How many alacranites do exist?   
A structural study of non-stoichiometric As₈S₉₋ₓ crystals

Abstract: Crystals of arsenic sulphide (reported as alacranite), coming from the burning dump of Kateřina Mine (Czech Republic), have been investigated by single crystal X-ray diffraction and chemical microanalysis.

Both analytical data and unit-cell parameters strongly suggest the existence of a continuous series between the high-temperature polymorph (β-As₈S₉) and the mineral alacranite (As₈S₉). As the S content increases in the series, the unit-cell volume increases accordingly. The structural model has been obtained for two crystals, exhibiting different unit-cell volumes (ALA15: a = 9.940(2), b = 9.398(2), c = 9.033(2), β = 102.12(2), V = 825.0(3), R_ads = 6.12 %; ALA2: a = 9.936(2), b = 9.458(2), c = 9.106(2), β = 101.90(2), V = 837.3(3), R_ads = 6.41 %). We found that the non-stoichiometric compounds crystallize as a disordered mixture of two kinds of cage-like molecules, packed together as in the β-As₈S₉ phase. The first one is identical to the As₈S₉ molecule found in the structures of both realgar (α-As₈S₉) and β-As₈S₉. The second molecule is chemically and structurally identical to that found in the As₈S₉ compound. The simultaneous presence of As₈S₉ (C2/c) and As₈S₉ (P2/c) microdomains could be a reason for the observed gradual change of the translation symmetry from the β-phase to alacranite s.s.

Key-words: alacranite, crystal structure, arsenic sulphides, chemical composition, Kateřina Mine.

Introduction

Three phases among the known crystalline modifications of tetra-ar senic tetrasulphide (i.e. realgar, pararealgar, and β-phase¹) occur as minerals. Realgar is the low-temperature form, α-As₈S₉ (Hall, 1966; Clark, 1970; Roland, 1972; Blachnik et al., 1980; Bryndzya & Kleppa, 1988), which commonly occurs as a sublimation product in active volcanic areas, in low-temperature hydrothermal deposits, and, to a lesser extent, as a minor constituent of lead, silver, and gold ore veins. Pararealgar occurs as a yellow film covering realgar crystals which have been exposed to light (Roberts et al., 1980; Bonazzi et al., 1995). The β-As₈S₉ phase is the high-temperature form, stable in the system As-S at temperatures higher than 256 ± 5 °C (Hall, 1966). The occurrence of a natural phase exhibiting a diffraction pattern quite similar to that of the synthetic β-As₈S₉ was first reported by Clark (1970), who found both low- and high-temperature forms in the Ag-As-Sb vein deposit at Alacran (Chile). According to Clark (1970), the natural β-As₈S₉ phase forms irregular masses and exhibits optical properties similar to those of realgar, but the colour is slightly paler and more yellowish than realgar. At the Alacran Mine the mineral occurs closely associated to smithite, orpiment and arsenolamprite. Although the main properties of the mineral (XRD data, chemical composition, optical properties and Vickers’ hardness) are similar to alacranite, a structural study of this mineral is necessary in order to gain a better understanding of its crystal structure and properties.

hardness) were defined by Clark (1970), the proposal of a new mineral species corresponding to the natural $\beta$-As$_2$S$_3$ polymorph was not approved by the NMMN – IMA Commission (Popova et al., 1986). Later, a new arsenic sulphide was found at the Uzon caldera (Kamchatka, Russian Federation) by Popova et al. (1986).

