0 was similar at both temperatures, AMX was more sensitive to a decrease in pH at lower temperatures. Ammonium and nitrite concentrations linearly modify FA and FNA, whereas pH affects them exponentially (low pH favours FNA accumulation and high pH values that of FA) (Table 1). Therefore, it is difficult to determine whether pH or FNA is responsible for the decrease in SAA at low pH. The loss of SAA at pH 6.5 is greater at higher nitrogen concentrations (higher FNA) (Fig. 2. B). For example, at 30 °C, the %SAA is 65% at 30 mg N/L (18 µg FNA-N/L), while it is less than 15% at 70 mg N/L (54 µg FNA-N/L) (Fig. 2B). A clear relationship was observed between the %SAA and FNA concentrations (Fig. 2B), confirming that FNA is mainly responsible for AMX inhibition at low pH.

PN systems often generate wastewater with low pH and moderate nitrite concentrations. Although SAA decreased at low pH, AMX are still active. To ensure the robustness of the process, the operating strategies of the AMX reactors should be adjusted to avoid shocks during feeding.

Abstract
Two new wastewater treatment alternatives focused on resource recovery are proposed. In both scenarios, after the primary treatment, the raw water is treated by means of Ultrafiltration (UF) membrane to increase the organic matter valorisation as biogas in the sludge line. The nitrogen obtained from the permeate can be removed through a Partial Nitrification (PN) process followed by an Anammox stage, allowing the use of existing facilities and reducing the energy consumption of the aeration of the biological treatment. Another alternative consists on the nitrogen recovery in the form of fertilizer. For this purpose, in a first step the ammonium is concentrated in an ion exchange (IE) stage and subsequently valorised by means of a hollow fiber membrane contactor (HFMC).

Análisis de dos alternativas de eliminación de nitrógeno

INTRODUCTION

Conventional wastewater treatment plants (WWTPs) has been identified as a process with high energy demand, in addition, a large part of the resources present in the water cannot be recovered following this treatment (McCarty et al., 2011). The growing pressure on water resources, the need to reduce energy consumption and increasingly strict discharge requirements have caused the study of new treatment alternatives to involve transforming WWTPs into water resource recovery facilities (WRRF). However, these alternatives usually imply huge modifications in the present WWTP. In this work, two treatment alternatives are proposed, making modifications to existing infrastructures to enhance the recovery of wastewater resources. Both scenarios (Figure 1) include a Carbon redirection technology (UF process) to maximize biogas production, followed by A) IE-HFMC to recover nitrogen as a fertilizer and B) a Partial Nitrification-Anammox biological stage to remove nitrogen in existing reactors but with lower energy cost.

MATERIALS AND METHODS

Experimental works have been carried out in a pilot plant located in Carraixet WWTP, Valencia. The ultrafiltration plant (0.03 µm pore size) was fed with real wastewater at 320 L/h. The characterization of the inlet water and the permeate obtained are shown in Table 1.

Partial Nitrification was studied in a 15L sequencing batch reactor (SBR) coupled to a 1L UF membrane to decouple the hydraulic and sludge residence time. A diagram of this pilot plant is shown in figure 2. In this reactor, the main mechanisms to stop the oxidation of NH_4 into NO_2 and generate an effluent suitable for the Anammox process were analysed.

According to previous studies and taking into account the high hardness of the working water and the affinity of the different adsorbent materials for ammonium and divalent cations (Zhou et al., 2021), the cation exchange columns were filled with Na-activated natural zeolites (Na-Z). A laboratory-scale set-up of 110ml of Bed Volume (BV) was carried out to evaluate the feasibility of concentrating ammonium from the UF permeate of wastewater. Also, the regeneration phase was studied to obtain a concentrated current in nitrogen valid for the HFMC. The diagram of this set-up is shown in figure 3.

RESULTS AND DISCUSSION

Partial Nitrification

PN could be carried out in the mainstream controlling the nitrite-oxidizing bacteria (NOB) growth to avoid NO_2 oxidation into NO_3. The pH and ammonia inhibition were not used for process control due to the high alkalinity and low ammonia concentration of the working water, which favours the complete oxidation into NO_3 (Pedrouso et al., 2017). Other mechanisms were used to favour ammonium-oxidizing bacteria (AOB) growth over NOB, such as the aerobic phase duration control and maintaining low dissolved oxygen levels between 0.3 -0.6 mg O_2/L. Despite the high accumulation of NO_2 reached (Figure 4), it is necessary a further work to guarantee the process stability.

The viability of this alternative supposes being able to maintain part of the existing biological reactors in the current WWTPs to carry out the PN. In addition, since there is hardly any organic matter to be oxidized and only part of the NH_4 is converted into NO_2, the energy consumption associated with aeration will be significantly reduced. If it is not possible to control the amount of oxidized ammonium during the PN and decreases the NH_4:NO_2 ratio necessary for the Anammox process, a bypass stream can be used in order to adjust the NH_4:NO_2 ratio in the influent to the Anammox process (Figure 1b).

Ion Exchange

Zeolite column proved to be able to concentrate ammonium up to 30 times, obtaining an ammonium stream at a concentration of 760 mg N-NH_4/L treating 180BV until achieva a concentration of 0.5 mg N-NH_4/l in the effluent (Figure 5). In addition, the use of NaOH as a regenerant allows to increase the pH in the concentrated stream above 12, leading the nitrogen to NH_3 form. The high concentration of ammonium and high pH makes this stream an ideal influent for HFMC process, where nitrogen is finally recovered in the form of fertilizer, such as $NH_4(SO_4)_2$ (Figure 1a).

This treatment train not only allows to valorize the nitrogen present in wastewater, but also has other advantages over conventional biological treatment: it is not conditioned by temperature and flow variations due to it is a modular physical-chemical process. However, the consumption of reagents such as NaOH and H_2SO_4 must be taken into account.

Abstract

The paper presents the possibilities of using free nitrous acid (FNA) to conduct the shortcut nitrification process in the mainstream wastewater treatment plant; this will be achieved, among other things, by inhibiting nitrite-oxidizing bacteria (NOB) by FNA in a separate reactor (selector). The effect of free nitrous acid contact time and concentration on the activity of nitrifiers of the first and second nitrification phases is presented. The research subject was samples of activated sludge taken from the municipal sewage treatment plant.

Keywords

Shortcut nitrification; activated sludge; free nitrous acid; nitrite-oxidising bacteria; NOB

INTRODUCTION

Many municipal wastewater treatment plants (WWTPs) receive wastewater with a low C/N ratio; an insufficient carbon source can reduce the denitrification process and leave a relatively high nitrogen load. The use of so-called nitrite pathways represents a modification of biological nitrogen removal processes, as it reduces the need for a carbon source by 40% and aeration by 25% (Rodriguez-Garcia et al., 2014). It is still challenging to achieve a stable performance of the nitrite pathway, i.e., suppressing or leaching nitrite-oxidizing bacteria (NOB) while developing ammonium-oxidizing bacteria (AOB). Shortening the nitrification process in mainstream WWTPs remains challenging due to low nitrogen concentrations and temperatures. However, it has been shown that using FNA allows for maintaining stable development of AOB, unrestricted by aeration systems, and that FNA production from liquid anaerobic digestion is sustainable and economically beneficial (Duan et al., 2018). However, due to low nitrogen concentrations in municipal wastewater, an adequate concentration of FNA cannot be achieved. However, it is possible to produce nitrite in a side stream on the reject water and then mix it with activated sludge in a particular selector reactor (Fig. 1). Such an assumption is being tested in the shortened nitrification in the mainstream results in nitrites instead of nitrates in the outflow of the treatment plant (SNIT) project. The determination of FNA treatment conditions is still unclear, as some studies have shown the adaptation of NOB to FNA in the past (Ma et al., 2017). The study aimed to determine the optimal parameters of NOB inhibition (FNA concentration, contact time, pH) based on activity in short laboratory tests..

MATERIALS AND METHODS

Oxygen uptake rate (OUR) measurements

A conventional fed batch respirometer with a small closed reactor vessel was used for the measurements. The respirometer contained an oxygen electrode connected to a program for automatic recording of readings. The measurement of activity was verified in accordance with the methodology presented in Surmacz-Górska *et al.*, 1995. Allylthiourea (ATU) and sodium azide/sodium chlorate solutions were used as a selective nitrification inhibitors. The activated sludge for OUR measurements was taken from WWTP. Experiments were carried out in the range of pH from 5.5 to 7.0 and FNA concentration 0.004÷2.3 mgHNO_2-N/L. The AOB and NOB activities after FNA treatment were measured. The response of the tested nitrification inhibitors was compared.

Batch tests

The activated sludge collected from municipal WWTP, was treated with 2.3 mgHNO_2-N/L FNA concentration. The test with adding 0 mg HNO_2-N/L was a control test (pH was 7.0±0.2). The pH value was controlled at 6.0±0.2 by adding 1.0 M HCl or 1.0 M NaOH. Experiments of FNA treatment were carried out for 2, 4, 16, 18, 20, 24 h, under anoxic conditions (T=21±2 °C; constant stirring). After FNA batch treatment, activated sludge was washed for three times in a centrifuge at 3600 rpm for 4 min to remove nitrite. Then, in the second part of the experiment the sludge was stirred, in aerobic conditions (DO = 0.5÷1.5 mgO_2/L) with 0.004 mgHNO_2-N/L of FNA (pH was 7.0±0.2), for 2 h. The AOB and NOB activities after FNA treatment were measured and represented as percentage of activities compared to the control test. The effect of FNA treatment time on AOB and NOB was also investigated.

RESULTS AND DISCUSSION

NOB activity expressed as a relative percent activity decreased after sludge FNA treatment. However, also in the case of AOB activity, the value deteriorated. In the low FNA concentration range, it was challenging to demonstrate the effect of contact time on NOB inhibition; for example, at FNA = 0.2 mgHNO_2-N/L and pH=7.0, the extension of the contact time from 1 to 2 h resulted in an increase in relative activity from 86.73 to 64.99%. At the same time, some analyses noted a decrease in AOB activity (Fig. 2a). A major problem of the conducted OUR measurements was the lack of repeatability of the results. The activated sludge for the tests was each time taken from a real facility, so the condition and conditions of the processes could change (Fig 2a-c). Vadivelu et. al. 2007, showed that FNA concentration of 0.40–0.63 mgHNO_2-N/L inhibited NOB culture by 50%. During the measurements of the oxygen uptake rate, the possibility of using various inhibitors of the nitrification process was tested, no significant effect on the final results was demonstrated. OUR tests are quick and easy-to-use tests that report AOB and NOB activity, but the authors have noted big problems with the reproducibility of the results. In batch tests, on the other hand, it has been shown that the most effective contact time for NOB inhibition is 18h, with an FNA concentration of 0.4 mgHNO_2-N/L, which coincides with literature data (Jiang et al., 2018). Studies have shown the potential of FNA in inhibition of NOB while aching still good condition and properties of AOB.

The project was funded by the Polish-Norwegian Research Program operated by the National Centre for Research and Development under POLNOR 2019 in the frame of Project Contract No NOR/POLNOR/SNIT/0033/2019-00

Abstract

Nitrite pathway is often recommended to reduce organic matter requirements. However, no previous studies have been conducted on what the minimum COD requirements would be to meet the total nitrogen and phosphorus discharge limits when integrating enhanced biological phosphorus removal with nitrite pathway. This work is a simulation-based study of a conventional A^2/O WWTP. An ASM2d-N_2O model extended with all the biological and chemical processes involving nitrite and N_2O description was used. This study provides novel correlations and a practical decision tree on the benefits and drawbacks of using nitrite pathway. These correlations are useful for a fast and a priori assessment of the required influent COD/N/P in the ranges of 3-11 mgPO_4^{-3}·L^{-1} and 20-60 mgNH_4^+-N·L^{-1}.

Keywords

Denitritation; enhanced biological phosphorus removal (EBPR); nitritation; nitrite pathway; wastewater; N_2O emissions.

INTRODUCTION

The main pollutants of wastewater are organic compounds and nutrients (N and P). N is removed with biological nitrogen removal (BNR), involving nitrification and denitrification. P removal is based either on chemical precipitation or biological accumulation via enhanced biological phosphorus removal (EBPR). EBPR relies on the enrichment of the sludge with polyphosphate accumulating organism (PAO). Anaerobic-anoxic-aerobic (A^2/O) configuration combines three operating conditions in the simplest way to integrate EBPR with BNR. Various operational A^2/O strategies have been proposed to improve the effluent quality and to reduce the energy requirements. For instance, nitrite pathway, i.e., autotrophic ammonium oxidation to nitrite (nitritation) and posterior heterotrophic nitrite denitrification (denitritation), results in 40% lower COD requirements for denitrification (Xu *et al*. 2021), savings in aeration costs and lower sludge production compared to the conventional processes. On the other hand, when implementing novel strategies, the potential increase of greenhouse gas (GHG) emissions needs to be accounted for. Carbon source limitations or high nitrite concentration can trigger off N_2O emissions. N_2O can be produced by: i) biological reduction of NO to N_2O (hydroxylamine oxidation pathway, NN pathway), ii) N_2O production by AOB in the reduction of nitrite to NO and N_2O (nitrifier denitrification pathway, ND pathway) and iii) heterotrophic denitrification (DEN pathway). Influent COD limitation is nowadays a concern when aiming at integrating BNR and EBPR since an electron donor is required for both processes. The failure due to low influent C/N/P ratios can be overcame with addition of external carbon source at expenses of an increase in the operational cost. In this frame, innovative configurations or strategies are needed to deal with low COD-loaded influents that do not increase neither energy requirements, operational costs nor GHG emissions. Mathematical modelling is a useful tool for the prediction of the WWTP performance under different conditions/configurations. The activated sludge models (ASM) are biokinetic models describing the transformations occurring in the WWTP. Several extended ASM-based models have been proposed to predict the WWTP performance under different scenarios. The ASM2d-N_2O model has been recently proposed and applied to account for N_2O emissions in WWTPs with C/N/P removal (Massara *et al*. 2018; Solís *et al*. 2022).

This work aims to provide plant designers with instantaneous and easy-to-use reference information to help them decide whether nitritation/denitritation nitrogen removal should be implemented in each wastewater scenario.

MATERIALS AND METHODS

A conventional A^2/O configuration is proposed for the biological removal on N, P and organic matter. This configuration combines three different reactors, anaerobic (2800 m^3), anoxic (2800 m^3), aerobic (9000 m^3). The kinetic model used was the ASM2d-N_2O (Massara *et al*. 2018). Nitrate and nitrite pathway were simulated for a wide range of wastewater compositions (3-9 mgP·L^{-1} for P, 20-60 mgN·L^{-1} for N). The minimum amount of organic matter that was necessary to meet the discharge limits for N and P, considering soluble nitrogen (S_{NH4}, S_{NO3}, S_{NO2}) and phosphate (S_{PO4}) was obtained for each pair of N and P concentrations in the wastewater under two different scenarios. In the first scenario, all organic matter was introduced as fermentation products (S_A) to simulate the most favourable organic matter composition for PAO, whereas in the second scenario only slowly biodegradable organic matter (X_S). The effluent legal discharge limits considered were PO_4^{3-} < 1 mg P·L^{-1} and TN < 10 mgN·L^{-1} (ECC Council 1991). The minimum required concentrations of S_A and X_S were estimated using the MATLAB optimisation function *fminbnd*.

RESULTS AND DISCUSSION

Figure 1 shows the minimum S_A (readily biodegradable) and X_S (slowly biodegradable) requirements to meet the legal P and TN effluent limits when operating under nitrate pathway and nitrite pathway conditions. S_A (or X_S) concentration should be high enough to simultaneously accomplish both discharge limits. COD requirements decrease when implementing nitrite pathway for both for N and P-removal. Moreover, higher X_S is required when compared to S_A since the limiting step may be hydrolysis of X_S or fermentation of S_S under anaerobic conditions. These increases are up to 290% for nitrate pathway and 208% for nitrite pathway. Nitrite pathway route has several advantages compared to the nitrate pathway (conventional BNR), such as less aeration needs, less COD demand in the anoxic stage and less sludge production. Therefore, the implementation of the nitrite pathway reduces energy requirements and external COD needs, allowing BNR and EBPR with low COD/N influents.

The full presentation will describe the main outcome of this work, which is the obtainment of general correlations (*Table 1*) to easily quantify the organic matter requirements when implementing either the nitrite or the nitrate pathway scenarios. These correlations can describe S_A and X_S requirements based only on the influent N and P. Correlations for S_A-P [(1) (3)], and X_S-P [(5) (7)] were expressed as linear equations ($y=b_0+b_1·P+b_2·N$), while correlations for S_A-N [(2) (4)] and X_S-N [(6) (8)] were extended with a non-linear summand ($y=b_0+b_1·P+b_2·N+b_3·P·N$) for a better description of the observed N-P dependence. Moreover, *Figure 2* shows a useful decision tree based on these correlations to select the best operational conditions for the proper treatment of a given wastewater under an A^2/O configuration. If the S_A (or X_S) content is too low to meet the desired effluent concentrations, alternatives should be considered: the addition of an external carbon source, the addition of chemicals for phosphate precipitation, or the implementation of the nitrite short-cut pathway. *Figure 3* compares the correlations obtained in this work to those in Metcalf and Eddy (Tchobanoglus *et al*. 2014) in three different case studies. The correlations obtained in this study predict approximately the same S_A requirements under the nitrate pathway. The full presentation will also disclose all the simulations related to the GHG emissions and the operational costs (*Table 2*) for each of the scenarios studied. For example, the nitrite pathway presents lower costs (between 4%-9% less) but a parallel increase of N_2O emissions. The main differences appear in the aeration costs (AE is reduced in the range 36%-37%), and sludge production (SP is reduced 1%-2%). A full discussion on the trade-offs of the nitrite pathway, aiming at reducing operational costs but incrementing the carbon footprint of the WWTP will be provided.

Table 1. Correlations of S_A of X_S requirements for nitrate and nitrite pathway.

	S_A requirements	Equation
Nitrate pathway	S_A-P = 2.51 + 14.03 P + 1.046 N	(1)
	S_A-N = 66.51 – 14.67 P + 4.72 N + 0.600 P·N	(2)
Nitrite pathway	S_A-P = -4.51 + 14.12 P + 0.517 N	(3)
	S_A-N = -32.92 – 3.169 P + 4.144 N + 0.066 P·N	(4)
	X_S requirements	
Nitrate pathway	X_S-P = -7.21 + 31.45 P + 3.22 N	(5)
	X_S-N = -18.73 – 7.67 P + 8.80 N + 0.305 P·N	(6)
Nitrite pathway	X_S-P = -29.52 + 27.67 P + 1.68 N	(7)
	X_S-N = -78.00 – 0.367 P + 5.69 N + 0.008 P·N	(8)

A novel wastewater treatment process incorporating acidophilic ammonia oxidation

M. Zheng*

*Australian Centre for Water and Environmental Biotechnology, The University of Queensland, St Lucia, Queensland 4072, Australia, (Email: m.zheng@uq.edu.au)

Abstract

Growing interest in achieving energy-neutral wastewater treatment requires a parallel focus on maximizing bioenergy recovery and minimising energy consumption, and the chemical enhanced primary treatment (CEPT) followed by partial nitritation and anammox (PN/A) and anaerobic digestion (AD) is one of the most recognised solutions. However, the acidification of wastewater caused by ferric (Fe^{3+}) hydrolysis in CEPT and the suppression of nitrite-oxidising bacteria (NOB) in PN/A are two major challenges associated with this paradigm in practice. This study proposes a novel wastewater treatment scheme utilising the newly discovered acidophilic ammonia oxidation as a solution to solve these challenges. Long-term demonstration on real domestic sewage showed that, by dosing $FeCl_3$ at 50 mg Fe/L, the CEPT process removed > 60% of COD and > 90% of phosphate, and the molar ratio of $CaCO_3$-alkalinity to ammonium was reduced to below 1. Due to the low alkalinity, stable nitrite accumulation was achieved in an aerobic moving bed biofilm reactor (MBBR) operated at pH of 4.35 aided by the novel acid-tolerant AOB "*Candidatus* Nitrosoglobus". Through the autotrophic nitrogen removal in a following anoxic MBBR (anammox), a satisfactory effluent, containing COD at 41.9 ± 11.2 mg/L, total nitrogen at 5.1 ± 1.8 mg N/L, and phosphate at 0.3 ± 0.2 mg P/L, was achieved. Moreover, the stable performances of this integration (i.e., CEPT, acidic PN and anammox) were well maintained at a low operating temperature (12°C), and ten selected micropollutants were removed from the wastewater with varying degrees. Overall, this integration opens a new avenue for domestic wastewater treatment to achieve energy neutrality

Keywords

Domestic wastewater treatment; CEPT; mainstream anammox; acidophilic ammonia oxidation; low temperature; energy neutrality

Wastewater treatment plants (WWTPs) remove pollutants and protect water bodies while consuming considerable energy, i.e., the electricity consumed can account for about 3% of the total annual electricity demand. In recent years, WWTPs are pursuing technologies to maximise bioenergy recovery and to minimise energy consumption, enabling energy neutrality. It has been recognised worldwide that the widely applied chemical enhanced primary treatment (CEPT) together with anaerobic digestion (AD) is one of the easiest-to-use approaches for bioenergy recovery. However, the maximization of bioenergy recovery by CEPT and the energy-efficient nitrogen removal via partial nitritation and anammox (PN/A) in domestic sewage treatment are both limited by critical issues in practice, as elaborated below.

The CEPT usually uses iron salts (i.e., $FeCl_3$) as the flocculant and is efficient in eliminating organic carbon and phosphorus in wastewater. However, the dosed $FeCl_3$ can cause a secondary effect of decreasing alkalinity via the hydrolysis of metal ions (i.e., Fe^{3+}), probably resulting in the molar ratio of alkalinity (calculated as $CaCO_3$) to ammonium in mainstream wastewater to below 1:1.5. The decrease of wastewater alkalinity is generally neglectable for traditional denitrification but critical to the PN/A process. This is because denitrification can regenerate alkalinity while the anammox process cannot. Moreover, microbial ammonia oxidation in the downstream nitrogen removal process further consumes alkalinity at 1 mol equivalent $CaCO_3$ per mol ammonia oxidized. Therefore, the alkalinity becomes insufficient to maintain the neutral pH of wastewater during the PN/A process, which can drop to below 6 when the alkalinity is depleted and no base is re-supplemented. Such low pH poses adverse effects on the traditional ammonia-oxidizing bacteria (AOB) and anammox bacteria that prefer neutral conditions.

Apart from the issue caused by low wastewater alkalinity, another key challenge for the application of mainstream PN/A is the stable suppression of nitrite-oxidizing bacteria (NOB). Many technologies have been developed to achieve this aim, including the use of low dissolved oxygen (DO), intermittent aeration, shortening sludge retention time (SRT), and sidestream sludge treatment using different strategies. Among all, free nitrous acid (FNA) is known as one of the most effective reagents for NOB inactivation, which is also one of the major reasons for the stable PN achieved in treating high-strength ammonium wastewater (~1 g N/L). However, due to the significantly lower total nitrogen in domestic sewage (40−60 mg N/L) and the generally neutral pH level (> 6) required by traditional AOB, it was deemed impossible to achieve an in-situ FNA level sufficient for NOB suppression under mainstream conditions.

These two issues associated with CEPT and PN/A can be tactfully solved by a novel microbial process: acidophilic ammonia oxidation. This process can be catalysed by the extremely acid-tolerant AOB "*Candidatus* (Ca.) Nitrosoglobus", with the first member discovered from an acidic soil sample recently (Hayatsu et al., 2017). Unlike the AOB *Nitrosomonas* commonly found in wastewater treatment, the novel *Nitrosoglobus*-like AOB (Figure 1.1) are active at pH as low as 2 (Wang et al., 2021). This capability to tolerate acidic condition indicates that a PN process can be operated under slightly acidic condition. By performing the acidic ammonia oxidation, AOB can produce protons and nitrite to lower the wastewater pH and form a high FNA concentration at a parts per million (ppm) level in situ. This technology fundamentally differs from all previous NOB inactivation strategies, which uses in-situ self-sustained stress (i.e., FNA) instead of ex-situ treatment of sludge and is proved energy-efficient and robust. To be noted, it is theoretically only possible to achieve such a low pH for domestic sewage with low alkalinity (i.e., $CaCO_3$-alkalinity/ammonium molar ratio < 1), which perfectly fits the scenario using CEPT for carbon removal (Figure 1.2). Two birds with one stone, the acidic PN process has great potential not only to cope with the low-alkalinity CEPT effluent and also to maintain stable PN for autotrophic nitrogen removal by anammox.

Collectively, this study demonstrated a novel integration of CEPT and PN/A in domestic wastewater treatment by incorporating acidophilic ammonia oxidation. A long-term experiment assessment was conducted in a laboratory system consisting of three units including a CEPT, an acidic PN, and an anammox reactor, which were continuously fed with real wastewater for one year. After the long-term evaluation, the impact of temperature variation mimicking the seasonal change (12−23°C), and the system's removal capacity on selected organic micropollutants were further examined, which were reported for the first time for acidic AOB and would provide a comprehensive assessment of the technology. Throughout the 360-day operation, microbial communities were monitored by 16S rRNA amplicon sequencing. This novel integration of CEPT, acidic PN, and anammox provided a valuable solution to achieve energy neutrality in wastewater treatment (Figures 1.3 and 1.4).

Abstract

This paper describes a full-scale wastewater treatment plant treating liquid wastes (composed mainly by landfill leachate) by comparing the energy demand before and after a revamp that introduced the shortcut biological nitrogen removal (SBNR) technology. Despite a similar volume of waste treated, after the revamp the total energy consumption was about 29% lower. Energy saving is present in every month of the year but is more evident during the summer period. It is important to underline that this reduction in energy demand has not compromised the performance of the system, which has indeed improved. The new plant has made it possible to reduce the energy requirement by over 220 000 kWh each year, for an overall saving of around 31·000 €/year. This energy saving has led to a reduction in CO_2 emissions equal to 57.6 ton CO_2 per year.

INTRODUCTION

Aerobic biological treatment for wastewater and/or liquid wastes is an effective yet highly energy-consuming technology (Davery et al, 2019). It estimated that conventional activated sludge (CAS) processes consume about 0.3-0.6 kWh/m^3 of which 50-70% is due to the aeration process (McCarty et al., 2011, Panepinto et al., 2016). In this scenario, improvement in the aeration efficiency and/or changes in the management of the plant aimed at reducing energy requirement of the aeration process liquor has therefore an important impact in the total energy demand of the whole plant. A simple yet efficient technology is the Shortcut Biological Nitrogen Removal (SBNR), which refers to biological nitrogen removal when ammonia is not converted to nitrate, but halts at nitrite to shortcut the conventional nitrification/denitrification process. While full nitrification requires 4.57 mgO_2/mgN, nitritation only requires 3.43 mgO_2/mgN, therefore, suppressing nitratation can save 25% of aeration costs (Winkler and Straka 2019). In order to achieve nitritation only it is necessary to control NOB and enriching AOB and this can be achieved alternating anoxic and oxic conditions in the same biological tank.
In this context, this paper describes a full-scale WWTP treating liquid wastes (composed mainly by landfill leachate) by comparing the energy demand before and after a revamp that introduced the SBNR technology.

MATERIALS AND METHODS

The old plant, a membrane biological reactor (MBR), has been described elsewhere (Coppini et al., 2018) and the treatment train consisted of the following sections: (1) an aerated equalization tank, with a volume of 2000 m^3, where all the leachates are discharged and mixed together; (2) a denitrification tank, with a volume of 2000 m^3, equipped with a dissolved oxygen (DO) probe, a pH probe, and a redox probe; (3) an oxidation/nitrification tank, with a volume of 5000 m^3, equipped with 6 rotor brushes as surface aeration system, a submerged mixing system and probes for the measurement of DO, pH, and redox potential; and (4) two ultrafiltration units placed in an external tank. After the revamping, the treatment train is composed by: (1) six equalizations tanks, with a total volume of about 3900 m^3, where the leachate and the other wastes are discharged and mixed in the desired proportions, (2) two biological tanks, each a volume of 2000 m^3, equipped with one pH probe, two ORP probes, two DO probes and one TSS probe and (3) two ultrafiltration units, not changed after the revamp. Moreover, the aeration system has been changed and fine bubble diffusers has been installed in the biological tanks, together with submerged propeller mixers for the anoxic phase.

RESULTS AND DISCUSSION

For the purpose of energy comparison of CAS and SBNR in the present paper it has been considered the energy consumption related to the biological compartment (meaning energy for aeration and for mixing) and for ultrafiltration, taking into consideration differences due to season (temperature affect greatly the energy demand for aeration) and amount of treated wastes.
Results are presented in the following tables and pictures.

Table 1. Mean treated volume, total and specific energy consumption of the plant before the revamping.

	Total energy	2.50	2.50	2.80	3.07	3.80	4.76	3.91	4.21	4.39	4.78	3.41	2.56

Figure 1. Comparison of total energy consumption before and after revamping, divided by month.

Figure 2. Comparison of specific energy consumption before and after revamping, divided by month

As can be seen, despite a similar volume of waste treated (167 922 m^3 per year before revamping and 167 822 m^3 after revamping), the total energy consumption was about 29% lower. Energy saving is present in every month of the year but is more evident during the summer period (July, August and September). Indeed, in this period, the total volume of waste treated is generally lower (since most wastes are represented by landfill leachates which are affected by the amount of rainfall) and the new system is more flexible in adapting the amount of energy used compared to the old system.
It is important to underline that this reduction in energy demand has not compromised the performance of the system, which has indeed improved. In fact, as reported in Table 3 the COD and total nitrogen (TN) in the plant effluent were almost always lower after the revamping.

Table 3. Comparison of COD and Total Nitrogen left in the effluent of the plant before and after the revamping

	BEFORE REVAMPING		AFTER REVAMPING	
Month	**COD (mg/L)**	**TN (mg/L)**	**COD (mg/L)**	**TN (mg/L)**
January	2424	268	1161	76
February	2068	260	1128	90
March	1802	294	1558	183
April	3083	533	1651	113
May	2485	125	1750	100
June	2259	292	1879	156
July	2567	244	1969	211
August	2884	362	2056	202
September	3013	332	2118	347
October	2381	277	2036	447
November	1771	227	2057	442
December	1737	712	1398	264

Conclusions

Considering the reported results, it is possible to conclude that the new plant has made it possible to reduce the energy requirement by over 220 000 kWh each year, while increasing the removal of COD and TN, for an overall saving of around 31 000 €/year (with reference to average price of 2021). Considering the average CO_2 produced per kWh consumed in Italy equal to 260.5 gCO_2/KWh (ISPRA 2022), this energy saving has led to a reduction in CO_2 emissions equal to 57.6 ton CO_2 per year.

Abstract

The direct monitoring and quantification of fugitive greenhouse gas (GHG) emissions are essential towards the successful development of mitigation strategies. In this work, an ongoing long-term methane (CH4) and nitrous oxide (N2O) monitoring campaign has been conducted in an Australian wastewater treatment plant (WWTP) where the secondary treatment receives a mixture from anaerobic lagoon effluent and raw sewage. The results showed clear GHG spatial variations due to the step-feed configuration of the plant. N2O is the dominant GHG while CH4 only contribute to 3.43% of the plant fugitive emissions. The assessment of N2O emissions revealed that even in the same reactor with continuous operation, the production pathways and seasonal emission variations can be significantly different in different locations, i.e., AOB and HB respectively dominated N2O productions in different locations. It was revealed that the COD removal in the anaerobic primary treatment leads to insufficient organic carbon for denitrification. The mitigation strategy has been correspondingly developed.

INTRODUCTION

Greenhouse gas emissions (GHG) must be significantly reduced in the next few decades to minimise the most devastating climate change. Nitrous oxide (N_2O) and methane (CH_4) are the two main fugitive GHG emissions from the sewage treatment processes. The international reporting guideline IPCC has mandated the use of fixed emission factors for the report of these two emissions, which can deviate greatly from the actual emissions and give no incentive to the production pathways and the development of mitigation methods.

In this work, a long-term monitoring approach has been developed to directly measure and quantify the off-gas emissions from an Australian WWTP. The spatial and seasonal variations of fugitive emissions have been assessed. The underlying mechanisms that stimulate the generation of N2O have been analysed and the corresponding mitigation methods have been developed. This is the first long-term (>1 year) GHG monitoring campaign conducted in Australia and the results from which can contribute to the global monitoring inventory.

MATERIALS AND METHODS

The ongoing long-term monitoring campaign has been conducted since October 2021 in a step-feed reactor with four anoxic and aerobic passes, treating a mixture of raw wastewater and anaerobic lagoon effluent with a mixing ratio of 1:4. The wastewater is split into four streams with a splitting ratio of 4:3:2:1 from Pass 1~4. The floating hood systems have been designed to capture off gas to be sent to gas analysers for gas composition analysis. Five gas collection hoods with four hoods are placed in the centre of each aerated pass and one additional hood to assess the spatial variations (Figure 1). Besides, the plant operating information including wastewater characteristics, airflow rates and dissolved oxygen is monitored online. Intensive sampling campaigns were conducted to grab hourly samples for the analysis of potential N2O production pathways. Preliminary mitigation methods have been developed based on model-assisted data analysis.

RESULTS AND DISCUSSION

The GHG emissions from the studied WWTP have been continuously monitored for over a year. The emission patterns for both N_2O and CH_4 have been obtained. Figure 2A and 2B present the daily averaged GHG fluxes. Both N_2O and CH_4 emissions varied substantially over the course of the year. The carbon footprint analysis converted the N_2O and CH_4 fluxes into carbon dioxide equivalent (CO_2-eq). CH_4 only contributes to 3.43% of fugitive emissions from the secondary treatment processes, while N_2O accounts for the majority of the carbon footprint which requires further analysis and mitigation (Figure 2C).

By analysing the influent TKN loading, the daily emission factors of N_2O were shown to vary from 0.22% to 3.88%, with a mean of 1.12%, approximately 30% lower than the fixed emission factor of 1.6% by IPCC. Further investigation of the N_2O emissions from the individual pass showed that Pass 4 made the highest contribution (38.53%) to N_2O emissions (Figure 2D), while Pass 1 which received the most influent contributed to the least (15.92%).

To explore the potential N_2O production pathways, the grab samples from intensive sampling have been analysed for wastewater characteristics, dissolved N_2O and isotope (δ15N abundance). As seen in Figure 3, the dissolved N_2O concentration in each zone was highly correlated with nitrite accumulation. Nitrite accumulated in all 4 aerobic passes. The accumulation of nitrite is known to stimulate N_2O emissions by AOB via the nitrifier denitrification pathway (Foley et al., 2010). In addition, N_2O emissions from aerobic 4 can also be attributed to the accumulated N_2O in the preceding anoxic zone. Anoxic zone 4 exhibited a very different N profile compared to other anoxic zones. High N_2O, as well as NO_2^- accumulation were observed in anoxic zone 4, indicating incomplete denitrification. The above hypotheses were verified by the isotope results where 15N bulk abundance saw an obvious decrease from Pass 1 aerobic to Pass 2 aerobic, and a dramatic increase from Pass 3 aerobic to Pass 4 aerobic, which indicated the nitrous oxide productions were driven by nitrification and denitrification respectively.

The incomplete denitrification in Pass 4 was likely due to the COD deficiency. Assuming a theoretical COD/N ratio of 4.5 for full denitrification (Metcalf et al., 2014), a mass balance analysis during the intensive sampling periods in each anoxic pass showed Pass 4 anoxic is in most deficiency of COD, in at least 30% of COD shortage. It is therefore proposed to alter the mixing ratio between raw wastewater and anaerobic lagoon effluent to above 1:1 to make up for the COD loss in the anaerobic lagoon. The mitigation strategy will be verified through calibrated models and to be implemented at full-scale if working.

Various seasonal variation patterns of N_2O emissions have been reported in previous studies (Daelman et al., 2015; Gruber et al., 2021). However, the cause of different seasonal variation patterns remains unclear. Interestingly, it was observed different N_2O dominant production pathways may lead to different seasonal emission patterns as seen in Figure 3C. The N_2O emission in Pass 4, contributed by denitrification had a high peak in summer and gradually decreased after that with a low peak before winter, while the emission in Pass 1 (contributed more by nitrification) had an earlier high peak and stayed relatively stable for the rest of the year. The different seasonal patterns may be attributed to the different responses of N_2O producing microbes (nitrifiers and denitrifiers) to operating and environmental conditions.

Carbon capture and energy recovery have been increasingly applied in WWTPs to improve energy efficiency (Gu and Liu, 2020). Despite the benefits of carbon recovery, this work showed that there is a potential risk to stimulate N_2O emissions in the nitrogen removal stage due to incomplete denitrification caused by COD deficiency. Therefore, the application of carbon capture and recovery should be considered holistically regarding the overall carbon footprint of the plant.

Abstract

Nitrous oxide (N_2O) is a greenhouse gas (GHG) that contributes significantly to the water sector's carbon footprint. It is estimated that approximately 26% of global emissions from the water sector are from N_2O. The major contribution of N_2O in wastewater treatment plants (WWTPs) is due to nitrification and denitrification processes in biological reactors. This study will assess the impact of environmental stressors under different operational conditions on N_2O generation using supervised and unsupervised modelling techniques. Long-term data collected from a full-scale WWTP are being used to investigate the behaviour of N_2O emissions. To this aim, a low-cost data driven methodology was developed by combining a Bayesian ensemble changepoint detection technique with Random Forest regression and post hoc model interpretation strategies. The results will identify main pathways for N_2O mitigation through the operation and control of the WWTP.

Keywords (maximum 6 in alphabetical order)

INTRODUCTION

Wastewater treatment plants (WWTPs) contribute to global warming through direct emissions of greenhouse gases (GHGs) such as nitrous oxide (N_2O). N_2O emissions from WWTPs increased by 44% from 1990 to 2014, contributing about 3% of total emissions (US EPA, 2016). In addition, these emissions account for up to 26% of GHGs from the entire water supply chain (Vasilaki et al., 2019). N_2O is considered the most ozone-depleting substance of anthropogenic origin, with a global warming potential 265 times greater than that of carbon dioxide (CO_2). The main source of N_2O emissions occurs during the secondary treatment process in the biological reactor, where most of the organic matter and nutrients are removed, contributing up to 75% of the total carbon footprint of a WWTP (Massara et al., 2018).

The methods for measuring N_2O in biological processes have evolved over the years. The most commonly applied method includes offline analysis by gas chromatography with electron capture (GC-ECD) (Saynes and Ramirez, 2018). However, this method can lead to over- or underestimation of the emissions due to daily and seasonal variability, as well as losses during sample transport and handling. Currently, in most cases, the measurement of gas-phase N_2O is performed using gas analyzers based on Fourier transform infrared spectroscopy (FTIR) or non-dispersive infrared (NDIR) sensors (Lebegue et al., 2016). More recently, N_2O emissions are analysed and quantified before they are formed and released into the atmosphere, through their concentrations in the dissolved form. In this case, cathodic Clark-type sensors are gaining interest in this field (Marques et al., 2016; Vasilaki et al., 2020).
The large number of variables that can trigger N_2O emissions makes difficult the establishment of specific mitigation strategies. In addition, correlating emissions with the operating conditions and configuration types of WWTPs and biological reactors in particular remains a challenge (Vasilaki et al., 2019). In this study supervised and unsupervised modelling techniques will be applied to data collected from a long-term monitoring campaign to investigate how environmentally generated stresses of treatment processes (rainfall events, shocks, temperature changes) impact the N_2O generation. The behaviour of N_2O under different operational conditions will be also studied, considering real-time monitored parameters and laboratory analyses. Main pathways for N_2O mitigation through the operation and control of a full-scale WWTP will also be reported.

MATERIALS AND METHODS

Site description and experimental setup

The full-scale WWTP treating domestic wastewater is located in Sant Feliu de Llobregat (Barcelona). The plant consists of an activated sludge process and treats an average influent of 47,000 m^3 day^{-1}. The experimental study is being conducted in one of the biological reactors that applies nitrification-denitrification processes to remove nitrogen. The reactor is a plug flow type divided into a small anoxic compartment and an aerobic one.

The duration of the campaign at Sant Feliu WWTP is planned for 12 months (August 2022-July 2023). Two Clark-type sensors (Unisense, Denmark) are used to continuously measure the dissolved concentration of N_2O in the reactor. In addition, gaseous N_2O emissions are measured online at the reactor surface with a non-dispersive infrared (NDIR) gas analyser (Horiba-VA3116) connected to a floating stainless-steel hood (AC'SCENT Flux Hood, 40L).
The sensors, as well as the floating hood, are placed at various points in the reactor: anoxic zone, anoxic-aerobic transition zone, and different points in the aerobic zone.

Data mining and knowledge discovery

Figure 2 shows the methodology for data analysis that was applied in the project. Data pre-processing comprises all required steps to (a) handle missing data, (b) filter outliers in data, and (c) smooth noisy input. Changepoint detection methods and unsupervised machine learning techniques were applied (Vasilaki et al., 2020) to unveil patterns in (a) environmentally generated stresses of treatment processes, (b) N_2O generation, (c) different operational conditions.

A Bayesian ensemble modelling technique (Zhao et al., 2019) was deployed to detect seasonality, trends, and abrupt changes in time series data of environmental stresses, and N_2O emissions. Random Forests (RFs) were used to identify key variables that impact N_2O emissions under different operational conditions. The RF algorithm assesses the relevance of external forcings in predicting accurately N_2O concentrations through a permutation variable importance metric (VIM). This type of analysis indicates the influence of the predictors in the overall structure of the random forests. Additional interpretability efforts were undertaken to decipher how the model predicts N_2O concentrations. The Shapley values (Lundberg and Lee, 2017) were estimated for the model, and for predictions that correspond to the "highest" observed concentrations of N_2O during each period. The Shapley value of a predictor, evaluates the contribution of the predictor to a prediction. s, by providing an inkling of their relevance in the prediction of extremes.

RESULTS AND DISCUSSION

The performance of the reactor in terms of NH_4-N removal, was stable during the monitoring campaign. The average removal efficiency of COD and NH_4-N, was 97% and 95%, respectively. Influent and effluent concentrations of the system for the duration of the monitoring campaign are given in Table 1.
Figure 3a shows boxplots of typical diurnal profile of the dissolved N_2O concentration during the monitoring campaign. The concentrations follow the diurnal influent and effluent NH4-N profiles in the reactor. The dissolved N_2O concentration ranged between 0.09 and 0.37 mg L^{-1}. Figure 3b illustrates the behaviour of N_2O concentration in respect to NH_4-N and NO_3-N concentrations.

The analysis is ongoing and the final results will be presented in the conference. The applied methodology and key findings contribute significantly towards carbon reduction challenges the water sector currently faces. The study expands the current datasets for long-term N_2O monitoring campaigns in different wastewater treatment processes considering the seasonal variations and plant operational and control strategies. Additionally, a low-cost data driven methodology was developed by combining a Bayesian ensemble changepoint detection technique with RF regression and post hoc model interpretation strategies to (a) understand the influence of the model predictors (operational variables) to model predictions, and (b) unveil why and when the model fails or succeeds to describe the underlying processes. In this case, the benefit is twofold. On one hand, this methodology uncovers potential emission triggering conditions from monitoring data (data valorization) and, on the other hand, it indicates how to improve the models, and, thereby, move from diagnostic levels ("Why something happened?") to predictive ("What is likely to happen?") or even prescriptive ("What to do next?") analytics. Data valorization can be easily adapted in different plants and can support the understanding of the key contributor factors for N_2O generation under different operational and environmental conditions. The methodology facilitates the development of adaptive mitigation options considering different temporal operational conditions and N_2O triggers.

Abstract

Nitrification is a key process in biological nitrogen removal from wastewater. Its first step is ammonia oxidation to nitrite (nitritation) by ammonia-oxidizing bacteria (AOB) or archaea (AOA) or recently identified complete ammonia oxidizers. Most AOB grow optimally at mesophilic temperatures, while thermophilic nitritation in natural and engineered ecosystems is mainly carried out by AOA. This may result in lower N_2O emissions in AOA-dominated thermophilic nitrification compared to AOB-dominated counterparts. Nevertheless, no such information is available yet. We aim to unravel the N_2O from thermophilic nitrification reactors for the first time. The reactors demonstrated stable full nitrification with an influent of 500 mg NH_4^+-N/L and loading rate of 0.5 g N/L/d. The dominating AOA and nitrite-oxidizing bacteria belong to the genera *Candidatus Nitorsosphaera* and *Nitrospira* respectively. Preliminary results showed low N_2O emissions from both the gas and liquid phase of the reactors, indicating a potentially lower carbon footprint of thermophilic nitrification processes.

