Hyperhydroxyprolinaemia: a new case diagnosed during neonatal screening with tandem mass spectrometry

Hydroxyproline oxidase deficiency (MIM 237000) is a rare autosomal recessive defect in the catabolism of the imino acid hydroxyproline derived from endogenous collagen turnover and the breakdown of dietary collagen. The most important biochemical finding is an increase in the hydroxyproline plasmatic level with an abnormal urinary excretion. Scanty data report ambiguous information about clinical involvement, such as mental retardation or visual perceptual dysfunction; they seem, therefore, to be possibly due to analytical bias. Up to now only one case of hydroxyprolinaemia diagnosed during newborn screening has been reported.

During expanded newborn screening in Tuscany using tandem mass spectrometry (MS/MS), we diagnosed a newborn with hydroxyprolinaemia. The patient, a male, was born at term (A.I. 9⁻¹⁰⁵) to non-consanguineous parents from Tuscany, with a weight of 2980 g after a pregnancy during which diabetes was treated with insulin. No clinical abnormalities were found in his first days of life. His dried blood spot was collected on the fourth day of life and analysed during the fourth day.

The dried blood spot was punched into a micro 96-well plate, and 200 μL of methanol containing labeled acylcarnitines and amino acid standards were added. The sample was shaken on a vortex system for 20 min. After shaking, the extracted solution of amino acids and acylcarnitines was transferred to a new micro 96-well plate, and was then dried under a nitrogen flow at 50°C. The extracted acylcarnitines and amino acids were derivatised to butyl esters using n-butanol with HCl (3 M) at 65°C for 25 min. After derivatisation the sample was dried under a nitrogen flow at 55°C and then redissolved in 200 μL of an aqueous solution of 50% acetonitrile containing 0.1% formic acid (mobile phase) and 40 μL of the diluted sample were injected using flow injection analysis (FIA) for the MS/MS experiments.

An Applied Biosystems-MDS Sciex API 4000 triple-quadrupole mass spectrometer equipped with a TurbolonSpray source was employed for this study. The TurbolonSpray source was operated in positive ion mode with a needle potential of +5900 V and with a “Turbo” gas flow of 10 L/min of air heated at 150°C (nominal heating-gun temperature). Mass calibration and resolution adjustments on the resolving quadrupoles were performed automatically using a PPG solution (10⁻⁴ mol/L) introduced via the built-in infusion pump. The peak width was set on both resolving quadrupoles at 0.7 Th (measured at 1/2 height) for all MS and MS/MS experiments. Collisionally activated dissociation (CAD) MS/MS was performed in the LINAC Q2 collision cell, operating with 10 mTorr pressure of nitrogen as collision gas. The declustering potential (DP) and collision energy (CE) were automatically optimised for amino acids using the Analyst 1.4 software. The resulting DP was +20 V, and optimal CE was found to be 32 eV (laboratory frame) in the case of amino acids.

MS and MS/MS spectra were collected in continuous flow mode by connecting the infusion pump directly to the TurbolonSpray source. For these optimisation experiments, a standard solution of 10 ng/μL of each amino acid in an aqueous solution of 50% acetonitrile containing 0.1% formic acid was infused at 10 μL/min.

The quantitation experiments were performed using a series 1100 Agilent Technologies (Waldbronn, Germany) CapPump coupled to an Agilent Micro μWS autosampler, both fully controlled from the API 4000 data system. The flow rate was 50 μL/min using an aqueous solution of 50% acetonitrile containing 0.1% formic acid. The eluent from the high-performance liquid chromatography (HPLC) system was directed to the TurbolonSpray probe. The acquired data were processed using the Analyst 1.4 proprietary software including the “Explore” option (for chromatographic and spectral interpretation) and the ChemoView software (for quantitative information generation).

The amino acid analysis was performed using a neutral loss scan in the m/z range 130–280. In this case, the leucine/isoleucine/hydroxyproline MS/MS signal (m/z 188.2→86.1, i.e. a neutral loss of 102.1 Da) was unusually high (Fig. 1), indicating a concentration of 390 μmol/L (normal values [n.v.] 60–195, calculated as the average ±2 × standard deviation [SD] from ~5000 newborn dried blood spots) for the newborn spot and to 412 μmol/L for the analysis of a subsequent sample taken at 6 days of age. The labelled internal standard was [H3]leucine (m/z 191.2 → 89.1). The dried urine spot analysed by the above MS/MS screening method for dried blood spots confirmed abnormal levels up to 2742 μmol/mmol creatinine (n.v. 0–143). Maple syrup urine disease (MSUD, MIM 248600), a metabolic disorder affecting the metabolism of branched-chain amino acids, was immediately excluded because no abnormal valine level was detected.

Only two cases of hyperleucinosisleucinemia that were not associated with the more common MSUD (normal valine levels), but were associated with hyperprolinaemia type II, have been described previously; these two defects appear to be not correlated. However, in our case, quantitative amino acid detection, using an HPLC-based amino acid analyser (Biochrom20 plus, Manchester, UK), confirmed an abnormal hydroxyproline plasma level of 339 μmol/L (n.v. 16–53) and urinary excretion of 2960 μmol/mmol creatinine (n.v. 0–143). The patient was clinically normal at 10th day of age, and at 4 months the psychomotor developmental, visual evoked potentials, and fundus oculi were normal. It was not possible to confirm the
diagnosis by genomic analysis since, to our knowledge, the hydroxyproline oxidase gene has not yet been characterized.

Profiles of acylcarnitines and amino acids, obtained during newborn screening with LC/MS/MS, permits detection of more than 30 inborn errors of metabolism. However, in some cases, absence of specificity can be a limitation. For example, drug interferences on acylcarnitine profiles have been reported by Abdenur et al.9 In the present case, butyl esters of leucine, isoleucine and hydroxyproline are isobaric, with the same m/z value (188.2) for the [M+H]+ ions and for their major fragment ions (86.1), making their differentiation by MS/MS impossible.

Therefore, it possible to draw a general conclusion that this report confirms that, in some cases, newborn screening with tandem mass spectrometry is only the first diagnostic approach, and that further confirmatory analytical tests are indispensable to confirm the original diagnosis.