These authors assumed this mineral to be identical to the species previously described by Clark (1970) due to the similarity of their XRD powder patterns. For this reason, the mineral was named alacranite (Popova et al., 1986). As shown in Table 1, the lattice parameters of alacranite resemble fairly those of the synthetic $\beta$-As$_2$S$_3$ (Porter & Sheldrick, 1972) and those of the natural $\beta$-phase from Alacràn (Clark, 1970). In keeping with the greater unit-cell volume, alacranite exhibits a different chemical composition (As$_8$S$_9$). According to Popova et al. (1986), alacranite is monoclinic, $P2_1/c$, while the synthetic $\beta$-As$_2$S$_3$ crystallizes in the $C2/c$ space group. During a recent sampling of the seafloor around Lihir Island (Papua New Guinea), a specimen mainly consisting of pyrite, sphalerite, and galena, together with red and orange arsenic sulphides, was recovered at the top of Conical Seamount (Percival et al., 1996). The complexity of the problem is further increased due to the alteration induced by light on the tetraarsenic tetrasulphides. It is long known that both polychromatic and monochromatic light alter realgar and the $\beta$-phase from Alacràn (Clark, 1970). In keeping with the greater unit-cell volume, alacranite exhibits a different chemical composition (As$_8$S$_9$). However, one may wonder whether this mineral is actually the same mineral species defined as alacranite by Popova et al. (1986). Indeed, the alacranite described by Burns & Percival (2001) is quite similar to that from Alacràn (Clark, 1970), but, as also noted by Jambor & Roberts (2002), it appears to differ with respect to chemical formula, unit-cell volume and space group from the mineral approved with the name alacranite by the NMMN – IMA Commission (Hawthorne et al., 1988).

The complexity of the problem is further increased due to the alteration induced by light on the tetraarsenic tetrarsulphides. It is long known that both polychromatic and monochromatic light alter realgar and the $\beta$-phase up to pararealgar through an intermediate product (the $\chi$-phase) (Douglass et al., 1992; Bonazzi et al., 1996; Muniz-Miranda et al., 1996). The light-induced formation of the $\chi$-phase obtained from the $\beta$-phase occurs with a strong anisotropic increase of the unit-cell volume. Therefore, crystals of the $\beta$-phase partially altered by exposure to light exhibit unit-cell volumes greater than the unaltered crystals.

For these reasons, we were intrigued by a new recovery of alacranite coexisting with realgar, and other As-S phases (Záček & Ondruš, 1997) from the burning dump of the Kateřina colliery, Radvanice (Czech Republic). On the basis of its lattice parameters (Table 1), this mineral appears to be very similar to the true alacranite described by Popova et al. (1986).

Occurrence and sample description

A sample from Kateřina Mine (Czech Republic) was submitted to our attention by Dr. Giovanni Pratesi (Museo di Storia Naturale – Università di Firenze, Italy).

![Fig. 1. SEM micrograph of a crystal of alacranite together with amorphous As-S alloy from Kateřina Mine, Czech Republic.](image)

Kateřina Mine is located at Radvanice, near Trutnov and belongs to the Lower-Silesian coal basin in the north-eastern part of Bohemia (Czech Republic). Disseminated sulphide (pyrite, marcasite, pyrophyllite, chalcopyrite, chalcocite, bornite, galena and sphalerite) and uranium (earthy uranium oxides and rare coffinite) mineralizations accompany the coal measures of the Radvanice Group of Coals (Záček & Ondruš, 1997). A secondary mineralization originated as a consequence of more than a decade lasting subsurface fire of a large dump at the Kateřina colliery. According to Záček & Ondruš (1997), several “minerals” were formed from escaping gasses and vapours, including native elements (sulphur, selenium, Bi-antimony, bismuth and lead), sulphides (galena, greenockite, antimonite, arsenic sulphides, and monoclinic GeSnS$_3$), oxides (molybdite, arsenolite, hexagonal GeO$_2$), halides (sal ammoniac, cryptohalite, bararite), sulphates (anglesite, mascagnite, lenotiecite), and organic compounds (kratochvilite, kladnoite). In addition, a variety of sulphates formed by alteration. Among the arsenic sulphides, As-S alloy, realgar, alacranite s.s., orpiment and a “monoclinic As$_8$S$_9$” close to alacranite have been reported (Záček & Ondruš, 1997).