INTRODUCTION

Anthropogenic alteration of the nitrogen (N) cycle has far exceeded the safety boundaries of our planet, making it one of the major global challenges (Steffen, Richardson, et al., 2015). N removal from wastewater is a key component in sustainable N management. Nitrification is a key process in global nitrogen cycling and for biological N removal from wastewater. It consists of two steps, nitritation (ammonia oxidation to nitrite) by ammonia-oxidizing bacteria (AOB) or archaea (AOA), and nitratation (nitrite oxidation to nitrate) by nitrite-oxidizing bacteria (NOB). Recently discovered complete ammonia oxidizers (Comammox) can perform both steps (Van Kessel, Speth, et al., 2015). Most AOB grow optimally at mesophilic temperatures, while thermophilic nitritation in natural and engineered ecosystems is mainly carried out by AOA instead of AOB (Courtens, Spieck, et al., 2016). Physiological characteristics, including mechanisms for nitrous oxide (N_2O) production, vary within and between AOA and AOB, and AOA usually have a lower N_2O yield (Prosser, Hink, et al., 2020). N_2O is a potent greenhouse gas (about 300 times CO_2) and is among the dominant ozone-depleting substances (Ravishankara, Daniel, et al., 2009). The AOA-dominated thermophilic nitritation may have nitrous oxide (N_2O) emission and, thus, lower carbon footprint compared to AOB-dominated counterparts. Nevertheless, no data on N_2O emissions from the thermophilic nitrification process is available yet, which also hinders the evaluation of the sustainability of rising thermophilic nitrogen removal processes. This contribution aims to unravel the microbial communities and N_2O from two unique thermophilic nitrification reactors.

MATERIALS AND METHODS

Reactor setup and operation

Two lab-scale membrane bioreactors (MBRs, Fig. 1) with a working volume of 2.1L were operated for more than 300 days. The two MBRs were inoculated with the same biomass from previous thermophilic nitrification reactors in the lab (Courtens, Spieck, et al., 2016). The pH was controlled between 6.8 and 7.2 by dosing 0.1 M hydrochloric acid and 0.1 M sodium hydroxide. The temperature was controlled at 49 ± 1 °C by using a heating water jacket connected to a circulating bath. The dissolved oxygen was controlled at a setpoint of 5.0 mg/L (Liquiline CM448, Endress+Hauser, Germany). Both reactors were continuously fed with synthetic medium consisting of $(NH_4)_2SO4$ (up to 500 mg N/L), 12 g $NaHCO_3$/g N, KH_2PO4 (10 mg P/L) and trace elements (Vandekerckhove, Kerckhof, et al., 2019).

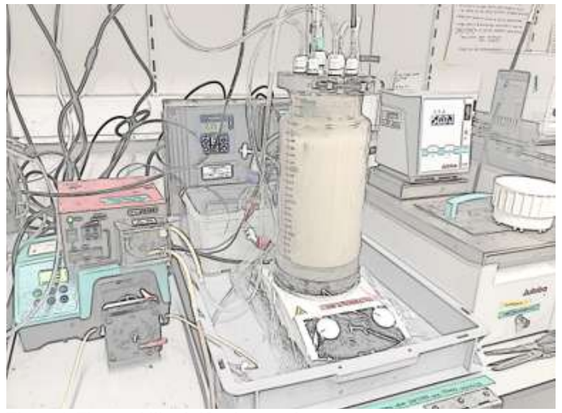

Figure 1. Thermophilic nitrification membrane reactor 1

Liquid, solid, gas and molecular Analysis

Liquid samples were filtered through 0.2 µm disposable filter before measuring the concentrations of ammonium, nitrite, and nitrate. The biomass concentration was determined as total suspended solids (TSS) and volatile suspended solids (VSS) according to standard methods. To systematically quantify the N_2O emissions, online monitoring was set up for both gas phase (gas phase analyser, X-STREAM, EMERSON, Germany) and liquid phase (N_2O-R microsensor, Unisense, Danmark). To infer the microbial community, samples were taken for 16S rRNA gene amplicon sequencing.

RESULTS AND DISCUSSION

Reactor performance

The concentrations of nitrogen compounds in the influent and effluent of the thermophilic nitrification reactor 1 were shown in Figure 2. The results demonstrated stable nitrification activities at influent ammonium concentrations of 500 mg NH_4^+-N/L and a loading rate of 0.5 g NH_4^+-N/L/d. The achieved nitrification rate was two times higher than previous thermophilic nitrification reactors (Courtens, Spieck, et al., 2016; Vandekerckhove, Kerckhof, et al., 2019). Nitrite accumulation was occasionally observed (e.g., day 56, Fig. 2) and effectively eliminated by temporarily lowering the nitrogen loading rate. These results highlight the potential of thermophilic nitrification for biotechnological applications.

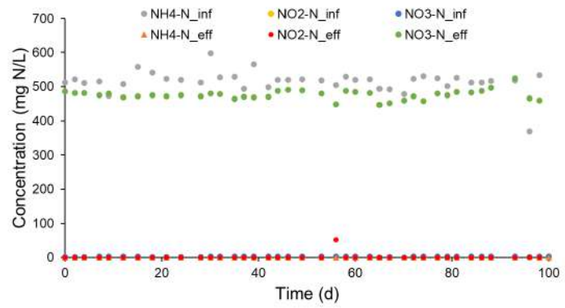

Figure 2. Reactor performance during the stable operation of the thermophilic nitrification reactor 1

Microbial community

The 16S rRNA gene amplicon sequencing indicated that ammonium oxidation was done by AOA belonging to the genus *Candidatus Nitorsosphaera*, with a relative abundance of 56.70%, while no known AOB was detected. Nitrite oxidation was carried out by NOB from the genus *Nitrospira*, accounting for 25.21% of the whole microbial community (Fig. 3). The microbial community was similar to previous studies on thermophilic nitrification in bioreactors (Vandekerckhove, Kerckhof, et al., 2019).

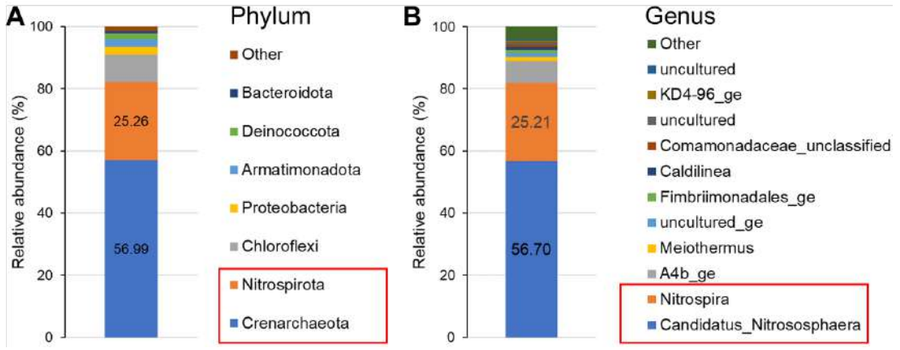

Figure 3. Relative abundance of the top phyla and genera in thermophilic nitrification reactor 1

N_2O emissions

To systematically quantify the N_2O emissions, online monitoring was set up for both the gas and liquid phase. Preliminary results showed no noticeable N_2O in the off-gas of the reactors (ranging between 0-2.3 ppmv, i.e., up to 0.004 mg N_2O/L). Interestingly, the N_2O microsensor showed a relatively stable N_2O concentration of 3.78 ± 0.06 mg N_2O/L in the liquid phase. These preliminary data indicate low N_2O emissions. The online measurement will continue for the following months to quantify N_2O emissions under different operating conditions (e.g., different DO concentrations, and especially with nitrite accumulation while transforming the MBRs from thermophilic full nitrification to yet to-be-reported thermophilic partial nitritation reactors as nitrite accumulation is often associated with high N_2O emissions (Vasilaki, Massara, et al., 2019). This will provide N_2O emission data from AOA-dominated thermophilic nitrification reactors for the first time, which is essential for the holistic evaluation of thermophilic biological nitrogen removal processes, as well as a better understanding of N_2O emissions during the N cycling in thermophilic ecosystems.

A laboratory-scale study to mitigate greenhouse gas emissions from open sludge lagoons

Abstract

Open sludge lagoons are employed by wastewater treatment plants (WWTPs) as an economic and efficient means to dewater and stabilise wastewater sludge in countries with an arid climate and inexpensive land. Previous studies revealed that open sludge lagoon methane emissions could contribute one-quarter to two-thirds of the WWTP carbon footprint, highlighting a need for further investigation. Our research aimed to directly quantify methane and nitrous oxide emissions of open sludge lagoons of anaerobically-digested sludge using triplicate laboratory-scale sludge lagoon column incubations. Two different methane emission mitigation strategies were also trialled against an untreated control, whereby sources of nitrate (10 to 15 mg-N/L) and high nitrite (400 to 500 mg-N/L) were continuously applied to the sludge lagoon column natural water-layer. Methane emissions, primarily from ebullitive sources, were the dominant GHG emissions in the control and treated sludge columns. The cumulative methane emission as a percentage of the initial total COD was 23.5 ± 0.5 % in the untreated control after 29 months of incubation. This was reduced by approximately 5.3 % through the high nitrite dosed strategy despite excess nitrous oxide emissions. The nitrate dosed was unable to sufficiently penetrate the sludge-layer to achieve methane emissions reduction, highlighting a limitation that will guide future GHG mitigation strategies. Nitrous oxide emissions that coincided with temporal nitrite accumulation in the water-layer were observed and warrant further investigation. These findings suggest that open sludge lagoons are an overlooked source of GHG emissions that must be considered to achieve sustainable wastewater treatment.

Open sludge lagoons; Greenhouse gas emissions; Dewatering; Stabilisation; Wastewater treatment

INTRODUCTION

In countries with an arid climate and inexpensive land, wastewater treatment plants (WWTPs) often employ open sludge lagoons as an economic and efficient means to dewater and stabilise wastewater sludges (Alvarez-Gaitan *et al.* 2016). In Australia, approximately 40% of WWTPs utilise some form of sludge lagoon. Open sludge lagoon operation is highly diverse, where lagoon depths range from 1-3 metres deep and lagoons are operated for months to years. Natural sedimentation of sludge forms distinct water and sludge layers, and in most cases a water-layer is maintained as an odour abatement measure. The high organic matter load of wastewater sludge means that open sludge lagoons are likely sources of greenhouse gas (GHG) emissions. An indirect mass balance assessment of an open sludge lagoon revealed that these systems could contribute one-quarter to two-thirds of the WWTP carbon footprint (Pan *et al.* 2016). However, complementary experiments are required to validate these observations and identify mitigation options. Accordingly, our research employed laboratory scale column incubations for the first direct assessment of methane and nitrous oxide emissions from open anaerobically-digested (AD) sludge lagoons, as well as trialled strategies for the mitigation of methane from AD sludge lagoons.

MATERIALS AND METHODS

Laboratory scale AD sludge column incubations, termed sludge columns, were established in triplicate to mimic the cross-section of a common AD sludge lagoon (Figure 1) and to investigate two separate mitigation options. In the first mitigation strategy, nitrate was dosed to the water-layer of one set of treated sludge columns to a concentration of 10 to 15 mg-N/L to mimic the use of secondary effluent as an alternative water-layer. In the second mitigation strategy, nitrite was dosed to the water-layer of another set of treated sludge columns to a high concentration of 400 to 500 mg-N/L. This nitrite dose was selected to represent partially nitrified centrate that can be available at WWTPs that employ mechanical dewatering alongside open sludge lagoons. Ad hoc dosing of stock concentrations of sodium nitrate and nitrite to the water-layer was performed to maintain the desired treatment range. Direct methane and nitrous oxide emission quantification and physiochemical depth profiling of the ammonium, nitrate, nitrite, methane, nitrous oxide and the soluble chemical oxygen demand was performed during a 29-month incubation period.

RESULTS AND DISCUSSION

Methane emissions were the dominant GHG emission in the untreated control and treatment columns (Figure 2). Nitrous oxide emissions were observed but were small in comparison to methane emissions (Figure 3). After 29 months of incubation, the cumulative methane emission as a percentage of the initial total COD of the untreated control AD sludge columns was 23.5 ± 0.5 %, with approximately one-third of the emissions observed in the first month. Nitrite accumulation in the water-layer was observed inconsistently during the first eight months due to the partial nitrification of ammonium (Figure 4). Periods of nitrite accumulation led to nitrous oxide emissions, while the conclusion of nitrite accumulation coincided with the stabilisation of the ammonium concentration in the water-layer.

The methane emission rate reduced in high nitrite dosed sludge columns, where a decreased rate was observed after three months of incubation (Figure 2). At this time point, the high nitrite treatment permitted nitrite penetration to 15cm below the sludge-water interface. High nitrite presence led to the production of excessive nitrous oxide emissions (Figure 3). After 28 months of nitrite dosing, the cumulative methane emission as a percentage of the initial COD of the control and high nitrite dosed sludge columns were approximately 15.6 ± 0.6 % and 10.3 ± 0.4 %, respectively. However, the cumulative nitrous oxide emission as a percentage of the initial total nitrogen (TN) of the treated columns was exorbitant at 3.7 ± 0.9 %, counteracting the benefits achieved with methane abatement. In the nitrate dosed sludge columns, limited mass transfer of nitrate into the sludge-layer was observed, and as a result, no reduction in methane emissions was observed compared to the control (Figure 2). Interestingly, nitrate dosing increased the extent and duration of nitrite accumulation in the water-layer, which lead to increased nitrous oxide emissions (Figure 3 and 4). After 28 months of dosing, the cumulative nitrous oxide emission as a percentage of the initial TN of the control and nitrate dosed sludge columns was approximately 0.19 % and 0.37 %, respectively (Figure 3). Additionally, nitrate accumulation in the water-layer was observed after 12 months in the control and nitrate dosed sludge columns and nine months in the high nitrite dosed sludge columns (Figure 4). This coincided with the loss of nitrite accumulation, ammonium exhaustion (or ceased ammonium consumption in the untreated control) and increased dissolved oxygen in the water-layer, all of which are indicative of the anaerobic oxidation of ammonium (ANAMMOX) process.

Methane emissions were predominantly ebullitive rather than diffusive in the control and treated sludge columns. Ebullitive methane emissions represented an average of 87 ± 15%, 90 ± 17 % and 88 ± 15 % of the total methane emissions of the control, nitrate-dosed and nitrite-dosed sludge columns, respectively. These findings highlight that unlike the methane mitigation efforts employed here, future emissions reduction strategies must consider ebullitive methane sources.

This research demonstrated that methane emissions in open AD sludge lagoons contribute greatly to the carbon footprint of the WWTPs. While methane mitigation efforts trialled here were unsuccessful at achieving net GHG emission reduction, an invaluable understanding of open sludge lagoons was uncovered that will guide future strategies for methane mitigation. These are currently underway, alongside the assessment of open waste-activated sludge (WAS) lagoons in this context.

Abstract

Nitrous oxide (N_2O) was monitored in an SBR treating synthetic N-concentrated wastewater through nitritation. N_2O production factors (PF) per ammonium oxidized were quantified depending on the phase where N_2O was found when exiting the reactor. N_2O PF accounted for 18± 4% of total N_2O PF during decanting phase. During aerobic phase, N_2O emissions were found to be heterogeneous along the cycle. An initial N_2O peak was found when transition from anoxic to aerobic conditions took place corresponding to 49±9% of total PF mainly due to hydroxylamine accumulation. In order to maximize N_2O PF, changes in cycle structure will be implemented by adding extra anoxic to aerobic transitional states.

Nitrogen valorisation; nitritation; nitrous oxide; waste resource recovery facility.

INTRODUCTION

A waste resource recovery facility (WRRF) is a facility that, while treating wastewater, transforms organic matter and nutrients into energy or various products such as fertilizers, biopolymers, building block chemicals or other advanced bioproducts, that can be used as raw materials and value-added products in other processes (Pott *et al*., 2018). The WRRF proposed here (Figure 1) aims to recover organic matter in form of PHA and biogas, while for nitrogen valorization, nitrite as electron acceptor and nitrous oxide production are considered.

N_2O has been used as a fuel additive in motor racing to increase the power output of engines. Considering the stoichiometric ratio of four (N_2O/CH_4), approximately 37% more energy can be produced using N_2O instead of oxygen during methane combustion. Since anaerobic digestion has been widely stablished for organic matter valorization, it should be noted that nitrogenous compounds contain an estimated value of 0.3 kWh/m^3 that could be recovered. Hence, nitrogen valorization through N_2O has been explored in several studies. The most promising system proposed is the Coupled Aerobic-anoxic Nitrous Decomposition Operation (CANDO) (Scherson, *et al.* 2014). The process involves two reactors for treating the reject water from an urban WWTP: the first stage is a partial nitrification for ammonia oxidation to nitrite; in the second stage, nitrite is reduced to N_2O with organic matter as electron donor (nitrous denitritation). The nitrous denitritation process requires organic matter as electron donor during the second stage, thus the energy gain is compromised since the available organic matter for anaerobic digestion is reduced. To overcome this critical drawback, we propose as a novel alternative the use of nitrifier denitrification, hydroxylamine oxidation and abiotic pathways to produce N_2O so that no organic matter is required.

Hence, the objective of the present study is to investigate the possibility of nitrogen valorization through fully autotrophic pathways. In this presentation, we show a detailed study of the operational parameters affecting the N_2O production in a partial nitritation reactor in view to propose new operational strategies to maximize the N_2O production.

MATERIALS AND METHODS

Reactor configuration and operation phases

A 25 L reactor with a working volume of 20 L was inoculated with sludge from an urban WWTP (Sabadell, Spain). The reactor was operated in SBR mode treating synthetic N-concentrated wastewater (300 mg N-NH_4^+ L^{-1}). The pH was controlled and maintained at 7.8 ± 0.1 throughout the experimental campaign. Compressed air was supplied through an air diffuser placed in the bottom of the reactor at a flow rate of 105 L h^{-1}. During all periods, the cycle length was kept at 6.5 h distributed as follows: 1.14 h of feeding, 4.5 h of aerobic phase, 1 h of anoxic phase, 1 h of settling phase and 0.33 h of decanting phase.

Analytical methods, N_2O measurements and calculations

Ammonium, nitrite and nitrate concentrations in influent and effluent were regularly measured off-line with both, Hach Lange test kits (Hach Lange, Germany) and ionic chromatography using ICS-2000 (DIONEX Corporation, USA) in previously filtered (0.22 µm pore) samples. Hydroxylamine was measured spectrophotometrically after pretreatment with sulfamic acid as in Fear and Burrell (1955). N_2O in the liquid was measured using a Clark type sensor (Unisense, Denmark). N_2O concentration in the gas phase was estimated based on the volumetric mass transfer coefficient.

In the present study, N_2O production factors in relation of the total ammonium oxidized to nitrite were divided into N_2O gas emission factor and N_2O liquid production factor, depending on the phase where N_2O was present when exiting the reactor. The N_2O emitted in the gas phase was quantified as the emission factor (EFgas), while the dissolved N_2O when decanting was quantified as the liquid production factor (PFliq). When necessary, $EFgas_{peak}$ was set in order to estimate the N_2O emission peak contained in EFgas. The total N_2O production factor (PFtot), was calculated by the sum of EFgas and PFliq.

RESULTS AND DISCUSSION

Reactor performance

A stable nitritation operation was required to study the N_2O generation (Figure 2). A start-up process (day 0 to 100) was necessary to enrich the biomass in ammonia oxidizing bacteria (AOB) while supressing the nitrite oxidizing bacteria (NOB). This was possible by maintaining a high free ammonia (FA) concentration during the whole cycle phases as a well-known NOB suppression strategy (Jubany et al., 2009).

Nitrous oxide production

In SBR operation, two main N_2O generation phases are found depending on reactor conditions. In the anoxic phase, N_2O is accumulated in the liquid during decanting which account for an 18±4% of PFtot. In aerobic conditions, EFgas accounted for the remaining 82±4% of PFtot. However, highly heterogeneous emissions were found during aerobic phase with an initial peak which represented the 59±11% of EFgas (set as $EFgas_{peak}$ in Figure3A). Three main processes are reported to be involved in aerobic phase: (I) the accumulation of nitrous oxide during anoxic condition and its subsequent stripping when aeration phase started, which we estimated to be 23±3% of N_2O emitted during peak; (II) the metabolic imbalance caused by the changing conditions that provoked hydroxylamine accumulation (as shown in Figure 3B) thus hydroxylamine oxidation took place and (III) nitrifier denitrification occurring when nitrite acted as final electron acceptor. When stable conditions were stablished (balanced metabolism), hydroxylamine was hardly detected thus, nitrous oxide was produced mainly through nitrifier denitrification.

Finally, in order to maximize N_2O generation of the SBR respect to baseline operation described in this presentation, changes in operational conditions will be implemented. As shown by the results, transition from anoxic to aerobic condition led to a significant N_2O emissions thus, incorporating extra transitional states during the cycle would add extra N_2O production events favouring the PFtot maximization.

Low nitrous oxide emissions and its mechanisms in a pilot-scale mainstream Partial Nitritation/ Anammox process

Abstract

Mainstream Partial Nitritation/Anammox (PN/A) has been proposed and dedicatedly investigated for more than a decade for its promising energy potential in wastewater treatment. High nitrous oxide (N_2O) emissions from PN/A are reportedly one of the major challenges hindering its applications. In this work, low N_2O emissions (0.178 ± 0.04%, N_2O-N / NH_4^+-N loading) were observed in a pilot-scale mainstream PN/A operated stably over one-year. Systematic batch tests were designed and conducted to reveal the mechanisms of low N_2O emissions from the process. In the PNA system, flocs were shown to be the major contributor for N_2O emissions, while heterotrophic denitrifiers were the N_2O sink. As a result of FNA side-stream treatment on flocs from PN/A tank, which was applied as a strategy to maintain PN, more resistance to NO_2^- shocks for flocs was found, especially under higher NO_2^--N concentrations, leading to a lower N2O emission factor (5.45% VS 15% at NO_2^--N 10 mg/L, compared with sludge without FNA treatment). Besides, low DO (0.2~0.4 mg/L) and low NO_2^--N concentration (~0.1 mg/L) also contributed to low N_2O emissions from the system, with higher N_2O production as a result of increased nitrifier denitrification pathway observed under higher DO or NO_2^- concentrations. The results of this work will provide guidance to the operation of mainstream PN/A process to minimize N_2O emissions.

Keywords: ***mainstream Partial Nitritation/Anammox; GHG emissions; nitrous oxide.***

INTRODUCTION

Mainstream Partial Nitritation/Anammox (PN/A) is widely recognized as a promising wastewater treatment process. High nitrous oxide (N_2O, a potent greenhouse gas) emissions from PN/A are reportedly one of the major challenges hindering its applications. While anammox process does not generate N_2O, the N_2O emissions from its integration with PN process has great uncertainties. N_2O emissions have been mostly investigated in PN systems receiving high strength wastewater (NH_4^+ > 500 mgN/L). Compared with conventional nitrification and denitrification, higher N_2O emission factors were reported from side-stream PN processes, ranging from 1.7% to 19% of the NH_4^+-N converted [1, 2]. This is mainly caused by the limited DO (i.e. 0.05-1.5 mg/L) [3, 4] to achieve PN and the ensuing NO_2^- accumulation (i.e. 15- 1680 mg/L) [3, 5].

To the best of our knowledge, there is no study on N_2O production from one-stage pilot-scale mainstream PN/A system to date. In this study, we discovered low N_2O emissions from a one-stage pilot-scale mainstream PN/A process during the long-term onsite measurement and investigated the mechanism for the low N_2O emissions from mainstream PNA system. This is the first study reporting the N_2O emissions from one-stage pilot-scale mainstream PNA system, and its mechanism was thoroughly studied.

MATERIAL and METHODS

The pilot-scale mainstream anammox-based system contains high rate activated sludge (HRAS) tank, pre-anammox tank and PN/A tank. The detailed operation conditions of the whole system were described in our recent study [6]. Briefly, the system was operated under a continuous mode based on residual NH_4^+-N control in the PN/A tank; and a portion of the flocs from PN/A reactor was regularly treated by Free Nitrous Acid (FNA, 2 mg N/L) to control the growth of nitrite oxidizing bacteria (NOB). Continuous online N_2O monitoring was carried out in the pilot-scale system. In addition, a series of batch tests were conducted to study the mechanism of N_2O emissions in the pilot mainstream PNA system.

RESULTS and DISCUSSIONS

During the stable state of the pilot reactor operation, the N_2O emissions from the PN/A tank were monitored online continuously, with the representative dynamics shown in Fig. 1. The overall N_2O emissions from the PN/A tank were low during the long-term, ranged between 3-6 ppmv, with an average of 4.25± 0.94 ppm, while the NO was even lower to negligible. Compared with the N_2O emission factor (~1.6% of the nitrogen loading) from the full-scale N/D treatment plant[7], the N_2O emission factor (mass N_2O-N emitted/ NH_4^+-N loading) was lower from our study, averaging at 0.178±0.04%. This was also notably lower than other studies on N_2O emissions from mainstream PN in lab-scale investigations.

Batch test showed flocs contributed to the majority of the N_2O emissions in the PN/A tank. For the N_2O emissions from the three batch tests (carriers only, flocs only, and carriers+ flocs), the highest N_2O emissions occurred from scenario with flocs only (Fig. 2). This finding was in line with the study by Zhuang et al. [8], in which flocs was proposed to be the main source of N_2O in a high-rate anammox granular sludge reactor. One of the possible reasons for the dominant role of flocs for N_2O emission was that AOB was the main species in flocs, acting as the N_2O contributor [9].

Notably, N_2O emission without the presence of COD was 5 times higher than that from with COD from flocs. This was possibly a result of the high abundance of N_2O reducers in flocs. In fact, the emissions from tests with COD were lower than those from without COD (Fig. 2). This is further confirmed with additional experiments showing the addition of external organic carbon reduced N_2O emissions from the PN/A process (Fig. 3). Heterotrophic denitrification is likely a sink for N_2O in the PN/A system.

In addition, the batch tests showed flocs and carriers in PN/A tank have adapted to NO_2^- presence, leading to relatively low N_2O emissions (Fig. 4). N_2O emissions from flocs only, carriers only and normal WAS under elevating NO_2^- concentrations were measured to evaluate its response to NO_2^- concentrations. Significantly different responses of N_2O emissions were observed, which suggested the flocs and carriers in PN/A tank have adapted to NO_2^- presence.

The impacts of operational conditions on N_2O emissions from the mainstream PN/A system was also evaluated in batch tests. The N_2O emissions from different conditions are summarised in Table 1. As can be seen, the total N_2O-N emissions from conditions without COD were all higher than those from with COD (Table 1). These results further confirmed the role of HD as a N_2O sink in the PN/A tank. The promoting effects of nitrite are obvious. Higher DO levels are also found to increase N_2O emissions. The low DO (0.2~0.4 mg/L) and low NO_2^--N concentration (~0.1 mg/L) in the pilot mainstream PNA system also contributed to low N_2O emissions.

Overall, this work reported low N_2O emissions from a pilot-scale mainstream PN/A system and illustrated the underlying mechanisms of the low N_2O emissions. The insights will provide critical guidance for the operation of mainstream PN/A process to minimize the N_2O emissions.

Abstract

Biomethanation has become an attractive process for biogas upgrading. In this work, a microbial culture with fermentative and homoacetogenic bacteria was enriched in hydrogenotrophic methanogenic archaea. Both cultures were characterized for their microbial diversity and biological activity, the later assessed both in classical serum bottle tests (SBTs) and through a novel methodology to perform pressurized, headspace-free hydrogen uptake rate (PHF-HUR) tests. PHF-HUR under pressure allows increasing H_2 solubility to overcome potential mass transfer limitations of SBTs tests. PHF-HUR tests let us calculate rates and kinetic parameters under a range of conditions by monitoring the dissolved H_2 concentration over time.

Keywords

Biomethanation; hydrogen uptake rate (HUR); microbiological enrichment; yeast extract.

INTRODUCTION

Among different technological innovations and processes tackling the upgrading of biogas to the required methane contents, biogas upgrading using hydrogenotrophic methanogens arises as a key step towards a sustainable model to produce green energy. Hydrogenotrophic methanogenic archaea (H_2-MA) are chemoautotrophic microorganisms capable of converting CO_2 to CH_4 using H_2 as electron donor by a direct reaction (Eq. 1).

$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$ $\quad \Delta G\square = -130.7$ kJ/mol Eq. 1

$4H_2 + 2CO_2 \rightarrow CH_3COOH + 2H_2O$ $\quad \Delta G°' = -104.5$ kJ/mol Eq. 2

$CH_3COOH \rightarrow CH_4 + CO_2$ $\quad \Delta G°' = -31.0$ kJ/mol Eq. 3

The presence of other microbial populations such as homoacetogenic bacteria, that may compete with H_2-MA for the same e-donor (Eq. 2), and acetoclastic methanogens producing CH_4 (Eq. 3) may lead to apparently unbalanced results with respect to Eq. 1 and to puzzling stoichiometric and kinetic results. Thus, a proper mechanistic characterization of the microbial culture is needed.

Hydrogen Uptake Rate (HUR) tests are a cost-effective tool to characterize the biological activity of hydrogenotrophic cultures and to study the mechanisms, rates, kinetic parameters or growth yields. The conventional approach for a typical H_2-activity test is to use a batch system as serum bottles with a H_2-rich headspace and measuring the headspace pressure to assess H_2 consumption. However, direct measurements of the liquid-phase H_2 concentration by in-situ H_2 probes demonstrated the problems associated with slow and limited H_2 G-L transfer, leading to inaccurate estimation of kinetic parameters. Therefore, a reliable methodology to properly identify hydrogenotrophic cultures rates and kinetic parameters through batch tests is still lacking.

In this sense, a novel methodology is proposed in this work to perform HUR tests avoiding G-L mass transfer limitations. Different selected variables (pH, temperature and the presence of inhibitors such as O_2 or H_2S) were tested. Stoichiometric and kinetic parameters were assessed from the resulting H_2 profiles during the monitoring of the decrease of dissolved H_2 concentration over time. Two microbial populations were assessed through HUR: one fed with mineral medium with yeast extract and an equivalent one enriched without yeast extract. In addition, serum bottle tests and Illumina were used to assess the contribution and role of homoacetogens and fermentative bacteria.

MATERIALS AND METHODS

From one side, characterization of the initial microbial culture with yeast extract in its mineral medium (MM) (not enriched in H_2-MA) as well as without yeast extract in the MM (enriched in H_2-MA) were performed in 250 mL serum bottles (125 mL liquid + 125 mL headspace gas). Preliminary serum bottle tests (SBTs) were performed to assess the contribution of H_2-MA to H_2 consumption vs. that of homoacetogens both in yeast-MM and no-yeast-MM cultures. In addition, a novel pressurized, headspace-free HUR (PHF-HUR) methodology was developed to further assess kinetics of both, enriched and non-enriched cultures. A pressurized 120 mL Miniclave reactor (BuchiGlas, Switzerland) equipped with a dissolved H_2 microsensor (Unisense) was used to perform PHF-HUR tests (Figure 1a). In essence, the liquid phase (with or without biomass) is saturated with H_2 under a selected pressure in a headspace-free reactor. A liquid injection chamber is used to feed either the microbial culture or CO_2, depending on the type of test.

Analyses of total suspended solids (TSS) and volatile suspended solids (VSS) were conducted as described in Standard Methods. Analyses of methane (CH_4), carbon dioxide (CO_2) and hydrogen gas (H_2) were conducted through gas chromatography (GC 7820A, Agilent Technologies). High performance liquid chromatography (Ultimate 3000, Agilent Technologies) was used to measure VFA's accumulation in the liquid phase. Total inorganic carbon (TIC) and Total Organic Carbon (TOC) were measured using a Multi N/C analyzer (Analytikjena). All the samples were filtered with 0.22 µm filters (Millipore). DNA extractions were performed using a Norgen Biotek Corp. Kit to isolate the DNA samples and perform Illumina tests to assess microbial populations.

RESULTS AND DISCUSSION

Methane production pathways were studied for a methanogenic mixed culture with yeast extract in its MM by performing SBTs. Results showed not only the presence of VFAs in the medium, but also an overproduction of CH_4 compared to the inorganic C consumed during the tests. Thus, the presence of acetoclastic methanogens was considered. Feeding composition in the MM was reformulated, removing yeast extract to avoid VFAs production from C sources such as proteins. SBTs in the presence and absence of yeast extract allowed assessing the rates of both biomethanation pathways (H_2-MA and acetoclastic). By removing the yeast extract, the presence of VFAs became negligible and C balances showed an increment in the contribution of the target pathway (H_2-MA) from 69.1 to 82.7% (Table 1). DNA samples were taken after 11 months feeding a yeast extract free medium to observe the evolution of the microbial populations due to the change in the feeding (Figure 2). An enrichment in *Methanobacterium* genus, a H_2-MA , was observed, as expected from the SBTs results.

In parallel, a methodology based on dissolving H_2 under pressure into the liquid medium was used to run several HUR tests. The main characteristic of this methodology is the absence of headspace, thus, avoiding G-L mass transfer limitation of H_2 during the experiment. Different configurations were tested consisting of either injecting bicarbonate to a CO_2-free microbial culture saturated with H_2 or injecting a microbial suspension to a CO_2-rich MM saturated with H_2. In both cases, the liquid phase is first saturated by bubbling H_2, then, the reactor is filled through a pressurized injection chamber ensuring a headspace-free reactor. At that point, the reaction starts and the profile of dissolved hydrogen in the liquid is monitored by the sensor along time. Figure 1b shows the typical profile of dissolved H_2 concentration over time for a PHF-HUR test. In the selected test, H_2 is consumed by the microorganisms at a specific volumetric rate of 24.45 $mmol_{H2}/(gVSS \cdot d)$ when running the PHF-HUR test at 1.5 bars of initial pressure, 37ºC and a pH of 7.6. A battery of PHF-HUR tests were carried out both with the non-enriched and enriched (Table 2) methanogenic cultures under different conditions. Temperature, pH and inhibitory species were assessed through PHF-HUR tests with this novel methodology, thus making possible to study the rates and kinetic parameters of the culture, avoiding potential mass transfer limitations that could occur in the traditional batch tests with serum bottles. These preliminary results show the promising capacity of this methodology as a tool to monitor the culture's hydrogenotrophic activity at different conditions to assess biogas upgrading activity.

Abstract

Bulking episodes and loss of nitrification capacity are two recurrent issues in municipal WWTPs. This research explores the relation between these phenomena and the dynamic changes of the activated sludge system and the anaerobic digesters microbial community in Lleida WWTP. The decrease of *Nitrosomonas* (AOB) and *Nitrospira* defluvii (NOB) relative abundance was concomitant to the deterioration of the nitrification capacity between March and April 2022. Similarly, the bulking episodes of spring 2022 were associated with an increase of the relative abundance of *Ca. Microthrix* species, which showed a marked seasonal dynamic.

Keywords

Activated sludge; anaerobic digestion; filamentous bulking; microbial time-series; nitrification; wastewater treatment plant.

INTRODUCTION

Wastewater treatment plants rely on complex biological systems for sanitation and resource recovery. However, there is still limited knowledge of the underpinning microbial dynamics on which these mixed-culture biotechnologies performance relies on. This knowledge is essential because uncertainty surrounding the microbial community dynamics is a key barrier preventing the intensification of this biotechnologies and shift the conservative approach of decision-makers.

Bulking episodes and loss of nitrification capacity are two recurrent issues in WWTPs worldwide (Gruber, Niederdorfer, et al., 2021; Johnston, LaPara, et al., 2019; Wágner, Peces, et al., 2022). Between March and April of 2022, the WWT under study experienced a decrease on nitrification activity and a filamentous bulking episode. The latter affected both the activated sludge and the anaerobic digesters. The main goal of this research is to determine whether dynamic changes in the microbial community of the activated sludge system and the anaerobic digesters could explain these two operation issues.

MATERIALS AND METHODS

Lleida WWTP

The WWTP of Lleida (Spain) treats 50,000 m^3/day of municipal sewage (160,000 P.E.). The activated sludge system of the WWTP has biological nitrogen removal and enhanced biological phosphate removal (EBPR). The WWTP has two anaerobic digesters to treat a the primary and waste activated sludge. Further details about the WWTP configuration and operation can be found in Palatsi et al. (2021) and Romero-Güiza et al. (2022).

Microbial community sampling

Activated sludge and anaerobic digestion biomass were sampled weekly from 05-Oct-2021 to 05-Jul-2022. Samples were stored at -20 °C until analysis. Activated sludge samples were collected in the aerobic basin (48 samples), and anaerobic digestion samples were collected in the digesters' recirculation line (40 samples). DNA extraction and sequencing (V3-V4 region of the 16S rRNA) was carried out by Novogene Co. (UK). The ASV (amplicon sequence variants) table was obtained as for Peces et al. (2022). Taxonomy was assigned to each ASV using MiDAS 4.8.1 database.

RESULTS AND DISCUSSION

Microbial ecology results showed that the microbial community of the activated sludge and the anaerobic digesters are dynamic showing a seasonal pattern. The seasonality of the activated sludge microbiome was recently described in Peces et al. (2022). However, the seasonal dynamics of the anaerobic digestion microbiome have not been previously reported. Figure 1 illustrates that temperature have a strong influence on the microbial community beta diversity, although the relative importance of other environmental and operational factors needs further analysis.

Activated sludge microbial community

Nitrosomonas was the only genus of ammonium oxidation bacteria (AOB) detected in the activated sludge microbiome. *Nitrospira* defluvii and an unclassified *Nitrotoga* (ASV12810) were the main nitrite oxidation bacteria (NOB) in the activated sludge microbiome. There was a decline of both *Nitrosomonas* and *Nitrospira* defluvii relative abundance between January and May of 2022, which started two months earlier than noticing a decrease on the nitrification activity (March 2022). These results suggest that microbial community analysis could be used as an early warning, however, further research is required to understand the associations between process performance and microbial dynamics. The nitrification capacity of the system was recovered once the *Nitrosomonas* relative abundance increased.

Tetrasphera, a polyphosphate accumulating organisms, was the main genus with the higher relative abundance in the activated sludge system, as previously reported in Palatsi et al. (2021). The most abundant *Tetrasphera* species (*Tetrasphaera* midas_s_5) also showed a clear seasonal dynamic, with its higher abundance between December 2021 and March 2022 and its lower abundance between May and July 2022. Interestingly, this species did not showed a seasonal dynamic in Danish WWTP plants (Peces, Dottorini, et al., 2022).

Ca. Microthrix (parvicella and subdominans) were the main known filamentous bacteria in the activated sludge, among the over 20 different species detected. Both species have been found to be responsible of bulking episodes in other WWTPs (Nierychlo, Singleton, et al., 2021). The relative abundance of *Ca.* Microthrix species also showed a marked temporal dynamic, with its higher abundance occurring between April and May of 2022 (relative abundance up to 15%), when a severe bulking event occurred at the WWTP.

Anaerobic digestion microbial community

The microbiome of the anaerobic digesters was dominated by *Methanotrix* (a.k.a. *Methanosaeta*), an aceticlastic methanogen. *Methanotrix* is the main methanogen in most WWTP digesters (Jiang, Peces, et al., 2021). Hydrogenotrophic methanogens were also found but at a very low (<1%) relative abundance (e.g. *Ca. Methanofastidiosum*, *Methanospirillum*).

Some putative hydrolytic and fermenting bacteria showed a clear seasonal pattern (*Bacteroidetes* midas_s_19, *Sedimentibacter* midas_s_1214,), while others were washed out from the digesters (e.g. ST-12K33 midas_s_22). However, hydrolytic and fermenting bacteria are considered functionally redundant, hence a decrease of their relative abundance may not imply a lower hydrolytic efficiency. The microbial community of the anaerobic digesters also showed a high diversity of syntrophic bacteria (*Syntrophorhabdus*, *Syntrophomonas*, *Smithella*, *Syntrophobacter* or *Ca. Propionivorax*), indicating a high diversity of the acetogenic degradation pathway.

Several genera from the activated sludge system were detected in high abundance in the anaerobic digesters, despite lacking a role in the anaerobic digestion degradation pathway (e.g. *Tetrasphera*, *Ca. Microthrix*, *Rombustia*), indicating that they are merely immigrating from the activated sludge.

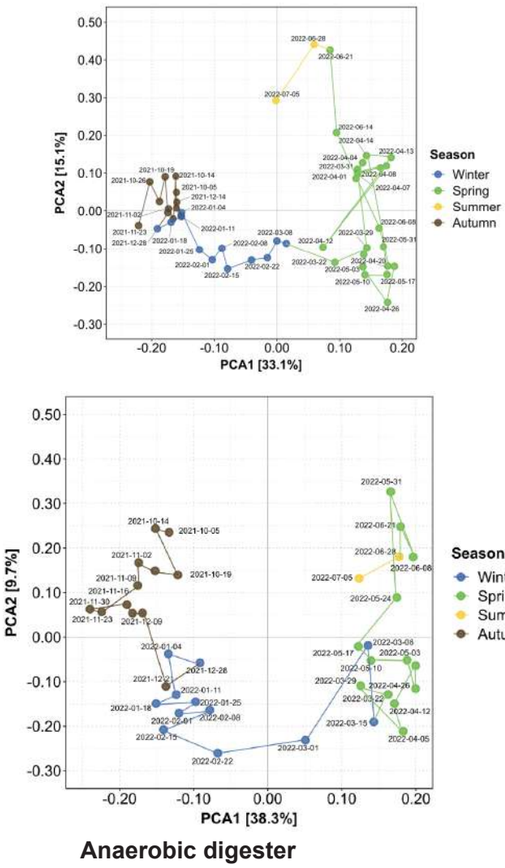

Figure 1. Principal component analysis (PCA) of the microbial community of the (top) activated sludge and (bottom) anaerobic digester. Colours differentiate the seasons of the northern hemisphere (winter, spring, summer and autumn).

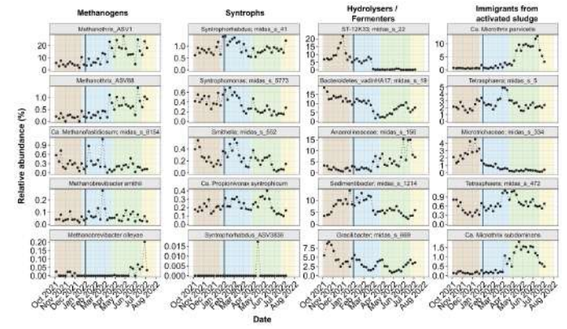

Figure 2. Time-series of the anaerobic digesters' microbial community. The microbial community is clustered in the four functional groups (methanogenesis, acetogenesis, fermenters/hydrolyser and immigrants)

Abstract
Nature-based solutions (NBS) have the ability to contribute towards the development of circularity for the urban environment. While the qualitative description of the provided functions, processes and benefits is fully available in the literature, there is often a lack of quantification of resource streams and, consequently, of knowledge of the real contribution of NBS. To change this approach, a framework providing guidance on how to achieve the quantification using a simplified and detailed approach is presented in this work. This also includes the description of the actual demands of the urban space for the implementation of NBS as well as their provided services in order to select appropriate NBS units.

Keywords: Circular economy, guidance, nature-based solutions, quantification, resource recovery

INTRODUCTION

The implementation of nature-based solutions (NBS) in the urban context is known to provide multiple benefits towards sustainable development, climate change adaptation, biodiversity improvement, public health, pollution control and resource management. An important aspect, therefore, lies in their application in closing resource cycles and contribute to the transition towards urban circular economy (Langergraber et al., 2021).
Within the COST Action CA17133 Circular City (Langergraber et al., 2020), a set of NBS units, interventions and supporting units was defined to foster the paradigm change towards circularity in the management of natural resources. The work (Langergraber et al., 2021a) evaluated the qualitative potential of NBS to address one or more defined urban circularity challenges (UCC) (Atanasova et al., 2021)resource depletion, climate change, and degradation of ecosystems. To cope with these challenges, the transformation of our cities into sustainable systems using a holistic approach is required. The pathway to this urban transition is adopting the concept of circular economy for resource management. In this way, resources are kept and reused within the city. Nature-based solutions can be implemented for these tasks, and besides the circularity, they can provide additional benefits for the urbanites and the urban environment in general. This paper describes which urban challenges related to circularity can be addressed through nature-based solutions. This systematic review was developed within the COST Action CA17133 Circular City that investigates how nature-based solutions can be used to progress the circular economy in the urban built environment.”,”author”:[{“dropping-particle”:””,”family”:”Atanasova”,”given”:”Nataša”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Castellar”,”given”:”Joana A.C.”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Pineda-Martos”,”given”:”Rocío”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Nika”,”given”:”Chrysanthy Elisabeth”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Katsou”,”given”:”Evina”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Istenič”,”given”:”Darja”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Pucher”,”given”:”Bernhard”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Andreucci”,”given”:”Maria Beatrice”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Langergraber”,”given”:”Guenter”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””}],”container-title”:”Circular Economy and Sustainability”,”id”:”ITEM-1”,”issued”:{“date-parts”:[[“2021”,”3”,”17”]]},”title”:”Nature-Based Solutions and Circularity in Cities”,”type”:”article-journal”},”uris”:[“http://www.mendeley.com/documents/?uuid=098ef175-e9bf-43b8-a71a-6cc0f152370c”]}],”mendeley”:{“formattedCitation”:”(Atanasova et al., 2021, namely (1) restoring and maintaining the water cycle, (2) water and waste treatment, recovery, and reuse, (3) nutrient recovery and reuse, (4) material recovery and reuse, (5) food and biomass production, (6) energy efficiency and recovery, (7) building system recovery.
While the qualitative description of the functions, processes and benefits of NBS is generally available, a quantitative determination on the actual extent is often missing. The quantitative assessment would enable evidence-based decision-making. Therefore, it is important to provide this information to 1) inform stakeholders of potential benefits, and 2) provide inputs for commonly applied methods in decision-making (e.g., multi-criteria analysis, cost-benefit analysis). Otherwise, the potential benefits of NBS can be overlooked and not taken into account in the decision-making process, jeopardizing their implementation.
Furthermore, the quantification of NBS processes and subsequent resource streams would enable the implementation of so called NBS systems. These are carefully designed cascade systems of connected NBS units, where each unit provides a service, vital to the functioning of the system. Quantification of NBS streams plays a vital role in an optimal design of NBS systems.
This work provides a framework developed within the COST Action CA17133 Circular City to achieve the needed quantification and subsequently the decision process towards the implementation of NBS within the concept of CE.

MATERIALS AND METHODS

The methodology to develop a framework towards the quantification of resource streams utilized by the implementation of NBS in the urban context includes the following steps: (i) the determination of specific demands based on the description of the defined UCCs (Atanasova et al., 2021)resource depletion, climate change, and degradation of ecosystems. To cope with these challenges, the transformation of our cities into sustainable systems using a holistic approach is required. The pathway to this urban transition is adopting the concept of circular economy for resource management. In this way, resources are kept and reused within the city. Nature-based solutions can be implemented for these tasks, and besides the circularity, they can provide additional benefits for the urbanites and the urban environment in general. This paper describes which urban challenges related to circularity can be addressed through nature-based solutions. This systematic review was developed within the COST Action CA17133 Circular City that investigates how nature-based solutions can be used to progress the circular economy in the urban built environment.”,”author”:[{“dropping-particle”:””,”family”:”Atanasova”,”given”:”Nataša”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Castellar”,”given”:”Joana A.C.”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Pineda-Martos”,”given”:”Rocío”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Nika”,”given”:”Chrysanthy Elisabeth”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Katsou”,”given”:”Evina”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Istenič”,”given”:”Darja”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Pucher”,”given”:”Bernhard”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Andreucci”,”given”:”Maria Beatrice”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Langergraber”,”given”:”Guenter”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””}],”container-title”:”Circular Economy and Sustainability”,”id”:”ITEM-1”,”issued”:{“date-parts”:[[“2021”,”3”,”17”]]},”title”:”Nature-Based Solutions and Circularity in Cities”,”type”:”article-journal”},”uris”:[“http://www.mendeley.com/documents/?uuid=098ef175-e9bf-43b8-a71a-6cc0f152370c”]}],”mendeley”:{“formattedCitation”:”(Atanasova et al., 2021)”},{“dropping-particle”:””,”family”:”Andreucci”,”given”:”Maria Beatrice”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””},{“dropping-particle”:””,”family”:”Langergraber”,”given”:”Guenter”,”non-dropping-particle”:””,”parse-names”:false,”suffix”:””}],”container-title”:”Circular Economy and Sustainability”,”id”:”ITEM-1”,”issued”:{“date-parts”:[[“2021”,”3”,”17”]]},”title”:”Nature-Based Solutions and Circularity in Cities”,”type”:”article-journal”},”uris”:[“http://www.mendeley.com/documents/?uuid=098ef175-e9bf-43b8-a71a-6cc0f152370c”]}],”mendeley”:{“formattedCitation”:”(Atanasova et al., 2021 to give a clearer focus for the implementation of the NBS, (ii) a description of the services required to meet the demand, and (iii) the determination of the NBS units providing the defined service.
All three parts have been determined during two expert workshops. For the demands, (i) the texts of the UCCs have been analysed to extract specific demands to be met by one or multiple NBS. As the determination of the exact NBS unit to be implemented depends on multiple boundary conditions, the term services (ii) was introduced to provide a description of the processes and functions needed to meet the demand. Based on the services, (iii) a list of multiple NBS units capable of providing the required services was defined.
At this stage, the available quantification models for the resource stream were identified. Two complementary approaches were used: (1) a simplified approach based on the demand level and (2) a detailed approach based on the service level.

RESULTS AND DISCUSSION

Framework

The overall approach of the developed framework is illustrated in Figure 1. In order the design a NBS system consisting of one or more NBS to address a specific UCC, a demand has first to be determined. Table 1 provides a preliminary list of demands focusing on key circularity needs. This is by no means a finished list, but includes the main objectives following the work of the COST Action CA17133 Circular City as presented in (Langergraber et al., 2021b, 2021a)and the mainstreaming of NBS in the urban fabric. Existing frameworks describing the use of NBS to address urban challenges do not specifically consider circularity challenges. Thus, the new framework provides the following: (1. Based on the selected demand, the needed services describing e.g. functions or processes, can be identified (Table 1) and reported in detail. Lastly, an expert based ranked list of specific NBS units to provide the required service will be provided and described.

Table 1: Demands (in bold) and needed services determined from the UCCs. The list can be extended based on individual needs. (RW - rainwater; WW - wastewater; FW - food waste; BM - biomass).

Alternative water source RW	**Land restoration**
Collection	Revalorization (Soil)
Treatment (RW)	
Storage (RW)	
	Biomass waste harvesting (from all NBS)
Alternative water source WW	
Collection/Separation	Biomass recovery
Treatment (WW)	
Storage (WW)	
	Urban heat island mitigation and reduction
Alternative nutrient source from Wastewater	
Collection/Separation	Microclimate regulation
Revalorization (liquid)	
Storage	
Alternative nutrient source from bio waste	**Increase energy sufficiency**
Collection (FW)	Increase building insulation
Revalorization (FW)	Energy recovery from BM or FW
Storage	Energy recovery from WW
Food and biomass production	
Production of eatable BM	
Production of non-eatable BM	

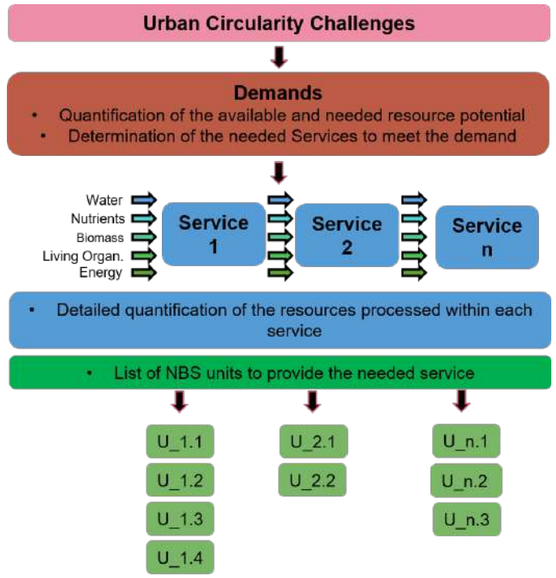

Figure 1: General approach of the framework to identify the needed Demand, Services and NBS units including the steps for resource quantification within the process.

Quantification

The quantification approach also follows the framework (Figure 1) and is split into two parts, namely a simplified approach at the demand level and a detailed approach at the service level. On the demand level, the simplified quantification can illustrate the potential of the available and needed resources to support the decision-making processes. On the service level, the detailed quantification is able to provide input data for the planning and designing of the needed units and thereby support the unit selection process. For example, for the demand “Alternative water source (rainwater)”, a simplified quantification would determine a potential amount of rainwater that could be collected (e.g., from green roof) for future use. While, on service level, a more detail hydological-hydraulic methods would be used to determine water flow through different NBS units.

Next steps

To present the full work, quantification models for the simplified and detailed approach will be generated and tested using case studies. The final product will be embedded in a guidance support system (GSS) using a web-based application providing (i) a descriptive part of the demands, services and units, including their utilization for CE application; (ii) the simplified quantification approach to present the potential of shifting towards CE application for urban resource management using NBS and (iii) the application of the presented framework on multiple case studies.

Abstract

Decentralised EXTensive systems provide adequate sanitation with low operation and maintenance, but require large footprints. The LIFE INTEXT project proposes a reduction in footprint through INTensification into innovative INTEXT technologies. A demonstrative technological platform has been constructed in Talavera de la Reina (Toledo, Spain) to promote innovative sanitation systems (combining extensive and intensified technologies) and demonstrate their economical and treatment efficiencies adapted for small communities as well as awareness through site visits to the facilities. This communication presents a description of the project, the platforms, the INTEXT technologies and the 24 pilots that are part of it.

Keywords (maximum 6 in alphabetical order)

Constructed wetlands, Forced bed aeration, High rate algae ponds, Nature-based solution, Small communities, Wastewater.

INTRODUCTION

Decentralised wastewater systems play an innovative role in delivering sanitation in rural areas. Extensive systems are adequate wastewater treatment technological solutions in rural areas due to their capacity to meet discharge requirements with low operation and maintenance costs, but as a drawback they require relatively large footprints.

Further developments are thus required for these systems to become more compact and efficient while maintaining reasonable investment and operational costs. The LIFE INTEXT project, led by Aqualia, proposes the reduction of this footprint through the INTensification of EXTensive treatment systems into innovative INTEXT technologies. In addition to technical and economic targets, the project has constructed a demonstrative technological platform in Talavera de la Reina (TLR) WWTP (Toledo, Spain) and upgraded the existing Carrión de los Céspedes (CC) WWTP (Seville, Spain) to promote communication and awareness through site visits to the facilities.

This communication describes the innovative INTEXT technologies installed on the INTEXT platforms. The monitoring of performance will allow the validation of the technologies and their optimisation with the target of reducing investment costs, maintenance and footprint (<1m^2/PE).

INTEXT TECHNOLOGIES

The main characteristics and layout of the INTEXT technologies are summarised in Table 1 and Figure 1. Some of the technologies are operated in combination, to evaluate the best wastewater treatment performance and treat onsite the produced sludge.

Anaerobic pretreatment - PUSH® reactor

Upflow Anaerobic Sludge Blanket (UASB) process with pulsed feeding. The PUSH® reactor system has been modified with a top feed that will allow operation during high rainfall events, preventing the biomass to be washed out of the system in an "Imhoff operation mode".

High-Rate Algae Ponds - HRAP

HRAP systems are based on the synergy between microalgae – that produce oxygen through photosynthetic processes – and facultative bacteria that degrade pollutants such as organic matter, nitrogen and phosphorus. Two HRAP have been installed, one with an innovative turbine passive mixing system to evaluate its efficiency against a control.

Constructed wetlands (CW)

Several CWs have been built in the INTEXT platform due to the international recognition of these systems for wastewater treatment: (i) a traditional 2-stage "French system" (Troesch et al., 2014) CW has been built as a control for raw wastewater, (ii) Rhizosph´air® - a one stage CW patented by SYNTEA combining vertical and horizontal flow with forced aeration treating raw wastewater (Petitjean et al. 2022), (iii) Aerated Horizontal Flow CWs (HFCW) with forced aeration or 2nd stage of the "French system" treating effluent from the anaerobic pretreatment (PUSH® reactor), , (iv) floating CWs receiving effluent from PUSH® reactor or Rotating Biological Contactor (RBC), with forced aeration and recirculation, (v) clarifying CW to treat effluent from HRAPs or trickling filter as a polishing step, (vi) sludge drying reed beds treating sludge from PUSH® reactor or activated sludge from the full scale WWTP.

Hybrid secondary treatment

Traditional biofilm systems have been intensified in the project to improve performances and are combined with CWs as a polishing step: (i) RBC intensified with recirculation and a Floating CW for effluent polishing, (ii) Trickling filter intensified with forced aeration (air extraction with fan) and a Sludge Clarifying Drying Reed Beds for sludge dewatering and effluent polishing.

Granular Aerobic Reactor

This system operates in batches, fed sequentially according to the designed loading regime. Alternating anaerobic, anoxic and aerobic cycles allow the removal of organic matter and nutrients, and promotes conditions for granule formation which offer good settlement properties. After the settlement stage there is an emptying cycle, and the process is started again. The INTEXT project will evaluate the best combination of parameters for this technology adapted to small populations.

FINAL REMARKS

The effluent from the INTEXT technologies receives further treatment for: (i) Phosphorus recovery with adsorbent materials, (ii) solar-based disinfection, (iii) water reclamation and reuse with smart irrigation control. The project is also complemented with the evaluation of greenhouse gases emissions, assessment of emerging pollutants and the development of a decision support system (DSS) based on a Life Cycle Analysis (LCA) and Life Cycle Cost Analysis (LCCA).

The fact that the technologies are operated in different climatic conditions (Continental - TLR WWTP, Mediterranean – CC WWTP) allows to determine accurate operating and design parameters that will serve as a base to develop the next generation standards for the treatment of wastewater for small communities in Southern Europe. During the conference, the authors will present results data from the TLR INTEXT platform (Figures 2 and 3).

ACKNOWLEDGEMENTS

The LIFE INTEXT project has received funding under the LIFE financial instrument of the European Union LIFE18 ENV/ES/000233.

Abstract

The LIFE SPOT project has as main objective to remove groundwater pollution (nitrates, pesticides, antibiotics, and antibiotic resistance genes) to supply drinking water for human and livestock in decentralized areas and prove an alternative water management technology for very small water supplies. For that, a combined photobioreactor and cork-wood pellet filter treatment technology is being assessed at pilot scale in Spain. The added value of the developed SPOT technology is the removal of nitrate and microcontaminants in the groundwater as well as to decrease carbon footprint by enhancing CO2 sequestration and nutrient recovery.

Keywords

Emerging contaminants, groundwater, natural-based treatment, nitrates.

INTRODUCTION

In rural areas, groundwater is used for drinking and for irrigation purposes. Many communities in the Mediterranean area they suffer from severe drinking water shortages due to groundwater pollution or drought. Anthropogenic pollution by nitrate and pesticides is one of the major water quality problems in small and very small water supplies. In fact, approximately 13% of groundwater monitoring stations across Europe exceed the 50 mgNO3/L limit (91/676/EEC), thereby reducing the amount of usable drinking water. In addition, a major public health concern has been raised across Europe during the last years due to the occurrence of antibiotics and antibiotic resistance genes (ARGs) in groundwater, derived from manure application in agriculture. Therefore, the main objective of this work, enclosed in LIFE SPOT project (lifeSPOTproject.eu), is to assess the efficiency of pollution (nitrates/ pesticides/ antibiotics/ ARGs) removal of contaminated groundwater to supply drinking water for livestock in rural areas.

MATERIALS AND METHODS

The scheme of the pilot plant is shown in Figure 1. It combines a continuously stirred photobioreactor (PBR; 15-18 m^3), built with floating light-pits, a clarification step within a dissolved air flotation (DAF) unit, and a corkwood biofilter (CWF; 5 m3) treatment, at field scale (treatment capacity of 1-5 m3/d). The pilot plant is being run under field environmental conditions and assessed by means of a deep physicochemical and microbiological characterization. The real polluted groundwater (Barcelona, Spain) is contaminated due to organic fertilization (manure), which has led to a high level of nitrate, antibiotics, ARGs and pesticides.

RESULTS AND DISCUSSION

The SPOT pilot plant has been working for more than 1 year. The results shown in this work were collected during two periods of continuous and stable operation: summer 2022 (days 222-273) and autumn 2022 (days 343-373), where the average nitrate content in the groundwater was between 162 and 290 mgNO3/L, respectively (Table 1). Micropollutants detected in summer and autumn 2022, were i) 8 antibiotics (sulfonamides and fluoroquinolones) with a concentration from 0.5 to up to 98 ng/L; ii) ARGs (intl1 and sul1 genes) content ranged from 10^4 to 10^5 gene copies/L; and iii) pesticides (desethylatrazine, DEET; surfactants as surfynol 104) with a concentration <20 ng/L.

Table 2 summarizes the average values of operational parameters of the PBR and CWF of the pilot plant at field scale. A natural mixed consortium of bacteria-microalgae, cultivated in conditions like those of the pilot plant, was used to inoculate the PBR in winter 2022. The continuous operation began in spring 2022, when the operation of the PBR and the CWF were synchronized in continuous mode. During the entire operation of the pilot plant, the real polluted groundwater of the site was improved by adjusting its nitrate to phosphate molar ratio (22 and 27 in summer and in autumn, respectively) and by a CO_2 injection (to adjust pH to 7.0-7.5) in the PBR, to enhance the culturing of microalgae and bacterial biomass. The occurrence of Cyanobacteria (Fig.1A) was monitored in the PBR to avoid the presence of cyanotoxins. The biofilter was always operated with a hydraulic residence time (HRT) of 2 days, while the PBR was run with an HRT of 8 days with recirculation of the concentrated biomass from the DAF in summer, and 16 days without recirculation in autumn.

The suspended biomass and microbial biofilms in PBR, DAF and CWF materials were higher in summer than in autumn, in general but with the same tendency. Bacterial biofilms in PBR were ≥10^{11} copies 16SrRNA/mL, composed by 10% of denitrifying bacteria; nonetheless, denitrifiers became 100% of bacterial population in autumn. The flocculated biomass in DAF was like PBR biomass, depicting the same tendency in both seasons. It is noteworthy that denitrifying populations in CWF were highly maintained in both seasons (10^9 *nosZ* copies/g, representing the 95-100% of total population), confirming the important role of nitrate removal by anaerobic denitrifying bacteria. In the CWF, a high abundance of fungal populations was also established growing on corkwood pellets (10^9 ITS copies/g). Therefore, the hydrolysis and fermentation of the filling materials was carried out and controlled by a specific consortium composed of fungi, cellulolytic and bacteria, where volatile fatty acids boosted the denitrifying activity under the saturated water conditions within the CWF.

The denitrifying activity in CWF led to a nitrate removal of 83 and 69 % in-NO_3 in summer and autumn 2022, respectively, but with a higher depletion rate in autumn (28 gNO_3/m^3d) than in summer (20 gNO_3/m^3d) (Table 2). Although denitrifying potential was detected in the PBR (Fig.2), the nitrate removal observed was 19 and 16 % in-NO_3 in summer and autumn 2022, respectively, with a similar depletion rate (4 gNO_3/m^3d) in both seasons (Table 2). The biomass recirculation from DAF in summer negatively affected the removal of nitrates in the PBR (excess flocculant), which affected the microalgae population in summer together with high water temperatures (>27 ºC; Table 2) and light intensity. The planktonic species *Tetradesmus* and *Chlorella* dominated the biomass in suspension (0.15 gTSS/L) in winter-spring but in summer, diatoms and *Tetradesmus* grew in biofilms with a lower planktonic biomass (0.05-0.1 gTSS/L). In autumn, less biofilm was observed and again *Tetradesmus* microalgae presence increased in suspension (0.1 gTSS/L).

Importantly, the whole SPOT plant was shown to be effective for reducing 8 detected antibiotics (ciprofloxacin, sulfamethoxazole, sulfathiazole, sulfadiazine, sulfacetamide, sulfapyridine, sulfamethazine, and sulfamethizole): a depletion of 73 and 78 % was observed in summer and in autumn, respectively, reaching a final concentration <10 ng/L in the treated water (Table 2). The elimination (Fig.3) took place in the the PBR (9 and 40 % in summer and in autumn, respectively), in the DAF (47 and 23 % in summer and in autumn, respectively) and in the CWF (17 and 14% in summer and in autumn, respectively). The higher removal in the DAF can be explained by the coagulation and precipitation of some antibiotics due to the addition of the flocculant agent. In the microalgal biomass, only some sulphonamide was detected (5-20 ng/g-dry weight). The effectiveness of the biofilters can be mainly due to sorption and biodegradation process as it has already been observed in lab-scale cork columns (Rambaldo et al. 2022). ARGs profile is being assessed currently.

CONCLUSIONS

The high content of nitrates and the presence of micropollutants, such as antibiotics and ARGs in the groundwater in rural areas, caused by on-going intensive agriculture and/or organic fertilization, was reduced by the SPOT technology, reaching water quality standards which might allow the supply of drinking water. The on-going work in the SPOT pilot plant (winter-summer 2023) is addressed to validate the usage of the treated water as drinking water for livestock at farm level, the completion of the 2022-23 sampling campaigns and the valorisation of the residual mixed biomass.

Abstract

Cities around the world face a number of challenges, including climate change and ecosystem degradation. Nature-based solutions (NbS) can help protect us from the impacts of climate change while also ensuring ecosystem services. However, NbS still face implementation barriers, mainly in developing countries. In order to identify and compare the state of NbS implementation and the main challenges to be addressed in European and Latin American cities, we reviewed and analyzed different case studies and projects published in peer-reviewed articles and gray literature. It was reported that NbS are still evolving as a concept and are not widely implemented in Latin America, mainly due to limited availability of financial resources. There is a marked imbalance in the distribution of studies, with most cases concentrated in the global north, although southern global countries are generally most vulnerable to the impacts of climate change. In Europe, the concept is more integrated into urban planning, however, there are also barriers such as limited understanding of the benefits of NbS by society. The main challenges that Latin American cities aim to address with NbS are agrobiodiversity and improved water management. On the other hand, in Europe, there is a priority to increase urban green infrastructure, as it plays an important role in carbon storage and mitigating the impacts of greenhouse gas emissions in cities.

Keywords

Climate change, Europe, Latin America, Nature-based solutions, Social challenges

INTRODUCTION

Nature-based solutions (NbS) are a concept that is currently gaining ground to address urban challenges. NbS mainly address 7 social challenges including climate change adaptation and mitigation, reduction of natural disaster risk, reversing ecosystem degradation and loss of biodiversity, human health, socio-economic development, food security and water security (IUCN, 2020). In regions with different economic and social realities than developed countries, nature-based solutions are a foreign concept, whose enforcement presents many challenges and limitations. This study aims to describe the state of implementation and challenges that NbS seek to address in Europe and Latin America through a comparative analysis.

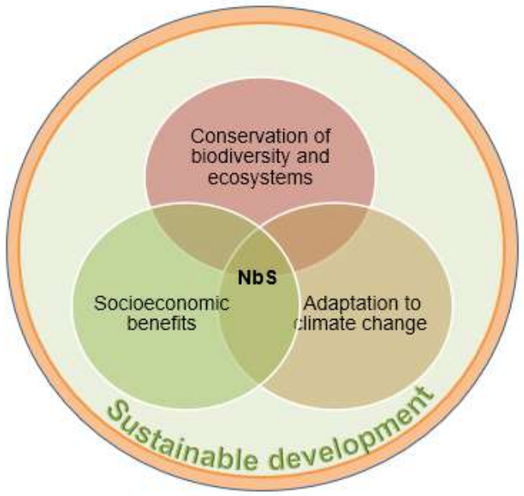

Figure 1. Challenges addressed by NbS

MATERIALS AND METHODS

This work involved a structured search of scientific and grey literature related to Nature-based Solutions (NbS) projects or studies in Europe and Latin America. The obtained literature was analyzed based on the review of the evolution of the NbS topic, its implementation level and the social and environmental challenges to be addressed in these two regions. In addition, limitations, knowledge gaps and opportunities for the implementation of NbS were identified by comparing the literature available in the north and south global. This qualitative method serves as an exploratory tool to achieve a clear picture of the development trajectory of NbS implementation.

RESULTS AND DISCUSSION

The EU has positioned itself as a world leader in NbS research and innovation. Increasingly, European cities are adopting NbS in their public policies, urban plans and programs and their implementation. On the other hand, Latin America society, in general, still does not perceive the importance and benefits of NbS. In this way, public works of another nature associated with the traditional infrastructure are prioritized. Thus, a large part of the projects that are being implemented are still in the phase of preparation and search for financing. One of the main limitations in both Europe and Latin America is the lack of information and data necessary to measure the potential benefits. However, since 2012 the EU has funded multisectoral projects with case studies in Europe and Latin America, which has boosted NbS research in this region as well (Davies et al., 2021). In general, most government objectives for NbS are focused on forests, therefore funding is currently channeled mainly towards tree planting (Seddon et al., 2021). However, this perception is different in Europe and Latin America. The low access of people to green areas is the main challenge in European cities. In Latin America, projects combining conservation and agriculture and solutions focused on improving water management, such as controlling runoff, floods, and rainwater, predominate (Ozment et al., 2021). In general, the social and environmental challenges that NbS are intended to address are different in the two regions. This depends on the local contexts in the environmental, political, economic and social spheres; therefore, more research is needed in terms of cost/benefit analysis and implementation opportunities.

Abstract

MULTISOURCE project is operating seven pilots of diverse Enhanced Natural Treatment Solutions (ENTS). The ENTS are treating domestic wastewater, urban surface water runoff or combination of these streams. While the pilots are monitored for conventional water quality parameters by each MULTISOURCE partner, we are supplementing the monitoring activities by performing target and non-target analysis of organic micropollutants. Many of the target compounds (pharmaceuticals, surfactants, pesticides and other) are considered of ecological concern and some are included in current European regulation. Our aim is to provide field-based knowledge about the compound occurrence, removal and transformation in the different ENTS. Our results will later be used for the risk assessment for treated water discharge and potential reuse and contribute to the implementation of ENTS in the future. Monitoring activities are running since the summer of 2022, we will show selected results of the non-target screening analysis, as well as treatment potential of several pilots.

Keywords

Black water; Emerging pollutants; Greywater; Non-target screening; Road runoff; Wastewater

INTRODUCTION

There is a growing demand for water treatment, storage and reuse in urban areas. While the demand can potentially be largely addressed by nature-based solutions, full and pilot scale data about long-term performance of such systems is generally lacking (Yang et al. 2022). MULTISOURCE, the EU Horizon 2020 project exploring ModULar Tools for Integrating enhanced natural treatment SOlutions in URban water CyclEs, aims at addressing this. MULTISOURCE aims to i) demonstrate seven Enhanced Natural Treatment Solutions (ENTS) for a wide range of urban wastewater streams, and ii) develop innovative tools, methods and business models that support implementation of such solutions through a co-creation approach. The pilots are build based on different approaches (green roofs, green walls, raingardens and constructed wetlands) in France, Belgium, Italy, Spain, Norway, Germany and USA (Figure 1).

One of the critical points covered by MULTISOURCE are organic micropollutants, as these can hinder the technology and management options for urban waters. MULTISOURCE investigates the efficiency of seven different Enhanced Natural Treatment Solutions (ENTS) to remove pathogens, priority substances and contaminants of emerging concern, including microplastics. The empirical results will result in recommendations to optimise pilots and their operation for pollutant removal. Long-term monitoring data will be assessed and recommendations for system implementation in urban areas will be proposed.

METHODS

The partners responsible for the pilot plants regularly sample the influent, mid-flow (where relevant) and effluent waters, analyses basic water quality parameters and provides samples to specialised laboratories for microplastic, pathogen and micropollutant analysis. The team from Aarhus University (AU) represented here is responsible for coordinating activities of all pilots, as well as measuring organic micropollutants in their water. For characterizing the pilot performance in terms of the micropollutant removal efficiency, the work is being carried in close collaboration with all partners.

The analytical work includes target analysis by GC-MS and LC-MS/MS, applying three different analytical methods in order to quantify the selected compounds in the different water matrices. Specific methods for wastewater and urban runoff were implemented. For the non-target and suspect-screening approaches we have used high-resolution mass spectrometry (GC-orbitrap and LC-QTOF) and an in-house library of organic pollutants. These results will be further treated for the planned risk assessment analysis by NIVA (Norway). Also, by the different project partners for a detailed characterization of the pilot operation.

RESULTS AND DISCUSSION

The first months of the project have been dedicated to develop a harmonized monitoring plan that ensures comparability of the different ENTS, as well as a tailored approach for each pilot (e.g. type of water, operation mode, seasonality, pollutants of relevance). For the monitoring plan AU has developed *MULTISOURCE suspect screening list* comprising 300 different compounds of relevance for which we will validate their presence or absence in different waters and regions, as well as quantify several. The list includes domestically and industrially applied compounds that are known or suspected to enter environment via wastewater/stormwater streams and cause adverse ecological effects. These include broad range of pharmaceuticals, surfactants, pesticides, combustion products, UV sunscreen agents and other (Figure 2). The *MULTISOURCE suspect screening list* has been combined referring to well-known and emerging micropollutants of environmental concern reported by other studies (Schulze et al. 2019) and European regulation (EU Water Framework Directive 2000/60/EC, EU water policy substances “watchlist” 2018/840), and MULTISOURCE partner consultation.

For quantitation of the organic micropollutants, the wastewater target list includes approx. 90 compounds, majority of which are pharmaceutical compounds representing different therapeutic uses. For the urban runoff, the target list includes approx. 60 compounds, mainly comprising oil and combustion products and urban biocides (Figure 2). Compound quantification lists are updated ongoing based on suspect screening analysis.

The first samples arrived at AU in the spring/summer 2022 and the main commonly found micropollutants have been quantified. The first results indicate that the different MULTISOURCE pilots are receiving a wide variant of organic micropollutants. The French pilots from INRAE have at their inlet several pharmaceutical compounds from different therapeutic classes (antibiotics, anti-inflammatory, antidepressant, anaesthetic anti-convulsant, anti-anxiety, antihypertensive (Figure 3). The Bridger Bowl (Sky Resort) pilot in the USA had at the inlet some biocides and psychotropics, besides several pharmaceutical compounds. Several compounds were measured up to 5 µg/L in the influent.

In terms of first performance results, the Belgium Pilot treating wastewater from a Camping site showed removals above 77% for compounds such as sotalol, venlafaxine, DEET, DDAC or caffeine (Figure 4). Gabapentin, usually showing weak elimination in sewage treatment plants (Herrmann et al. 2015), was removed up to 76% from black water by the phytoparking system. It should also be noted difference in occurrence and treatment between the greywater and black water. Notably we see not only good removal rates, but also concentrations at the effluent bellow PNEC values, for example for venlafaxine (PNEC of 0.1 µg/L).

MULTISOURCE monitoring work keeps developing and new samples are continuously analysed. At ecoSTP2023 we will provide updated results from the monitoring work, as well as the first results from our suspect and non-target screening work that is ongoing. We should also be able to provide data on pilot performance efficiency to remove these compounds.

Abstract
Wastewater and groundwater from industrial areas have been shown to be impacted by the so- called persistent, mobile and toxic (PMT) compounds. This study assessed the capability of using an intensified constructed wetland based on coke for the remediation of 5 PMT compounds (benzotriazole, methyl-benzotriazole, perfluoropentanoic acid, perfluorobutanesulfonic acid, and trifluoromethanesulfonic acid) from both, groundwater and wastewater. The evaluated design parameters inbiofilter packed-columns were: coke granulometric sizes (5-2 mm vs 2-0.5 mm), the presenceofvegetation(*Cyperusalternifolius)*,andhydraulicloadingrate.Thecolumnswere initiallyfedwithrivergroundwater spikedwithdifferentPMTcompoundsat5 and 10µg/L.After 6 operation months, the columns were fed with real secondary-treated wastewater spiked with the same compounds. Both inlet and outlet of the system were analysed by UHPLC-HRMS obtaining removals for benzotriazole and methyl-benzotriazole between 60 and 90%, respectively. Whereas these removal efficiencies were between 20 to 50% for PFAS.

INTRODUCTION

The occurrence of Persistent, Mobile and Toxic (PMT) substances in groundwater and wastewaters have emerged a big concern due to the capacity of these compounds to travel long distances with water, even throughout bank-filtrate and thus spread over large spatial and temporal scales, posing ecosystem and human health threats (Hale et al., 2022). Some examples of PMTs are organochlorinated compounds, benzotriazoles and per- and polyfluoroalkyl substances (PFAS) which are used by industrial manufacturing processes ending up in wastewater treatment plants (WWTP) and finally into the groundwater (Ateia et al., 2019).

The concern about the widespread presence of PMTs in water bodies has resulted in a common EU strategy to fight against them based on the replacement of these chemicals by more safe and sustainable substances, followed by their minimization and control, and finally, the assessment of advanced technologies for their removal (*EC. Chemicals Strategy for Sustainability Towards a Toxic-Free Environment*, 2021). In this sense, the use nature-based solutions such as constructed wetlands (CWs) have shown to be capable of removing PMTs such as chlorinated solvents or benzotriazoles from wastewater (Hansson, 2019; Shi et al., 2019), but there is low information available of how the use of intensified CWs based on different materials such as coke can be used for removing PMTs from both wastewater and groundwater. In this study we will assess the effectiveness of using coke and vegetation in intensified CWs for removing benzotriazole (BTr), methyl-benzotriazole (MBTr), perfluoropentanoic acid (PFPeA), perfluorobutanesulfonic acid (PFBS) and trifluoromethanesulfonic acid (TFMS) from groundwater and wastewater.

MATERIALSANDMETHODS

The study was conducted in laboratory-scale biofilters under water-saturated conditions duringmore than 200 operational days for the removal of PMTs. Twelve methacrylate columns (43.5mm int.Ø,x-320mmheight)weredesignedandconstructed(Fig.1).Eachcolumnwasfilledwith25mm ofgravel followed by300 mm ofcokeofdifferent granulometricsizes (3columns with particle size of 5-2 mm and 3 columns with 2-0.5 mm) or washed sand (2 mm Ø). 9 of the 12 columns were planted with *Cyperus alternifolius*. All columns were fed with either, groundwater or secondary treated wastewater at a HLR of 70 and 40 mm/d. Plants were acclimatized during 8 weeks and the system started to operate with spiked groundwater at 5 µg/L (BTr and MBTr) and 10 µg/L (TFMS, PFBS and PFPeA) for 8 additional weeks. After that, columns were fed with real secondary treated wastewater spiked with the same PMTs and the performance of the technologywas monitored for 2 additional months. Every week inlet and outlet water samples from each column was collected and analysed for physico-chemical properties (pH, redox, dissolved oxygen) and general quality parameters (chemical oxygen demand, ammonium, nitrates, phosphates, and sulphates). Moreover, same filtrated water samples were injected into a UHPLC-HRMS instrument (Bruker-Impact II) equipped with an Intensity Solo C18-2 column (100 x 2.1 mm, 1.8 µm) for the determination of the selected PMTs and their transformation products.

RESULTSAND DISCUSSION

Preliminary results show that at a HLR of 70 mm/d intensified CW based on coke were able to remove benzotriazoles by more than 60%, and PFAS by 20-50%. from groundwater This can be explained by the capacity of the coke to promote the grow of *Dehalococcoidesspp.*, bacteria which has been observed to enhance the attenuation of organic matter and organic compounds such antibiotics from wastewater (Löffler et al., 2013). The use of wastewater enhanced the attenuation of PMTs by 30 to 50%, probably due to the greater biofilm production and co-metabolism with the organic matter and other constituents of the treated wastewater. In order to enhance the attenuation capacity of the CWs we reduced the HLR to 40 mm/d, achieving removal efficiencies greater than 80%. In the presentation these results will be explained along with the identification of transformation products and the potential ecosystem and human health risk of the treated water. Furthermore, microbial 16S characterization will be used to elucidate the main microbial contributors to the attenuation of PMTs.

CONCLUSIONS

The preliminary results indicate that the use of intensified CW based on coke can be a suitable nature-based solution for removing PMTs from groundwater and wastewater. Future studies will include the long-term performance and scale-up of the technology under real environmental conditions (Technology Readiness Level 5).

Abstract
The selection of the appropriate filling material in constructed wetlands (CWs), depends on the required treatment, the cost, availability and the hydraulic behaviour of the system. This work examined material of various origins (sand, recycled glass, biochar and gel beads), that can be used in unsaturated vertical subsurface flow CWs. The suitability of the materials was initially determined by their granulometry and porosity, that affect hydraulic conductivity (sand 0.23, recycled glass 0.16 and biochar 0.04 cm/s). Preliminary results for the treatment of anaerobic effluents produced by a UASB process treating domestic wastewater indicated promising performance of the materials without any clogging issue. Under the so far maximum applied loading (OLR = 8.7 ± 1.8 gCOD m^{-2} d^{-1}, SLR = 3.5 ± 1.5 gTSS m^{-2} d^{-1}, NLR = 2.6 ± 0.4 gNH_4-N m^{-2} d^{-1}), removal efficiency of sand, biochar and glass was greater than 93% for TSS, 86% for COD and 99% for NH_4-N, while gels achieved 83%, 61% and 86%, respectively.

Keywords
Constructed wetlands; filling material; wastewater treatment; hydraulic conductivity

INTRODUCTION

Various materials have been used as an alternative to sand that is usually used as filling material in vertical subsurface flow constructed wetlands (VSSF CWs) such as recycled glass (Humeniuk et al., 2019) and biochar (Gupta et al., 2016). The selection of the filling materials depends on the treatment requirements and therefore the required removal of pollutants e.g., organic matter, nutrients, heavy metals, surfactants and emerging contaminants (Wang et al., 2020) and, thus, the required removal mechanism. The orientation of wastewater treatment has been shifting from safe-to-discharge to safe-to-reuse effluent; the preservation of nutrients in the treated effluent is of crucial importance. Materials that precipitate phosphorus e.g., those that have Ca content >10% (Moreno-Perez et al., 2018) should be avoided. The present work investigated the suitability of three different filling materials (recycled glass, hydrogels and biochar) in comparison to sand for the treatment of anaerobic effluents produced by aUASB) process treating domestic wastewater.

MATERIALS & METHODS

Four columns packed with each substrate were implemented to simulate VSSF unsaturated (UNSAT) CW (Figure 1). Coarse gravel covered the bottom 20 cm as drainage, while 20 cm of finer gravel was placed on top of it to support the main filter media, whose total height was 40 cm. On top of the main filter media 20 cm of the same fine gravel was placed to distribute wastewater uniformly to the filter media. The diameter of each column was 25cm. The first tests of the materials included granulometry, porosity and hydraulic conductivity determination.

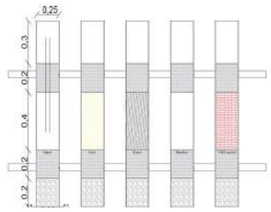

Figure 1. Layout of the four simulation columns (sand, hydrogels, recycled glass, biochar)

Granulometry

Granulometry was carried out for sand, biochar and glass by sieving to produce the granulometric curve. Since fine media was required for VSSF UNSAT CWs, sieves of 2, 1, 0.5, 0.25 and 0.1 mm were used. The gels were commercially available of biodegradable polymer origin and standard uniform size so there was no need for granulometry determination, since the expanded gel (after water absorption) was spherical with 8 – 10 mm diameter.

Porosity calculation (n)

The porosity was calculated according to Eq. 1. Once the sample was dried at 105°C, water was added inside the test device to record added water weight until saturation. Three samples were examined to extract the average value.

$$n = \frac{V_{H_2O}}{V_{sample}} = \frac{w_{H_2O}/\rho_{H_2O}}{A*L} n = \frac{V_{H_2O}}{V_{sample}} = \frac{w_{H_2O}/\rho_{H_2O}}{A*L}$$ Equation 1

where:
A: vessel area (cm^2)
L: vessel length (cm)

w_{H_2O} w_{H_2O} : water weight for saturation of the sample (g)

ρ_{H_2O} ρ_{H_2O} : water density at 20°C (= 0.998 g/cm^3)

Hydraulic conductivity calculation (k)

The hydraulic conductivity was calculated with the variable head method according to Darcy's law. A known volume of water (10 L) was instantly added to the column and the height of the water column above the material was recorded versus time. Hydraulic conductivity was calculated every 1cm drop between the initial 20 cm and last 5 cm, according to Eq. 2 (the bottom 5 cm were not recorded to avoid possible disturbance). Therefore, for each trial k was calculated as an average of 15 values.

$$k = \frac{L}{t_i - t_0} * \ln\left(\frac{h_0}{h_i}\right) k = \frac{L}{t_i - t_0} * \ln\left(\frac{h_0}{h_i}\right)$$ Equation 2

where:
L: filter media height (40 cm)
h_0, h_i initial (20 cm), instant water height above the filter (cm)
t_0, t_i start time (=0 s), time from measurement start for h_i recording (s)
This test was repeated until the pore volume factor (PVF) was equal to 20, as a material is considered to be saturated when PV gets replaced 20 times with new water (Wanigarathna et al., 2013).

Treatment start-up

Plants were not used to avoid the effect of the roots' development. Start-up was performed with UASB effluent and the applied organic loading rate (OLR), solids loading rate (SLR) and nitrogen loading rate (NLR) is given in Table 1. Feeding was intermittent respecting a hydraulic load of the unsaturated beds of 2 cm per flush.

Table 1 VSSF columns operational parameters

Period	Day start	Day end	Q (L/d)	T (°C)	OLR (g_{COD} m^{-2} d^{-1})	SLR (g_{TSS} m^{-2} d^{-1})	NLR (g_{NH4-N} m^{-2} d^{-1})
1	1	101	1	25.5 ± 1.1	4.7 ± 1.2	2.3 ± 0.8	1.1 ± 0.1
2	102	193	2	13.9 ± 2.3	8.7 ± 1.8	3.5 ± 1.5	2.6 ± 0.4

RESULTS & DISCUSSION

Filling material properties

Fine fragments' (<0.3 mm) proportion should not exceed 10% to avoid clogging issues Biochar had similar granulometry with sand (control material) besides the fine fragment (<0.3 mm), that also affected hydraulic conductivity. Both sand and biochar were quite uniform in terms of particle size. Recycled glass was less uniform and fine fragments were present at the range of biochar (Figure 2). Regarding porosity, sand and glass had the same porosity explained by the glass origin that is sand, while biochar had larger porosity. Gels' porosity was almost equal to 1.0, since it was a water absorbent material, which could be expanded more than 100 times in volume terms (Figure 2).

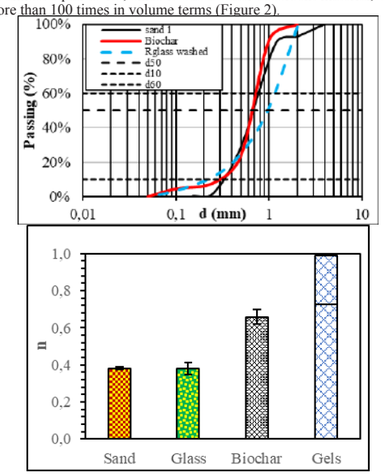

Figure 2. Left: Granulometric curves for the tested materials. Right: Porosity of the tested materials

Hydraulic performance

The hydraulic conductivity of the recycled glass was in the same order of magnitude with sand (0.16 and 0.22 cm/s, respectively), but its reduced percolation was attributed to the presence of very fine fragments in a greater proportion than in sand. Biochar had the slowest percolation (0.04 cm/s), being almost 6 times slower than sand due to the presence of significant amount of fine particles (<0.3 mm) (Figure 3). The test repetition up to PVF 20 indicated that only couple of repetitions are not enough to obtain a steady value which – here – came after PVF 6 -8. This was due to the presence of unsaturated zones inside the material and indicated the need for repetition. Due to the biochar slow percolation volume of added water among PVF 8 and PVF 20 no measurement was performed.

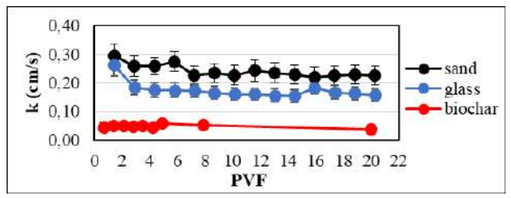

Figure 3. Hydraulic conductivity calculation up to PVF 20

Treatment performance

TSS and COD removal was high for all the tested materials except from gels' COD removal, which was due to the material's self-release of soluble COD (Figure 4). In the latter case, the large deviation of the results was due to the gradual decrease of this COD release, which was less during the second period. Ammonium removal was initially due to adsorption/ion exchange, while nitrification increased relatively fast for sand, biochar and gels. It took more the 100 days for biochar to develop nitrification mechanism and, even after this happened, ammonium adsorption was still a major removal mechanism. The NH_4-N adsorption capacity of sand, glass and gels was almost depleted after the forementioned period and nitrification was the dominant removal (transformation) mechanism thereafter.

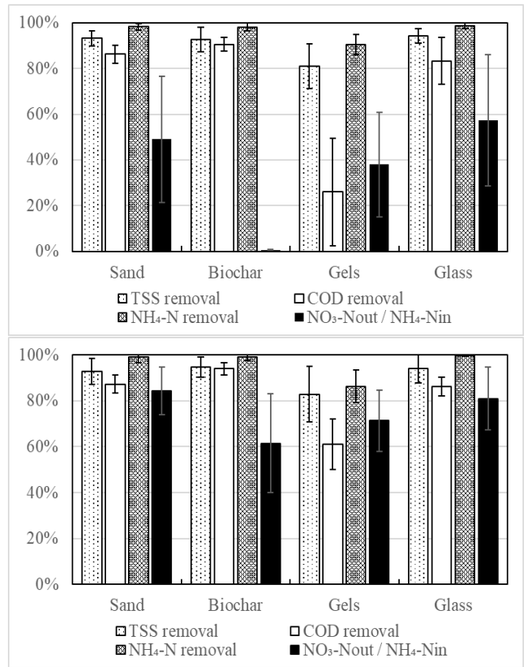

Figure 4 Filling material's performance (average ± st.dev) for period 1 (left) and period 2 (right)

CONCLUSION

All the materials appeared to be suitable to use in unsaturated VSSF CWs applications based on their hydraulic performance and, according to the ongoing results of treatment performance, biofilm growth seemed possible to all materials. However, the leaching of COD is an issue of concern for the gels.