The sample examined consists of a siltstone partially covered by acicular crystals of anhydrite. Scattered euhedral deep-red transparent crystals of realgar with a variable film of pararealgar are coexisting with orange-red to orange crystals, with pinacoidal prismatic habit (Fig. 1). Crystals are rarely transparent, with greasy luster. The orange mineral is extremely brittle, with orange-yellow streak; maximum size is approximately 100 µm. Associated minerals are mainly orpiment and native sulphur, together with botryoidal or dendritic aggregates of amorphous As-S alloy similar to those already described by Záček & Ondruš (1997).

Experimental

Several well-formed crystals were selected for X-ray single-crystal investigations. On the whole, the diffraction quality

was found to be fairly good for the orange-red crystals, whereas reflections are weaker and broader for paler orange crystals. For some of these latter, no diffraction effects were detected, although long-time exposures were used. When possible, the unit-cell dimensions were determined by means of least-squares refinements using the same set of 25 reflections ($24 < 2\theta < 30^\circ$) measured with a CAD4 single-crystal diffractometer. Surprisingly, a wide variety of parameters were obtained (Table 1). In particular, orange-red crystals (ALA11, ALA12) exhibit unit-cell parameters similar to those of a synthetic $\beta$-phase, whereas orange and pale-orange crystals show greater unit-cell volumes (up to 840.6 Å$^3$ for ALA 6).

Due to the brittleness of the mineral, it was not possible to obtain polished surfaces for crystals embedded in resin; therefore, semi-quantitative analyses were performed by means of an EDS-EDAX system. A crystal of realgar was used as standard. As shown in Table 2, the As/S ratio ranges from 8:8.0 to 8:8.9 for the crystalline material (ALA11, ALA12, ALA7, ALA6); amorphous material exhibits wider variation of the As/S ratio (ranging from 8:8.5 up to 8:14). Suspiciously high sulphur contents were locally found for single crystals having poor diffraction quality (e.g., ALA1), probably due to intergrowth of alacranite and an amorphous S-rich phase.

Two crystals of relatively high diffraction quality (ALA15 and ALA2) were chosen for the structural study. Intensity data were collected up to $2\theta_{MoK\alpha} = 50^\circ$ and subsequently corrected for Lorentz-polarization. Absorption correction was performed using the semi-empirical method of North et al. (1968). Experimental details are given in Table 3. (This table can be obtained from the authors or through the E.J.M. Editorial Office – Paris.)

### Structure solution

For all the crystals tested (Table 1) the $h0l$ reflections with $l = 2n + 1$ were systematically absent. Moreover, most intensities were consistent with the $C$-centered lattice, although some $hkl$ reflections with $h + k = 2n + 1$ were observed. In particular, the most evident violations are the following: 5 0 0, 2 2 1, 1 3 2 2, 2 4 2, 3 0 4. It was also noted that the greater the unit-cell volume, the stronger and sharper the reflections violating the $C$ lattice symmetry, thus suggesting a gradual change of the translation symmetry from the $\beta$-phase ($C2/c; V = 803(2) \text{ Å}^3$) to alacranite ($P2/c; V = 860(3) \text{ Å}^3$). Although these observations pointed towards a $P2/c$ (or $Pc$) rather than $C2/c$ (or $Cc$) symmetry, the number of the observed reflections with $h + k = 2n + 1$ was too scarce to attempt a structure determination using a primitive unit-cell. Therefore, the $C2/c$ structure of the synthetic $\beta$-phase (Porter & Sheldrick, 1972) was assumed as starting model. Structure refinements were performed on $F_\alpha^2$ using the SHELXL-97 program (Sheldrick, 1997). Isotropic full-matrix least-squares cycles were initially run assuming the atom sites as fully occupied, although the unusually high value of the isotropic displacement factor for the S2 atom strongly suggested partial occupancy at this site. An examination of the $\Delta F$-Fourier map revealed the presence of residual peaks clearly indicating split positions for both As atoms (As1b and As2b) and an additional position for a sulphur atom (S4). The convergence was quickly achieved by adding these peaks to the atom array without constraint on their occupancy factors. For both ALA15 and ALA2 crystals the occupancy factors of As1, As2 and S2 resulted close to a common value (k), while the occupancy factor for As1b, As2b and S4 resulted approximately equal to 1-k. For both crystals, S1 and S3 appeared as fully occupied. An attempt to refine independently the split positions S1-S1b and S3-S3b did not lead any significant improvement due to the low number of observed reflections (Table 3). Furthermore, the coexistence of As1b + As2b with S2 and of As1 + As2 with S4 in the same molecule had to be excluded on the basis of the bond distances. Therefore, in order to reduce the number of free variables and to obtain a reliable model, only one parameter (k) was refined to constrain occ.(As1) = occ.(As2) = occ.(S2) = k, and occ.(As1b) = occ.(As2b) = occ.(S4) = 1-k. Successive cycles were run with an anisotropic model. Final $R_{\text{obs}}$ were 6.12 % for ALA15 and 6.41% for ALA2, respectively. Fractional atomic coordinates and atomic displacement parameters are given in Table 4 and Table 5, respectively. (They can be obtained from the authors or through the E.J.M. Editorial Office – Paris.)