Abstract
Water scarcity in Southern European cities presents challenges for the implementation of Nature-based solutions (NbS) in urban environments, particularly during dry warm periods. The NICE project promotes the use of NbS within the urban water cycle for river basin restauration and the treatment and reuse of wastewater, greywater, stormwater and combined sewer overflow. This communication provides a description of the approach followed to mitigate these challenges in the implementation of NbS pilots in Algeciras and Madrid.

Keywords (maximum 6 in alphabetical order)
Nature-based solution; Sustainable; Grey water; Storm water; Wastewater; Combined Sewer Overflow

INTRODUCTION

Water scarcity in cities may be defined as a structural imbalance between available water and demand, which changes with the seasons and the changing nature of economic activities such as industrial and urban use, including tourism and commercial activities. In Southern Europe, one of the main reasons for water scarcity in cities is the combination of increased demand for water during the warm months due to increased tourism and agricultural production, with a reduced precipitation during this period (EIT Climate-KIC, 2022).

Nature-based Solutions (NbS) are sustainable technologies that are being under consideration for their integration in urban water management transitioning towards more sustainable water, sewerage and storm water systems. NbS can constitute an attractive and integral part of the urban landscape, and provide services such as pollution and runoff mitigation, climate change adaptation, river basin and biodiversity restauration and increasing water availability (Boano et al., 2020).

However, their implementation in Southern European cities faces important challenges. Warm periods with limited rainfall extend several months, increasing the risk of water stress on the plants in the case of lack of water supply for treatment. This may result in an impact on the aesthetic values associated to NbS technologies, reducing their acceptance from the citizens. This communication presents the approach followed by two NbS case studies in Southern Europe in the context of the H2020 NICE project.

H2020 NICE

The NICE project aims to promote the use of NbS as circular urban water solutions. The project will cover the whole urban water cycle: wastewater (WW), greywater (GW), river basins (RB), stormwater runoff (SW) and combined sewer overflow (CSO).

High-potential NbS technologies such as green walls, vegetated rooftops, rain gardens and constructed wetlands will be enhanced with especially tailored bioaugmentation strategies, reactive materials and filling media, novel design and plants in order to obtain highly innovative and efficient NbS for urban water management.

These enhancements will be validated at 11 urban pilots or “Urban Real Labs” (URLs) with a surface of 20-100 m^2. The URLs will be located in 8 countries with different climate, geographical, environmental and socioeconomic characteristics, including large, medium-size and small urban areas. Other pilots will be installed in 4 of the 7 NICE fellow cities.

Five of the URLs will be built and validated in Spain, in order to evaluate NbS under Southern European warm temperate and dry summer climate conditions. AQUALIA will collaborate with EcoBIRD, IRIDRA and other project partners in the design of these systems and will be responsible for their construction and validation. The integration of two of these pilots in the urban environment is provided below.

URL 3: Algeciras

Algeciras is the largest urban area in Campo de Gibraltar (Southwest Spain) with >260.000 inhabitants and the 7th largest port in the EU. Storms are common between autumn and spring, causing severe runoff events from the city to the adjacent port.

A constructed wetland pilot will treat storm water abstracted from the stormwater network in order to demonstrate the potential of NbS to prevent undesired runoff events to the port. The pilot will be built integrated in the surroundings of the Bay of Algeciras boardwalk. The main challenge in the design is the almost absence of rain and the warm temperatures in the period May – September which is likely to cause strong evapotranspiration and hydric stress to the wetland. To prevent this, the project considers the intervention in a local High School next to the location of the pilot, in order to separate and collect up to 2 m^3/day of greywater to be treated in the NbS.

The innovative pilot will be designed as a vertical and horizontal flow constructed wetland combining the treatment of both greywater and stormwater. The discharge will maintain saturated conditions in the filter, allowing enough water for the plants to survive the dry summer period.Plants adapted to the local climate and therefore to periods of water stress will be selected.

URL 6: Madrid

Madrid is a large urban area with >6.3M inhabitants with strong temperature differences between winter and summer. As most of the European cities that has to face with climate change by improving its resilience to extreme events (rain and temperature), NbS will help to mitigate the flooding risk, Heat Island effect, reuse locally stormwater or wastewater and bring many others ecosystem services. Construction of a pilot in a large office building (Aqualia FCC Corporative Offices) will be representative for the future replication of NbS technologies in the urban centre of large EU cities.

New connections in the toilets of the bathrooms within the building will allow the collection of greywater. Two NICE pilots are being considered at this point: a constructed wetland pilot will treat greywater in a plot located at the ground level in the back street of the building, whereas a green rooftop will be used for potential greywater treatment and mitigation of strong temperatures during summer. Greywater treatment and consumption will be monitored to evaluate the reduction in water use for irrigation, and the reduction of water being discharged to the sewer. The regular occupancy of the building even during summer will allow continuous generation of greywater required for the maintenance of the NbS.

Abstract

Nature-based Solutions (NBS) become a complementary solution for decentralised water management. They are extensive technologies that require urban planning. The MULTISOURCE decision-support tool will facilitate selection and provide pre-sizing of NBS. The tool will assist decision-makers to choose the best technology for a given scenario regarding wastewater treatment and operational requirements. This study concerns mainly its pre-sizing module.

To mitigate models predictions unacurracies, we test the hypothesis that hybrid modelling can improve model predictions for NBS pre-sizing. We propose a methodology from the gathering and validation of data, to the development and validation of a hybrid model for horizontal subsurface flow TW. Hybridisation is restrained to the use of the tank-in-series model and a learning model.

We expect that this methodolody for hybrid modelling will lead to more reliable predictions of NBS functionning and design, hence better assessment of the feasibility of their implementation.

INTRODUCTION

Urban water management faces challenges in water resource preservation and pollution control with underground water scarcity and propagation of sanitary and environmental risks. The European regulations 2020/741 offer an alternative to activities consuming water through the controlled use of non-conventional water source, in particular: treated wastewater reuse.

Treatment wetlands for circular cities

Wastewater is conventionally centralised and evacuated towards a treatment plant (WWTP). But in some cases, centralisation has overpassed a threshold where the capacity of the WWTP is overwhelmed and costs in sewer network and pumping "exceed the economies of scale of the WWTP" (Eggimann et al. 2015). A complementary solution to treat wastewater in this context and in case of urban expansion is the use of Nature-Based Solutions (NBS), in particular treatment wetlands (TW). They are extensive but flexible technologies: there exist multiple designs and can be implemented within cities at different scales, providing an alternative source of water and co-benefits (Langergraber et al. 2021).

Decision-making support systems

To facilitate projects of urban wastewater treatment and reuse, decision-making support systems are developed. In particular, SNAPP tool (https://mltsrc-snapp.icradev.cat/) has been implemented by the Catalan Institute for Water Research (ICRA) to ease selection and pre-sizing of all possible NBS (Acuña et al., 2023, IWA 2021). The selection and pre-sizing modules rely on an expert-driven and a data-driven approach respectively. The first module selects among 27 different natural treatment technologies the ones that fulfill a given scenario, based on inlet concentrations and outlet requirements. The data to develop the data-driven pre-sizing module was retrieved from scientific papers (329 papers for all technologies, and ~ 180 case studies for TW).

Further development of SNAPP tool is ongoing in the framework of the MULTISOURCE European project (https://multisource.eu/). New features will include a multi-criteria decision analysis that not only consider treatment performances but also costs (OPEX and CAPEX), environmental impacts based on a life-cycle analysis and multifunctionality in terms of ecosystem services provided. Finally, the pre-sizing module will be also upgraded to mitigate current prediction inaccuracies.

Multiple models

Multiple models are developed for treatment wetlands: from fully expert-driven (mechanistic) for description or design, including hydraulics, transport, microbial growth, pollutant degradation, clogging, etc. (Samsó et al. 2016; Meyer et al. 2015), to fully data-driven (empirical) models (Rousseau et al. 2004).

Models limits.

Learning or data-driven models require data which is difficult and expensive to produce for TW. Often, models developed overfit data leading to bad prediction, and they do not offer a proper physical understanding of the process. Mechanistic models present the drawback of either high mathematical complexity of describing a process, or the oversimplification of the process. Many mechanistic models also rely on experimentally determined parameters.

Hybrid modelling.

Hybrid models are developed such that models can balance out each other's drawbacks. There exist multiple hybridisation methods: corrective, compositional (or serial), embedded (IWA 2020). The hypothesis tested in this project is that following a rigorous methodology for hybrid modelling of TW leads to more reliable predictions than current individual models.

MATERIAL AND METHODS

Dataset construction

A dataset is formed from pollutant removal performances of NBS Technological Units (NBS TU) reported in the scientific literature. Focus is made on horizontal flow TW, however, vertical flow TW and free water surface flow TW were also reported in the final dataset.

Data collection.

Data are extracted from peer-reviewed papers obtained from two rounds of searches (from Web Of Science and from SCOPUS). Papers are downloaded if presenting adequate title and abstract, filtered with a script based on defined terms and selected after full reading.

Dataset storage.

Finally data are aggregated in an online database hosted by ICRA, with a data structure and terminology based on an ontology for TW description.

Data validation and preparation

A script is developed based on data reconciliation methodologies for experimental data (Rieger et al. 2010) to: (i) check unusual/outliers values (concentrations, dimensions) and measuring errors (compounds relationships), (ii) convert concentrations of compounds into N and P-equivalents when applicable, and (iii) impute missing data from other variables and expert knowledge (compounds concentrations, temperature, location coordinates).

Then, Factor Analysis of Mixed Data (FAMD) and Focused-Principal-Component Analysis (F-PCA) are used to determine relevant variables for learning models. FAMD handles continuous and categorical variables and F-PCA visualises variance relative to a given variable.

Model development

Corrective and compositional hybrid modelling is done coupling the tank-in-series (TIS) model to machine learning models. TIS model represents the functioning of a treatment wetland as a series of N Continuously-Stirred Tank Reactors, where N is determined empirically (von Sperling et al. 2023). These models are also compared to data-driven models, i.e. linear, power and exponential regression models where the surface S is predicted from the inlet load L_{in} and the outlet load L_{out} of the TW.

Model validation

The dataset is divided into a train and a test set (0.8:0.2 ratio) and Leave-one-out Cross-Validation is performed on the empirical models with the train set to avoid overfitting. Two efficiency criteria (Hauduc et al. 2015) are used to assess models performances:

- Determination (Nash-Sutcliffe) coefficient (closer to 1^- the better):

$$R^2 = 1 - \frac{\sum_{i=1}^{n} (O_i - P_i)^2}{\sum_{i=1}^{n} (O_i - \bar{O})^2}$$

- Normalised Maximum Error (MEn, closer to 0^+ the better):

$$MEn = max\left|\frac{O_i - P_i}{O}\right|$$

RESULTS AND DISCUSSION

Dataset construction

Data extraction method is described in Figure 1. It resulted in 614 papers downloaded and 381 papers filtered. Some false-negative cases are due to different nomenclature of compounds and non-legible formats of tables/figures for the script. Half of filtered papers are eventually reported in the database. The exclusion of others is notably due to missing elements in the technology description (dimensions, flowrate, concentrations), irrelevant type of water, contaminants and laboratory scale. Struggles to gather data point out the need for more rigorous reporting and characterisation of technologies and study conditions.

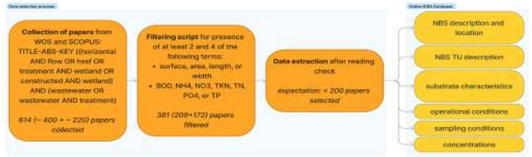

Figure 1. Database creation workflow

Comparison of models

Assessment of prediction performances on a test set for TIS model and regression models is reported in Table 1. Depending on the test set, varying performances are obtained for both types of models on *NO3* outflow predictions, as well as for *TN* and *TP*.

Table 1. Comparison of performances for mechanistic and empirical models on prediction of C_{out} and L_{out} values of a given test set.

		TIS model		Data-driven (linear, power or exponential regression)	
Parameter of interest	**Total number of points in dataset**	$C_{out} = tis(C_{in}, inflow\ rate, surface)$		$L_{out} = m(L_{in}, surface)$	
		R^2 for test set	**MEn for test set**	**R^2 for test set**	**MEn for test set**
BOD	87	0.66	1.90	0.83 exp	5.99..
NH4	65	0.98	0.86	0.85 lin	3.99
NO3	38	0.54	1.42	0.65 exp	1.41
TN	81	0.72	0.96	0.94 exp	3.61
TP	57	0.24	1.93	0.99.. lin	0.26

Variables selection

In cases where model performances vary greatly, other potential explanatory variables are assessed for development of new learning models. These models will be coupled with TIS model. Exploratory tools are used on *NO3* dataset. Figure 2. shows variance described according to quantitative and categorical variables using FAMD.

Figure 2. Variance of *NO3* dataset explained by ~ 50% by two principal components using FAMD.

Future hybrid models

The objective of the methodology is to propose a flexible and adequate modelling of TW according to available knowledge and data. This ongoing study shows that with limited data and TIS model available, a regularisation with a hybrid model provides more reliable predictions. Further research will be done for the cases in-between and testing other hybrid models. We aim at a rigorous methodology for hybrid modelling leading to more reliable predictions of NBS functioning and surface area requirements, hence better assessment of the feasibility of the NBS implementation.

ACKNOWLEDGEMENTS

This project is part of MULTISOURCE European project, which has received funding from the European Union's Horizon H2020 innovation action programme under grant agreement 101003527. This particular research in collaboration between INRAE and ICRA has also received fundings from the International School of Research of Agreenium Alliance (EIR-A) and from H2O'Lyon university school of research on water and hydrosystems sciences.

ECO STP 2023

Are circular economy strategies always environmentally sustainable? Including the end-of-life stage when assessing seafood plastic packaging

Jessica Pérez-García, Brais Vázquez-Vázquez and Almudena Hospido

CRETUS, Department of Chemical Engineering, Universidade de Santiago de Compostela, 15782, Santiago de Compostela, Spain

Abstract

Plastic litter is known to be one of the main global environmental concerns currently. Life Cycle Assessment (LCA) is the appropriate method to assess the environmental performance, nevertheless all process stages must be covered. To date, LCA does not normally include the impacts of the end-of-life (EoL) phase, in particular the unmanaged flows (i.e. direct plastic leak on the environment). By developing the characterization factors for two plastic packaging prototypes for the seafood industry, this study can cover the full life cycle of both materials. Results show that the inclusion of uncontrolled plastic waste causes significant impact on the environment.

Keywords:

Characterization factor; end of life; environmental impact, life cycle assessment, oil-based plastic

INTRODUCTION

The fish processing industry in Spain, and in particular Galicia, which accounts for 80% of total national production, it plays an important role in the world market. It is known that the activities seafood processing sector generate a complex wastewater with high pollutant load, so its correct treatment is essential (Roibás-Rozas et al., 2021)PHA accumulating capacity was below 10%, so several strategies were tested. In the acidification unit, Na(HCO3. Furthermore, this industry is highly dependent on oil-based plastic for use in the packaging of its products; polyethylene and polypropylene (PE and PP, respectively) are the most demanded plastics by this industry (Plastics Europe, 2021).

The national funded project BIOCENPLAS put together the National Association of Manufacturers of Canned Fish and Shellfish (ANFACO-CECOPESCA), the Galician Water Technology Centre (CETAQUA) and the academia (USC) to materialize circular strategies of waste valorization by means of transforming effluents rich in lipids from the seafood canning industry into biopolymers able to replace oil-based plastic (i.e. conventional plastic).

Over the last decades, it has become undeniable the significant impact of oil-based plastic in the ecosystem and the human health (Saling et al., 2020)the impacts of marine plastic debris are not considered. However, this type of particulates can be assessed like other emissions with the systematic and quantifiable approach in life cycle assessment (LCA. Currently, there are numerous studies addressing the environmental assessment of conventional plastics, but them only consider the stages cradle to gate, including raw material extraction, plastic production and moulding and waste management (landfill, incineration and recycling), regardless of plastics leakage associated with the use and the end-of-life stage (Figure 1) regardless of plastics leakage associated with the end-of-life stage (Marie et al., 2021; Saling et al., 2020){“id”:”ITEM-2”,”itemData”:{“DOI”:”10.1007/s11367-020-01802-z”,”ISSN”:”16147502”,”abstract”:”Purpose: Plastic pollution in marine environments is a severe problem in the world due to misuse and mismanagement of the materials. Microplastics are a specific form of pollutants in this context and its handling is very difficult due to its very small size of particulates. Currently, the impacts of marine plastic debris are not considered. However, this type of particulates can be assessed like other emissions with the systematic and quantifiable approach in life cycle assessment (LCA. So the aim of this work is to integrate the complete EoL stage in the life cycle environmental evaluation of two food packaging items, i.e. a sheet of polyethylene (PE) (120 x 120 mm) with a thickness of 100 µm which contains as a chemical additive bis(2-ethylhexyl) phthalate, and a tray of polypropylene (PP) (228 x 145 x 30 mm) with a thickness of 450 µm which contains dibutyl phthalate, selected as representative by the seafood.

METHODS

Life Cycle Assessment (LCA) is a standardized method (ISO 14040 and 14044) where inputs and outputs are transformed into potential environmental impacts by means of a four-stage procedure.

At the inventory stage, data were collected from companies of the sector, national and region al statistics of plastic waste management and secondary data (i.e. background processes for plastic production, transport, and so on) come from the Ecoinvent v3 database (Bishop et al., 2021)inventory completeness (e.g. inclusion of additives. According to Jambeck et al. (2015) the total uncontrolled waste depends on the country´s waste management systems, being estimated to be around 4% for Spain. For the EoL stage, the Plastic Leak Project (PLP) is, to the best of our knowledge, the only initiative that has developed a standardised methodology to quantify the plastic flows to each compartment environmental (Peano et al., 2020) and is the one followed here. So, the release rate of the plastic litter to the marine and terrestrial compartments are estimated based on the size of the material and its residual value, is defined as the probability of waste being reintroduced back into the value chain (Table 1), both materials are small size, and it has been assumed that PE has a low residual value while PP has a medium residual value.

At the impact assessment stage, impacts related to chemical released are measured as in eq. 1 where IS is the impact score, CF is the characterization factor, and M is the mass of substance emitted. Then, the CF is calculated considering the principal cause−effect chains; thus, through fate, exposure, and effect factors (FF, XF, and EF, respectively), according to eq. 2 (Rosenbaum et al., 2008).

$$IS = CF \cdot M \quad \text{(eq. 1)}$$

$$CF = FF \cdot XF \cdot EF \quad \text{(eq. 2)}$$

The FF is associated to the plastic transport and their fragmentation and degradation, it represents the residence time of the plastic in the compartments and is expressed in days, and it was modelled according Corella-Puertas et al., 2022, where the rate of degradation involves mass loss in each compartment calculated by a kinetic of first order. The EF deals with the sensitivity of the species to the released pollutant and is expressed in PAF m^3/kg. EF is modelled under the USEtox perspective by Species Sensitivity Distribution (SSD) curve that is determined by the concentration of the pollutant released in relation to the variation of the affected species studied (Rosenbaum et al., 2008). The USEtox model considers both the exposure and the concentration of the pollutant in the final compartment, considering the effect on the species affected by the exposure. The XF states the probability of exposure of living organisms by the release of the pollutant into the final compartment.

Recipe 2016 v1 was the chosen impact assessment method as it addresses the most appropriate categories for this system (Bishop et al., 2021)inventory completeness (e.g. inclusion of additives, complemented with the development of specific CF for plastic materials leakage in the natural environment following Corella-Puertas et al. (2022).

RESULTS & DISCUSSION

The contribution of each stage of the process (excluding EoL) to the selected impact categories is presented in the Figure 2 for each material. Both plastic items have similar environmental profiles, with significant contribution observed from the production and moulding stages in all categories, followed by intermediate transport (includes all transport of packaging and plastic waste). In terms of waste management, it is worth highlighting the environmental benefit derived from recycling, negatives values in the Figure 2, and the low contribution of incineration and landfilling.

Concerning EoL stage, the results of CFs are shown in Table 2. The higher values of the FF are linked to a slow degradation of plastic in each compartment mainly due to increased persistence. Regarding EF, it is observed in the SSD curves (Figure 3) that when the additives concentration present in the plastic increases the effect in the species is higher.

The impacts caused by plastic leakage are relevant (Table 3) and the inclusion of theses environment impacts contribute up to 40% of quality ecosystem. Therefore, this work shows that incorporating impacts caused by plastic leakage can aid in addressing these environmental problems.

Taking everything into account, there is an uncertainty in the development of characterization factor for the quantification of environmental impacts that need more research.

Abstract
The production of Volatile Fatty Acids (VFA) from wastewater is an interesting process that contributes to the transition of Wastewater Treatment Plants (WWTP) into resource recovery facilities. This transition needs to be supported by a better environmental performance, so Life Cycle Assessment (LCA) was used to evaluate the production of VFA from dairy wastewaters and to compare it to the actual treatment process. Two major limitations were identified in that comparison: i) a fermentation yield of at least 0.34 g VFA-COD/ g CODin is required to be environmentally competitive; and ii) the use of ethyl acetate as extraction solvent is a significant bottleneck due to its high environmental cost across all evaluated impact categories. Although this technology was proven not mature enough to replace the business-as-usual approach at this stage, these results will help shaped the next steps of its development.

Keywords
Environmental performance, Life Cycle Assessment, Resource recovery

INTRODUCTION

To address the challenges faced by society, including climate change, and environmental degradation, and ensure the sustainability of further generations, a paradigm shift from linear economy (extract-use-dispose) to circular economy (extract-use-recycle) must occur. In the case of wastewater (WW) management, moving from the simple treatment and discharge alternative to the recovery of valuable substances strategy, is an interesting, and usually more sustainable approach. Wastewater from food processing industries often contains high amounts of organic matter and nutrients such as Nitrogen (N) and Phosphorous (P). Although research shows the potential for resource recovery in food-processing WW, this practice is not commonly applied in industrial settings apart from anaerobic digestion to obtain biogas (Stasinakis et al., 2022).

Volatile Fatty Acids (VFA) production is among the innovative routes of valorisation being studied because of their high demand and market value and for its potential to displace their petro-chemical analogues (Atasoy et al., 2018). These new valorisation approaches present great interest due to their perceived lower environmental impact; however, this needs to be assessed and proved, as not all circular economy initiatives are intrinsically contributing positively to sustainability. Life Cycle Assessment (LCA) is presented as a systematic methodology capable of quantifying the environmental burdens associated with products, processes, and services along their respective life cycle and is widely used at an early stage of technology development (van der Giesen et al., 2020).

The dairy industry is a key sector of the Spanish economy with an approximate turnover of 9,500 million euros per year (FENIL, n.d.). Dairy processing plants generate significant amounts of wastewater. Around 4.6 L/kg of WW are generated in fermented milk products and up to 3.25 L/kg in cheese production. Although dependent on the production processes, organic loads are often high enough to merit some form of treatment before discharge (Stasinakis et al., 2022).
The purpose of this work is twofold: firstly, to quantify the environmental impacts associated with a novel technology to produce VFA from dairy wastewater and secondly, to compare the environmental performance of this valorisation strategy to the environmental impacts of the current treatment option in the dairy industry.

SELECTED CASE STUDY

Wastewater from a dairy industry located in Pontevedra (NW Spain) that produces yoghurt and cheese was selected as feed because it presented not only a higher VFA potential production on laboratory scale test but also better technical viability in terms of feed availability and stability than the other industrial WW tested. The characteristics of this particular waste stream (i.e., virtually all its COD is soluble, and no significant amount of fats are present) favour the anaerobic fermentation of this stream and thus VFA production.

The selected feed is an ultrafiltration (UF) permeate that is separated at the dairy industry and managed as a residual stream (Figure 1a) where some low-value added valorisation occurs: the UF permeate is sent to a nanofiltration (NF) unit, and the retentate is sent to evaporation to obtain a powder that is then converted into animal feed, while the permeate is treated in an industrial wastewater treatment plant (IWWTP) before being discharge to the sewage.

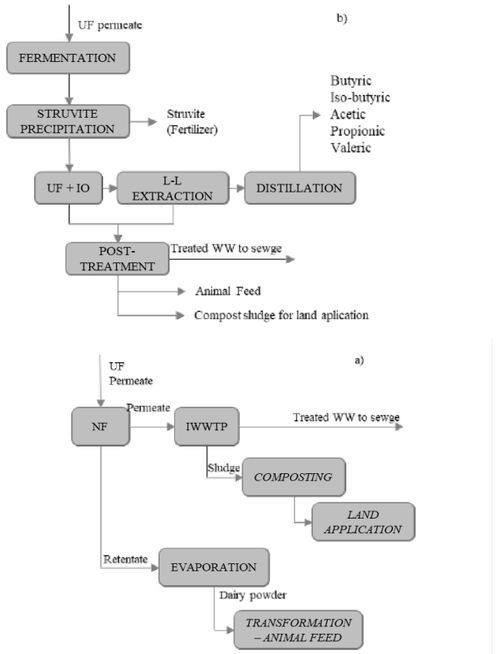

Figure 1: Process schemes for current treatment (a) and novel VFA production (b)

The novel valorisation scheme (Figure 1b) consists of the fermentation of the UF permeate to inhibit methane production and obtain VFA. Afterwards, VFA are separated, concentrated, and purified to recover the different acids individually and other added value products (e.g., struvite). Along the VFA downstream train, several residual streams are generated that will need further treatment before being ready for discharge.

The function of both processes is to manage the UF permeate produced at the dairy industry, so the functional unit (FU) has been defined based on its daily production (34 m^3) and stated in terms of organic load (1882.73 kg of $COD_{soluble}$/ day). No environmental loads were allocated to the UF permeate as it is considered a residual stream and all the burdens were then allocated to the main products of the dairy industry (yoghurt and cheese). Additionally, only the operation stage was considered. Given the significant uncertainty associated with these activities in this early stage of technology development (van der Giesen et al., 2020), the construction and dismantling of the required facilities, the distribution, commercialization, and use of all the obtained products in both scenarios were left outside the scope of the study.

INVENTORY STRATEGY AND IMPACT ASSESSMENT METHOD

Different sources of data were used to compile both scenario life cycle inventories. Primary data from the operation of the dairy plant was used, alongside with the results from operating pilot plants of the novel technology. Additionally, lab-scale tests combined with computer simulation were used for modelling the liquid-liquid extraction and distillation stage, as no pilot scale results were available at the time. Finally, other necessary information was obtained from bibliographical sources as well as LCA databases.

ReCiPe 2016 was chosen as the impact assessment method and the selected categories were: Global Warming Potential (GWP), Terrestrial Acidification (TA), Freshwater Eutrophication (FE), Marine Eutrophication (ME) and Fossil Resource Scarcity (FRS).

RESULTS

The results show that with the average fermentation yield obtained in the VFA production pilot plant (0.16 gCOD-VFA/$gCOD_{in}$), the novel technology presents higher environmental impacts in 4 of the 5 studied impact categories (Figure 2). The main reasons behind this are the low fermentation yield and the use of ethyl acetate as solvent for the liquid-liquid extraction stage. Meaning at this point the current scheme is more sustainable. Different additional scenarios were analysed to determine the technology hotspots and possible solutions.

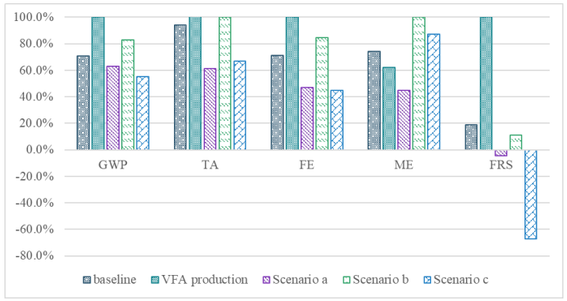

Figure 2: Normalized life cycle characterization results for the evaluated scenarios.

When the highest reported fermentation yield for dairy WW was used (i.e., 0.39 g VFA-COD/g COD_{in}) according to Magdalena et al., 2019 the production of VFA has a lower environmental impact across all categories regardless of the type of solvent use (Figure 2, scenario a).

As mentioned before, the use of ethyl acetate as solvent implies significant environmental loads. A scenario involving the use of a "bio ethyl acetate" produced by esterification of acetic acid with bioethanol instead of the petro-based was analysed (Figure 2, scenario b). The results showed a reduction of the environmental impact across categories. However, these impacts are still higher than the baseline in all but the FRS category. This result reinforces the hypothesis that although ethyl acetate places an important role in the environmental performance of the VFA production the biggest challenge is still unconverted COD and its means of treatment.

The use of a bio-solvent reduces the environmental burden of the VFA production in the GWP, TA, FE and FRS impact categories (Figure 2, scenario b). For the ME impact category, the trend reverses from the original setting (where the VFA production had a lower impact than the baseline). This occurs, because the bioethanol process used for the assessments is obtained from the fermentation of rye and carries a significantly bigger impact in this category that is then transferred to the Bio ethyl acetate. Even when the highest yield obtained in the pilot plant (i.e., 0.334 g VFA-COD/g COD_{in}) is combined with bio-based solvent the ME category continues to have a larger impact than the baseline (Figure 2, scenario c). Showing that not always the bio – product is the most sustainable choice, and that a detailed and holistic study of each situation is needed.

CONCLUSIONS

The production of VFA from dairy industry WW is shown to have the potential to be a more sustainable approach than treatment once certain challenges are overcome. Mainly higher fermentation yields are necessary and further research into alternative extraction solvents.

The results obtained in the pilot plant show that it is possible to reach the breakpoint of the technology. The conclusions of this LCA can now inform further pilot tests and assist in decision making surrounding the next steps in the technology development.

Abstract

Desalination sector faces environmental and economic challenges due to brine discharge. Treating brine and recovering valuable materials from it, potentially brings environmental and economic benefits. This is addressed by the Minimal Liquid Discharge (MLD) and Zero Liquid Discharge (ZLD) approaches; however, to analyse the full potential, a sustainability assessment is required. Additionally, as both, MLD and ZLD, approaches are based on circular economy model, it is also important to ensure a sustainable transition from linear to circular practices in the desalination sector by measuring the circularity level. The preliminary Life Cycle Assessment (LCA) results show that the water produced by the MLD has overall higher environmental impacts compared to the reverse osmosis, mainly due to the higher energy consumption. On the other hand, the minerals production shown a significant lower impact compared to mining scenarios, showing that brine as a secondary source could reduce environmental pressure caused during the mineral's extraction stage.

Assessment; Circularity; Minimal Liquid Discharge; Sustainability

INTRODUCTION

Desalination technologies has received increased attention in recent years as a viable option to meet the fresh water domestic and municipal needs, however they face challenges due to certain barriers related with relatively high economic costs and diverse environmental problems (Jones et al., 2019). Desalination plants produce a saline wastewater, brine, as a by-product, resulting from separating water from the salts, and therefore it is seen as a waste that desalination plants should further deal with. The amount of global brine produced by desalination plants was calculated to be around 129 000 000 m^3/d (IDA, 2019), and coastally-located desalination plants and facilities usually discharge brine back into the sea, potentially causing issues with the ecosystem and the environment (Ogunbiyi et al., 2021). Treating brine is seen as a beneficial option to eliminate its impact, increasing the water production yield, and extracting valuable materials (Panagopoulos and Haralambous, 2020). The brine contains a mixture of metals and minerals at various concentrations with recovery potential, and economic advantages. Salts, such as NaCl, Na_2SO_4, $Mg(OH)_2$ and $Ca(OH)_2$ are potentially recoverable resources from the brine (Morgante et al., 2022; Culcasi et al., 2022). This practice is in line with the circular economy model that has been promoted by European Union (Panagopoulos and Haralambous, 2020), therefore measuring and assessing the circularity level (e.g. minimal or no waste, limited emissions and efficient resource utilization) is an important step to ensure a sustainable transition from linear to circular practice. Recent works have evaluated different Minimal Liquid Discharge (MLD) and Zero Liquid Discharge (ZLD) concepts from a techno-economic point of view (Morgante et al., 2022; Panagopoulus, 2022), however we still lack a comprehensive circularity and sustainability assessment. Therefore, the objective of this work is to measure and assess the circularity and sustainability level of a MLD system configuration that desalinates seawater and produces water, while recovering valuable materials like NaCl, Na_2SO_4, $Mg(OH)_2$ and $Ca(OH)_2$. To address this, a methodology has been used to measure the circularity and sustainability performance of the MLD at a process and product level.

MATERIALS AND METHODS

MLD description

The system under investigation has been operated at pilot-scale in the Lampedusa (Italy) desalination plant, therefore the full-scale scenario was modelled. The MLD is composed of 7 technologies (Figure 1) – i.e. Multimedia filtration (MMF) Nanofiltration (NF), Multi-effect distillation (MED), Thermal crystallizer (TC), Multiple feed plug flow reactor (MF-PFR), Eutectic freeze crystallizer (EFC) and Electrodialysis with bipolar membrane (EDBM). The resulting products are: Industrial water, NaCl, $Mg(OH)_2$, $Ca(OH)_2$ and Na_2SO_4. The EDBM produces NaOH and HCL, and both are used onsite in the process. The flowrate of raw seawater is 3000 m^3/d, and the thermal energy consumed by the MED and TC is supplied by Lampedusa power station. Additionally, antiscalant and NaOH are sourced externally. The NaOH produced in the EDBM is not enough to cover the demand for $Mg(OH)_2$ and $Ca(OH)_2$. The ions composition of the streams and flowrates of products are given in Table 1 and 2.

Circular and sustainable measurement and assessment

The scope of the assessment is to measure the circularity and sustainability of the MLD products (Industrial water, NaCl, $Mg(OH)_2$, $Ca(OH)_2$ and Na_2SO_4) and to compare them with conventional productions (e.g. seawater reverse osmosis (SWRO), mining). Data for the conventional production (e.g. mining) scenarios are collected from the Ecoinvent database v3.8. The system boundaries are cradle-to-gate, i.e., they include the MLD system, production and transportation of the MLD products. Therefore, the functional unit of the assessment is 1 kg of each MLD product. The circular measurement and assessment are based on the methodology developed by Nika et al., 2022 (figure 2). The methodology includes the system development that identifies the information needed for indicator selection, the type of measurements and models required, while also resulting in a system testing of the indicators (sensitivity to changes), and finally, the circularity assessment. The selected circularity indicators focus on the resources, water and energy categories at product level (e.g. energy intensity per product). The objective is to assess and compare the resources demand (e.g. Na, Cl, K, Mg, Ca, SO4, others) for the MLD products, and compare with the conventional products, e.g. how much virgin non-renewable resources are required per product. Moreover, with a similar objective, water and energy related circularity indicators have been calculated for the MLD products and conventional products. The sustainability assessment is performed through established methodologies, such as Life Cycle Assessment (LCA), Life Cycle Costing (LCC) and social LCA (sLCA).

RESULTS AND DISCUSSION

Figures 3, 4 and 5 show the LCA results (the $Mg(OH)_2$ and Na_2SO_4 results will be presented in the full manuscript) for the reference products. The industrial water produced by the MLD system results in higher environmental impacts than the SWRO. The global warming impact score is close to 80% reduction for SWRO. Energy requirements of the MED can be 5-6 times higher than the conventional SWRO (Raluy et al., 2006), and because the source of electrical energy in the current study are the diesel engines, this explains the higher impact on global warming. Additionally, as the MED receives the permeate from the MF-PFR and NF processes, a fraction of energy consumption of these processes is allocated to the water production. A climate change impact reduction is expected if solar-driven is integrated with the MED (Alhaj et al., 2022). On the other hand, the MLD production of NaCl and $Ca(OH)_2$ results in environmental benefits when compared with conventional production of these products. Regarding the production minerals and metals, studies have demonstrated that the mining and beneficiation (separation/concentration processes before refining) stages contribute significantly to the environmental performance (Marmiroli et al, 2022). Despite, the use of secondary sources (e.g. brine) will not fully cover the demand for minerals (Marmiroli et al, 2022), the MLD shows a significantly smaller impacts on minerals production. Similar results are seen for $Mg(OH)_2$ and Na_2SO_4.

A detailed circularity and sustainability assessment will be further presented in the full manuscript, and the results will be discussed.

Abstract

Phosphorus (P) is an essential agricultural nutrient. Mineral P fertilizers are produced from phosphate rock; the associated environmental impacts have been assessed with life cycle analysis (LCA) studies. LCAs quantify the impacts of a product or process based on a functional unit for a defined system boundary. LCAs have also assessed processes that recover P as a fertilizer from municipal wastewater treatment facilities. Only a few LCA studies compare mineral and recovered P fertilizer production processes simultaneously. This work reviews, compares, and contrasts the functional units, impact categories, and system boundaries of peer-reviewed LCAs for mineral and/or recovered P fertilizer production. Variances in the functional units, impact assessment categories, and system boundaries limit meaningful comparisons. A metric tonne of P and/or P_2O_5 functional unit would improve LCA comparisons. Reasons for improbable standardization of impact criteria or system boundaries for mineral and recovered P-fertilizer are discussed.

Keywords (maximum 6 in alphabetical order)

INTRODUCTION

Phosphorus (P) is a vital nutrient for agricultural productivity, second only to nitrogen (N) in importance (Sharma, Sayyed, Trivedi, & Gobi, 2013)in both organic and inorganic forms, its availability is restricted as it occurs mostly in insoluble forms. The P content in average soil is about 0.05 % (w/w. Soluble phosphate is a component of fertilizers that is critical for global food production. Unlike ammonia production from N and hydrogen gases with the Haber-Bosch process, phosphate cannot be synthetically produced (Cordell, Drangert, & White, 2009)-- it is refined from mined "phosphate rock". P-rich ores are primarily located in Morocco, China, and the US. Global P supply chains and food security are therefore vulnerable to geopolitical instability (Rosemarin & Ekane, 2016)within the monitoring and regulation of these components, and surrounding the role of stakeholders in the process. As a result the intrinsic objectives of a governance system for P are not well formulated and yet to be implemented. Phosphorus is a mineral and is produced and marketed much like other minerals. But since P is also an essential element in our food systems, critical for all forms of life and very dispersed in different products, it requires special attention concerning data collaboration especially regarding rock phosphate (RP. Environmental concerns associated with mineral P fertilizer production include air and water emissions, eutrophication, and soil contamination with cadmium and uranium from sedimentary-type phosphate rock deposits (Lottermoser, 2010). Some mineral P demand may be replaced with P recovered from municipal wastewater treatment plants (WWTP) as struvite ($NH_4MgPO_4{\cdot}6H_2O$) or calcium phosphate (Egle, Zoboli, Thaler, Rechberger, & Zessner, 2014).
Effective comparisons of P-fertilizer production by primary (linear) technologies or secondary (circular) technologies can be undertaken with life cycle analyses (LCAs). LCAs require defined functional units (FU), impact categories (IC), and system boundaries. This work reviews and compares published LCAs for mineral P-fertilizer production and technologies for P-recovery for reuse as P-fertilizer. Significant variation in FU, IC, and system boundaries between and within LCAs for mineral P-fertilizer production and P-recovery processes prevents meaningful comparisons. The P-community may consider a standardized LCA approach to assess P-fertilizer production to guide the generation of future, comparable, LCA analyses.

MATERIALS AND METHODS

This review work was completed in two steps. The first step was a literature search using the keywords "life cycle analysis" and one or more of phosphorus, phosphorus recovery, phosphorus fertilizer, phosphorus processing, phosphate rock processing, wastewater treatment plant, wastewater, nutrient recovery, sewage sludge, struvite, and enhanced biological phosphorus removal (EBPR). The search engines Web of Science, Scopus, and Google Scholar identified 31 publications (Fig. 1). The second step compared, contrasted, and identified gaps between the FUs, ICs, and system boundaries in the LCA publications identified in Step 1.

RESULTS AND DISCUSSION

The subjects of the identified LCAs, and selected references, are presented in Fig. 1. Mineral P and recovered P fertilizer processes were compared with respect to LCA FUs, ICs, and system boundaries.

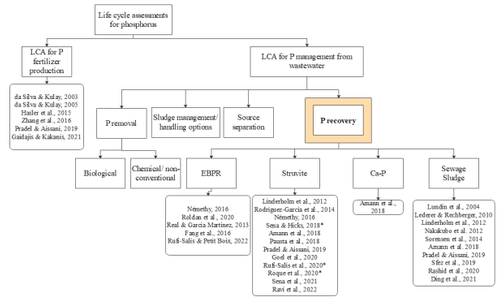

Figure 1. Themes identified in LCA studies of mineral P fertilizer production and P recovery from municipal wastewater. Review articles are indicated with *.

FUs for P fertilizers were masses of fertilizer (ex: monoammonium phosphate (MAP)), and/or P, and/or $\%P_2O_5$. FUs for recovered P from WWTP varied by definition and units. 25% of studies used the volume of treated wastewater as an FU. The recovered P mass (kg, ton, tonne, unspecified if metric or US short or long ton) or recovered rate (mass per year) was used for ~40% of LCAs. The P-product bioavailability was not assessed in any of the reviewed LCA studies. Other FUs for recovered P technologies included person equivalents and eutrophication potential reduction with respect to P removed. FUs used in thermal P-recovery technologies included "dry matter mass recovered" (40% of studies). The balance was "recovered P mass" or "annual P production". These different FUs limit meaningful LCA study comparisons.
Six IC methods were identified in the LCAs (Fig. 2A). The most common IC methods were ReCiPe (impact characterization factoring) and CML (product environmental impact). 47 specific ICs and their use frequency are presented in Fig 2B. Nearly 70% of the LCAs used global warming potential as an IC. Acidification and eutrophication were the next most frequent ICs.

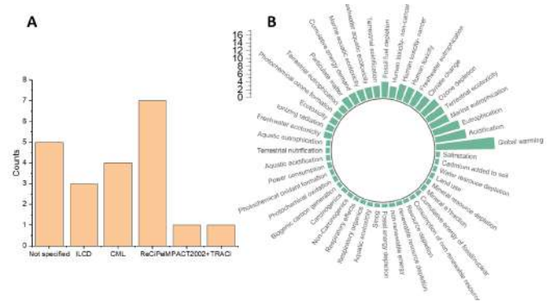

Figure 2.A LCA frameworks used in the studies assessed. **B** All impact assessment outcomes from the selected studies and the number of times they were studied.
System boundaries for LCAs of P fertilizer production are presented in Fig. 3. Most LCAs focused on mineral P production processes from phosphate rock. Mining and wastewater treatment were not included in all studies. LCA system boundaries for **P recovery from WWTP included P-recovery processes as struvite or calcium phosphate from water, sludge, and incinerated sludge ashes (Fig. 4).** The system boundaries covered P-fertilizer manufacture, field application, consumption, and wastewater treatment (Pausta, Razon, Promentilla, & Saroj, 2018), to smaller studies of a municipal wastewater treatment process (Zhou, Remy, Kabbe, & Barjenbruch, 2019). Few LCA studies directly compared mineral P production and recovered P-fertilizer production (Goel, Kansal, & Pfister, 2021; Linderholm, Tillman, & Mattsson, 2012).

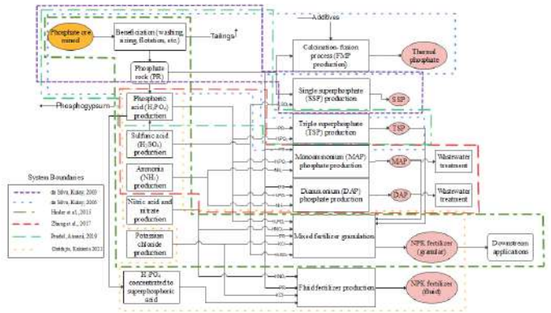

Figure 3. LCA system boundaries of different mineral P fertilizer production processes.

P-fertilizer LCA comparisons also have different inventory data types and qualities. Some LCAs analysed commercial, full-scale processes, others assessed pilot plant data or model data. Overall, this study shows how most mineral and recycled P-fertilizer production LCAs are not easily comparable due to different FUs, ICs, and system boundaries. A recommended general and potentially translatable FU for future LCAs across different P-fertilizer production options could be a metric tonne of P or P_2O_5. The wide range of options for ICs and system boundaries may preclude a common set for P-fertilizer production LCA studies.

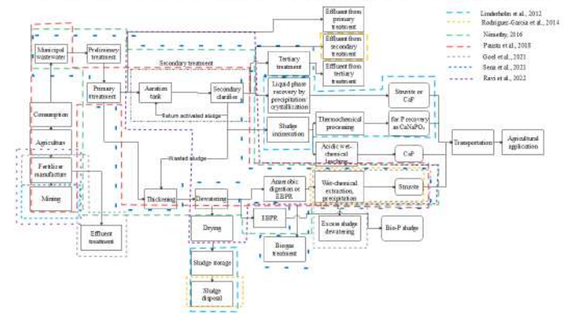

Figure 4. LCA system boundaries for P recovery from municipal wastewater solutions or solids.