### Results

The models obtained for both ALA15 and ALA2 are consistent with the coexistence in the structure of two kinds of

The first one (2As₁ + 2As₂ + S₁ + S₂ + 2S₃) is identical to the As₄S₄ molecule found in the structures of both realgar and β-phase (Mullen & Nowacki, 1972; Porter & Sheldrick, 1972), in that each As atom links one As and two S atoms (Fig. 2a). The other molecule (2As₁₁ + 2As₂₂ + S₁ + 2S₄) is chemically and structurally identical to that found in the As₄S₄ compound (Whitfield, 1973). It can be derived from the As₄S₄ molecule by removing S₂ (4e Wyckoff position) and adding two S₄ atoms (8f Wyckoff position). In such a molecule, two As atoms link one As and two S atoms, whereas the other two As atoms link three S atoms (Fig. 2b). In both the molecules, the As atoms lie at the vertices of a disphenoid. In the As₄S₄ molecule, two edges of the disphenoid correspond to As-As bonds, while the other four edges are bridged by S atoms, which form a square parallel to (102). The As₄S₄ molecule possesses a D₂d symmetry within the experimental errors. In the As₄S₅ molecule, five disphenoid edges are bridged by S atoms, thus causing a lowering of the molecular symmetry to C₃v (approximately). Four S atoms lie at the vertices of a square parallel to (010).

Table 6 reports selected intramolecular distances for both As₄S₄ and As₄S₅ molecules for ALA15 and ALA2, respectively. In the As₄S₄ molecule, the As-As distances (2.593(7), 2.58(1) Å) are very similar to those observed in the synthetic β-phase (2.593(6) Å; Porter & Sheldrick; 1972) and in the natural β-phase from Papua New Guinea (2.596(2) Å; Burns & Percival, 2001).

The structural models obtained for ALA15 and ALA2 differ from each other mainly in the percentage of the As₄S₅ molecule (21 and 35% for ALA15 and ALA2, respectively). Accordingly, the following chemical formulae can be...
written: $\text{As}_8\text{S}_{8.42}$ (ALA15) and $\text{As}_8\text{S}_{8.70}$ (ALA2). The difference in the chemical composition estimated from the refinement is in accordance with the difference observed in the unit-cell volume for ALA15 ($V = 825.0(3)$ Å$^3$) and ALA2 ($V = 837.3(3)$ Å$^3$).