End-user Perspective Life Cycle Environmental Impacts of Wastewater-derived Phosphorus Products

K. L. Lam

Division of Natural and Applied Sciences, Duke Kunshan University, 8 Duke Avenue, Kunshan, 215316, China

(E-mail: *kaleung.lam@dukekunshan.edu.cn)*

Abstract

Recovering phosphorus from wastewater in more concentrated forms has potential to sustainably recirculate phosphorus from cities to agriculture. This study assessed life cycle environmental impacts of substituting half of the conventional phosphorus rock-based fertilizers used in an average U.S. soybean production system with wastewater-derived phosphorus products (i.e., struvite, Ca-P, rhenania phosphate-like product, single superphosphate-like product) from six recovery pathways. The results show that the substitution reduces global warming, smog formation, acidification, eutrophication, and ecotoxicity potential of the assessed crop production system in most recovery pathways and scenarios. As more wastewater-derived products being available, this perspective contributes toward better understanding the potential systemic environmental consequences of a broader uptake of these products.

Keywords

Agricultural land application; environmental impacts; life cycle assessment; phosphorus recovery; resource recovery; wastewater

INTRODUCTION

Resource recovery from wastewater is gaining increasing attention, especially phosphorus recovery (Kehrein *et al.*, 2019). Depleting phosphate rock reserves is becoming a driver for phosphorus recovery. In wastewater treatment plants, phosphorus can be recovered in different concentrated forms (Harder *et al.*, 2019). The recovered phosphorus products can be used as fertilizers. Life cycle assessment (LCA) has been used to evaluate the potential environmental impacts of various wastewater-based phosphorus recovery and reuse opportunities (Diaz-Elsayed *et al.*, 2020; Lam *et al.*, 2020). Most LCA studies related to wastewater-based phosphorus recovery used the *process perspective* or the *product perspective* in their assessments (Figure 1) (Lam *et al.*, 2022).

This study assesses the life cycle environmental impacts of the agricultural use of wastewater-derived phosphorus products in an average U.S. soybean production system. It demonstrates the application of the *end-user perspective* to understand the life cycle environmental consequences of substituting conventional inputs with recovered products at the end user's product system.

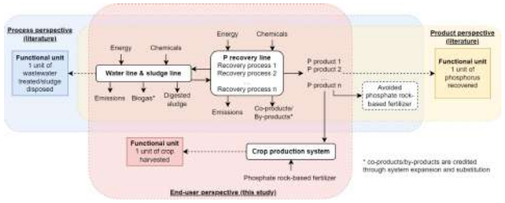

Figure 1. Process, product, and end-user perspectives of phosphorus recovery (Lam *et al.*, 2022).

MATERIALS AND METHODS

Goal and Scope

The primary goal of this study is to assess life cycle environmental impacts of substituting conventional phosphate rock-based fertilizers with wastewater-derived phosphorus products in crop production systems from the end-user perspective via six recovery pathways (Figure 2). Each pathway was modelled considering three different influent wastewater compositions, three alternative sludge disposal methods (incineration, landfill, land application), and three carbon intensity levels of grid electricity (low, medium, high).

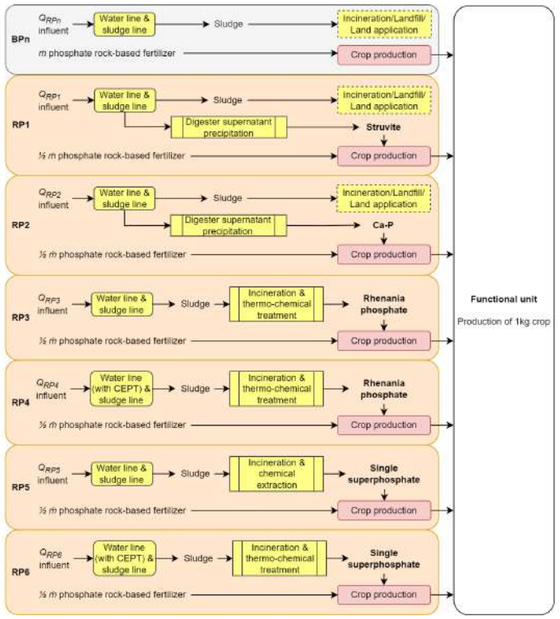

Figure 2. Baseline pathways (BPn) without P recovery and six possible P recovery pathways (RP1-RP6), differing in the recovered phosphorus products (i.e., struvite, Ca-P, rhenania phosphate-like product or single superphosphate-like product) and the possible inclusion of chemically enhanced primary treatment (CEPT) in the treatment line. For all RPs, the wastewater-derived phosphorus product was assumed to substitute half (½ ṁ) of the conventional phosphate rock-based fertilizers used in the baseline pathways (BPn). (Modified from Lam *et al.*, 2022).

Life Cycle Inventory

This study is based loosely on the U.S. context. The recovered phosphorus product inventory is from Lam *et al.* (2022), while the U.S. soybean production inventory is from Ecoinvent 3.6.

Impact Assessment

The Tool for Reduction and Assessment of Chemicals and Other Environmental Impacts (TRACI 2.1) was used as the impact assessment method. The LCA results are presented as the changes in impacts compared to those in the baseline scenarios.

RESULTS AND DISCUSSION

Life Cycle Environmental Impacts of Applying Wastewater-Derived Phosphorus Products

The LCA results are presented as the changes of life cycle environmental impacts compared to the baseline pathways (Figure 2). Substituting half of the conventional phosphate rock-based fertilizers originally used in the soybean production system with wastewater-derived phosphorus products from RP1, RP2, RP3, and RP4 reduces the assessed life cycle environmental impacts of these production systems in most scenarios. RP3, RP5, and RP6 would increase global warming potential in all scenarios, while RP3 and RP6 are mostly favourable for reducing eutrophication potential and acidification potential.

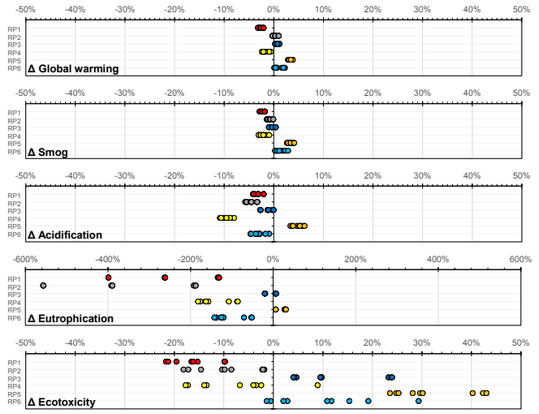

Figure 3. Changes in global warming, smog, acidification, eutrophication, ecotoxicity potential for six different recovery pathways (RPs), compared to the baseline pathway. Within a recovery pathway (RP), each dot is a scenario – one of the 27 combinations of influent pollutant concentration, sludge disposal method, and carbon intensity of grid electricity.

The Role of End-user Perspective

Life cycle assessments of wastewater-based resource recovery could generally be categorized as the *process perspective*, the *product perspective*, and the *end-user perspective* (Figure 1) (Lam *et al.*, 2022). The *process perspective* (also called the waste management perspective) evaluates the integration of resource recovery processes into conventional wastewater treatment plants. This perspective often aims to quantify and optimize the influence of resource recovery processes to the overall environmental performance of wastewater treatment plants. The focus is on the primary functionality of wastewater treatment and sludge disposal. The *product perspective* shifts attention from wastewater treatment plants to wastewater-derived products. This perspective often aims to evaluate and compare potential environmental impacts of the wastewater-derived products derived from different recovery approaches.

The *end-user perspective* extends on the *product perspective*. It centers on how the application of wastewater-derived products impacts on the overall environmental performance of the end users' product system (i.e., in this study, the end user is the agricultural sector using wastewater-derived phosphorus products). One major difference between the *product perspective* and the *end-user perspective* is that the *product perspective* typically credits the recovered phosphorus products for avoiding an assumed conventional phosphate-rocked fertilizer production, while the *end-user perspective* only implicitly considers that when there is a baseline of using conventional fertilizer (i.e., not being considered for a new crop production system).

This study demonstrates the application of the *end-user perspective* for conducting life cycle assessments of "downstream" product systems that utilize wastewater-derived products as inputs. The *end-user perspective* can serve three major purposes. First, the *end-user perspective* can complement with the process perspective and the product perspective to give a more holistic picture of environmental impacts along the "circular economy value chains" of wastewater-based resource recovery. Second, the *end-user perspective* is essential to evaluate system-wide environmental impacts of wide uptake of wastewater-derived products at downstream product systems. Third, the *end-user perspective* has an advantage of drawing more attention to the need of understanding the long-term environmental impacts and agronomic effectiveness of applying wastewater-derived phosphorus products (e.g., soil context, phosphorus uptake, contaminants). As more wastewater-derived products being available, this *end-user perspective* is becoming more important.

Abstract

This study focuses on the sustainability assessment of the digitalization technology applied in the advanced wastewater treatment stage aimed at eliminating organic micropollutants using activated carbon. Powdered activated carbon is currently dosed proportional to the inflow volume in a wastewater treatment plant (WWTP 1, Germany, 55.000 population equivalent). A mathematical model-based dosing strategy will be implemented in the WWTP 1 to improve the treatment efficiency and reduce PAC consumption. Comparing the reference technology (volume-proportional dosage) and the new digitalization technology, digitization technology can save ca. 4 % PAC and lower the carbon footprint of the PAC treatment stage by ca. 8000 kg CO_{2e}/a in WWTP 1. The reduction of CO_{2e} emissions after implementing the new control technology at WWTP1 will be evaluated. More potential systematical benefits of mathematical model-based dosage are recognized. Detailed ecological, economic, and social aspects based on life cycle analysis will be carried out.

Keywords (maximum 6 in alphabetical order)

carbon foodprint; digitalization technology; organic micropollutant; powdered activated carbon; wastewater treatment plant

INTRODUCTION

Organic micropollutants can be removed from wastewater treatment plants by applying activated carbon or ozone. In the wastewater treatment plant (WWTP) investigated in this study, powdered activated carbon (PAC) is dosed proportionally to inflow volume (such as 8 mg PAC/L), regardless of the wastewater characteristics. In the planning digitalization technology, PAC is dosed according to a mathematical model-based regulation. The mathematical model calculates the necessary PAC dosage to achieve a mean removal of more than 80% for a selection of micropollutants.

The digitalization technology incorporating the mathematical model-based dosing strategy can potentially reduce PAC consumption and improve the removal efficiency of micropollutants. However, the new digitalization technology involves additional production of hardware such as PCs and power consumption due to the usage of the additional hardware. The objective of the study is to compare the sustainability of the reference technology (current volume-proportional PAC dosage) and the digitalization technology (mathematical model-based dosage) by qualitative assessment and life cycle assessment (carbon footprint).

MATERIALS AND METHODS

Sustainability assessment on a qualitative level

A working hypothesis concerning the potential benefits and drawbacks of the digitalization technology is identified based on the three orders of the environmental impact: 1) first-order effect or direct effect: e.g., resource and energy consumption due to digitalization infrastructure and equipment; 2) second-order effect or indirect effect: e.g., immediate positive/negative effects of the new technology; and 3) third-order effect or systematic effect: e.g., mission statements, values, acceptance (Kampffmeyer & Gensch, 2019).

Sustainability assessment through the evaluation of carbon footprint

The carbon footprint of reference technology (volume-proportional PAC dosage) and digitalization technology (mathematical model-based dosage) used in WWTP 1 was compared. The mathematical model for WWTP 1 (Germany, 55.000 population equivalent) has been developed based on a published model (Atallah Al-asad et al., 2022). The model simulates the adsorption competition between background organic matter and micropollutants, and calculates the necessary PAC dosage. The developed mathematical model will soon be coupled into the IT infrastructure of WWTP 1. The calculation in this paper is based on a case study and not real data yet.

In a case study, benzotriazole was used as a reference substance for the mathematical model to calculate the required PAC dose to remove 80% of benzotriazole. The model was simulated on a time scale of 31 days using dynamic inflow (Figure 1) and inflow UVA_{254}. The concentration of benzotriazole corresponded to the same dynamics as soluble inert organics according to DWA-A 131 (DWA, 2016). The carbon footprint was calculated based on a tool developed by Öko-Institut in Germany (Gröger, 2020; Öko-Institut, 2020).

RESULTS AND DISCUSSION

Qualitative sustainability assessment: potential benefits and drawbacks

By replacing the volume-proportional PAC dosage with model-based PAC dosage, additional materials and resources are consumed for the production of extra servers and computers, which in turn increases the carbon footprint of WWTPs. This is recognized as a potential drawback of digitalization technology (direct first-order effect). However, the process reduces the amount of operational material (e.g., PAC) needed in the improved process control, a potential benefit of digitalization technology (indirect second-order effect). Moreover, the application of the model-based control strategy will improve the elimination efficiency of organic micropollutants, which results in many potential benefits such as protection of the ecosystem, reduction of diseases, and increase in the acceptance of the reuse of the treated wastewater (Table 1)

Comparison of the carbon footprint in both technologies

Comparing the reference technology and digitalization technology:

- Extra hardware is produced in digitalization technology: 500GB of online data storage and 2.5 GB/month of data exchange is needed. PCs are already equipped in WWTP 1.
- Additional power consumption due to the extra hardware mentioned above.
- PAC is supposed to be saved in the digitalization technology.

Case study

A case study has been carried out for WWTP 1, which applies PAC as an advanced treatment step. Results show that the reference technology involving volume-proportional dosage consumes averagely 70.02 kg PAC/day. The mathematical model-based dosage reduces the average PAC consumption to 67.51 kg/day, around 3.6% lower compared to volume-proportional dosage. The greenhouse gas emission of fresh activated carbon from hard coal is 8.7 kg CO_{2e}/kg PAC (Mousel et al., 2017). The annual reduction of carbon footprint due to saving of PAC is 7970 kg CO_{2e} when digitalization technology is used. The additional energy consumption of the 500 GB online data storage and the extra data transfer for the digital twin causes only 6.5 kg CO_{2e} per year (Table 2). The annual carbon footprint reduction is therefore 7963.5 kg CO_{2e}/a according to the calculation.

In general, digitization can reduce the carbon footprint of the advanced wastewater treatment stage using PAC. The reduction of CO_2e emissions after implementing the new control technology at WWTP1 will be evaluated. More potential benefits of mathematic-model-based dosage are recognized in the study, such as improved micropollutant removal and protection of the ecosystem.

Table 1. Three orders of the environmental impact regarding digitalization technology, including analysis of the contributions to the Sustainable Development Goals (SDGs) formulated by the United Nations General Assembly.

	Potential benefits		Potential drawbacks	
	Effect	SDG	Effect	SDG
First-order effect (direct)			Resource consumption for the production of digitization technologies (e.g., computers, servers)	SDG 8.4
			Power consumption for the operation of digitization techniques (e.g., processing, transfer, and storage of data)	SDG 7.3
Second-order effect (indirect)	Saving of operating materials in the process control (e.g., activated carbon)	SDG 8.4		
	Reduction of the energy requirement in the process control	SDG 7.3		
	Waste avoidance (e.g., by saving activated carbon and thus reduction of sludge production)	SDG 8.4		
Third-order effect (systematic)	Reduction of pollutants in water, soil, and air	SDG 3.9 SDG 6.3 SDG 12.4		
	Reduction of diseases (e.g., due to hazardous chemicals)	SDG 3.9		
	Increase in the acceptance of the reuse of the treated wastewater	SDG 6.3 SDG 6.4 SDG 12.2 SDG 6.6		
	Protection of the integrity of ecosystems (e.g., surface water)	SDG 14.2 SDG 15.1		

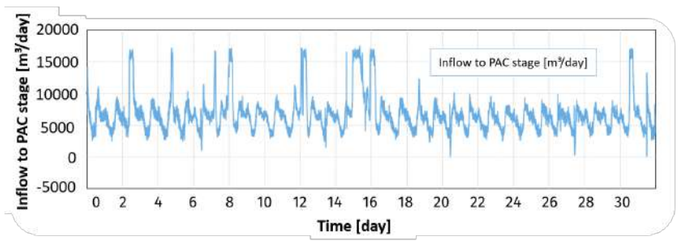

Figure 1. The inflow of the PAC treatment stage in the case study.

Table 2. Calculation of the increase and decrease of carbon footprint when using digitalization technology in a case study.

Items	Additional CO_{2e}-emission [kg CO_{2e}/a]
Online data storage (500GB)	+6,0
Data exchange (2.5 GB/month)	+0,5
PAC dosage	-7970
Sum	-7963.5

Abstract

Value propositions are used to link the strategic goals of an organisation with the circular actions of innovative wastewater technologies. The value proposition canvas 'gains creators' are used to identify value creating actions of the circular solution for selecting relevant performance indicators, these indicators then guide complementary sustainability indicator selection to quantify value creation for stakeholders. The method developed is applied to a small-scale wastewater treatment plant with a novel photobioreactor technology that produces biofertilizer. The indicators show that all strategic and value creating goals were achieved and resulted in sustainable value creation across all pillars of the triple bottom line.

Keywords (maximum 6 in alphabetical order)

Abstract; circularity assessment, indicator selection, sustainable value creation, value propositions

INTRODUCTION

The circular use of wastewater has attracted significant attention in recent years, shifting the focus from treatment to recovery. There are already many circular technologies available to the wastewater sector for resource recovery and water recycling, but implementation is limited through lack of planning and performance analysis (Smol and Koneczna, 2021). It has been shown that technological aspects are not barriers to the circular transition, rather a company culture stemming from the view these investments are not economically favourable in the short term (Kirchherr, Piscicelli, et al., 2018), and is compounded with limited research on how the circular economy (CE) provides a competitive advantage (Lahti, Wincent, et al., 2018). Currently, assessment frameworks focus on measuring material flows, with circularity indicators aligned against triple bottom line (TBL) dimensions to evidence that sustainability is adequately measured. This results in patchy assessments and consequences such as impact leakage (Chen, 2021). For sustainable innovations, a lack of similar market options creates difficulties when assessing aspects such as acceptability, therefore the creation of customer value should be emphasised (da Luz Peralta, Echeveste, et al., 2020)especially in startups, where the degree of uncertainty is high, and the business model has no consolidation. To this end, different approaches, which are mostly supported by learning cycles of experimentation, have emerged to assess customer and stakeholder value in innovation projects. To understand how these approaches and practices represents an alternative for value identification and proposition, this study aims to demonstrate a method to conduct practices and techniques in innovative solutions to anticipate customer value during the front-end phases of a sustainable product. The main contribution is the application of the framework in the case of a startup focused on agriculture for the development of a grain drying machine. The main technology behind this innovation is the drying through oxyhydrogen burn, which is extracted from the water. The framework proved to be useful for organizing market-bound information to form customer value proposition. The results allow the startup to reduce or solve uncertainties in its business model, which are challenges inherent to the innovation market. The learning from the application of the framework resulted in a remodeling of the business model to achieve a broader public as the startup pivoted initial customer needs into product requirements."

In this work, a method for selecting indicators to assess the value creating circular actions of wastewater systems is provided, and how this can guide the use of complementary sustainability analysis for quantifying the resultant sustainable value created.

MATERIALS AND METHODS

To understand the physical impacts of circular actions to wastewater systems, the circular solution should be modelled to facilitate resource flow analysis as this is a key aspect of any circularity assessment. For the first step of indicator selection, the method of da Luz Peralta et al. (2020)especially in startups, where the degree of uncertainty is high, and the business model has no consolidation. To this end, different approaches, which are mostly supported by learning cycles of experimentation, have emerged to assess customer and stakeholder value in innovation projects. To link the goals identified from VPCs with relevant action indicators, they are grouped based on circular strategic goals. Strategic goals are the high level aims of the project, commonly defined as quantitative targets, such as a reducing waste or emissions production by a certain percentage. These are used to create generic CE actions that are initiated by the circular solution, which can be found in literature (such as recycling or renewable energy generation). Simultaneously, VPC development recognises how the circular solution aims to create sustainable value for stakeholders, by using 'gain creators' to highlight technology expectations. These are combined with the CE actions to create circular value creating actions that are specific to the project. Lastly, the specific circular actions are used to select appropriate indicators for the assessment of system performance to achieve the defined goals. A summary of these steps is provided in Figure 1 and are applied to the example of a novel photobioreactor (PBR) (H2020 Deep Purple) for treatment of wastewater in rural Spain for a population equivalent of approximately 10,000 to produce biofertilizer. The results provided by these indicators will show whether the goals are met, and the circular actions of the technology have been successful at generating sustainable value for stakeholders.

RESULTS AND DISCUSSION

The strategic goals of the technology were taken from H2020 Deep Purple project documentation and website (Deep Purple, 2019). The terminology of minimising, maximising and reducing several operational constraints such as cost, waste, GHG emissions and energy demand, reveals the strategic goal of *optimising the performance of supply chains*. The emphasis on generating economic value from bioproducts and recovering energy from waste stream means that the technology must also have the ability to *cascade biomaterials*. Recovering the organic and nutrient contaminants in wastewater and minimising waste production is achieved through the action of *recycling* wastewater resources. Therefore, three strategic goals were identified, and these must then be combined with the outcomes from a sustainable VPC to select relevant indicators. The stakeholders used to generate the VPC in this example were the PBR technology developers. The resultant Lean Canvas is presented in Figure 2 with the 'gain creators' category used to understand the PBR's individual value creating actions. The four 'gains creators' identified were related to cost, carbon footprint, sludge valorisation and energy consumption.

A summary of the step to select indicators including the gains creators, CE actions and value creating actions is provided in Table 1, with results provided as the percentage change compared with a conventional small-scale wastewater process. Results show that nearly all of the indicators highlight an improvement in performance of the PBR technology versus conventional treatment (except waste eco-efficiency due to the increase of pretreatment solids captured). This is attributed to a reduction in grid electricity demand and direct emissions, resulting in a significant decrease to carbon footprint. Also, material and energy consumption reduction lowers costs, and biofertilizer sales increases revenue streams from sludge. Therefore, the PBR technology is effective at achieving the defined value creating goals. Additionally, action indicator calculations provide insights into which complementary sustainability indicators are required to quantify the value creation of the system. It is clear from the results that the photobioreactor technology instigates economic, environmental and social value creation, as shown in Table 2.

CONCLUSIONS

The method described selected indicators for the assessment of a small-scale wastewater treatment plant with a novel PBR for producing biofertilizer. The indicator results show that all strategic and value creating goals were achieved and resulted in sustainable value creation across the TBL.

Abstract

This research extends the system boundaries of life cycle assessment (LCA) of wastewater treatment technologies, which typically focus on construction, operation, and maintenance, to include resource recovery. LCA of three different nature-based wastewater treatment solutions (treatment wetland, evapotranspirative willow system and high-rate algae pond) were compared with and without the use of recovered resources. The results showed that despite the higher use of some materials (e.g., irrigation system) LCA results were in favour of the systems with reuse of resources. Treatment wetland with the use of reclaimed water provided the best results in 4 of the 6 categories studied (climate change, freshwater eutrophication, water depletion, and metal depletion). Considering CO_2 uptake as a positive impact, evapotranspirative willow system showed the best results due to the greatest carbon storage in woody biomass compared to the treatment wetland and the high-rate algae pond.

Keywords

high-rate algae pond, LCA, reclaimed water, system boundaries, treatment wetland, willow system

INTRODUCTION

Resource recovery is a response to increasing demand for resources and increasing waste production due to increasing economic and population growth. The circular approach to wastewater management has been studied mainly for cities, where nature-based solutions (NBS) are gaining attention (Atanasova et al. 2021). Robust NBS for wastewater treatment are an even more appealing solution for rural areas, where space is not as critical as in urban areas. To reduce the environmental impact as much as possible, a suitable wastewater treatment technology must be selected and the life cycle assessment of the technology and the reuse (irrigation) system must be evaluated.

In the field of wastewater treatment, LCA focuses mainly on the construction and operation of wastewater treatment plants (Morera et al. 2017, Morera et al. 2020), while the system boundaries do not consider the circularity in terms of capturing the reuse of recovered wastewater treatment products. This can significantly change the outcome of the LCA analysis and the environmental performance of a wastewater treatment solution. In particular, the outcome may be different when NBS are evaluated and their co-benefits are included in the assessment.

The objective of this study was to evaluate and compare the environmental impacts of constructing and operating three different NBS for wastewater treatment for small volumes of water (5 PE). Treatment wetland (TW), high-rate algae pond (HRAP) and evapotranspirative willow system (EWS) with different resource recovery options, namely discharge of water to a nearby river or reuse of treated water for irrigation in the case of TW and HRAP, and in the case of EWS, reuse of the woody biomass produced as woodchip for soil amendment or composting.

MATERIALS AND METHODS

The LCA methodology followed ISO 14040-14044. The LCA study considered the extraction of resources needed for the construction, operation and to produce the products (treated water and recovered resources).

Goal and scope definition

The functional unit of the study is the volume of water treated by the treatment and recovery plants during the 20-year operation, including the construction of these plants and the maintenance of the main equipment. The life of the NBS treatment systems tested was assumed to be 20 years for the entire plant; however, we considered the life of individual components and considered replacement with shorter lives (e.g., pumps). Whenever possible, real data from the technologies tested were used, but when this was not possible, information from other studies or from the manufacturers was used. 20 years was used for all the civil works, 5 years for aluminum pumps, and 15 years for the ultrasound unit and engine.

A total of seven scenarios were analyzed:

- **Scenario A: TW to treat domestic wastewater; treated water is discharged to a nearby stream; reeds produced are harvested and used as structural material for composting.**
- **Scenario B: same water treatment as in Scenario A, but treated water is reused to irrigate a lawn; reeds produced are treated as in Scenario A.**
- **Scenario C: EWS to treat domestic wastewater; all influent is used for evapotranspiration; woody biomass produced is used as woodchip for soil amendment or composting.**
- **Scenario D: aboveground HRAP to treat domestic wastewater; the pond is made of polystyrene; the treated water is discharged to a nearby stream; the produced algae-bacteria biomass is used as fertilizer.**
- **Scenario E: same water treatment as in Scenario D; the treated water is used to irrigate a lawn; the algae-bacteria biomass produced is used as fertilizer as in Scenario D.**
- **Scenario F: same as Scenario D, but the HRAP is constructed as an earthen pond sealed with an EPDM liner.**
- **Scenario G: same as Scenario E, but the HRAP is constructed as in Scenario F.**

Inventory phase

In the inventory phase, data on the type and quantity of the system's inputs (materials, energy, resources, etc.) and outputs (emissions to air, water and soil) were collected through direct measurements related to construction and operation. The inventory obtained was then compared with background information from the Ecoinvent database (version 3.3). Some assumptions were necessary because the Ecoinvent database did not have information on all the materials used (e.g., due to no data on EPDM it had to be replaced by polyethylene membrane) and in some cases equivalent materials were used (e.g., chromium steel for stainless steel).

Impact assessment

Environmental impacts were calculated based on previously collected inventory data using ReCiPe 1.13 in the midpoint version. This method considers 18 midpoint impact categories, although only 6 were selected in this case: climate change, freshwater eutrophication, marine eutrophication, water depletion, metal depletion and fossil depletion.

Interpretation

Interpretation of the results followed the recommendations of ISO 14044: analyzing the most important aspects for each environmental impact, looking for possible solutions to reduce the environmental impact, performing an additional sensitivity analysis of the results considering different processes.

RESULTS AND DISCUSSION

Figure 1 shows the overall results (construction and operation combined) for all scenarios studied for the three treatment technologies. Scenario B provides the best results in 4 of the 6 categories studied, namely climate change, freshwater eutrophication, water depletion and metal depletion. Scenario C, on the other hand, provides the best results for marine eutrophication, and finally, Scenario A is the best for fossil depletion.

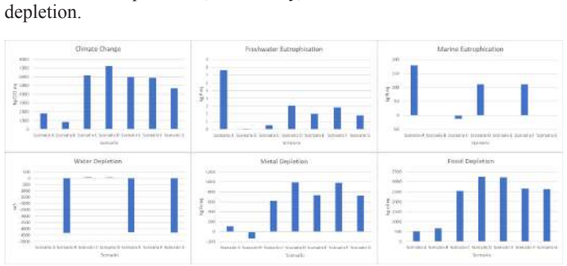

Figure 1. Total impact results for all categories for all the scenarios considered.

Figure 2 shows the same results, but differentiated by construction and operation. These results show that the scenarios with water reuse have positive effects on the impact categories of climate change, water depletion, metal depletion, and fossil depletion, since water reuse can save the use of potable water for gardening. In terms of eutrophication categories, Scenario C has the best results for marine eutrophication, as the reuse of willow woodchip saves the production of this material. In terms of freshwater eutrophication, Scenario B is the best, also because of the positive effect of water reuse. In general, construction is a relatively large contributor to impacts compared to operation, which is in contrast to activated sludge technologies where construction accounts for only about 10% of impacts (Morera et al., 2017). This is due to the fact that nature-based treatment systems have very low energy requirements for operation compared to conventional technologies.

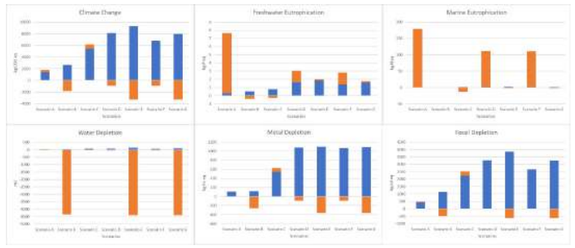

Figure 1. Impact results for all the scenarios considered differentiating between construction (blue) and operation (orange).

Sensitivity analysis

Impacts on the climate change category were analysed when CO_2 uptake is considered a positive effect or not, which is common practice as the CO_2 from the biogenic cycle is considered neutral and positive if it is stored in woody biomass for longer period. The EWS (Scenario C) shows the best results in terms of CO_2 uptake by plants, with a value of -17324.80 kg CO_2 eq (Table 1), which means that this wastewater treatment technology plays a positive role for the climate change impact category because it eliminates CO_2 eq from the atmosphere.

Table 1. Comparison of the climate change impact considering or not the effect of CO_2 uptake.

Scenario	Positive effect of CO_2 uptake	No consideration of CO_2 uptake
A	1166.29	1792.74
B	192.47	818.92
C	-17324.80	6172.85
D	3170.84	7222.51
E	1946.71	5998.38
F	1845.43	5897.09
G	621.30	4672.96

CONCLUSIONS

In general, the results were better when the system boundaries included the use of reclaimed water despite the installation of an irrigation system. Scenario B (TW with water reuse) is the best scenario because it provides the best results for 4 of the 6 categories analysed (climate change, freshwater eutrophication, water depletion, and metal depletion) and the second best for the other two categories (marine eutrophication and fossil depletion). This is due to the positive effects of water reuse and the fact that this scenario consumes less energy compared to the other treatment technologies. The contribution of construction to the total impact is relatively high for all the technologies studied which is due to the low energy required for operation. Considering the absorption of CO_2 by the plants as a positive effect in the climate change category, the EWS is the best solution.

Sustainability assessment at early stages of technology development: phosphorus recovery for fertiliser from dairy wastewater

M. Behjat*, M. Svanström and G. Peters

Department of Environmental System Analyses, Chalmers University of Technology, Gothenburg SE-412 96, Sweden

*Corresponding author: [marta.behjat@chalmers.se]

Abstract

A reduction in the availability of phosphate rock resources for fertiliser production coincides with an increase in phosphorus-rich dairy wastewater in Europe. Interest into the development of technologies for phosphorus recovery from wastewater and the use of the products as fertilisers in agriculture has increased. The dairy wastewater is a potential waste stream for these technologies. This work aims to contribute both to the technical development of this emerging technical system and methodological development of assessing the sustainability of it with regard to (1) the identification and selection of sustainability indicators, and (2) the assessment of life cycle environmental impacts. The work describes an approach developed for identifying and selecting the indicators as well as an approach employed for performing a meta-analysis of previously published life cycle assessment results to cope with lack of inventory data.

Keywords

dairy wastewater, meta-analysis, LCA, phosphorus recovery, sustainability indicator, wastewater treatment

INTRODUCTION

In abiotic systems, phosphorus (P) does not occur naturally other than in the form of phosphate rock. Phosphate rock is a finite, non-renewable resource that is largely needed for fertiliser production. Also considering the lack of exploitable phosphate mineral reserves in Europe (Schröder et al., 2010), the European Union (EU) has prioritised the recovery and safe reuse of P from food and municipal waste flows through its circular economy package (European Commission, 2016). This confluence of events has led to the development of technologies for phosphorus recovery from dairy wastewater and the use of the products as fertilisers in agriculture. An emerging technology combines dairy wastewater treatment (DWWT) with the recovery of P-rich products for such products to be used as fertilisers in agricultural activities. The purpose of this research was to contribute to both the technical development and methodological development of assessing the sustainability of this innovative technology. This work provides guidance on methods to partially overcome the lack of information by contributing to (1) the selection of a broad range of sustainability indicators for assessing impacts of the recovery system of P from DWW to produce fertilisers for agricultural activities and to (2) the environmental assessment by a meta-analysis, or rather, the mining and refining of information from previous life cycle assessment (LCA) studies.

MATERIALS AND METHODS

The overall methodological approach of this research work is represented in Figure 1.

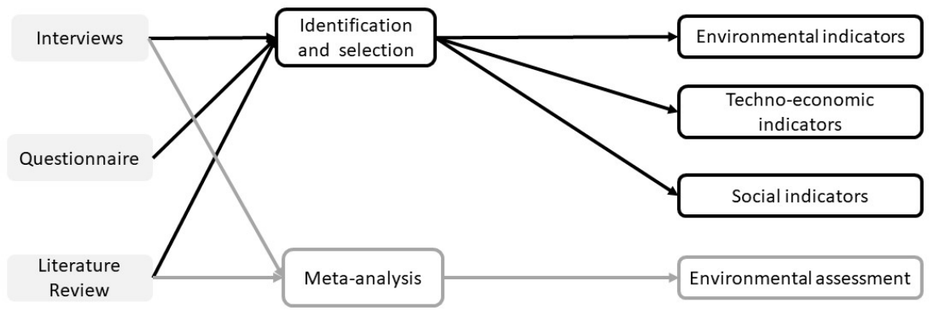

Figure 1 Workflow of the research. This figure represents how the research could achieve its aim by obtaining the listed expected results: sustainability indicators and the environmental impacts.

The research work was supported by three research tools: interviews, questionnaire, and literature review. The information collected by using these tools was used to (1) identify and select a list of sustainability indicators and to (2) perform a meta-analysis focused on life cycle environmental impacts.

Interviews

The interviews aimed to provide information about the innovative technologies that constitute the system. This information includes material flow data, actors, and EU policies and contributes to the development of a conceptual system description as well as to the development of a framework used in indicator selection. The framework highlights elements of the system and maps correlations between elements.

Questionnaire

The questionnaire is a form developed to gather information about actor priorities with regard to various aspects of sustainability in relation to the considered system. The approached actors evaluated these aspects, which are referred to the environment, economy and society. These aspects were graded from “not important” to “very important”.

Literature review

Different documents were selected and reviewed for various parts of the research to collect information to contribute to both methodological development and sustainability assessment.

Identification and selection of sustainability indicators

Specific documents were consulted for identifying an initial list of sustainability indicators (382). However, a practical subset of this long list of indicators was selected using three screening processes. The first screening process consisted of comparing the indicators found in the literature with the elements that constitute the developed screening framework. Next, the list of indicators obtained from the first screening was filtered based on the actors’ interests collected through the results of the questionnaire. Finally, a further screening was applied based on the indicator selection criteria proposed in literature.

Meta-analysis

With the meta-analysis, literature results were extracted and recalculated owing to the lack of published LCAs on P recovery from DWWTs. The information on environmental impacts was rescaled to the same FU (1 kg of P recovered). Impacts of the DWWT, as gathered from the dairy LCAs, was recalculated to relate to the P in the DWW. The extracted and rescaled environmental impact results of the DWWT process were related to those of the P recovery process in the conceptual combined system.

RESULTS AND DISCUSSION

The results presented in this study, apart from the methodological contributions, is a set of 26 sustainability indicators screened from an initial set of 382. Furthermore, according to the results presented in this study, installing P recovery as part of or after DWWT would normally not incur large additional environmental costs compared to the current DWWT with regard to climate impact or energy use; in general, the processes recovering from a liquid flow have a lower impact than when sludge is the P source.

Abstract
Feedback from 46 small to medium wastewater treatment plants equipped with chemical precipitation with iron chloride for phosphorus removal was gathered. Chemical precipitation with iron chloride is efficient to reach the phosphorus levels required for all the processes studied, except when the requirements are too low (< 1 mg TP/L). But an injection of iron chloride in a small WWTP requires a more complex and more frequent follow-up and significantly increases the operation costs.

Keywords (maximum 6 in alphabetical order)
Iron chloride; phosphorus removal; rotating biological contactors; vertical flow treatment wetlands; trickling filters

INTRODUCTION

The accumulation of phosphorus discharged in the environment by wastewater treatment plants (WWTPs) is one of the main causes of eutrophication. As a consequence, in France, an increasing number of small WWTPs are required to treat phosphorus, sometimes to reach very low levels, under 1 mg Total Phosphorus (TP)/L. Conventional processes installed to treat wastewater in small plants such as vertical flow treatment wetlands (VFTWs), rotating biological contactors (RBC) or trickling filters are not designed to remove phosphorus (Cramer et al., 2016). Chemical precipitation is then often implemented in order to reach the required levels of phosphorus in treated wastewater (Di Capua et al., 2022). This process is very frequent in large WWTPs, in particular in activated sludge systems (Strom, 2007). However, there is a lack of feedback on the use of chemical precipitation for phosphorus removal associated with technologies for small WWTPs (Bunce et al., 2018). Implementing chemical precipitation on smaller treatment plants presents new challenges as they cannot benefit from economies-of-scale, rigorous monitoring and in-house operating expertise as the larger WWTPs. For this reason, the French national working group Epnac (www.epnac.fr, gathering all the public organisms working on wastewater treatment in France) started a study in 2020 on phosphorus chemical precipitation implemented in different treatment technologies in small WWTPs. The objectives were to evaluate the performance of phosphorus treatment and to identify potential bottlenecks.

MATERIALS AND METHODS

The first step of the study was a national survey to collect data (water treatment regulatory monitoring, information on the phosphorus removal process selected at the plant, feedback from the operation of this process...) from the members of the Epnac group. Specific sites were then selected to proceed to extended monitoring in order to evaluate the performance of the process for phosphorus removal using a common experimental methodology.

Data from 367 regulatory monitoring (24-hour-flow composite samples) in 46 WWTPs treating phosphorus with a capacity of 260 to 8 000 Population Equivalents were gathered. The processes implemented at the studied plants were activated sludge systems (9 treatment plants), rotating biological contactors (16), vertical flow treatment wetlands (4), VFTWs with forced aeration (5) and trickling filters combined with VFTWs (12). All these WWTPs are equipped with a chemical precipitation unit using iron chloride ($FeCl_3$) to reach the low levels of phosphorus required at the outlet.

31 specific 24-hour-flow composite samples monitoring were produced for this study with additional parameters in regard to the classical parameters followed during the mandatory self-monitoring of the WWTP. The extended monitoring consisted in flow proportional sampling at each treatment steps in order to analyse global parameters as well as additional relevant parameters regarding phosphorus chemistry (iron, bicarbonate ions, volatile fatty acids…).

RESULTS AND DISCUSSION

Global performance of chemical precipitation for phosphorus removal in small WWTPs

Chemical precipitation with iron chloride is efficient to reach the phosphorus levels required except when they are too low (lower than 1 mg TP/L) as shown in Table 1. This confirms that levels of total phosphorus under 1 mg/L are hard to reach with chemical precipitation alone and require additional techniques such as filtration (Bunce et al., 2018).

Table 1. Percentage of 24-hour-flow composite samples meeting the phosphorus levels required at the outlet of the WWTPs according to the TP level required

Phosphorus level required (mg TP/L)	Number of 24-hour-flow composite samples	Percentage of samples under the required phosphorus level
>=0.7 and <=1	7	43%
>1 and <=1.5	34	85%
>1.5 and <=2	235	88%
>2 and <=4	62	69%
>4	26	77%

As seen in Table 2, the activated sludge system seems to be the most reliable process as 97% of the samples are below the required phosphorus level. Other processes such as trickling filters + VFTWs or VFTWs with forced aeration allow a good compliance with the total phosphorus discharge requirements (compliance over 75%).

Table 2. Percentage of 24-hour-flow composite samples meeting the phosphorus levels required at the outlet of the WWTPs according to the process

Process	Number of 24-hour-flow composite samples	Percentage of samples under the required phosphorus level
Activated sludge	117	97%
Rotating biological contactors	135	61%
Trickling filters + VFTWs	76	75%
VFTWs	30	70%
VFTWs with forced aeration	10	80%

As shown in Figure 1, TP removals above 67% were obtained for all the processes. Concentrations of phosphorus in treated water were the lowest with activated sludge. Low concentrations could also be obtained with VFTWs with forced aeration. Lower levels of total suspended solids (TSS) are associated with a better removal of phosphorus as around 2-3% of organic solids is phosphorus (Strom, 2007).

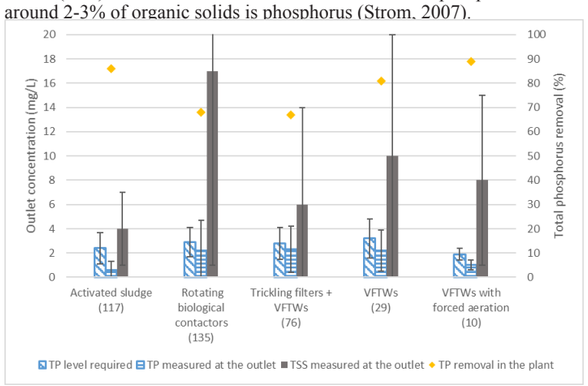

Figure 1. Comparison of processes for phosphorus removal.

Lessons learned

As chemical precipitation and sludge management can be implemented differently, even in a particular biological treatment technology, it is interesting to analyse more deeply the effect of the choice of the precipitation step implementation on efficiencies. A comparison of the different configurations for each process allowed to draw conclusions. For rotating biological contactors for example, 3 of the 16 WWTPs had an injection of iron chloride inside the biological rotating disc tank as shown in Figure 2. A similar removal of phosphorus (77%) was measured for these plants. In comparison with WWTPs where iron chloride was injected before or after the rotating discs tanks, a similar performance was obtained while lower iron chloride dosage was used (226 mg/l of commercial iron chloride for the injection inside the rotating discs, 98 mg/l for the injection before the rotating discs). The rotation of the discs is very slow and does not allow a good mixing of iron chloride, necessary to precipitate P. Iron chloride, as in activated sludge systems, should be injected in the most turbulent part of the tanks.

Figure 2. Injection of iron chloride inside the biological rotating disc tank.

Trickling filters followed by VFTWs can have 1 stage of filters, 2 stages or a lamella clarifier as a second stage. Iron chloride is injected before or after the first stage of VFTWs, as shown in Figure 3. The WWTP with no second stage did not remove as much phosphorus (48%) and suspended solids as the WWTPs with the two other configurations (78% removal for total phosphorus). This configuration without a second stage should be selected only when higher levels of phosphorus are required at the outlet.

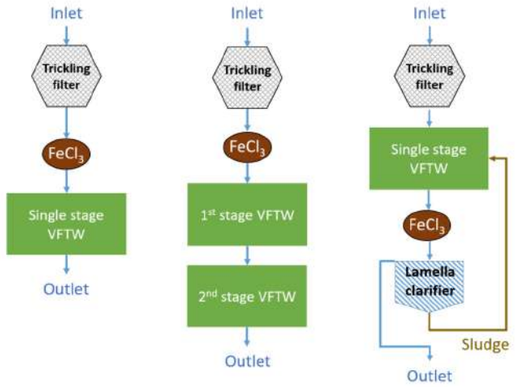

Figure 3. Three configurations for phosphorus removal by chemical precipitation for trickling filters followed by VFTWs.

Application of iron chloride in excess is frequent in small WWTP due to a less frequent follow-up, generating high reagent costs. Based on the data gathered in this study, the consumption of iron chloride for a theoretical 1 000 PE WWTP can vary from 4.3 to 11.4 tons per year. The quantity depends on the inlet phosphorus concentration, the removal objective and the regulation of the injection. Iron chloride can represent a cost of 0.8 to 5.7 euros per year per PE excluding taxes (up to +114% on operation costs of the plant in comparison with a similar plant without P precipitation).

Conclusions

Multiple systems exist for chemical precipitation of phosphorus in small WWTP (injection point, regulation of the injection, separation of the resulting solids residuals…) and can be efficient. It is not necessary to choose activated sludge if low levels of phosphorus are required in a small WWTP, other processes can be combined with chemical precipitation. But an injection of iron chloride in a small WWTP requires a more complex and more frequent follow-up in comparison with a classical plant without P precipitation and increases the operation costs. Phosphorus removal with iron chloride should only be implemented if the aquatic ecosystem really requires it, alternative to treatment should be considered (infiltration in the ground, reuse, evaporation…) to limit the discharge of P in superficial water.