**Discussion**

Structural evidences (ALA15 and ALA2) together with chemical data and unit-cell parameters (ALA11, ALA12, ALA7, ALA6) indicate that *alacranites* from Kateřina Mine exhibit non-stoichiometric chemical composition ranging from $\text{As}_8\text{S}_8$ to $\text{As}_8\text{S}_9$. As the S content increases, the unit-cell volume increases accordingly. The expansion of the unit cell appears considerably anisotropic: in particular, a lengthening of $c\sin\beta$ and, to a lesser extent, of $b$ is observed, whereas $a$ remains almost unchanged (Fig. 3). In Figure 4 the unit-cell volume is plotted against the chemical composition for the crystals from Kateřina Mine together with data from literature. The data fit the regression line $V = 801(2) + 1.04(5) [\% \text{As}_8\text{S}_9](\text{Å}^3)$ ($r = 0.989$), thus confirming a continuous series between $\beta\text{-As}_8\text{S}_4$ (unnamed mineral) and alacranite ($\text{As}_8\text{S}_9$). The doubled unit-cell volume of synthetic $\text{As}_8\text{S}_5$ ($2 \times 453.0$ Å$^3$ for 4 molecules; Whitfield, 1973), despite its different crystal structure (space group $P2_1/m$), is consistent with the model obtained (Fig. 4). *Alacranite* from Papua New Guinea should be close to stoichiometric $\beta\text{-As}_8\text{S}_4$, as confirmed by the structural investigation (Burns & Percival, 2001). However, a content of $\text{As}_8\text{S}_8 = 10\% (V = 811.4$ Å$^3$) in this mineral can be predicted using the linear regression obtained in our study. Indeed, according to Burns & Percival (2001), the larger residual peaks in the final difference-Fourier map (3.21 e/ Å$^3$) were located within 1 Å of the As positions.

**Conclusions**

Chemical and crystallographic data obtained for *alacranites* from Kateřina colliery strongly suggest the existence of a continuous series between natural $\beta\text{-As}_8\text{S}_4$ and alacranite *s.s.* $\text{As}_8\text{S}_9$. From the results of the structure refinements, it appears that non-stoichiometric compounds crystallize as disordered mixtures of $\text{As}_8\text{S}_4$ and $\text{As}_8\text{S}_5$ molecules packed in the same way as in the $\beta\text{-As}_8\text{S}_4$ phase. To establish whether this is a long- or a short-range disorder is an arduous task. However, a hypothesis can be made. Because the $\text{As}_8\text{S}_5$ stoichiometry (alacranite *s.s.*) seems to be the upper limit of the compositional range, one can speculate that alacranite ($P$ lattice symmetry) consists of an ordered sequence of $\text{As}_8\text{S}_4$ and $\text{As}_8\text{S}_5$ molecules. The $[\frac{1}{2} \frac{1}{2} 0]$ translation vector can be eliminated by ordering $\text{As}_8\text{S}_5$ and $\text{As}_8\text{S}_4$ molecules along this direction. The simultaneous presence of $\text{As}_8\text{S}_4$ ($C2/c$) and $\text{As}_8\text{S}_5$ ($P2_1/c$) microdomains accounts for the observed gradual change of the translation lattice symmetry from the $\beta$-phase to alacranite *s.s.*

Finally, an additional remark on nomenclature is due. Despite the first occurrence of natural $\beta\text{-As}_8\text{S}_4$ phase is that from Alacrán Mine (Clark, 1970), this mineral remained un-named. On the other hand, the name alacranite was approved for a mineral with the chemical formula $\text{As}_8\text{S}_9$ (Popova et al., 1986). On the basis of their structural study, however, Burns & Percival (2001) stated that this formula had been incorrectly determined. It is now evident that minerals with chemical composition ranging continuously from $\text{As}_8\text{S}_8$ to $\text{As}_8\text{S}_9$ can crystallize.

**Added in proofs:** In the Strunz Mineralogical Tables recently published by Strunz & Nickel (2001), alacranite is reported with the chemical formula $\text{As}_8\text{S}_9$ and the space group $C2/c$, according to the results obtained by Percival et al. (1999). It appears evident that the name alacranite has to be referred to the mineral originally described by Popova et al. (1996).