Nitrate electro-bioremediation as a decentralised water treatment: from the proof-of-concept to the *on-site* technology validation

Alba Ceballos-Escalera, Narcís Pous, M. Dolors Balaguer, Sebastià Puig

LEQUiA, Institute of the Environment, University of Girona, C/ Maria Aurèlia Capmany, 69, E-17003, Girona, Spain

Abstract
Up to 40% of rural areas cannot afford drinking water services due to the cost and difficult implementation of conventional centralised water treatments. Nitrate electro-bioremediation is emerging as an accessible decentralised treatment to increase drinking water availability in rural areas, where nitrate-contaminated groundwater is a widespread problem. This study moved towards scaling up the technology, including its validation in a relevant environment. The results validated the technology as a decentralised treatment in a rural area and paved the ground for further implementation.

Keywords:
Bioelectrochemical system; Biological denitrification; Groundwater; Microbial electrochemical technology; Reactor scaling up; Water recovery

INTRODUCTION

United Nations adopted the 2030 Agenda with the goal of universal access to safe drinking water (SDG 6, A/RES/70/1) since 2 billion people in 2020 still lacked safely managed drinking water. The high cost and complex implementation of conventional centralised water treatments in rural areas mean that up to 40% of these areas cannot afford drinking water services. A particularly exacerbated problem in rural areas is connected to agricultural and livestock production activities that often lead to nitrate contamination of groundwater (Yu et al., 2020). Because nitrates threaten groundwater potability, the European Directive 2020/2184 sets a safety concentration limit of 50 mg NO_3^- L^{-1}.

Many microorganisms have the ability to exchange electrons with solid electron conductors or other cells (electroactive microorganisms). This ability contributed to developing a broad range of practical applications, from bioenergy and bioelectronics to water treatment. In this area, electro-bioremediation is emerging as a decentralised and sustainable water treatment to increase the availability of treated water in rural areas (Pous et al., 2018). This treatment harnesses the capacity of electroactive microorganisms to perform selective oxidation and reduction reactions with solid electron conductors (i.e., electrodes), overcoming the lack of electron donors/acceptors. In nitrate-contaminated sites, these bioelectrochemical systems (BESs) could perform a selective nitrate reduction using the cathode as an inexhaustible electron donor and inorganic carbon as a carbon source (Clauwaert et al., 2007). The main advantages of this approach are: (i) independence of chemical reagents; (ii) modular reactor that provides flexible treatment capacity (iii) low operational cost; (iv) low environmental impact (e.g., no generation of brine); and (v) non-invasive and selective dosing of electron donors/acceptors avoiding side reactions.

Nevertheless, the technology is still in the transition from technology validated in the laboratory to a relevant environment. Against this backdrop, this study moved towards scaling up the technology using know-how on electro-bioremediation at a laboratory scale. For instance, it was noted that the low electrical conductivity of groundwater hinders the mass transfer (i.e., protons), requiring an external recirculation to minimise this limitation (Ceballos-Escalera et al., 2021). In addition, water softening was demonstrated to be a prerequisite to prevent scale formation in the reactor and increase treatment life in high-hardness groundwater (Ceballos-Escalera et al., 2022). The developed pilot plant was installed in a rural region (Navata, Spain), treating *on-situ* nitrate-contaminated groundwater for 3 months.

MATERIALS AND METHODS

A compact tubular bioelectrochemical fixed-bed reactor (**Figure 1**) was built with PVC (6.0 cm diameter and 1.7 m length). The cathode (inner part) and anode compartments (outer part) were separated with a tubular cation-exchange membrane (CEM, CMI-7000, Membranes Int., USA). Both compartments were filled with granular graphite (average diameter of 3.25 mm, enViro-cell, Germany) with a bed porosity of 50 %, resulting in a net cathode volume (NCC) of 1.2 L. The cathode electrode was previously inoculated with a denitrifying community obtained in the laboratory, dominated by *Sideroxydans* sp. (Ceballos-Escalera et al., 2021). The system was electrically operated in a two-electrode configuration, fixing the cell potential between 1.2 to 1.7 V by an external power supply.

The groundwater was treated with a commercial ion exchange softener to reduce the hardness from 300 to 45 ± 25 mg $CaCO_3$ L^{-1}. The main influent characteristics were a pH of 8.1, a conductivity of 0.8 ± 0.1 mS cm^{-1} and 92 ± 7 mg NO_3^- L^{-1}. The softened groundwater was pumped directly through the bottom of the cathode compartment and spilt over the top into the anode compartment towards the bottom, where the outlet was located. A fraction of the cathodic effluent was recirculated at a flow rate of 150 L d^{-1} to the influent. The reactor was operated at a room temperature of 30 ± 5ºC.

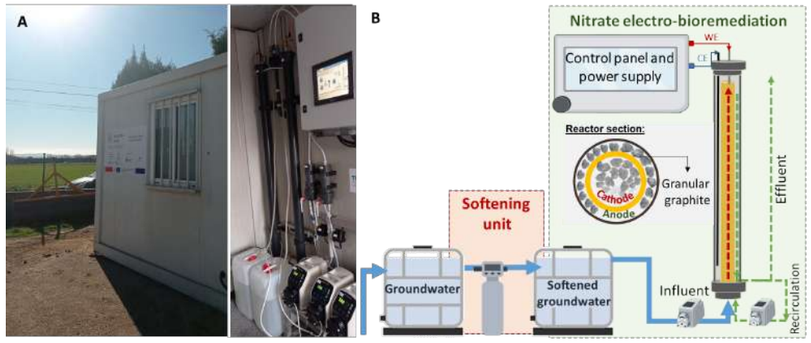

Figure 1. (A) Images of the pilot plant placed in Navata (Spain) (left) and bioelectrochemical reactors (right). (B) Process outline and scheme of the reactor.

RESULTS AND DISCUSSION

A nitrate electro-bioremediation pilot plant was operated for the first time with promising results. The pilot plant was tested in continuous flow mode for 3 months, decreasing the HRT_{cat} from 10.0 to 2.0 h (**Table 1**), corresponding to a flow rate from 2.9 to 14.3 L d^{-1}. Consequently, the nitrate reduction rate was increased to a maximum rate of 0.84 ± 0.11 kg-NO_3^- m^{-3} d^{-1} at the lower HRT_{cat}. In all HRT_{cat} tested, the nitrate removal efficiencies were higher than 90 % except for the lower HRT_{cat} of 2.0 h with an efficiency of 78 ± 11%. Even so, the effluent reached the drinking water quality in the whole operational time in terms of nitrate and nitrite concentration (> 50.00 mg-NO_3^- L^{-1} and >0.50 mg-NO_2^- L^{-1}, European Directive 2020/2184). Inclusive at the lower HRT_{cat}, the effluent kept a safe concentration of 20.16 ± 9.87 mg-NO_3^- L^{-1} and 0.00 ± 0.01 mg-NO_2^- L^{-1}. The results did not differ from those obtained on a laboratory scale, where the maximum rate of 2.28 ± 0.23 kg-NO_3^- m^{-3} d^{-1} was reached at HRT_{cat} of 1.5 h (Ceballos-Escalera et al., 2021).

Finally, the nitrate electro-bioremediation was energetically competitive with an average energy consumption of 0.31 ± 0.01 kW m^{-3} (**Table 1**) compared with conventional nitrate treatments, some of them with higher environmental impacts. For instance, reverse osmosis consumes between 0.9 - 2.2 kWh m^{-3} (Twomey et al., 2010), while generating nitrate-concentrated brines that must be treated afterwards. This evidenced the successful transition from the laboratory to the pilot scale and the technology validation in a real environment.

Table 1. Treatment performances and water characteristics according to the different HRT_{cat} tested (n ≥ 3). The table was coloured based on efficiency and water quality, where green is the best performing and yellow is the least performing.

Period	HRT_{cat}	Process efficiency			Effluent characteristics	
		Nitrate removal rate	Nitrate removal percentage	Energy consumption	Nitrate	Nitrite
(day)	(h)	(kg-NO_3^- m^{-3} d^{-1})	(%)	(kW m^{-3})	(mg-NO_3^- L^{-1})	(mg-NO_2^- L^{-1})
0-17	10.0	0.22 ± 0.02	94 ± 6	0.32 ± 0.02	5.64 ± 5.31	0.44 ± 0.23
17-28	8.0	0.28 ± 0.01	100 ± 0	0.31 ± 0.02	0.13 ± 0.22	0.09 ± 0.51
28-35	6.3	0.36 ± 0.02	100 ± 0	0.34 ± 0.01	0.17 ± 0.21	0.00 ± 0.00
35-42	5.1	0.43 ± 0.01	99 ± 0	0.30 ± 0.01	0.48 ± 0.24	0.19 ± 0.33
42-49	3.1	0.65 ± 0.07	93 ± 10	0.32 ± 0.02	6.11 ± 8.91	0.12 ± 0.33
49-85	2.0	0.84 ± 0.11	78 ± 11	0.30 ± 0.04	20.16 ± 9.57	0.00 ± 0.01

CONCLUSIONS

The present work validated nitrate electro-bioremediation in a relevant environment and paved the ground to move towards further scaling up the technology. Furthermore, the encouraging results demonstrated its applicability and evidenced the potential of the decentralised treatment to increase safely managed drinking water services in rural areas.

Abstract

An innovative decentralized wastewater treatment and resource recovery project has been set up for 400 households (1265 IE) in Belgium, based on source separation of grey and black wastewater. The segregated black water is mixed with collected kitchen waste and treated anaerobically in an UASB reactor, followed by phosphorus recovery. Grey water has the highest energy potential to recover. Separate collection and heat recovery through heat exchangers allows to transfer most of the energy to the district heating system. Together with energy recovery through biogas, almost 1/3 of the total heat demand of the urban area is provided by the decentralized reuse plant. Using UF-RO membrane filtration, the treated effluent is entirely recovered as process water for a local industry, and district heating allows recovery of the excess heat of the plant. As such, this remarkable demonstration project for sustainable transition in wastewater treatment in the city of the future combines water, energy and nutrient recovery, and contributes to the public acceptance of new urban resource recovery schemes. The project was part of the European projects Run4Life (H2020) and NEREUS (Interreg) and is in full operation now, at one fourth of its maximum design capacity. Hence, EcoSTP23 is the first opportunity to share the full-scale technical results, together with the importance of the socio-economic and governance aspects to be considered to set up such a project for cutting-edge ecotechnologies at the urban scale.

THE NEED FOR DECENTRALIZED WASTEWATER TREATMENT AND RESOURCE RECOVERY IN THE CITIES OF THE FUTURE

When dealing with the urban metabolism, there is an urgent need to rethink and redesign the currently used treatment lines, in the perspective of a sustainable bio-economy (Verstraete & De Gusseme, 2011). For example, the scarcity of water is no longer a problem relevant to arid zones only, but it occurs globally, even in regions considered water-rich (e.g. Belgium). A paradigm shift is needed to cope with these challenges and the sewage treatment plants (STPs) in the cities of the future should be regarded as an integral part of the municipal water production process of the 21st century (Qin et al., 2004). We have to reconsider the actual sanitation approach, which is entirely based on flushing excrements out of the city surroundings by use of ample amounts of water. Instead of centralizing the sewage treatment in major STPs considered as a cost factor, one should dare to examine the possibility to decentralize municipal waste treatment and to develop local water resource recovery facilities or biorefineries, making use of the resources in domestic wastewater, including water, nutrient, and energy recovery (Kisser et al., 2020).

To demonstrate the potential of urban resource recovery, a remarkable decentralized wastewater treatment project is set up in 2020, in a former harbor dock in Ghent, Belgium, called the "Nieuwe Dokken". An innovative multi-step treatment concept, referred to as ZeroWasteWater (Verstraete & Vlaeminck, 2011), is implemented with a total design capacity for 400 households (1265 IE). The approach brings new eco-technologies for STPs into practice, based on source separation of the grey (GW, sanitary) and black (BW, toilet) wastewater, with the overarching goal of recovering the maximum of its energy potential and redistribute it by means of a district heating system, and closing the water cycle by capturing >35.000 m^3/j treated effluent directly and reuse it as process water for the industry.

SOURCE SEPARATIONS AND ECOTECHNOLOGIES ALLOWING ENERGY AND NUTRIENT RECOVERY

The BW is collected undiluted by means of vacuum toilets and a vacuum collection system. The segregated BW is mixed with collected kitchen waste (KW) and treated anaerobically in an anaerobic digester (UASB). The system is designed to handle a maximum influent COD load of 165 kg O_2/d, which is degraded for 70% (COD_{sol} for >80% and COD_{SS} for 60%), resulting in a biogas production of max. 45 Nm^3/d. Biogas energy is recovered as heat (50-100 MWh_{th}/y at full capacity) and distributed back to the households by a district heating system. The UASB effluent is further treated in a struvite crystallization reactor, allowing phosphate recovery and reuse as fertilizer in the local green areas and urban farming projects.

GW has the highest temperature and energy potential to recover, about 700 MWh_{th}/y at full capacity, by collecting it at 25-28°C using isolated buffers and pressurized sewerage. Separate collection and heat recovery through heat exchangers allows to transfer most of the energy to the district heating system. Together with the energy recovery through biogas, almost 1/3 of the total heat demand of the urban area (2,1 GWh/y) will thus be provided by the WWTP. The GW is further treated in a nitrifying/denitrifying membrane bioreactor (MBR), together with the effluent of the BW treatment.

The MBR consists of two membrane units of 90 m^2 total membrane surface each, using newly developed PVDF ultrafiltration (UF) membranes (80 nm). The integrated permeate channel membranes are the first fully back-washable flat sheet membranes, especially designed to operate at high fluxes up to 40 L/m^2.h. The resulting excess sludge of the aerobic treatment is digested in the aforementioned UASB together with the BW and KW, to valorize its organic content and to increase energy production.

FIRST RESULTS AND ENERGY RECOVERY

The development of a new urban district goes in phases. To date, one of the three building areas is completely finished and in the second one, the first residents are arriving as well. As a result, respectively 88 and 30 housing units are already occupied on November 25th, 2022, with an average population density of 1,75 IE per unit. This results in an occupation of about 206 IE as continuous residents in the district, but also the local school and sports facilities of the City of Ghent are already connected to the decentralized WWTP. As a result, the system is operated at one fourth of its maximal capacity now, in November 2022. Two more large buildings are expected to be finished in early 2023, thus scale-up is expected very soon.

In Figure 1, the daily treated water flows in 2022 are shown as a function of time. On average, 12,73 ± 6,82 m^3/d is treated, of which 20,9% is black water. From January 1st up till November 25th, 3743 m^3 of wastewater was treated, of which 783 m^3 black water. For 2022, this already resulted in a total energy recovery of 15.352 kWh in the form of biogas. The struvite precipitation reactor was put in operation as well, resulting in an average struvite production of 175 g/day, which allowed to recover the first 50 kg of fertilizer for the local farming projects. A further update of the increasing full-scale technical results with the increasing number of residents in the district will be presented at EcoSTP23.

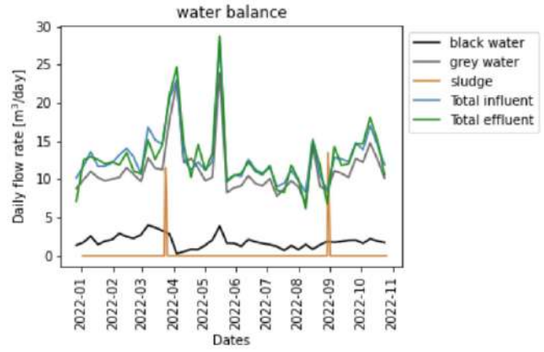

Figure 1. The daily flow rates of the separated streams treated in the decentralized WWTP at the Nieuwe Dokken in 2022. Excess sludge was removed two times, which resulted in the two peaks.

SAFE WATER REUSE FOR THE LOCAL INDUSTRY

Close to the newly developed urban area, a hygiene chemicals producing factory is located. The production process requires >35.000 m^3/y softened process water and 15.000 m^3/y demineralized water (<20 µS/cm). This need for water can be partially met by the reuse of the treated effluent. To meet the quality requirements, reverse osmosis (RO) is the key technology after the pretreatment by ultrafiltration in the aerobic MBR.

High quality water, free of pathogens, nutrients and hardness is achieved and completely reused in the factory. Hence, the decentralized water reuse plant can be considered as a zero-liquid discharge installation, as the RO concentrate is completely reused as well. Specific attention is given to the fate of organics during membrane filtration, since 25,79 ± 7,79 mg COD/L is still present in the effluent after the aerobic MBR. Therefore, organic carbon and specific organic compounds creating discoloring and bad odor of the final water are monitored.

To date, the first batches of reclaimed WWTP effluent have been produced and reused for the full-scale production of hygiene chemicals by the factory. Figure 2 shows the resulting waters after the different treatment steps, from UF filtrate to softened process water (< 0,3 °F).

Figure 2. The resulting waters after the different treatment steps in the water reuse process: (L) UF filtrate, (M) after organics removal with activated carbon, and (R) softened process water after ion exchange, ready to be used in the full-scale industrial process.

Moreover, the factory produces a lot of excess heat in the air chillers and heat exchangers of the production process. This heat will be recovered by coupling it to the district heating system in the urban area, thus meeting the remaining 2/3 of the total heat demand. This demonstration project of innovative STP layouts for the city of the future thus combines water, energy and nutrient recovery.

SOCIO-ECONOMIC MODEL AND GOVERNANCE: INVOLVEMENT OF THE LOCA COMMUNITY AND NEW BUSINESS MODEL

One of the most important aspects to remove the roadblocks for implementing new reuse schemes in an urban settlement, is the integration of the local community and a sound business model within the boundaries of the current legal framework for resources recovery. Therefore, an Energy Service Company (ESCO) has been set up to organize the technical maintenance and district services. This ESCO is a mixed private-public-citizens initiative in which the local inhabitants are represented, together with investors and public stakeholders such as the local water utility FARYS.

The local community benefits directly from the revenues of the recovered products and the local district heating system. This integrated approach in combination with the scale of the project will significantly contribute to the public acceptance of new urban water reuse schemes and the believe in the opportunities to turn STPs into profitable decentralized water resource recovery facilities, allowing affordable water reuse and resource recovery in the cities of the future.

The Nieuwe Dokken project was part of the Run4Life project, funded by the EU H2020 program CIRC-01-2016-2017 - "Systemic, eco-innovative approaches for the circular economy: large-scale demonstration projects", and the "New Energy and Resources from Urban Sanitation" (NEREUS) project, funded by the EU Regional Development Fund (Interreg 2 Seas). Prof. B. De Gusseme takes part in the EU COST action CA17133 "Circular City" – WG3: Resource recovery.

Abstract

Decentralized treatment and source separation hold the potential to drastically improve the technical, environmental, and economic performance of current technologies. This research assesses the techno-economic feasibility of implementing independent and community-level decentralized systems for rainwater harvesting, potable and wastewater treatment, and resource recovery in five main types of buildings (e.g., household, townhouse, high rise, etc.). Five different treatment layouts under five different climatic conditions were evaluated per each type of building. The proposed layouts consider varying levels of source separation (i.e., black, grey, yellow, brown, and, even, typical wastewater) using the corresponding toilet types (vacuum, urine-diverting, and conventional) and the necessary pipeline and pumping requirements. We show that the proposed layouts could satisfy 100% of the water demand in most of the scenarios (e.g., medium-sized buildings in wetter climates) while the worst scenario (i.e., high-rise building in arid climate) could satisfy up to 75% of the water demand. A comprehensive economic analysis considering CapEx and OpEX yielded that the cost of upgrading the buildings to become water and wastewater independent is 5.6-11.6% of the total construction cost of the building for larger buildings and individual dwellings, respectively, with relatively low space requirements. For buildings or combined water systems with more than 300 people, the total price of water (including harvesting, treatment, recycling, and monitoring) could range between $1.5/m3 and $2.7/m3 in comparison to the current $4-3.5/m3 in the USA and western Europe. Our results indicate that extreme decentralization is not only technically feasible but also has the potential to reduce the cost significantly and environmental impact of water services, improving the marginal cost of water and other societal benefits, which could facilitate the necessary transition in the urban water system.

Keywords: Decentralization, resilience, source separation, source recovery, modelling

Introduction

The push toward a transition in the urban water system keeps increasing as freshwater resources are under unprecedented pressure due to over-consumption from a growing population, climate degradation, and poor management (Daigger et al., 2019; IPCC, 2022; Olsson, 2015; Sedlak, 2014; van Loosdrecht and Brdjanovic, 2014). Traditional water and wastewater supply infrastructures, which involve centralized treatment and the energy-intense activated sludge (AS) process (which follows a disposal-oriented approach), are being questioned because of their environmental and economic underperformance and their low resilience against extreme natural events due to climate change. Alternatively, a decentralized system based on the source separation of grey (GW) and brown and yellow (BW+YW) water, together with rainwater capture and state-of-the-art resource recovery technologies, has the potential to improve the efficiency of the urban water system by reducing both energy consumption and greenhouse gas emissions, while allowing nutrient and energy recovery. Thus, extreme decentralization coupled with source separation and resource recovery is a potential venue towards sustainability, reliability, and resilience of the water system (Garrido-Baserba et al., 2018; Larsen et al., 2016; Peter-Varbanets et al., 2009; Piratla and Goverdhanam, 2015; Remy, 2010; Roefs et al., 2017).

Material and Methods

To evaluate the technical feasibility of implementing decentralized systems, this study covers the theoretical implementation (using state-of-the-practice technologies and methodologies) of an online monitoring and control system coupled with a real-time model-based digital twin. The digital twin corresponds to one of the treatment configurations applied to five housing types (i.e., from low-rise dwellings and high-rise buildings to city blocks). Creating a digital twin of one of the most cost-effective, sustainable, and resilient alternatives enabled: (i) a deeper understanding of all the required processes and steps (while confirming effluent water quality), (ii) improved reactor and equipment seizing to calculate the required space better, (iii) using resource models (aka LCA) for a detailed environmental and economic analysis, (iv) incorporate economic benefits (i.e., resource and energy recovery).

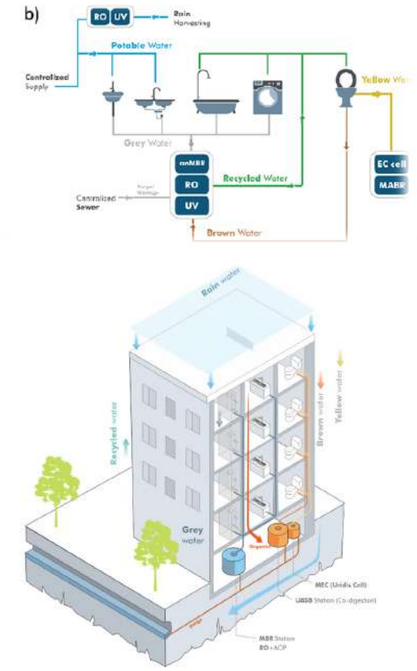

Figure 1. The upper flow diagram represents one of the fully decentralized approaches correspondings to the urine-diverting layout (b), and the larger is a conceptual 3D representation of the flows within one of the studied buildings (i.e., Medium-size)

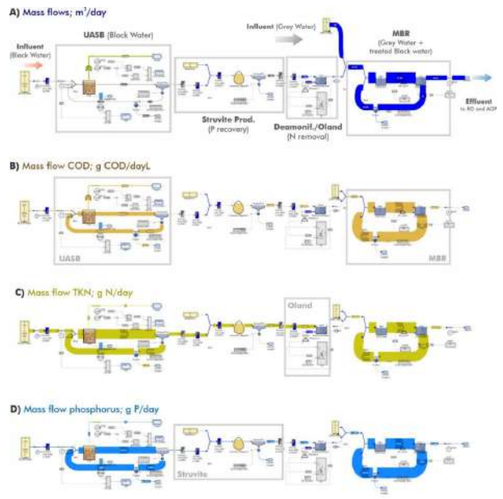

Figure 2. Model of the V1 layout with its corresponding Sankey diagrams obtained by the modeling software SIMBA#. The Sankey diagrams represent a) Blue, m3/day; b) Brown COD, mg COD/L; c) Green, TKN, mg N/L; and d) Light blue, Phosphorus, mg P/L. Five other models corresponding to the five scenarios under consideration were built and tested.

Results and Discussion

The modelling of the proposed decentralized systems confirmed the technical feasibility of extreme decentralization, and we made several observations:

- The simulations indicated that all the different effluents meet current quality regulations in terms of greywater reuse and drinking water. Existing institutional barriers (or non-technical barriers) are slowly adapting to new frameworks and financing schemes, facilitating the path toward a potential adoption.
- New developed models (i.e., anMBRs, UASB and biofilm reactors, and an improved co-digestion-biogas model) helped confirm their adequacy and identify the most cost-effective alternatives.
- A sewer model helped identify potential sewer management strategies that, coupled with a theoretical future large-scale decentralization adoption (reducing sewage from urban areas), could be used to ameliorate the effects of the changing climate; sewers could be used to better manage the alarming decrease in the return period of extreme events due to climate change.
- The use of resource models (SIMBA# nomenclature for LCA sub-models) helped evaluate environmental impacts and supported the creation of an inventory for operational costs calculations. Operational costs were added to capital costs, and it was identified that during the construction of new residential blocks, only 5.6-11.6% of additional investment would be required to deploy the required equipment and pipeline network.
- A digital twin of the most favorable alternative was built and implemented to a remote monitoring platform, enabling exhaustive and remote monitoring and control of the operations.

Conclusion

Extreme decentralization coupled with source separation is technically and economically feasible. Thanks to the most recent advances in modelling (e.g., biofilm and anaerobic processes, co-digestion for biogas, system-wide evaluations, rain harvesting & management, biogas, etc.) and new control tools (e.g., digital twins, predictive models), is possible to explore and study in great detail those treatment configurations better suited to tackle current climate challenges, which are aligned with key concepts such as resilience, circular economy, resource recovery, and sustainability. The most sustainable and decentralized treatment configurations (from an LCA perspective and top expert opinions) were implemented using modelling software. A digital twin was developed for the most economical and sustainable treatment configuration.

This study found that extreme decentralization has the potential to reduce the cost and environmental impact of water services significantly. In the upcoming years, the total cost (and amount) of water may well increase when considering the cost of maintaining the legacy of the centralized and the new decentralized infrastructure. However, this study shows that decentralization could improve the marginal cost of water (i.e., cheaper than building new reservoirs and desalination plants) and other societal benefits, facilitating the necessary transition in the urban water system.

The modelling of extreme decentralization enabled us to put numbers on some of the key concepts towards a potential transition towards source and energy efficiency, such as 92-98% of water recycling capacity (either rain harvesting or direct potable reuse), energy-neutral (Anaerobic-based plus co-digestion instead of the current aeration-based CAS, which is highly energy inefficient), resource production (Biogas or hydrogen and high-quality fertilizer), better integration with the whole urban sewer and wide-system management (i.e., resilience sewer strategies), and resilient (designed to be independent of the potable system and the electric grid, if needed).

Abstract

Decentralised wastewater treatment is becoming a suitable strategy to reduce cost and environmental impact. Besides, it presents a potential on reducing the release of contaminants of emerging concern (CECs) such as organic micropollutants (OMPs), antibiotic resistance genes (ARGs). In this research, a characterization of the performance of two technologies treating black water (BW) and grey water (GW) fractions of urban sewage is carried out in a decentralised treatment of the wastewater produced in three office buildings in NW Spain. An anaerobic membrane bioreactor (AnMBR) treating BW and a hybrid anoxic/aerobic membrane bioreactor (H-MBR) treating GW were operated at pilot scale. Their operation was characterised in terms of removal of conventional pollutants, such as COD, TN, TP, and CECs. Preliminary results showed a stable operation in both systems in terms of COD and TN removal in AnMBR and H-MBR, respectively. The behavior of selected OMPs was analysed in a first sampling campaign, in which it was found a different distribution of compounds among sewage fractions. A initial characterization of ARGs was carried out to select a list of genes to be monitored by q-PCR. Final results are expected to be received in the coming weeks.

Keywords (maximum 6 in alphabetical order)

Antibiotic resistances, decentralised treatment, membrane processes, organic micropollutants.

INTRODUCTION

Wastewater treatment is being adapted to achieve sustainability goals, such as resource recovery and water reuse. The conventional wastewater treatment strategy consists on the centralised treatment of the sewage produced by a certain populated area, which means high construction (sewers and full-scale plants) and operational (high flows and energy demanding technologies) costs. Currently, decentralised treatment is becoming an interesting alternative to achieve sustainability, by treating wastewater in its source of production and selecting the most suitable technologies according to its characteristics (Arias et al., 2020). Regarding contaminants of emerging concern (CECs), such as organic micropollutants (OMPs) and antibiotic resistance genes (ARGs), decentralised treatment is a promising strategy to reduce *in situ* their load released to the environment by implementing the most suitable technology for each matrix. Despite its potential, there is still a lack of knowledge in this topic (Hube & Wu, 2021), since the actual implementation of decentralised treatment is challenging yet.

The aim of this work is to characterize the decentralised treatment of three office buildings in NW Spain regarding conventional pollutants removal, OMPs presence and fate, and ARGs distribution.

MATERIALS AND METHODS

Experimental setup

The black water (BW) generated in the three office buildings was treated in an anaerobic membrane bioreactor (AnMBR) pilot plant. BW are collected after grit removal in a non-stirred equalization tank of 2 m^3. From this unit is fed to a digester of 2.4 m^3, where anaerobic digestion of organic matter takes place. The filtration step is carried out in a separated compartment of 1 m^3, where the produced biogas in the digester is recirculated to prevent membrane fouling. The AnMBR permeate comes from a 6.25 m^2 ultrafiltration plate membrane module. The generated grey water (GW) was collected in a non-stirred equalization tank of 1 m^3, and fed to a hybrid anoxic/aerobic membrane bioreactor (H-MBR, patent EP 1484287 B1). H-MBR consist of three compartments: a continuously stirred anoxic compartment (17.8 L), an aerobic compartment (20.2 L) and a filtration compartment (9.5 L). Both anoxic and aerobic chambers contained suspended biomass and Biochip carriers (20% of working volume each). The filtration chamber contains a hollow fibre membrane module of 0.6 m2. Suspended biomass is recirculated from the filtration compartment to the anoxic chamber.

Analytical methods

Conventional parameters. COD, N species, total and volatile suspended solids (TSS, VSS), etc. were monitored twice a week, according to the Standard Methods.

Organic micropollutants. A selection of eight relevant compounds was carried out. First, according to the latest EU Watch Lists (2020, 2022), three antibiotics were selected: sulfamethoxazole (SMX), trimethoprim (TMP) and ciprofloxacin (CIP). Then, another six compounds were selected due to their presence in the BW of the site: two anti-inflammatories, ibuprofen (IBP) and naproxen (NPX); and three hormones, estrone (E1), β-estradiol (E2) and α-ethinylestradiol (EE2). The selected compounds were not spiked to the system. OMP samples were preconcentrated by solid phase extraction (SPE) and determined by LC-MS/MS.

Antibiotic resistance genes. Initial information on ARGs was obtained using a chip-based HT-qPCR approach. This screening was carried out on biomass and water streams of the plants. For this procedure, different criteria were applied to select an initial list of 34 genes. According to these results and the ARGs health risk classification proposed by Zhang et al. (2021), a subset of genes (n=7) was selected for further quantification via qPCR

RESULTS AND DISCUSSION

General results

The decentralised system was operated for 226 d. AnMBR hydraulic retention time (HRT) was maintained at 2.36±0.19 d. Since the production of GW during weekends was not enough to maintain a continuous operation, H-MBR was operated 5 days a week, with a HRT of 4.71±0.03 h. The anaerobic treatment of BW efficiently removed COD, as shown in Figure 1a. Total nitrogen (TN) was not removed in this stage: 124.5±27.7 mg N L^{-1} at the influent and 115.4±20.1 mg N L^{-1} at the permeate. In BW treatment line, the COD removal efficiency achieved was 89.7±3.5 %. TN removal efficiency and nitrogen species concentration in this system are displayed in Figure 1b. Despite the relatively low influent TN concentration in BW, 4.1±1.1 mg N L^{-1}, it was achieved a removal efficiency up to 54 %.

OMPs behavior

Two sampling campaigns were carried out in each plant to characterize the occurrence and fate of the selected OMPs in the decentralised system. The concentrations of the different compounds found in the influent of both BW and GW treatment lines in the first sampling campaigns are gathered in Table 1. As expected, the occurrence of the selected OMPs is higher in BW than GW, where only TMP and IBP were detected at relatively low concentrations. The removal of these compounds in the H-MBR was 9.8±17 % and 22.5±5.3 %, respectively. The removal efficiencies of the detected compounds in BW line are shown in Figure 2. Although the low influent concentrations, compounds such as TMP and NPX were moderately removed in the AnMBR, which could be expected since both compounds are easily biodegradable in anaerobic environments (Alvarino et al., 2018).

ARGs characterization

The characterization of the ARGs present in the system was carried out in two sampling campaigns at the beginning and at the end of the operation. The initial characterization using HT-PCR resulted in a preliminary overview of the 34 selected genes SmartChip q-PCR. From this list, a final selection was chosen, considering the most relevant gene of each analysed class according to the methodology proposed by Zhang et al., 2021. The final selection is presented in Table 2. The normalised (-log) relative abundances of the final selection are presented in Figures 3a (BW treatment line) and 3b (GW treatment line). Lower relative abundances were found in the GW line, as expected. The results of the final characterization are still pending.

Decentralized hybrid wastewater treatment system for water reuse on a campsite at Costa Daurada

J. Llimós*, M. Casademont*, J. Herrero*, Q. Plana* and S. Casas*

* Eurecat, Water Air and Soil (WAS) Unit, Plaça de la Ciència, 2, 08242 Manresa, Barcelona, Spain
(E-mail: *Jordi.llimos@eurecat.org)*

Abstract
The risk of water scarcity in Spain is the highest among European countries. Wastewater reuse through decentralized systems could improve the sustainability of the water systems. Producing high-quality water effluent that can be used for a wide diversity of non-potable uses, can increase the water availability. In this context, a decentralized hybrid wastewater treatment system for water reuse is going to be implemented in the Tamarit Beach Resort Campsite at the Costa Daurada. It is expected to obtain a high-quality water for irrigation and cleaning purposes inside the campsite and a treatment system that could be applied to other similar campsite from the Mediterranean coast.

Water reuse; Decentralized system; Climate resilience; Upflow anaerobic sludge blanket

INTRODUCTION

Spain has the highest risk for water scarcity and aridification among European countries. Catalonia, in particular its coastline, is a region that struggles with the supply of potable water. Thus, since the early 2000's the Catalan government has made significant progression implementing water management strategies.

Campsites along the Catalan coast use commonly the public drinking water network for potable and non-potable uses. Alternatively, some of them used other sources, such as their own wells or rainwater tanks. Last decades, campsite resorts applied water-saving measures (WSMs) motivated by competitiveness, legitimation, and ecological responsibility (Llausàs et al., 2020). Wastewater segregation and reuse is one of the alternative and emerging approaches to cope up with sustainable and integral water management where the population faces acute water shortages (Ofori et al., 2021). However, some risks may arise when wastewater is reused. Among them, major constraints are associated with microbiological risks, and the impact of detergents and xenobiotic organic compounds and their toxic effects on the environment, on humans, and wildlife (Eriksson et al., 2002).

The wastewater treatment to be implemented depends on the reclaimed water uses and their specific requirements according to water quality standards and guidelines such as WHO and UNEP (2006); USEPA (2012); Real Decreto 1620/2007. For example, the previously studied aerobic and anaerobic biological wastewater treatment technologies including the sequencing batch reactor (SBR), the membrane bioreactor (MBR) and the upflow anaerobic sludge blanket (UASB) (Khalil & Liu, 2021) could be used to produce reclaimed water. The lower cost of anaerobic treatment compared to aerobic treatment, presents the anaerobic reactor as a suitable technology to be implemented.

In the context of the European project IMPETUS, the challenge addressed is to develop and implement, in the Tamarit Beach Resort Campsite, a decentralised hybrid water reclamation system to increase water availability for non-potable uses within the installations. The objective of the demonstration is to prove the economic, social and environmental benefits of wastewater reuse in the context of campsites on the Catalan coast.

MATERIALS AND METHODS

Lab-scale experimental design

The proposed treatment approach will be adapted to the production peaks during vacation period and weekend peaks during the mid-season. In addition, wastewater treatment will be adapted to the strict legislation for water reuse (i.e., Real Decreto 1620/2007) and the foreseen use for green zones and other cleaning purposes. Figure 1 shows the scheme for the proposed treatment. Three steps are foreseen: 1) dissolved organic carbon by UASB with ultrafiltration, 2) nutrients removal by a biofilter/NBS solution and 3) polishing step, with a disinfection. The UASB have an approximated working volume of 12 L and is coupled to a submerged ultrafiltration membrane. The concentrate of the ultrafiltration is recirculated to the anaerobic reactor in a relation of 6:1 respect the feed flowrate.

Scale-up of the treatment process on site

The proposed UASB treatment process tested at a bench-scale experiments will be implemented on the campsite installations, to treat between 0,5-1 m^3/h of wastewater. The final process design will be scaled-up from the results obtained in the bench-scale set-up maintaining the operating conditions selected during the experiments.

RESULTS AND DISCUSSION

Consumption data from the public network of the campsite

The initial data available from the campsite was used to study the seasonality of water consumption.
Water consumption is heavily dependent on the drinking water network, with a percentage that has been increasing steadily (data not sown). Furthermore, the water consumption from the public network clearly shows the seasonality of consumption and how it is highest in the summer season and lowest in the winter season (Figure 2), due to the vacation's period.

Initial characterization of the wastewater

First of all, an initial screening of 3 different point to characterize the water that will be treated was performed, as presented in table 1. Point 1 (P1) and point 2 (P2) seems to have a lower COD concentration than Point 3 (P3). The microbiological content (E.coli concentration) from the P3 is higher than P1 and P2. Also, the chloride concentration in P2 is high because some pool water is collected in this point. Due to the characterization performed, the results obtained and the amount of flow available during the year in each point, P3 water was selected to be treated.

Initial AnMBR (UASB) performance

Currently, the UASB with ultrafiltration is at the granulation stage of the biomass. To promote the granulation calcium sulfate was added in an approximated concentration of 200 mg/L Ca^{2+}. It was achieved up to 80% of COD removal during this initial stage performance. Due to that granulation has not yet been fully reached, the nutrients' removals are around 50%, but it is expected to have better nutrients removals when the granulation is achieved, and mature granules are formed. In addition, the biofilter/NBS and the disinfection steps have not been considered at the lab scale tests, and improved removal efficiencies are expected once the system is implemented on site.

Conclusions

The UASB reactor have high COD removal efficiencies even during the initial stage of the performance. When the biofilter/NBS steps coupled to the disinfection unit will be implemented it is expected to obtain a high-quality reclaimed water for self-consumption at the campsite.

Faculty of Civil and Environmental Engineering, University of Iceland, Hjardarhagi 2-6, IS-107, Reykjavik, Iceland; (E-mail: *seh34@hi.is; iuh1@hi.is; wubing@hi.is)*

Abstract

This study investigated the effects of reactor configuration, operation temperature, and periodically cleaning protocol on the performance of biocarrier-facilitated gravity-driven membrane (GDM) reactors in treating municipal wastewater. The results indicated that (1) the cake layer fouling was predominant, regardless of reactor configuration and operation conditions; (2) decreasing operation temperature had negligible effect on fouling resistance distribution patterns and permeate quality; (3) in the presence of periodic cleaning (at 50°C), the cleaning effectiveness followed a sequence as ultrasonication-enhanced water flushing > two-phase flow cleaning > chemical-enhanced water flushing > water flushing, regardless of GDM operation temperature. Furthermore, the wastewater treatment costs of the GDM reactors were estimated at ~0.3 Euro/m^3, which was lower than that of conventional membrane bioreactors under lower population scenarios.

Biocarriers; Gravity-driven membrane filtration; Low temperature; Membrane fouling; Periodic membrane cleaning; Permeate quality

INTRODUCTION

Recently, gravity-driven membrane (GDM) filtration has received great attention as an alternative decentralized wastewater treatment process. The advantages of the GDM process include that (1) it can produce superior treated water due to high membrane separation efficiency; (2) it is an economic process due to its lower capital cost (no permeate suction pump) and operation cost (without requiring physical and chemical cleaning) compared to the conventional activated sludge process and other membrane processes such as membrane bioreactors (MBRs) (Pronk et al., 2019).

However, a major challenge of GDM-based wastewater treatment process is its low permeate flux (< 5 L/m^{2}h without applying any cleaning protocols) due to limited driving force (< 1 m water head). To further improve GDM membrane performance and permeate quality, the biocarriers (such as granular activated carbon) were integrated with the GDM systems (Lee et al., 2019, 2021), aiming to pre-treat the wastewater before its permeating the membrane. However, there is still a lack of knowledge on the optimization of periodic cleaning protocols and fundamental mechanisms relating to flux enhancement in GDM systems operated under low-temperature conditions. Especially, the economic feasibility of GDM systems with periodically chemical cleaning has not been well illustrated.

This study aims to investigate membrane performance and permeate quality in lava stone facilitated GDM systems under combined effects of temperature and periodic cleaning. Several cleaning strategies at various cleaning frequencies were applied, such as geothermal water flushing, two-phase flow cleaning, ultrasonication- and chemical-enhanced physical cleaning. The membrane fouling mechanism was illustrated by fitting experimental permeate flux data with a previously reported constant pressure filtration model. The effects of temperature on biodegradation behaviours of biofilms and membrane separation efficiency were illustrated by periodically examining water quality in the GDM reactor and permeate.

MATERIALS AND METHODS

Reactor setup and operation conditions

In Stage 1, the effect of biocarrier types on the GDM performance was investigated. In detailed. R1, R2, R3 (Figure 1) with microfiltration membrane modules (0.2 µm) were operated at ~10°C in parallel, with periodic chemical (NaClO; 0.5%, 50°C) cleaning (60 min per 3-4 days). Synthetic fibers (~0.93 m), lava stones (~1 kg), and sands (~1 kg) were used as biocarriers for R1, R2, and R3, respectively. The water head was variable at 0.22-0.25, 0.22-0.25 m, and 0.24-0.34 m for R1, R2, and R3, respectively. In Stage 2, two identical R4 were setup and operated at ~8°C and ~22°C, respectively, to investigate the effect of temperature and periodic cleaning approaches on the GDM performance. Lava stones were used as biocarriers and microfiltration membrane (0.08 µm, with 0.6 m water head) was placed in the filtration cell. The operation conditions were described in Table 1. The feed wastewater (taken from wastewater treatment plant at Klettagarður, Reykjavík, Iceland). was delivered to the tank via a feed pump, and its flowrate was periodically regulated based on permeate flowrate. The permeate was collected and weighted periodically by a digital balance.

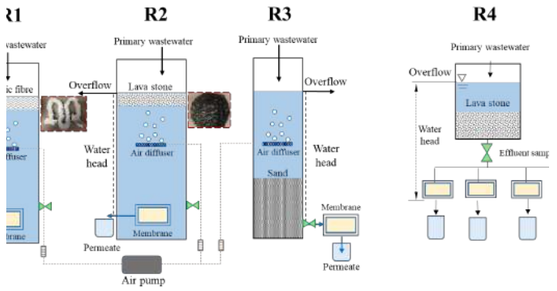

Figure 1. Schematic diagram of the GDM reactors.

Biofilm reactor operation time	Membrane cleaning condition	Membrane module			
		M1	M2	M3	M4
Day 0-15	**Phase I:** Geothermal water flushing (50°C)	No cleaning	10 min	30 min	60 min
Day 16-32	**Phase II:** Air sparging-enhanced geothermal water flushing (50°C)	0.3 L/min (60 min)	0.3 L/min (30 min)	0.6 L/min (30 min)	0 L/min (30 min)
Day 35-52	**Phase III:** PMS in geothermal water (50°C) for 30 min flushing	10 mg/L PMS	50 mg/L PMS	100 mg/L PMS	0 mg/L PMS
Day 56-66	**Phase IV:** No cleaning	No cleaning	No cleaning	No cleaning	No cleaning
Day 70-86	**Phase V:** Ultrasonication (50°C)	10 min	30 min	60 min	No cleaning
Day 90-108	**Phase VI:** Ultrasonication with flushing (50°C) for 30 min	Ultrasonication	Ultrasonication-enhanced geothermal water flushing	Ultrasonicated geothermal water flushing	No cleaning
Day 109-128	**Phase VII:** Comparison of physical and chemical cleaning (50°C, 30 min)	PMS (50 mg/L) in geothermal water flushing	Ultrasonication + geothermal water flushing	Air sparging (0.3 L/min) + geothermal water flushing	No cleaning

Table 1. A summary of membrane cleaning protocols in R4.

RESULTS AND DISCUSSION

The water qualities of feed, reactor effluent and membrane permeate in R4 are summarized in Figure 3. Both biofilm reactors achieved comparable COD removals, TN removals, and TSS removals, but increasing temperature significantly promoted biodegradable organic (BOD_5) removals in the biofilm reactors (56 ± 27% at 22°C *vs.* 47 ± 26% at 8°C, p<0.05).

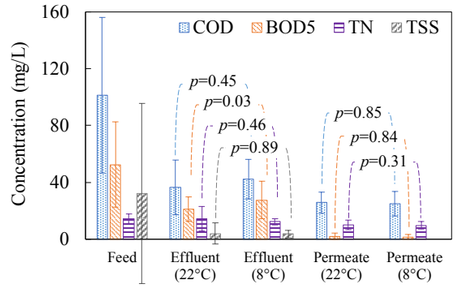

Figure 3. Water quality in feed, effluent and permeate (n=10-15).

The water production cost of R1-R3 ranged from 0.31 to 0.37 EUR/m^3, in which aeration energy cost (~70-83%) and membrane cost (~12-28%) were major cost items (Figure 4a). In MBR systems, the water production cost significantly dropped with population size and appeared to be constant above ~500 population condition, while in GDM reactors, there was almost no influence of population size on the water production cost (Figure 4b).

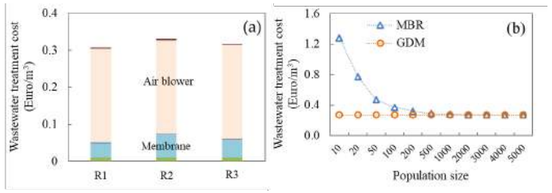

Figure 4. (a) Water production cost of R1-R3; (b) Comparison of water production cost in GDM and MBR systems.

As shown in Figure 5, extending cleaning duration benefited for fouling reduction. The cleaning effectiveness followed a sequence as "ultrasonication-enhanced water flushing" (~87% at 22°C and ~88% at 8°C) > "two-phase flow cleaning" (~67% at 22°C and ~81% at 8°C) > "chemical-enhanced water flushing" (~32% at 22°C and ~31% at 8°C). The operation temperature of the GDM system displayed insignificant effects on the fouling removal ratio (52 ± 21% at 22°C and 54 ± 23% at 8°C; p>0.05) and water productivity (0.28 ± 0.08 L/day at 22°C and 0.28 ± 0.08 L/day at 8°C; p>0.05). Cake layer resistances were dominant (>95%) in the GDM systems with periodic cleaning.

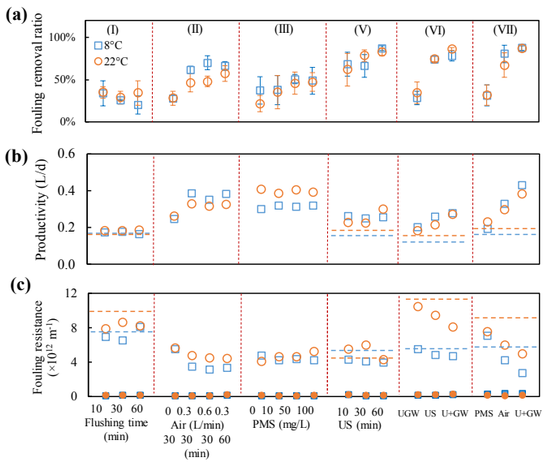

Figure 5. (a) Fouling removal ratio, (b) water productivity, and (c) fouling resistance (non-fill symbols represent cake layer fouling, solid-fill symbols represent irreversible fouling) in R4 with different periodic cleaning protocols. The dash line indicated the level in the control membrane module without periodic cleaning. "UGW" represents ultrasonicated geothermal water flushing; "US" represents ultrasonication; "U+GW" represents ultrasonication-enhanced geothermal water flushing.

Abstract

The combination of micro and macro-scale experimental approaches focusing on the role of natural freshwater microbiota was assessed as a highly nature-based solution to be implemented in wastewater tertiary treatment in small facilities (<10,000 PE). Both experiments were focused to evaluate removal efficiencies of nutrients, fecal bacteria (*E.coli*) and contaminants of emerging concern. Additionally, we tested the contribution of natural inoculum affected by treated wastewater release to reduce economical costs in the upscaling process that under laboratory-controlled conditions performed irrelevant differences compared to non-inoculum effect. Previous results demonstrated high removal capacity on nutrients (over 65% in laboratory conditions versus 25-70% in a real scenario).

INTRODUCTION

The treatment of sewage waters has improved significantly in last decades achieving a general reduction of the impacts generated by wastewater (WW) release to the environment. However, treated and untreated sewage waters are still one of the main sources of nutrients and pollutants to the environment worldwide. Current technologies adopted in wastewater treatment facilities generally focus on the reduction of suspended solids and organic matter to achieve the reduction of biological oxygen demand. In some cases, an additional step follows the secondary treatment with the main goal to reduce the high amount of nitrogen (N), phosphorus (P) and carbon (C) still present in treated sewage water. Small water treatment facilities rarely include this additional treatment step because of financial and infrastructural constraints. Moreover, this kind of wastewater treatment plant (WWTP) normally release its treated effluents to low-order streams with reduced dilution capacity. This can be a relevant issue particularly in arid and semi-arid zones (like Mediterranean area) subjected to long dry period that provoke water scarcity problems and frequent droughts in streams. Consequently, it is not rare to have streams in which the total amount of flowing water comes from WWTP effluents during droughts. It is therefore important to investigate the potential development of innovative low-cost technologies which implementation could be assumed by managers of small WWTP facilities in order to improve the quality of the treated wastewaters released to the ecosystem. This study aims to investigate the efficiency of freshwater microbial communities as potential nature-based solution for tertiary treatment in small WWTP facilities. To achieve this aim, two experiments were carried out at microcosms and macrocosm scale in order to test the removal efficiency of nutrients loads and fecal bacteria released to the aquatic environment. We hypothesize that microbial communities could have the capacity to obtain high nutrient removal in both conditions investigated. We also expected a rapidly growth of microbiota associated to maximal removal efficiency performance. These steps were essential before considering its implementation in a real scenario.

MATERIALS AND METHODS

We carried out two different experiments, one in microcosms under strictly controlled conditions (laboratory-scale) and the other in a pilot plant (mesocosm) installed in a WWTP. In the first case, a factorial experimental design was performed with benthic (B) and planktonic (P) compartments, separately and in combination (B+P), treating a secondary effluent of a WWTP (<10,000 PE) for 39 days. The effect of the addition of natural inoculum from an ecosystem affected by treated WW release was also assessed (BI, PI and BI+PI). In the second experiment, the pilot plant consisted in two connected modules in which benthic and planktonic microbial communities were growing for 49 days, respectively. In both conditions, the sampling collection was performed twice per week. The bioreactor received water from the effluent of a WWTP to reduce nutrients, fecal bacteria, and contaminants of emergent concern (CECs) before its release to the freshwater receiving ecosystem.

In both experiments, different water quality indicators (nutrients such as $N\text{-}NH_4$, $N\text{-}NO_3$, $N\text{-}NO_2$, TDN, $P\text{-}PO_4$, TDP and TP, faecal bacteria (*E.coli*) abundance, and CECs) were monitored to calculate and compare the removal efficiency of the respective bioreactor. A set of biological parameters of benthic and planktonic communities (total biomass (OM), algal biomass (Chlorophyll-*a*), microbial composition and photosynthetic efficiency) were also monitored simultaneously to be related with the removal performance in the bioreactor. The hydraulic retention time (HRT) was 3 and 1.6 days in microcosm and macrocosm experiments, respectively.

RESULTS AND DISCUSSION

Preliminary results were focused on phosphorus and nitrogen removal efficiencies in laboratory and WWTP conditions.

Laboratory bioreactor efficiency (microcosms)

Total phosphorus (TP) and total dissolved nitrogen (TDN) were strongly reduced over time in benthos (B) and combination with plankton reactors (B+P) in which the lowest removal efficiencies were obtained on WW impacted inoculum (BI and BI+PI) (>50%) (Figure 1).

Respect to biotic indicators we specifically focused on benthic algal biomass (which resulted highly correlated with total biomass $r = 0.81$; $p < 0.001$). In general, a significant negative non-parametric relation was obtained between chlorophyll-*a* and total phosphorus concentration in most of the treatments highlighting an important effect of algal biomass over the reduction of phosphorus (Figure 2.a) that was not detected for nitrogen reduction (Figure 2.b).

Macroscale pilot bioreactor optimisation

In real WWTP conditions high reduction of *E.coli* and nitrogen was observed (84.7 ± 30.8% and 72.5 ± 9.3% respectively) compared to phosphorus (23.8 ± 29.4%). Benthic algal biomass presented a clear increment in the first two weeks with a degradation of their composition after a month of the system operation. However, in the planktonic compartment the algal biomass peaked after two weeks and the gradually decreased until the end of the experiment (Figure 3). Additionally, the benthic algal biomass did not show any significant correlations with TDN and TDP concentrations. Nevertheless, in the planktonic compartment the increment of nitrogen was related to higher concentration of algal biomass (Figure 4).

Upscaling the process should be the last step before the implementation of this nature-based solution in small WWTPs, specifically below 10,000 PE in which European Legislation was less restrictive (European Commission 1998). Further research in incrementing the treated WW capacity of this bioreactor was required before its implementation in real conditions.

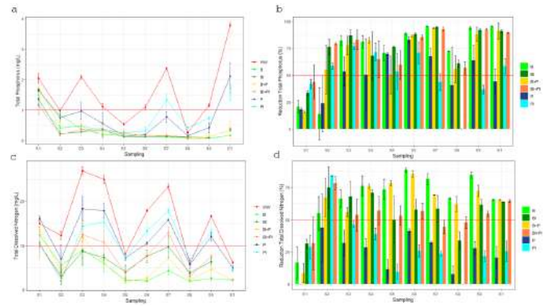

Figure 1. Total phosphorus and total dissolved nitrogen concentration over different sampling dates (a,c), red horizontal line fixed the limit of urban wastewater release by 98/15/CE UE Commission Directive of 27th February,1991. Reduction of total phosphorus and total dissolved nitrogen over different sampling dates (b,d), red horizontal line fixed the 50% attenuation efficiency of each nutrient.

Abstract
Human adenovirus type F-41 has been pursued as one of the potential reasons for the new acute hepatitis cases of unknown cause in young children. Tracking its spread in the population using wastewater can help clinical investigations. In this study, methods to detect human adenovirus type F and specifically type F41 were designed and implemented to quantify the amount of these pathogens in wastewater. An assay based on RT-qPCR reaction using TaqMan technology and primers targeting the three main capsid genes of adenoviruses: hexon, penton, and fiber, was designed. The hexon primers were specific to adenovirus F41, while fiber primers could quantify both adenoviruses, F40 and F41. Wastewater samples from Stockholm were used to validate the designed assay.
Our results can contribute to a better understanding of the possible causes of new cases of acute hepatitis.

Keywords
Acute hepatitis, human adenovirus F41 (HAdV-F41), human adenovirus F40 (HAdV-F40), wastewater-based epidemiology (WBE).

INTRODUCTION

Human adenoviruses are nonenveloped DNA viruses and are classified into seven species (A to G) and at least 104 genotypes [1]. Adenoviruses can cause respiratory illness, gastroenteritis, conjunctivitis, or cystitis in young children [2]. Adenovirus type F (40 and 41) usually causes acute gastroenteritis in children and cases of hepatitis have been reported in immunocompromised children associated with adenovirus type 41 (HAdV-F41) infection [2].

A sudden increase in acute hepatitis cases of unknown cause was reported to the World Health Organization (WHO) in 2022. Between April 5 and July 8, 2022, 1 010 probable cases and 22 deaths were reported by 35 countries, including five pediatric patients with severe hepatitis of unknown origin identified at a children's hospital in Alabama, U.S., in early October 2021 [3]. Of the 1 010 probable cases, 5% of the children required a liver transplant, and almost half of the cases (48%) were reported from European countries. The children were under 16 years old, had liver inflammation (including some with liver failure), and tested negative for hepatitis A to E (WHO, 2022). The cases were not associated with travel, and most children tested positive for adenovirus, in which type 41 was predominant. Of 251 cases tested for adenovirus in the UK, 68% gave positive results against this pathogen [4]. In Alabama, HAdV-F41 was detected in all five infected patients [5].

Wastewater-based epidemiology (WBE) is a useful tool to detect the occurrence of viruses in a population, as viruses do not possess the ability to grow outside their host and their concentration in wastewater can be representative of the infection rate [6]. Simultaneous detection of different adenoviruses genotypes was previously investigated to determine the removal efficiency of "generic" adenoviruses through the wastewater treatment process [7–9]. Few studies were able to specifically identify HAdV-F41 [10–12], and previously designed primers to detect HAdV-F41 can be less specific for emergent variants. According to Götting and colleagues (2022), HAdV-F41 has evolved significantly over the past decade, which possibly has resulted in altered virulence of this pathogen. The emergence of a novel strain of HAdV-F41 could be suspected, which may be causing hepatitis.

In this study, the gene sequences of these three major capsid genes, hexon, penton and fiber, were used to design the primers and probes for the quantification of adenovirus type F by RT-qPCR. The difference between the specificity of the primers was tested. In silico and in vitro validations were performed and wastewater samples from Stockholm were used to validate the designed methods.

MATERIALS AND METHODS

Primers and probes targeting the main capsid genes of adenovirus: hexon, penton and fiber, were designed using recently published genome sequences of HAdV-F41 variants current in 2021 and 2022: MW567962.1 (March 2021), ON532826.1 (May 2022) and OP174922.1 (August 2022). The primers were analyzed in silico using Basic Local Alignment Tool (BLAST) from the National Center for Biotechnology Information (NCBI) and the sequences of the three primer sets were confirmed to match HAdV-F41. Then, the primer sequences were aligned against twenty HAdV-F41 species and two HAdV-F40 species from NCBI GenBank. The alignments were performed using DNASTAR Bioinformatics Software. Subsequently, the hexon, penton, and fiber primers were evaluated against thirteen genotypes of human adenovirus for species A, B, C, D and E and three positive controls of adenovirus type F. The adenovirus species were provided by the Norrlands Universitetssjukhus (Klinisk Mikrobiologi, Umeå, Sweden).

RT-qPCR assays were performed using TaqMan Reliance One-Step Multiplex Supermix (BioRad, Cat # 12010221). 1 µL of 20 mg/ml Bovine Serum Albumin (BSA) (Thermo Scientific, Cat # B14) was added to reduce PCR inhibitors and enhance efficacy, for a final reaction volume of 20 µL. Reactions were considered positive if the cycle threshold (Ct) was below 42 cycles. Amplifications were carried out on the FAM channel. Standard curves were created using constructed plasmids containing appropriate regions for hexon, penton, and fiber (IDT, Custom MiniGene 25-500 bp).

Wastewater samples from Stockholm were used to validate the method. Approximately 500 ml of wastewater samples from each inlet were taken over a period of 24 hours from Monday to Tuesday, using a flow-proportional composite sampler. Wastewater samples were transported to the laboratory on ice and kept at 4°C until further analyses. Wastewater sample concentration and TNA extraction were performed using Maxwell RSC Enviro TNA Promega Kit and Maxwell RSC Instrument (Promega Biotech AB, Sweden). Two independent replicates were analyzed for each sample and tap water was used as a negative control for viral concentration and DNA extraction steps. The PCR amplicons from the wastewater samples obtained after RT-qPCR were purified using GeneJET PCR Purification Kit (ThermoFisher Scientific, Cat # K0701). Two pure PCR products per sample were sent for Sanger sequencing, which has been performed by Eurofins.

RESULTS AND DISCUSSION

In silico and in vitro validation of primer sets

The primers and probes were designed to be specific to adenovirus type F. To test their specificity, different adenovirus species (A, B, C, D and E) were used as negative controls. The three sets of primers (hexon, penton and fiber) gave negative results for species A to E, confirming that the primers are specific towards HAdV-F. Subsequently, the primers were in vitro tested against one positive control of HAdV-F40 (strain HoviX) and two variants of HAdV-F41 (strain Tak and strain isolated from a Swedish patient). Fiber and penton primer sets detected the HAdV-F40 (strain HoviX), while hexon primers gave negative results, showing no specificity towards HAdV-F40 (Figure 1a). The primers targeting the hexon region could not detect adenovirus F41 (strain Tak) (Figure 1b). However, the HAdV-F41 variant previously isolated from a Swedish patient was detected by all three primer sets, which quantified similar amounts of the virus, with no significant difference (P-value = 0.35, Figure 1c). The validation of primers in silico and in vitro showed that hexon primers are selective for recent HAdV-41 strains evolved in lineage 2. Fiber and penton primers can be used to detect both HAdV-40 and HAdV-41 variants. However, penton is less sensitive against HAdV-40 than fiber primers, but both primer sets can detect similar amounts of HAdV-41 strains.

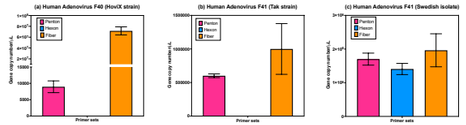

Figure 1. Analysis of positive controls for human adenovirus F40 and F41 using primers-sets for hexon, penton and fiber regions. Quantification of HAdV-F40 and F41 determined by RT-qPCR analysis of the hexon, penton or fiber region in three controls (a) Prototype HAdV-F40 HoviX strain (b) Prototype HAdV-F41 Tak strain (c) and an HAdV-F41 strain isolated from a patient in Sweden.

Validation of primer sets using wastewater samples

After in silico and in vitro validation, the primer sets were evaluated with raw wastewater from Stockholm. The results showed that primers targeting the hexon region detected lower amounts of adenovirus compared to penton or fiber primers (Figure 2). These results are in line with the outcomes obtained in the specificity study since hexon primers were more specific to HAdV-41 lineage 2 and did not detect HAdV-F40 or HAdV-F41 Tak strain. Fiber primers detected higher levels of adenovirus compared to penton primers in all the samples (Figure 2b). Fiber and penton assays detected the same trends of increasing or decreasing amounts of virus, whereas the hexon primers detect a different trend. The fiber and penton assays detected about 100 times more viral DNA copies (around 10^{17}) than the hexon primer (10^{15}). A recent study showed an increasing detection of HAdV-F40/41 in wastewater, which correlates to the increasing number of clinical cases in Northern Ireland [14]. In this study, statistical correlations were not performed due to the lack of clinical surveillance of adenovirus in Sweden.

Furthermore, Hexon, penton and fiber PCR products were analyzed by Sanger sequencing. The obtained sequences were compared in the NCBI databases by BLAST and Hexon PCR products showed specificity for HAdV-F41. In the case of penton and fiber, the DNA sequences were not specific to HAdV-F41 and a double detection of HAdV-F40 and HAdV-F41 can be suspected.

Clinical surveillance of adenovirus in the population is challenging because symptoms may not always be specific and laboratory tests are only performed after severe symptoms. Therefore, WBE could be a valuable tool for community surveillance of HAdV-F41 and for monitoring the newly evolved variants by sequencing. Furthermore, this study confirms the growing evidence that WBE can be used as an effective public health strategy for the surveillance of pathogens in addition to SARS-CoV-2.

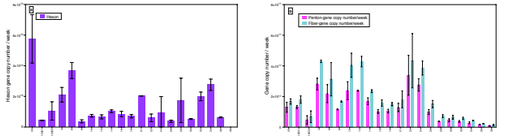

Figure 2. Quantification of HAdV- F40 and F41 using primers-sets for hexon, penton and fiber regions in wastewater samples. Gene copy numbers of HAdV-F41 and F40 per µL were determined by targeting (a) hexon region (purple), (b) penton (pink) and fiber (green) regions. Two biological replicates were analyzed for each sampling point.

Abstract
Wastewater-based epidemiology (WBE) has been used to track the spread of SARS-CoV-2 in several countries since the beginning of the pandemic. SARS-CoV-2 levels were monitored from April 2020 in Stockholm and August 2021 in Malmö, providing extensive information about the spread of Covid-19 in two of the biggest cities of Sweden.
During this long-term surveillance, two sampling protocols, two RNA concentration/extraction methods, two calculation approaches, and normalization to the RNA virus Pepper mild mottle virus (PMMoV) are presented and discussed. In addition, a storage condition study was performed, and we demonstrate that the decay of virus RNA (Nucleocapsid gene and PMMoV) was lower when glycerol was added to the wastewater before storage at -80°C. Furthermore, SARS-CoV-2 variants were detected using hpPCR and next-generation sequencing. Our results can contribute to a greater understanding of the multiple factors affecting SARS-CoV-2 surveillance in wastewater and provide valuable information that can be used in further investigations and by health public agencies to incorporate WBE as a prediction tool for possible future outbreaks and in preparations for future pandemics.

INTRODUCTION

The emergence of Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2), known as Coronavirus Disease 2019 (Covid-19), has been one of the major threats to public health in the recent century. This virus was initially identified in Wuhan, China in December 2019, and in March 2020, COVID-19 was categorized as a global pandemic by the World Health Organization(WHO, 2020). The rapid spread of SARS-CoV-2 resulted in unprecedented measures imposed by different governments such as lockdowns, closure of borders and travel restrictions. While the Swedish approach mostly relied on voluntary social distancing guidelines, creating a unique scenario compared to most parts of the world. The first case of Covid-19 in Sweden was confirmed in the city of Jönköping on February 4, 2020, and since then 2,7 million confirmed cases have been reported by the Swedish Public Health Agency. The Swedish capital, Stockholm, accounts for 23% and Malmö for approximately 10% of the total cases of Covid-19 in Sweden (Swedish Public Health Agency, 2022).

The concept of wastewater-based epidemiology (WBE) was initially perceived in 2001(Daughton C.G. and Jones-Lepp T.L., 2001) and applied in 2005 for the detection of illegal substance uses (Zuccato et al., 2005). WBE has been successfully implemented as a tool to grasp the circulation of viruses in previous outbreaks and during the Covid-19 pandemic, WBE has become an important tool to track Covid-19 prevalence in a population and approximately 72 countries (COVIDPoops19, 2021) implemented it as routine monitoring.

In this study, we present the outcome and analysis of long-term monitoring of SARS-CoV-2 in municipal wastewater of Stockholm and Malmö, where no stringent lockdowns or restrictive methods were enforced. Moreover, we also present the impact of sample storage conditions on the SARS-CoV-2 stability over prolonged time periods as this is one of the unsolved challenges of WBE. Furthermore, hpPCR and next-generation sequencing were used to analyze the different variants of concern for SARS-CoV-2. The outcomes of this long-term project can provide fruitful lessons on the application of WBE for the potential emergence of other public health challenges in the future.

MATERIALS AND METHODS

Long-term monitoring of the wastewater of Stockholm was performed for more than 33 months while Malmö wastewater has been monitored for more than 16 months. Stockholm is Sweden's capital and largest city with a population of approximately 1.6 million. Malmö is the third-largest city in Sweden, with a population of 350 647.
For Stockholm, samples are received from three different municipal wastewater treatment plants (WWTP), Stockholm Vatten och Avfall Bromma (377 500 inhabitants), Stockholm Vatten och Avfall Henriksdal (862 100 inhabitants), and Käppala WWTP (700 000 inhabitants). For Malmö, weekly samples are received from VA SYD (350 000 inhabitants).

Approximately, 500 ml of raw wastewater samples (prior to any biological or chemical treatment) from each WWTP were transported to the laboratory on ice. During the monitoring period, two sampling protocols were used. In the first protocol, an equal volume of flow-proportional-composite samples was collected each day for one week, stored at 4°C and then mixed prior to transfer to the laboratory. In the second protocol, representative samples (500 ml) were taken over a period of 24 hours from Monday to Tuesday every week, using flow-proportional composite samplers, which were flow compensated.

Two different protocols were used and compared for SARS-CoV-2 concentration and RNA extraction. In the first protocol, 10 ml of wastewater was concentrated through double filtration on the same day the samples were received, as previously described by Jafferali et al., (2021). In the second protocol, the viral total nucleic acid (TNA) was concentrated from raw wastewater samples using Maxwell RSC Enviro TNA Promega Kit and then RNA was extracted using Maxwell RSC Instrument (Promega Biotech AB, Sweden) following the manufacturer's instructions. In both protocols, two independent replicates were analysed for each sample and tap water was used as the negative control.

Reverse transcriptase quantitative polymerase chain reaction (RT-qPCR) was performed as previously described by Jafferali et al., (2021). The reaction was performed using SYBR Green one-step kit (Bio-Rad) according to the manufacturer's instructions, with the modification of adding 2 µL of 4 mg/ml Bovine Serum Albumin (BSA). N3 primers targeting the Nucleocapsid gene (N-gene) were used for the quantification of SARS-CoV-2 and Pepper mild mottle virus (PMMoV) was quantified for normalization purposes (Perez-Zabaleta et al., 2023). Reactions were considered positive if the cycle threshold (Ct) was below 40 cycles with a single melting peak at the correct temperature. The hpPCR analysis for the detection of SARS-CoV-2 variants of concern was performed using a custom kit assembled by APLEX Bio AB (Solna, Sweden) (Perez-Zabaleta et al., 2023).

RESULTS AND DISCUSSION

Statistical analyses between positive clinical cases number in Stockholm and Malmö area and the Total-gene copy number of SARS-CoV-2 detected per week correlated significantly with each other until week 6-2022 (Figure 1 and Figure 2). From this week, free Covid-19 tests were no longer offered to the Swedish population, and large-scale testing ceased. All Pearson correlations until week 6-2022 were equal or higher than 0.84 and considered statistically significant with a p-value < 0.001. Early warnings were observed in all the waves before week 6-2022 in both cities (Figure 1 and Figure 2). The measured values in the wastewater during the long monitoring were used to estimate the number of positive cases. This estimation revealed a significant positive Pearson correlation of 0.97 and this strong correlation confirms the high potential of WBE as a tool to estimate the infection rate in a region.

Few studies have monitored SARS-CoV-2 in wastewater over long periods of time. One study in Brazil presented 10-month data, while another study in Germany showed 6-month data (Agrawal et al., 2021; Claro et al., 2021). Our current study presents over two years of monitoring, which is a sufficient number and time frame to draw more certain conclusions about factors influencing SARS-CoV-2 wastewater surveillance.

Technical parameters relating to sampling protocols, RNA concentration/extraction methods, normalization/calculation approaches, and storage conditions were evaluated and discussed. Both RNA-isolation methods generated equally accurate data and no significant difference between the protocols was found. However, the Promega kit generated a higher yield enabling lower variations at low levels. Also, both tested sampling protocols and normalization/calculation methods worked well with different strengths and limitations. The storage study has demonstrated that wastewater samples can be stored for up to 18 weeks, if kept at -80°C with glycerol added, and still generate similar results to the ones obtained with fresh wastewater samples. Furthermore, hpPCR showed the potential to expand the WBE capacity by allowing highly multiplexed viral variant analysis on a routine basis, providing higher sensitivity and faster turnaround (within one workday).

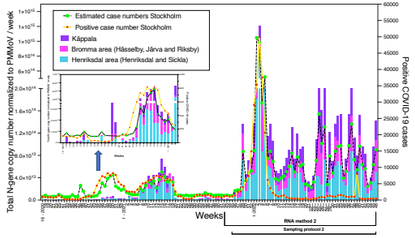

Figure 1. SARS-CoV-2 monitoring in the Stockholm region. Three major plants in Stockholm were monitored, Käppala WWTP (purple bar), Bromma WWTP (pink bar) and Henriskdal WWTP (light-blue bar). SARS-CoV-2 content was expressed as the Total N-gene copy number per week, which has been normalized with PMMoV content and flow rate. For the same monitoring period, the positive case numbers in Stockholm based on laboratory-confirmed PCR (yellow line/red dots) are plotted as well as the estimated case numbers based on SARS-CoV-2 measurements in wastewater (black interrupted line/green dots). Two RNA methods and two sampling protocols were applied.

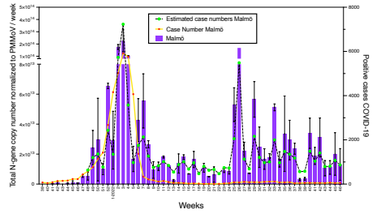

Figure 2. SARS-CoV-2 monitoring in the Malmö region. SARS-CoV-2 content was expressed as the Total N-gene copy number per week (purple bar), which has been normalized with PMMoV content and flow rate. For the same monitoring period, the positive case numbers in Malmö based on laboratory-confirmed PCR (yellow line/red dots) are plotted as well as the estimated case numbers based on SARS-CoV-2 measurements in wastewater (black interrupted line/green dots).

Our study shows the feasibility of tracking the spread of Covid-19 in a population, the ability to provide early warnings, and the accuracy of the method. The data generated here is published and updated weekly on a Covid-19 data portal (SciLifeLab Data Centre, 2022), and has become an important tool to allow both the healthcare sector, authorities, and the Swedish population to track changes in SARS-CoV-2 content in the wastewater.

Abstract
Human monitoring sewage as a way to track COVID-19 infection prevalence is by now ubiquitous. In this study, we sampled sewage from different buildings (a school, a university campus, a university residence, and an elderly residence) that host residents of different levels of vulnerability. Our main goal was to evaluate the efficacy and utility of sewage surveillance when implemented in buildings hosting communities of different ages, COVID-19 vulnerability, social habits, and case reporting. At the elderly's residence we used two sampling methods, passive and active, the latter of which was more sensitive. The other buildings were sampled using passive sampling. Altogether, we were able to detect the virus in all the buildings even when no cases were reported using clinical-based surveillance, demonstrating the potential of this method to provide cheap SARS-CoV-2 monitoring at building level.

Keywords (maximum 6 in alphabetical order)
COVID-19, passive sampling, wastewater-based epidemiology, wastewater surveillance

INTRODUCTION

The COVID-19 pandemic caused a global crisis since it was challenging to maintain economic activity without being able to work and interact physically together. For this reason, building managers had an interest to provide protective measures to enter a "co-existing with the virus" scenario phase. The measures were adapted to the building's hosts or visitors. The measures included the use of protective equipment, limiting the number of people in common spaces, and surveillance of the cases based on clinical testing. massive random screening to detect mild and asymptomatic cases has been common in some vulnerable communities but not applied at large scale (i.e., cities) because of its cost[1]. Wastewater-based epidemiology (WBE) has been demonstrated to be a non-invasive, cost-effective tool to track the circulation of SARS-CoV-2 by sampling influent wastewater at Wastewater Treatment Plants (WWTPs) but also in neighborhoods, hospitals, universities, schools, and households. Now the main challenge is to make the method cost-effective, and installation-friendly, thus finding an alternative to the autosamplers. Passive samplers are exposed to the wastewater over a known time, and it entraps the analytes of interest (i.e., SARS-CoV-2 RNA)[2]. Massive random screening to detect mild and asymptomatic cases has been common in some vulnerable communities but not applied at large scale (i.e., cities) because of its cost[1]. Wastewater-based epidemiology (WBE) has been demonstrated to be a non-invasive, cost-effective tool to track the circulation of SARS-CoV-2 by sampling influent wastewater at Wastewater Treatment Plants (WWTPs) but also in neighborhoods, hospitals, universities, schools, and households. Now the main challenge is to make the method more cost-effective, and installation user-friendly, thus by finding an alternative to the use of autosamplers. Passive samplers are exposed to the wastewater over a known timeframe, and it entraps the analytes of interest (i.e., SARS-CoV-2 in this case)[2]. While the results obtained using passive samplers are only qualitative, they are still comparable to those obtained using active sampling for the detection/non-detection of the virus.

Our main goal was to evaluate the efficacy and utility of sewage surveillance when implemented in buildings hosting communities of different ages, COVID-19 vulnerability, social habits, and case reporting. These were an elderly peoples' residence (*ElderlyRes*), a university residence (*UnivRes*) a university campus (*UniCamp*), and a school (*School*) For that purpose, we monitored one outbreak in four buildings using passive sampling. Additionally, in *ElderlyRes*, we also used active sampling to compare both protocols.

MATERIALS AND METHODS

Four buildings were sampled using passive sampling in a weekly basis between November 2021 and March 2022. The *ElderlyRes* was also sampled using active sampling. Samples were analyzed using qPCR for the SARS-CoV-2 targets N1 and N2. Wastewater results were compared with clinical data provided by the building managers.

RESULTS AND DISCUSSION

The high frequency of clinical testing and case reporting at the *ElderlyRes* allowed us to obtain a reliable comparison between the number of cases and sewage signals (Fig 1). We observe a good and significant correlation between the mean concentration of N1 and N2 and the number of clinically confirmed cases, with a Pearson coefficient of 0.61. This result guarantees the active sampling as a good validator.

To assess the validity of passive sampling, we compared the results to those from composite samples in the *ElderlyRes*. Results from composite samples were also converted into a binary outcome (values above the detection limit were considered "detected" and those below the detection limit were considered "non-detected"). Overall, we observed a good match between the detection of SARS-CoV-2 by both approaches since 14 out of 18 samples showed a perfect match. The mismatch came for samples collected during dates of low COVID-19 prevalence, with SARS-CoV-2 results from composite samples close to the limit of detection. The prevalence detection limit (PLD) in the *ElderlyRes* is 0.4% for active sampling and 1.5% for passive sampling, both values are close to the ones observed in other studies[3,4]. Passive samplers to those from composite active samples in the *ElderlyRes*. Results from composite samples were also converted into a binary outcome (values above the detection limit were considered "detected" and those below the detection limit were considered "non-detected"). Overall, we observed a good match between the detection of SARS-CoV-2 by both approaches since with 14 out of 18 samples showed a perfect match. The mismatch came for samples collected during dates of low COVID-19 prevalence, with SARS-CoV-2 results from composite samples close to the limit of detection. The prevalence detection limit in the *ElderlyRes* is 0.4% for active sampling and 1.5% for passive sampling.

As for the other buildings (Fig 2), *UnivRes* and the *ElderlyRes,* we consistently observed positive detection during the 6th wave period (January to February 2022). For the non-residential buildings (*UniCamp* and *School*), the detection was rather intermittent which probably reflects the fact that these buildings hosted a lot of temporary visitors, that are less likely to defecate there. Our study has revealed that sewage surveillance can also uncover blind spots in monitoring strategies implemented in different facilities to track and report COVID-19 cases among vulnerable populations. Sewage surveillance provides anonymous and cost-effective data on the communal circulation of the virus, allowing the fast implementation of protective measures should they be deemed desirable.

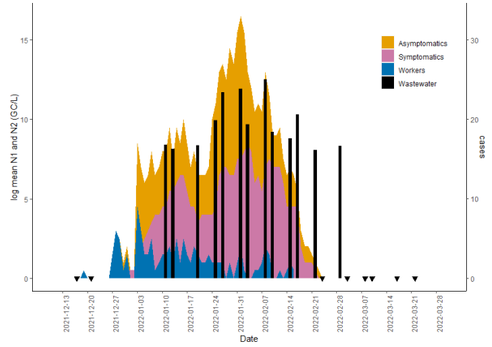

Figure 1. Geometric Mean concentration of gene targets N1 and N2 (black bars, in log of GC·L-1) and COVID-19 cases (shaded areas that are color-coded by subpopulation, see legend) in the elderly's residence during the studied period (December 2021-March 2022). Inverted black triangles show the dates where both gene targets were below the limit of detection.

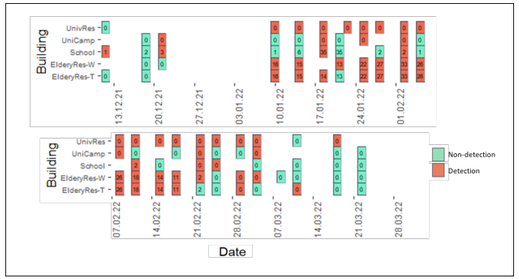

Figure 2. Detection of N1 or N2 in the wastewater of the studied buidings using passive samplers in all cases except for ElderlyRes-W, where an autosampler was used. Red cells indicate the dates where detection was positive and green cells when negative. The numbers inside the cells are the reported clinical cases in the corresponding building.

Urban Hydrosocial Cycle: Why should engineers care?

Assessment of flood vulnerability through a multidimensional index

A.N. Gomez, L.AS. Popartan, M. Poch, and I. Rodriguez-Roda

LEQUIA. Institute of the Environment, Universitat de Girona, C/ Maria Aur˙elia Capmany, 69, 17003, Girona, Spain

Abstract:
The vulnerability assessment is considered key to reducing the risk of floods, and the most widespread methodology for characterizing vulnerability is the creation of an index. However, the indices that have been obtained so far are fragmented or follow a very complicated methodology. To overcome the challenge of floods, urban planning must take into account innovative and simple strategies to achieve resilient and sustainable cities. This document addresses these gaps and proposes a methodology to simplify and holistically evaluate the vulnerability to floods in cities through a multidimensional index based on indicators that take into account five dimensions: social, economic, infrastructure, environmental and institutional.
The proposed methodology allows us to identify the sources of vulnerability and their causes by dimension, which contributes to improving flood risk management and encourages decision makers to formulate vulnerability reduction strategies.

Keywords
Cities, GIS, floods, indicators, multidimensional index, vulnerability

INTRODUCTION

Flooding in urban areas is associated with pluvial flooding that occurs when rainfall intensity exceeds the infiltration and conveyance capacity of the storm sewer system. (Bulti & Abebe, 2020; Tanaka et al., 2020). They account for approximately one-third of all global hazard events, and the number of extreme flooding incidents has increased significantly over the past decade (Tsatsaris et al., 2021). In addition, climate change, urbanization, the reduction of urban green spaces and the deterioration of urban water management infrastructures increase the risk of pluvial flooding (Kaykhosravi et al., 2019; Rangari et al., 2018).

Cities with complex hydro-meteorological environments may face multiple hazards from various types of urban flooding such as pluvial and fluvial flooding (Wu et al., 2018). Flood risk and vulnerability for different types of floods have been addressed in several studies (Pacetti et al., 2022; Tanaka et al., 2020; Tapia et al., 2017). The results show that the contribution of pluvial flooding should not be ignored, even in a basin where fluvial flooding is the main cause of flood damage. (Muthusamy et al., 2019). There is a need to improve our current understanding of the extent and impact of pluvial flooding in urban areas and how risks can be reduced.

Risk assessment along with its geolocation and flood mapping is an essential step to identify potential flood risk areas under rainfall events. Geographic information systems (GIS) are an important tool for mapping flood risk (Mudashiru et al., 2021; Quesada-Román, 2022).
The integration of remote sensing and GIS techniques together with the analytical hierarchical process (AHP) are the best techniques to assess flood risk and vulnerability (Ikirri et al., 2022).

On the one hand, flood risk maps represent areas that may be at various levels of flood hazard, identifying areas of low and high risk (Yang et al., 2015). As noted by Mutusamia (2019), modeling the spatial distribution of pluvial and fluvial floods using a 2D model based on a high-resolution digital elevation model (DEM) and developing a 2D model in HEC-RAS (v.5) can be a good alternative to generate flood risk maps.

In addition, vulnerability assessment must be multidimensional and integrated (Aroca-Jiménez et al., 2022; Birkmann et al., 2013). Vulnerability analysis is often driven by the derivation of vulnerability indices (Moreira et al., 2021). The most considered dimensions are: the social (Oulahen et al., 2015), physics (Papathoma-Köhle et al., 2019), economic (Veen & Logtmeijer, 2005), institutional (Papathoma-Köhle et al., 2021) and environmental (Damm, 2010).

The motivation of this study is to propose a simple evaluation methodology and apply it to a case study. First, we intend to model the spatial distribution of pluvial and fluvial floods using a 2D model based on digital elevation models (DEM) with hydro-geomorphological data that affect extreme events (altitude, mean annual precipitation, slope, distance to rivers, soil type and drainage density). Second, to assess flood vulnerability in five dimensions: social, economic, environmental, physical (infrastructure) and institutional, for the creation of a multidimensional index, using multi-criteria decision analysis (MCDA) and analytic hierarchical process (AHP) to delineate scenarios that reduce the risk and vulnerability associated with floods. Finally, adaptation/mitigation strategies to the effects of urban flooding are proposed through structural and non-structural measures, according to the most vulnerable dimensions or areas, which allow for more resilient and sustainable cities.

RESULTS

The proposed methodology for calculating a vulnerability index, shown in *Figure 1*, consists of two sections:

Hazard: development of a flood map that considers fluvial and pluvial floods in the case study, for different return periods. With the flood map we identify potentially flooded areas.

Vulnerability: This section is divided into five dimensions that can be defined as:

Social dimension. propensity for human well-being to be damaged by the disruption of individual (mental and physical health) and collective (health services, education, etc.) social systems and their characteristics (e.g. gender, marginalization of social groups) (Birkmann et al., 2013), describing the capabilities, knowledge and behaviors of the affected persons and/or organizations (Balica & Wright, 2010). Indicators: age, income, gender, employment, population density, nationality.

Economic dimension. reflects the income of the affected area, propensity for loss of economic value due to damage to physical assets and/or interruption of production capacity (Birkmann et al., 2013), that could be caused by flooding. Indicators: municipal debt, municipal budget, number of businesses, cafeterias, and restaurants.

Infrastructure dimension: potential for damage to physical assets, including built-up areas, infrastructure and open spaces (Birkmann et al., 2013). Indicators: hospitals, education centers, sewage infrastructure, drinking water infrastructure, monuments, and museums.

Environmental dimension: potential for damage to all ecological and biophysical systems and their different functions, including particular ecosystem functions and environmental services (Birkmann et al., 2013) that may be caused by floods or the interference of human activities on the natural environment, which may increase vulnerability in certain areas (Balica & Wright, 2010). Indicators: nature reserve, green areas, land use, quality of surface and subway water bodies.

Institutional dimension: potential for damage to governance systems, organizational form and function, as well as to formal/legal and informal/customary governing norms, any of which may be forced to change the following weaknesses exposed by the disaster and response (Birkmann et al., 2013). Indicators: availability of emergency plans, level of understanding of the national household warning system, warnings about recent floods.

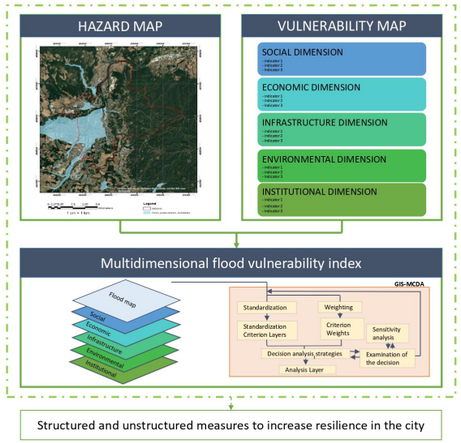

Figure 1 Methodology proposal

The indicators for each dimension will be considered based on context, as well as exposure, sensitivity, and adaptive capacity for better understanding.
The proposed index method is through GIS-MCDA consisting of criteria standardization, criteria weights, strategy analysis, sensitivity analysis and a layer analysis.
This methodology allows us to calculate a flood vulnerability index in cities in a simplified and holistic manner, as well as the most vulnerable dimensions according to the case study.

Eco-cultural technologies for rural and Māori community on-site wastewater treatment in New Zealand

R. J. Craggs, J. Sukias, Valerio Montemezanni, C. Picken, A. Dakers, and C. Tanner

* National Institute of Water and Atmospheric Research, PO Box 1-115 Hillcrest, Hamilton, 3210, New Zealand. (E-mail: *rupert.craggs@niwa.co.nz)*

Abstract
This multi-disciplinary research programme is focused on partnering with indigenous Māori communities in New Zealand to co-develop, eco-cultural wastewater treatment technologies (ECWT) that incorporate mātauranga Māori (Māori indigenous knowledge) and cutting-edge science to address current barriers to ecotechnology implementation. ECWT provide cost-effective and culturally acceptable "natural" options to upgrade failing rural wastewater infrastructure. This talk will discuss the co-design process and preliminary performance of:

Intensified wetland filters (IWF) for marae and papakāinga (māori housing development) wastewater treatment, using and intermittent dosing to enhance treatment performance in terms of nutrient and faecal indicator bacteria removal.

Final effluent wetlands (FEW) that provide habitat for native plants and animals and revitalise mauri (life force) and health (hauora) of water, the environment (taiao), and people (tangata) that depend on them.

Accumulating volume sludge digestion ponds (AVSDP) that reduce the volume of wastewater sludge requiring disposal.

Sludge treatment wetlands (STW) that convert wastewater sludge into a soil amendment, reducing Māori concerns and costs of sludge transport and disposal.

Affordability and sustainability of ECWT will be enhanced by co-development of culturally appropriate and resource recovery (biogas energy, bioproducts, and treated water).

Keywords
Biogas recovery, Māori co-development, Onsite sludge treatment, Wetland filters

INTRODUCTION

Limits to reduce water pollution and support iwi taiao kaitiakitanga (environmental stewardship) of freshwaters, being set under New Zealand's National Policy Statement for Freshwater Management (NPS-FM) require a significant upgrade of failing rural wastewater infrastructure. The estimated capital investment required to upgrade rural on-site treatment systems (OSTS) using advanced tank-based mechanical treatment (AMT) is NZ$20-40 million.

Ecotechnologies offer substantial advantages in affordability, cultural acceptability, energy efficiency and resilience compared to advanced mechanical WWTP upgrade options and hold great promise for sustainable development world-wide. However, they have yet to be widely implemented, and require further development in NZ to:
a) fully align with Māori cultural values for wastewater management and address stakeholder barriers to implementation;
b) improve treatment effectiveness, particularly during winter, to reduce land area requirements.
c) improve treatment resilience (maintain effectiveness) under highly variable wastewater loads, common for rural systems, to future-proof for population growth and climate change, and.
d) recover resources to accelerate transition to a circular economy.

The main barriers hindering the uptake of innovative wastewater treatment ecotechnologies have been identified (Etnier et al. 2007) as:
• decreased financial reward for engineering consultancies.
• lack of knowledge and experience of ecotechnologies, leading to the perception that they have greater risk and inflated costs.
• an unfavourable regulatory environment and,
• lack of holistic systems thinking and whole-of-life assessment.

These barriers tend to be propagated within the mindset of local government implementors, and the engineering consultancies that they depend on, resulting in preference for traditional advanced mechanical treatment solutions.

This project has partnered with indigenous Māori communities in New Zealand to co-develop four innovative, cost-effective and culturally acceptable eco-cultural wastewater treatment technologies (ECWT). ECWT are wetland and pond-based innovations that incorporate mātauranga Māori (Māori indigenous knowledge) and address barriers to ecotechnology implementation.

Intensified wetland filters (IWF)

Intensified wetland filters (IWF) have been co-developed for marae and papakāinga (māori housing development) septic tank effluent treatment. They are a substantial improvement on vertical flow constructed wetlands. Treatment performance and resilience to variations in wastewater load is enhanced by incorporating different active media and using intermittent wastewater dosing to cycle aerobic/anoxic conditions. IWF incorporate Mātauranga related to:

- Locally available media and indigenous wetland plants with potential resource recovery co- benefits.
- Passage through Papatūānuku (mother earth) to revitalise the mauri of the water.

IWF require less land (reducing costs) for effluent infiltration than that required for existing vertical-flow wetlands (Sukias et al. 2018).

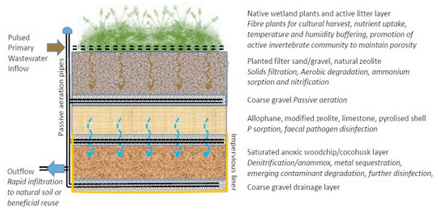

Figure 1 Intensified wetland filter concept.

Final effluent wetlands (FEW)

Final effluent wetlands (FEW) provide final cleansing of treated wastewater prior to discharge, since direct discharge of even highly treated wastewater into surface waters is abhorrent to Māori. FEW co-development has been guided by tikanga and Mātauranga Māori. The use of soils/rocks, landscaping and planting ensures provision of habitat for native plants and animals and the revitalisation of the mauri (life force) of the wastewater and protection of Te Hauora (health) of the waterbody, local environment, and associated community. Colonisation by taonga (culturally treasured) species physically indicate to Māori the efficacy of the system and limited open water habitat prevents waterfowl from re-polluting treated effluent.

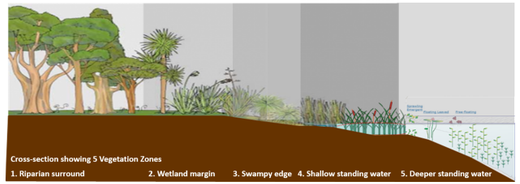

Figure 2 Final Effluent Wetland concept.

Accumulating volume sludge digestion ponds (AVSDP)

Accumulating volume sludge digestion ponds (AVSDP) substantially reduce the volume of, and recover energy from, wastewater sludge prior to disposal. Treatment, transport and disposal of septage and wastewater sludge is an expensive step in rural wastewater treatment and does not align with tikanga Māori (Ihaka et al. 2000). AVSDPs have extended residence times (~1Y), that promote similar biogas recovery under ambient conditions to conventional heated, mixed sludge digesters, but have much simpler operation because of annual (compared to daily) sludge handling.

Sludge treatment wetlands (STW)

Sludge treatment wetlands (STW) convert wastewater sludge into a soil amendment, reducing Māori concerns and costs of sludge transport and disposal. This co-design combines established designs from European and Australian industry partners (Orbicon Ltd and Wetland Ecological Systems Ltd) with Mātauranga Māori and knowledge of NZ soils and plants.

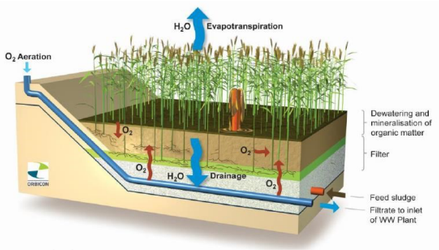

Figure 3 Sludge treatment wetland concept

Affordability and sustainability of ECWT is enhanced by co-development of culturally appropriate and resource recovery (biogas energy, nutrients, bioproducts, and treated water).

The co-design of ECWT ensures that they incorporate Mātauranga Māori and address ecotechnology implementation barriers (particularly the current preference of endusers for hard-engineered solutions) to promote widespread uptake. Hui and workshops using cross-cultural participatory methods have promoted understanding of linkages between western science and mātauranga Māori.

Successful ECWT co-development will enable Māori to achieve their objectives for WWT and overcome barriers to ecotechnology uptake identified by wastewater industry stakeholders. Widespread implementation of ECWT will benefit rural economies; reduce pollution of freshwater resources; and improve Te Mana o te Wai (the holistic well-being of freshwater).

Abstract
In this work, we assess the techno-economic and social performance of preventing and controlling phosphorus releases from municipal wastewater effluents in local communities. This multicriteria assessment framework accounts for the effects of the economies of scale and the population economics across the United States by considering geospatial public access information. The economies of scale have a significant impact on the costs of phosphorus removal, resulting in considerable increases in phosphorus removal costs in areas where small population centers are predominant due to the lack of economies of scale in their wastewater treatment plants. Additionally, the average per capita income of these areas is generally lower than large cities and their metropolitan areas. Therefore, the economic impact of requiring phosphorus removal systems to meet water quality criteria in local communities is crucial information to be considered in designing adequate incentive policies for supporting such water pollution control and prevention efforts.

Keywords (maximum 6 in alphabetical order)
Nutrient pollution, Wastewater, Phosphorus removal, Sustainability, Social impact

INTRODUCTION

Phosphorus pollution is an environmental concern impacting ecosystems and communities worldwide. The effects of phosphorus pollution include harmful algal bloom events, hypoxia of waterbodies, and impairment of drinking water sources. Therefore, to prevent these harmful effects, phosphorus removal or recovery operations must be implemented in point source releases like wastewater treatment plant effluents (Ansari, 2010).

In the United States, nutrient removal treatments are often installed in wastewater treatment plants (WWTPs) equipped with advanced treatments, which in turn are usually those serving large urban areas. These facilities are benefited from the economies of scale and can remove or recover phosphorus at a competitive cost for the served users. Conversely, WWTPs serving smaller population centers are usually limited to primary and secondary treatments. However, the lack of economies of scale hinders the adoption of phosphorus removal and recovery processes. Also, implementing countrywide regulations similar to the Urban Waste Water Treatment Directive (UWWTD 91/271) from the European Union will lead to adopting phosphorus removal processes at large and small scales (ESSP, 2023). However, removing and recovering phosphorus in these smaller facilities would result in large costs due to the lack of economies of scale. Therefore, the economic impact of requiring phosphorus removal systems to meet water quality criteria in local communities is crucial information to be considered in designing adequate incentive policies for supporting such water pollution control and prevention efforts.

MATERIALS AND METHODS

Technical information describing the WWTPs across the contiguous U.S. was retrieved from the HydroWASTE database (Ehalt Macedo et al., 2022). Such information includes the spatial location, treatment level, treatment design capacity, and served population. The HydroWASTE database reports the treatment level at each WWTP as primary, secondary, or advanced treatments. We consider that only WWTPs with advanced treatments have specific processes for removing phosphorus since secondary wastewater treatment systems do not limit nutrient releases considering the water quality criteria definition reported by the U.S. Environmental Protection Agency. Instead, it limits biological oxygen demand, total suspended solids, and pH. Thus, for these advanced treatment facilities, we assume a phosphorus removal efficiency of 88% (U.S. Environmental Protection Agency, 2015), while the phosphorus removal efficiency associated with primary and secondary treatments are assumed to be 23% and 40% respectively (Venkatesan et al., 2016; Shi, 2011). As a result, this study assesses 14,639 WWTPs reported in HydroWASTE.

The cost of phosphorus removal processes implemented in WWTPs is estimated based on the cost information reported by U.S. Environmental Protection Agency (2015). This report surveys numerous phosphorus removal systems installed in WTTPs throughout the U.S., with treatment design capacities ranging from 0.14 to 943.6 million cubic meters per year. Correlations in the form of exponential functions, as shown in Figure 1, are developed based on these data to estimate the cost of implementing phosphorus removal technologies in WWTPs as a function of their treatment design capacity. Thus, these correlations provide the capital and operating costs of phosphorus removal for WWTPs with primary or secondary treatment levels. For advanced WWTPs, the capital costs of implementing the phosphorus removal process are zero since we assumed they already have some installed phosphorus removal technology, and we only consider their operating costs.

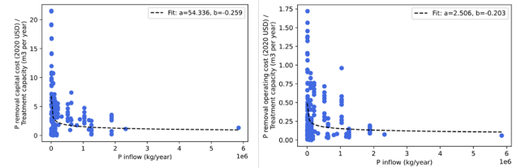

Figure 1. Capital and operating costs of phosphorus removal systems in WWTPs (U.S. Environmental Protection Agency, 2015).

We estimate the total removal costs as the sum of the annual operating and the annualized capital costs. The annualized capital cost was estimated through the annual capital charge ratio assuming an interest rate of 7% and a lifetime of 20 years.

RESULTS AND DISCUSSION

This population distribution is directly related to the average size of the WWTPs, whose average size is large in counties densely populated, as shown in Figure 2. Comparing the average size of WWTPs and their treatment level, we observe a predominance of WWTPs with more advanced treatments in the more populated areas, which are counties with larger WWTPs. As a result, we can establish a direct relationship between the population characteristics, the scale of the WWTPs, and the treatment level. Figure 3 describes the economies of scale for the operating expenses of WWTPs.

Figure 4 shows the phosphorus removal cost at WWTPs. Comparing the spatial distribution of removal cost with the WWTPs' average size shown in Figure 2, we can observe that they present opposite distribution patterns, confirming the significant impact of the economies of scale in phosphorus removal.

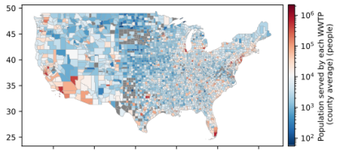

Figure 2. Average size of WWTPs in the contiguous U.S. at county level.

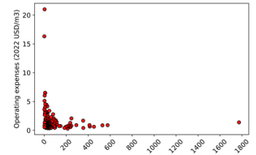

Figure 3. Estimated operating expenses of WWTPs in the U.S. for 2022, based on data reported by AWWA and RFC (2011).

Additionally, we estimate the economic impact of implementing P removal systems in all WTTPs on the users. Figure 5 collects the P removal cost per capita, and Figure 6 shows the household affordability index of P removal. These figures present opposite distribution patterns than the distribution of the WWTPs average size, resulting in a significant impact on the economy of the WTTPs users. In this regard, the U.S. Environmental Protection Agency recommends that wastewater treatment costs not exceed 2% of the household income (U.S. Environmental Protection Agency, 1997).

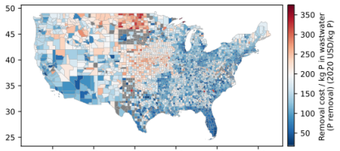

Figure 4. Spatial distribution of phosphorus removal costs.

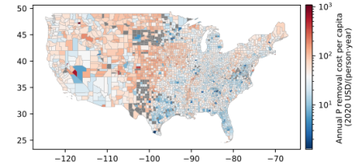

Figure 5. Annual phosphorus removal cost per capita.

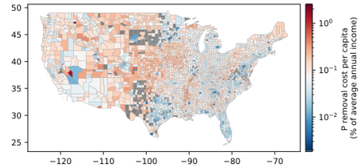

Figure 6. Household affordability index for phosphorus removal.

Therefore, this information is crucial for designing fair policies that balance environmental protection needs and financial equity for WWTP users. Also, it supports the design of WWTPs considering current phosphorus removal criteria. However, we aim to assist decision-makers in developing policies to incentivize water resource recovery facilities (WRRFs) with more advanced systems to recover and recycle valuable resources like phosphorus and transition from a linear to a circular economy paradigm.

Abstract
While the need of more sustainable and environment-preserving technologies is a consensus among the scientific community, that is not guaranteed when it comes to the whole society. Economic feasibility and efficient management are no longer the only criteria to ensure the success for the implementation of new eco-technologies and policies. It is becoming mandatory considering the social aspects implied in the whole process as well. That is, how the end users' satisfaction is being fulfilled. Therefore, it is necessary to have an insight in the socio-cognitive processes that mediate between the social perception on utility management, emerging technologies or policies and the satisfaction that is translated into, as well as the effects caused by different degrees of acceptance. Tools relying on artificial intelligence, such as agent-based models, can be extremely useful to deepen in the modelling of social acceptance processes as well as performing social simulations.

Keywords:
Agent-based modelling; artificial intelligence; satisfaction; social acceptance; socio-cognitive

INTRODUCTION

Classical offer-demand schemes considered customers' satisfaction as a matter of offering them a good quality-price relationship. Nevertheless, in recent years there has been increasing evidence that many other factors play a role in this sense. In the case of utilities such as domestic water, with the need to incorporate technical, environmental and social variables, complexity raises. To reflect this complexity, the "hydrosocial cycle" (Boelens, 2014) is a concept which aims to overcome the artificial separation between environment society and envisions the circulation of water as a combined physical and social process.

Thus, it is necessary to study the socio-cognitive framework of users, looking at how the relationship between perception and both conscious and unconscious reasoning, leading to different degrees of satisfaction or acceptance of water-related technologies and policies. Situations that can also lead to distinct decisions and behaviour of users. Demographic factors also play an important role in the perception of users when deciding, for instance, between tap water vs bottled water (Doria, 2010, March et al., 2020).

Studying final users' satisfaction and acceptance of innovative technologies, requires considering a wide range of factors, as there is a broad diversity among domestic water users. For this purpose, Agent Based Modelling (ABM) can be an advantageous tool which helps to capture differences between users, including demographic variables, housing types and even their mental frameworks or values driving their behaviour (Perelló-Moragues, 2020). Once the model is built, it can later be used to perform Agent-Based Social Simulations (ABSS) of different scenarios to analyse the effects and tendency changes in agents' behaviour caused by introducing new policies, ways of management or technologies.

This paper will use an ABM approach to study how the satisfaction of domestic water users —from Barcelona and its Metropolitan Area— is formed and to which extent the multiple factors implied in this process are important. Most studies taking an insight into water users satisfaction rely on a survey performed in a punctual time, which only permits analysing a specific picture. We aim to fathom in users' perception to unbox the processes implied in the definition of their satisfaction by using data gathered from wider time series of: i) satisfaction surveys, ii) water analysis results, iii) demography and adding a socio-cognitive factor through iv) value profiles.

MATERIALS AND METHODS

ABM models rely on a set of multiple computational entities: agents. Each agent can be programmed with specific features and Artificial Intelligence (IA), which will both guide actions pursuing their goals. At the same time, agents can form a network, being influenced by other agents. This architecture allows to study at the same time: how different individuals act and effects on the environment caused by aggregated activity of all individuals.

Nevertheless, the flexibility provided by ABM can become an issue when the process following the modelling is not transparent enough. Leading to difficulties in re-implementation or cases where similar models sharing the studied phenomena bring out completely different results (Daly et al., 2022). This situation has been assessed by raising different standardization approaches for developing and explaining ABM (Daly et al., 2022, Grimm et al., 2020).

In water use related ABM, each agent most commonly represents a household (Perelló-Moragues et al., 2021, Athanasiadis et al., 2005, Koutiva & Makropoulos, 2016), as that is the basic unit for billing and that scale has many information available. Such as consumption patterns and their changes easier to track trough water (smart)meters. As this simplification is assumed, it is necessary taking that in consideration to accurately represent in the model the variability and distribution of those variables relevant in the studied phenomena (i.e., values, age, gender, income, education…).

With the aim of studying users' satisfaction through an ABM, it was previously necessary to build a model which represented the case study —the Metropolitan Area of Barcelona— with the needed accuracy. For that purpose, the first step for building the ABM was a bibliographical review to choose the relevant variables necessary for the model and then obtaining that data to enter it to the ABM environment (see Table 1).

Table 1. Different variables considered to model the Metropolitan Area of Barcelona, their function and source.

	Purpose	Source
Supply zones	defining the zones with different water sources	GIS dataset
Municipalities inhabs.	distributing agents according to population	GIS dataset
Water analysis results	assigning different parameters to water depending on its source	Water company dataset
Demography	distributing age, income, house members, etc. according to reality	Public datasets
Users' value profiles	representing diversity of mental frameworks	Brouwer et al., 2019

Once all data was gathered the environment of the model was built using the integrated development environment (IDE) NetLogo. First step was loading the intersection of supply zones and municipalities GIS datasets, in order to delimitate the simulated physical space where households can be placed. Also, their quantity based on the relative population on each municipality. After that, demographic information was treated with R for clustering households in a few household types to be distributed in the model. Water analysis results were loaded to the environment and given to households as an input according to the supply zone they are placed in. Finally, value profiles —based on the segmentation of drinking water customers proposed by Brouwer et al., 2019— are randomly distributed. There was no data available which could be used to set a criterion for the proportion and placement of each of the value profiles used (aware & committed, down on earth & confident, egalitarian & solidary, quality & health concerned).

RESULTS

The work explained led to the first layer of the model expected to develop, the environment (see Figure 1). The following steps will be defining the rules which guide households' behaviour according of the variables defining them (age, income, education…).

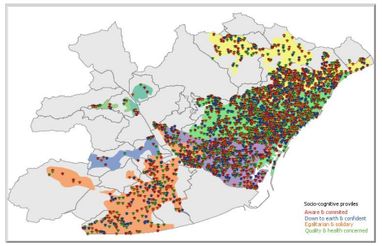

Figure 1. ABM interface representing the Metropolitan Area of Barcelona with 3 000 agents loaded. The legend distinguishes socio-cognitive profile of agents according to their colour.

Once agents' behaviour has been calibrated, the model should be able to become a useful tool to test how the satisfaction of users from Barcelona and its metropolitan area could vary under certain scenarios. For instance, variations leading to changes in water quality, the implementation of new technologies, or awareness campaigns.

DISCUSSION

While the use of the presented ABM can be advantageous for studying how satisfaction and social acceptance work in the hydrosocial cycle, human behaviour and reasoning are complex and diverse processes. Because of this, working on this kind of ABM requires simplifications and the results cannot be expected to be the exact reproduction of reality.

With that in mind, model will help to a better comprehension of the internal dynamics of the social phenomena studied —perception, satisfaction and social acceptance—and improving their understanding. Thus, the actual value of ABM is reached by answering the questions *Why agents are not behaving the way we expected them to do?* and *What do we need them to make different to achieve so?*

Studying these complex processes trough ABM additionally benefits from the multidisciplinary they require. The incorporation of multiple insights to address the issue eases the deeper perspective of factors involved and their interrelations.

Abstract
Contaminants of emerging concern (CEC) occurrence in river is a key challenge that the European Union is eager to address by 2027. We propose here a strategic foresight exercise to build a roadmap aiming to envision potential strategic routes for EU goal fitting WWTP treatment upgrades favouring CEC removal. Exercise starts with a screening and ranking of WWTP tertiary and advanced treatment technology upgrades in the context of the Shared Socioeconomic Pathways (SSPs) global change narratives interpretation for the EU region. Then, envisioned strategic routes allowed identifying and confronting core challenges such as the CEC removal agenda, technologies' performance, requirements for CEC removal and water scarcity. Results shaw that: (i) achieving CEC related EU water quality goals is unlikely before 2040 in all SSPs, (ii) enhancing circular economy solutions in WWTP, (iii) water reclamation, and (iiii) accelerated increase of the technology readiness level of nature-based will be key.

Keywords
Advanced treatment processes; contaminants of emerging concern; Foresight exercise; shared socioeconomic pathways

INTRODUCTION

The European Commission's ambitious target to attain by 2027 good chemical and ecological status in all EU surface water bodies (SWBs), therefore, puts the emphasis on monitoring and addressing contaminants of emerging concern (CEC) occurrence in SWBs. Indeed, the previous EU River Basin Management Plan reporting period (2015-2021), the number of SWB failing to reach a good chemical status rose from 3% to 34% when CEC are considered in the chemical status assessment (EEA, 2018). The chemical status being part of the assessment of the ecological status or potential of SWB, CEC impose decisive limitations on the ecological status of EU SWB. Consequently, the EU Commission's target to attain good ecological status in all SWB already appears challenging (Posthuma et al., 2020); and the situation will be even worse due to climate change (Abily et al., 2021).

The quality of the released urban wastewater concentrating these CEC is a trade-off between investment in wastewater treatment operation and infrastructure, and acceptable released pollutant concentration to comply with established contaminant threshold values. While a broad range of possible tertiary treatment technological solutions upgrades exists (CTO, 2021), envisioning the future of wastewater treatment to specifically target and control CEC release remains challenging. This is due to the complexity and variation in CEC behaviour, to the demanding assessment of the maturity and evolution of technologies toward this specific removal purpose and lastly, due to dependency upon political, environmental, economical and social drivers.

A strategic technological roadmap is a future mapping approach often based on scenario planning to cover a range of uncertain futures. At a practical level, scenario planning and strategic road-mapping approaches have been implemented in a broad range of fields to draw several projected sets of future conditions (Reardon et al., 2013; Rulleau et al., 2020), or to test the viability of strategies under variable circumstances, aiming to foresee and analyse a priori their success and failure potentials.

In this work, we chart and rank WWTP upgrade technologies' characteristics and merits to address the CEC removal goals. Moreover, because (i) the EU agenda for 2027 is expected to be unlikely attainable, and (ii) the WWTP upgrade technologies have a multi-decade lifespan, we matched in a tailormade roadmap these technologies charting and Shared Socioeconomic Pathways (SSP) narratives interpretation at the regional level (via performance, scalability, energy, sustainability, and economy dimensions). Following this, strategic routes are built for SSP narratives. The cross-analysis of the resulting strategic routes highlights common core challenges to be addressed and key opportunities to strengthen the shaping of WWTP technological upgrade investments targeting CEC removal.

It is expected that the key messages regarding challenges and opportunities stressed in this work will be a reference among the urban water sector's various stakeholders (urban planners, technologies providers, water utilities' decision-makers, academics, *etc.*) on the potential directions to prioritize technological development and their implementation direction favoring WFD goals achievement.

METHOD

The conducted approach for the strategic foresight exercise is summarised below.

- A generic roadmap framework was constructed with a structured framed as follow. The time horizon was set, up to 2080 which would represent the expected optimal lifespan of a WWTP upgrade implementation, then key layers of the roadmap were build up:
  - Policy objectives for CEC removal layer.
  - Trends and drivers. This layer is directly framed by our EU regional interpretation for the SSP of interest (O'Neill et all, 2017). The SSP storylines are in that case interpreted specifically for the EU region
  - Function/capability layer. This layer reflects key functions and capabilities in the wastewater treatment utilities/services, potentially developed as a result of technological upgrades.
  - WWTP upgrade technologies layer. This technological layer of the roadmap combines the selected technological upgrades with the appropriate SSP narratives upgrades.
- Screening process. Screening of WWTP technologies for treatment upgrade was conducted via:
  - A series of collaborative workshops, produce a technological layer definition for the roadmap with WWTP technologies upgrade enumeration and evaluation based on twenty criteria. The result of this process is synthetised in Figure 1.
  - A technology selection process where dimension reduction was used to gage the technologies level of performance toward five dimensions: Performance of CEC removal, Economical aspect of the technology, sustainability, energy and scalability performances
- A horizon scanning process has been conducted based on SSP narrative interpretation for the EU region. These interpretations were performed for namely: SSP1 ('Taking the green road'), SSP2 ('Taking the middle road') and SSP5 ('Taking the highway'). We looked at these future changes naratives in terms of (i) in water resource availability and (ii) in CEC levels of production and excretion. Changes in (i) and (ii) are driven by climate change impacts, policy, social behaviour, demographic changes such as urbanisation, population growth and evolution of demographic pyramids in member states and, for example, associated changing pharmaceutical use patterns.
- Strategic routes assessment based on the interdependency between established layer assessment within an iterative process and an adaptation of the framework for the different selected SSPs.

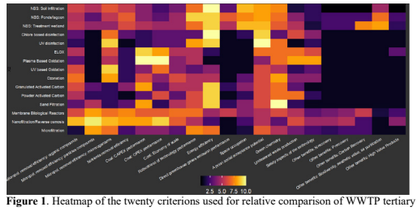

Figure 1. Heatmap of the twenty criterions used for relative comparison of WWTP tertiary treatment technology upgrade (the closer the value to ten, the more performant toward the criteria).

	Microfiltration	Nanofiltration / Reverse osmosis	Membrane Biological Reactors	Sand Filtration	Powder Activated Carbon	Granulated Activated Carbon	Ozonation	UV based Oxidation	Plasma Based Oxidation	EO/EL	UV disinfection	Chlore based disinfection	NBS: Treatment wetland	NBS: Ponds/ lagoon	NBS: Soil infiltration
Performance	3.0	8.0	7.0	3.0	3.0	4.0	3.0	3.0	3.0	4.0	3.0	4.0	3.0	4.0	3.0
Economy	9.0	3.0	3.0	3.0	3.0	4.0	3.0	4.0	3.0	3.0	7.0	7.0	5.0	9.0	9.0
Sustainability	4.0	3.0	5.0	5.0	3.0	4.0	4.0	3.0	3.0	3.0	4.0	3.0	5.0	8.0	8.0
Energy	7.0	3.0	4.0	6.0	6.0	6.0	5.0	4.0	3.0	3.0	9.0	10.0	9.0	9.0	10.0
Scalability	3.0	4.0	3.0	4.0	3.0	4.0	4.0	3.0	3.0	3.0	3.0	3.0	4.0	4.0	8.0

Figure 2. Heatmap of the twenty criterions used for relative comparison of WWTP tertiary treatment technology upgrade (where the closer the value to ten, the more performant the technology toward the criteria).

RESULTS

The presented result focusses only on the SSP5 ('Taking the highway') to illustrate the type production in a concise manner. In the Figure 3, the roadmap is the same for all the SSPs, but only the layer *Trends for drivers 'level of change* (in dashed) is adapted for each SSP. Then based on this roadmap of a potential future, a strategic road is built up to tentatively reach set goals (Figure 4). With an analysed summarized below, a strategic routes explains as follow: *The goal in the SSP5 driven roadmap is to match with the 2027 EU WFD ecological status objective. The need to do so would be a minimum of 85-90% CEC removal for 85-90% of the WWTP volume. As per interpretation of the narrative (IPCC6), temporality to reach these objective will be economically driven. The clear intent to achieve these goals will not start until the economic penalties and the environmental impacts become concerning for society. This ambition would translate into the late implementation of high and holistically performant CEC removal technology, accompanied by specific upgrades directly targeting selective CEC removal as a reactive remediation process. In terms of a technological upgrade selection (from Figure 4), the performance dimension of the technologies and the scalability of the processes are envisioned to favoured due to the increased urbanisation projections. The capabilities to be enhanced in such a scenario would be (i) holistic CEC removal, (ii) ease of implementation in an urban environment and, (iii) capability of the upgrade to combine with other tertiary treatments already in place. Microfiltration, nanofiltration, reverse osmosis and membrane biological reactors are seen as the most applicable for WWTP technological upgrades for this narrative.*

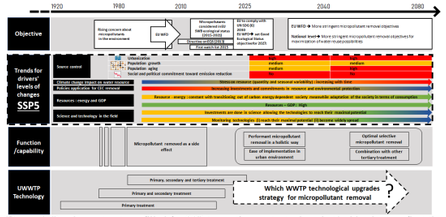

Figure 3. Roadmap structure, filled for SSP5 narrative context where hot/cold colours reflect the drivers' condition evolution

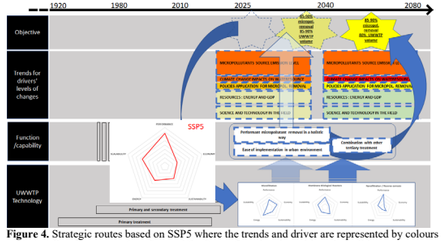

Figure 4. Strategic routes based on SSP5 where the trends and driver are represented by colours palette scaling from green (good) to red (bad) to reflect the given drivers' condition.

1.104	Novel ceramic SnO2 electrocatalytic membrane for advanced wastewater treatment and water reuse	Chao Yang	The university of Hong Kong
1.105	High-Rate Post-treatment of Sewage from Residential Community by the Down-flow Hanging Sponge System	WILASINEE YOOCHATCHAVAL	Kasetsart University
1.106	Microbial-fuel-cell driven intermitted aeration enhanced the removal of organic matter and nitrogenous compounds	Naoko Yoshida	Nagoya Institute of Technology
1.107	Giving four lives to osmotic membranes with innovative recycling processes (Osmo4Lives)	Bianca Zappulla Sabio	Lequia
1.108	Photocatalysis as a Remediation Technology for Wastewaters Containing Organic Dye Compounds	Elnaz Zehtab Lotfi	East azarbaijan Shahid madani university
1.109	Periodate activation with copper oxide nanomaterials for the degradation of ciprofloxacin-A new insight into the efficiency and mechanisms	Xi Zhang	KU Leuven
1.110	In-situ Fabrication of Titanium Suboxide-Laser Induced Graphene Composites with Enhanced Electrochemical Activity for Environmental Remediation	Ashish Kumar	Indian Institute of Technology Bombay
1.111	The new Hot Bubble Pilot Plant (HBPP) for water sterilisation and desalination.	Adrian Garrido Sanchis	University of New South Wales
1.112	Electrochemical oxidation of ammonia in aqueous solution using high catalytic CuCo bimetallic catalyst supported on Ni foam	Chih-Chao Wu	Feng Chia University

2. Decentralized Strategies

POSTER No.	TITLE	PRESENTING AUTHOR	AFFILIATION
2.1	Light greywater quality consistency: challenge for their treatment and reuse. Study case: Colombia	Jessica Burgos Arias	Universidad Industrial de Santander
2.2	Organic micropollutants in a Euro-Mediterranean resort: occurrence in the water cycle	Gianluigi Buttiglieri	ICRA
2.3	Earthworms influence on macroporosity and biofilm in constructed wetland	Siriane Cazaux	Laboratoire Écologie Fonctionnelle et Environnement
2.4	Industrial-urban symbiosis waste treatment for regional development in Alcoy region (Spain)	Raquel Tamarit	FACSA
2.5	Identifying substrates for greywater treatment in a novel green wall system based on trickling filters	Maximilian Grau	Zurich University of Applied Sciences
2.6	Fuzzy Risk Assessment for Hydraulic Detention Time in UASB Reactors	DAYANE LIMA	Universidade de Aveiro
2.7	Evaluation of a low-tech, passively solar-driven pilot plant for nutrients recovery from source-separated urine on household level	Laila Lüthi	Zurich University of Aplied Science
2.8	Multidimensional assessment of a Nature-based Solution for decentralized small-scale greywater treatment in Costa Rica	Maria Perez Rubi	Leibniz Universität Hannover(LUH)
2.9	Anaerobic digestion effluent treatment in constructed wetlands for agricultural reuse	Pau Porras i Socias	Universidade do Porto
2.10	Comparison of engineered, natural and hybrid wastewater treatment schemes for the removal of nanoparticles from wastewater	Radhika	Indian Institute of Technology, Delhi
2.11	Performance of Multi-module Biochar Filter for Onsite Wastewater Treatment System	Makoto Shigei	Uppsala University
2.12	Potential of integrated membrane and TiO?-based advanced oxidation processes for greywater reclamation	Haruka Takeuchi	Kyoto University
2.13	Nutrients and characterization of greywater from rural households	Adriano Luiz Tonetti	Unicamp
2.14	Adsorption of cadmium on raw and base treated Bolivian natural zeolite	Lisbania Velarde Arnez	Luleå University of Technology
2.15	Surfactant elimination in horizontal and vertical-flow constructed wetlands for greywater treatment	Karen Midori Takahashi	Federal University of Mato Grosso do Sul

3. Resource recovery and safe reuse

POSTER No.	TITLE	PRESENTING AUTHOR	AFFILIATION
3.1	Seasonal accumulation of pharmaceuticals in soils from a full-scale horticultural system irrigated with reclaimed water.	Lucas Alonso	ICRA
3.2	Effective radiation transfer as a major element for the optimized design and operation of purple phototrophic bacteria photobioreactors	Ali Amini	Politecnico di Milano
3.3	Bioelimination of different arsenic species by microalgae and bacteria grown in wastewater treatment plants	Beatriz Antolín Puebla	Institute of Sustainable Processes
3.4	Protein recovery from algal biomass grown in piggery wastewater using deep eutectic solvents	Beatriz Antolín Puebla	Institute of Sustainable Processes
3.5	Use of Industrial Magnetite in Wastewater Treatment	Yara Arbid	Ecole Nationale Supérieure de Chimie de Rennes
3.6	FlashPhos: The complete thermochemical recycling of sewage sludge	Sander Arnout	InsPyro
3.7	Study of struvite precipitation in a fluidised bed reactor using synthetic supernatant	Sergi Astals Garcia	Universitat de Barcelona
3.8	Integrated Resource Recovery from Aerobic Granular Sludge Plants	Nouran Bahgat	Wetsus/TU Delft
3.9	Design of a decision support system for wastewater sanitation in small population centers in the Besòs-Tordera Consortium	Aldo Barahona	Universidad de Barcelona
3.10	Assessment of the role of the solubilization time in the P-recovery process in the Murcia-Este WWTP	Ramon Barat	Polytechnic University of Valencia
3.11	FORWARD-FACTORY: Integrating forward osmosis and advanced biological reactor for water reuse and resource recovery factory	Gaetan blandin	University of Girona
3.12	Novel concentration process based on membranes for volatile fatty acids concentration (ConcentrA)	Gaetan blandin	University of Girona
3.13	Resource recovery from aerobic granular sludges: Gel-forming biopolymers extraction, fractionation and gelling capacity	Abdo BOU SARKIS	Laboratoire de Biotechnologies Agroalimentaire et Environnementale
3.14	Stabilization of sewage sludge in constructed wetlands for reuse in agriculture	Ana Cano	Universitat Politècnica de Catalunya
3.15	Toluene valorization into PHA by Rhodococcus opacus	Sara Cantera	Valladolid University
3.16	Modelling H2 conversion by purple bacteria enriched cultures: evaluating kinetics of gas-fed processes to assess feasibility	Gabriel Capson Tojo	INRAE
3.17	Biological Methanation of WWTP biogas with green H2 for sustainable mobility	Oriol Casal	Cetaqua Centro Tecnológico del Agua
3.18	Nitrogen recovery to produce Smart Fertilisers from wastewater	Oriol Casal	Cetaqua Centro Tecnológico del Agua
3.19	Pharmaceuticals occurrence in water bodies of Catalonia in the last decade, which are the most ubiquitous compounds?	Marc Castaño	ICRA
3.20	Enhancing reactive species exposure in a dielectric barrier discharge plasma reactor through lava rock packing in view of phosphonate-contaminated wastewater treatment and subsequent phosphorous recovery	Changtao Chen	Ghent university
3.21	Analysis of the enrichment in PHA-accumulating bacteria in mixed microbial communities fed with fish-canning waste	David Correa-Galeote	University of Granada
3.22	WATER-MINING Project: La Llagosta Case Study, a flexible fit-for-use wastewater treatment scheme for resource recovery	Teresa de la Torre	Sorigué
3.23	Development of methodologies and tools of risk assessment for wastewater and stormwater reuse	Lucia De Simoni	Polytechnic University of Marche (UNIVPM)
3.24	Degradation and erosion of polymers in alkalised fresh human urine collected in source-separating sanitation systems	Anuron Deka	Swedish University Of Agricultural Sciences
3.25	Drinking Water Treatment Residuals: from waste to a new promising adsorbent of emergent compounds	Rita Dias Santos	CENSE - Center for Environmental and Sustainability Research, School of Science and Technology, NOVA University Lisbon
3.26	Valorisation of the liquid waste of distilled gin production through high rate anaerobic co-digestion and biogas production	Rubén Díez Montero	Universidad de Cantabria
3.27	Enhancing Carbon recovery compromises low N2O emissions: example of a new municipal wastewater treatment.	Carlos Domingo Felez	University of Glasgow
3.28	Sustainability assessment framework and circular diagnosis of water treatment plants	Sofía Estévez Rivadulla	University of Santiago de Compostela
3.29	Exploiting the DO Profile for the Mathematical Modelling of a Mixed PHA-accumulating Microbial Community	Serena Falcioni	Universitat Autonoma de Barcelona
3.30	Improvement of activated sludge systems: should we pay more attention to the role of EPS?	Zoé FAU	INRAE
3.31	BIOUP – Biomethane production through the integration of renewable energy surpluses in WWTP	federico ferrari	acciona agua
3.32	Energy recovery from olive mill waste streams	Ivet Ferrer	Universitat Politècnica de Catalunya
3.33	From removal to recovery: opportunities for bioelectrochemical ammonia recovery from wastewater	Mariella Belén Galeano López	Universitat Autònoma de Barcelona
3.34	Effects of direct filtration of wastewater in anaerobic digestion	Jesús GODIFREDO CALVO	IIAMA (Universitat Politécnica De Valencia)
3.35	Simulation of outdoor conditions for the cultivation of microalgae in a small-scale photobioreactor for wastewater treatment	Félix Gonzalo Ibrahim	University of Valladolid
3.36	Polyhydroxyalkanoates production by mixed microbial cultures from fermented cheese whey under high salinity conditions	Matteo Grana	Politecnico di Milano
3.37	New modelling methodogy to improve phosphorus recovery in WWTPs	Tamara Guijarro	Depuración de Aguas del Mediterraneo
3.38	Upgrading of biogas produced from anaerobic digestion of sewage sludge through in-situ biological hydrogen methanation in mesophilic CSTR system	Mohamed Hellal	Silesian University of Technology
3.39	Development of copper-substituted Prussian blue analog immobilized ion exchange resins for high-performance ammonium recovery from wastewater	Seongwon Im	Korea institute of civil engineering and building technology
3.40	Effect of enhanced hydrolysis of a lipid-rich wastewater on the acidogenic fermentation	Montserrat Jiménez Urpí	VEnvirotech Biotechnology
3.41	Heavy metals uptake with energy crops biomass depending on soil amendment	Mykola Kharytonov	Dnipro State Agrarian and Economic University
3.42	Is bioaugmentation a successful strategy to manipulate biopolymer production from wastewater?	Kasra Khatami	KTH Royal Institute of Technology
3.43	Fate of pollutants in overloaded Wastewater Stabilization Pond (WSP) system	Szymon Kilian	Wroclaw University of Environmental and Life Sciences
3.44	Effect of extracellular polymeric substances (EPS) content on sludge dewaterability using filter-press	Sujin Lee	Pusan National University
3.45	Temperature effect over the PHA:TAG accumulation ratio with mixed microbial cultures and oily substrates	José Ramón Lorenzo Llarena	Universidade de Santiago de Compostela
3.46	Impact of high-rate activated sludge system on WWTP energy balance: Effect of HRT and dissolved oxygen	Cinta Martín Medrano	USC
3.47	Evaluation of the potential of carbon recovery from sewage sludge plus organic wastes by anaerobic co-fermentation in a region	Miguel Mauricio-Iglesias	Universidade de Santiago de Compostela
3.48	Mechanisms of Hexavalent Chromium Reduction by Rhodococcus qingshengii strain SC26	Alice Melzi	University of Milan
3.49	Vinyl Chloride Biodegradation In Contaminated Aquifer Undergoing Stimulation Treatment	Alice Melzi	University of Milan
3.50	Thermal treatment assessment to improve the phosphorus recovery as struvite from olive mill wastes	Marlene Del Mar Mendoza	IRTA
3.51	Starting points for the management of sewage sludge's digestate for phosphorus recovery in the concept of a circular economy	Vesna Mislej	JP VODOVOD KANALIZACIJA SNAGA d.o.o.
3.52	Gas-permeable membranes for the reduction of ammonia emissions in pig farms: A global approach.	Beatriz Molinuevo Salces	Agricultural Technological Institute of Castilla y Léon.
3.53	Production of Volatile Fatty Acids and Kinetic Study of the Anaerobic Digestion of Cheese whey	Beatriz Molinuevo Salces	Agricultural Technological Institute of Castilla y Léon.
3.54	Treatment of pickling waste liquors using a thraustochytrid for removal of organic carbon and nitrogen and simultaneous production of polyunsaturated fatty acids	Satoshi Nakai	Hiroshima University
3.55	Metabolic network reconstruction providing insights into the metabolism relevant for resource recovery in Rhodobacter sphaeroides	Adrian Oehmen	The University of Queensland
3.56	Onsite Sanitation Disinfection: A Modeling Approach for Lime Treatment of Fecal Matter Containing Viruses	Wakana Kaneko	Tohoku University
3.57	Insights on the Agronomic Potential of Structural Extracellular Polymeric Substances (sEPS) from Aerobic Granular Sludge	Benedetta Pagliaccia	University of Florence
3.58	Influence of system geometry and substrate on the removal of linalool and geraniol in zero-liquid discharge unplanted-NBS	Paula Paulo	UFMS
3.59	Reclaimed wastewater reuse impacts: from literature data gaps to integrated risk modelling	Luca Penserini	Politecnico of Milan
3.60	LIFE HIDAQUA: Sustainable water management in high water demanding industries	Queralt Plana	Fundació Eurecat
3.61	Valorizing Methane: Methanotrophs based Biorefinery for Extracellular Biopolymers Production (CH4-BIOPOL)	David Primo Catalunya	Institut Català de Recerca de l'Aigua
3.62	Monitoring and thorough behaviour of volatile methylsiloxanes through a wastewater treatment plant	Nuno Ratola	ALICE - LEPABE - Faculty of Engineering of the University of Porto
3.63	Volatile methylsiloxanes (VMSs) in biogas generation in WWTPs – a mass balance	Nuno Ratola	ALICE - LEPABE - Faculty of Engineering of the University of Porto
3.64	Green roofs and green walls for greywater treatment and reuse: a review of design and operational conditions	Anacleto Rizzo	IRIDRA Srl
3.65	Protein and carbohydrate recovery from secondary sludge biomass generated in wastewater treatment plant	Elena M. Rojo	University of Valladolid
3.66	Towards a more sustainable water treatment and reuse through brines valorisation	Adriana Romero	Cetaqua. Water Technology Center
3.67	Proteins: How electrochemistry can drive the food future of Microbial Protein production	Laura Rovira Alsina	LEQUiA / University of Girona

3.68	Low-cost natural by-products: an efficient way to improve emerging contaminants removal in Nature-based Solutions	Daiane Ruwer	CETIM
3.69	Preliminary study of anaerobic digestion of olive oil industry wastewaters in a conical spouted bed digester	Maria J San Jose	University of the Basque Country UPV/EHU
3.70	Dietary exposure and human health risk assessment of wastewater-derived organic contaminants in leafy vegetables irrigated with treated wastewater under real agricultural field conditions	Lúcia Santos	Catalan Institute for Water Research (ICRA)
3.71	Biofiltration of odorous emissions in WWTPs through the reuse of by-products of the integral water cycle	Lidia Saúco Bozic	DAM Aguas
3.72	LIFE REPTES - Renewable bio-hydrogen production technologies from lignocellulosic waste and sewage sludge co-fermentation	Lidia Saúco Bozic	DAM Aguas
3.73	New advanced applications of compost from sewage sludge. Compost-UP! Project	Lidia Saúco Bozic	DAM Aguas
3.74	Micropollutant uptake in lettuce irrigated with UASB-CW reclaimed wastewater in a water scarce area	Sofia Semitsoglou Tsiapou	Institut Català de Recerca de l
3.75	Soil contamination due to reuse of ZnO nanoparticles contaminated wastewater effluent	Radhika	Indian Institute of Technology, Delhi
3.76	Innovative and versatile integrated solution to remove contaminants of emerging concern in water treatment systems	Aina Soler-Jofra	Acciona
3.77	"Can Peracetic Acid disinfect wastewater?		
3.77b	A Portuguese pilot installation in a WWTP says it can	Diogo Sousa	CENSE - Center for Environmental and Sustainability Research, School of Science and Technology, NOVA University Lisbon
3.78	Enhancing purple phototrophic bacteria granulation by size classification	Samuel Stegman	The University of Queensland
