Abstract

Purpose After acute myocardial infarction (AMI), left ventricular (LV) remodelling may occur despite successful reperfusion. This study aimed to investigate by gated single photon emission computed tomography (SPECT) the long-term evolution of myocardial perfusion and LV function after AMI and to identify the predictors of LV remodelling. **Methods** Sixty-eight AMI patients successfully treated by primary percutaneous coronary intervention underwent ^{99m}Tc -sestamibi gated SPECT at 1 month (baseline) and over 6-month follow-up after the acute event. LV remodelling was defined as 20% increase in LV end-diastolic volume at follow-up. **Results** At baseline, patients with remodelling ($n=14$) showed larger (infarct size $29.3\pm 7.8\%$) and more transmural (infarct severity 0.28 ± 0.10) infarctions, and reduced

LV ejection fraction ($35.4\pm 5.6\%$), but similar LV volume indexes, compared to patients without remodelling ($n=54$) (infarct size $20.8\pm 14.4\%$, $p<0.05$, infarct severity 0.40 ± 0.11 , $p<0.001$, ejection fraction 44.5 ± 9.2 , $p<0.001$). At stepwise multivariate regression analysis, infarct severity showed the best predictive value for predicting LV remodelling ($F=5.54$, $p<0.05$). Using the thresholds identified by receiver-operating characteristic curve analysis, infarct size and severity detected patients with remodelling with 75% accuracy and 95% negative predictive value. Infarct resorption (defined as the defect size difference between follow-up and baseline) was comparable between patients with ($-4.4\pm 8.4\%$) and without remodelling ($-6.8\pm 9.4\%$) ($p=\text{NS}$).

Conclusion Perfusion parameters assessed by gated SPECT in the subacute phase after successfully treated AMI correlate with changes in functional parameters at long-term follow-up. Infarct severity is more effective than infarct size, but both are helpful for predicting LV remodelling.

Introduction

Left ventricular (LV) remodelling after an acute myocardial infarction (AMI) is defined as the progressive dilatation and change in shape, size and function of the left ventricle, occurring even after an effective reperfusion therapy such as thrombolysis or percutaneous coronary intervention (PCI) [1]. It represents an important cause of heart failure and is a predictor of mortality [2, 3]. Several factors have

been demonstrated to influence the evolution of LV volumes after AMI, among which there are size, location and transmural of the infarction, residual viability in the infarct territory and patency of the infarct-related artery [4]. The relative role of these factors, however, is still unclear. Previous perfusion single photon emission computed tomography (SPECT) data showed that infarct size measured 1 week after AMI is predictive of LV remodelling [5]. Using gated SPECT, a progressive reduction in infarct size was observed after primary PCI and was associated with a favourable short-term evolution of LV function [6]. These results have been confirmed also using cardiac magnetic resonance imaging. Orn et al. [7] showed that only scar size, but neither location nor transmural, was the primary determinant of long-term LV remodelling. Lund et al. [8] identified an infarct size threshold of 24% as predictive of LV remodelling; moreover, they found that patients with LV remodelling had a greater infarct size reduction, i.e. larger infarct resorption, than patients with preserved LV volumes. In disagreement with these data, studies exploring functional abnormalities by echocardiography [9, 10] or the presence of Q waves on the electrocardiogram [11] indicated that infarct transmural and the presence of residual viability in the infarct territory could be more important than the infarct size in influencing LV remodelling. The relation between infarct severity and LV functional outcome was also confirmed in gated SPECT studies, showing that infarct severity was more effective than infarct size for predicting subsequent LV remodelling [12, 13].

The purpose of this study was to investigate the evolution of perfusion and functional parameters using gated SPECT acquired at 1 month and then over 6 months after AMI in a group of patients successfully treated with primary PCI in order to evaluate the relationship between changes in myocardial perfusion and LV functional outcome at long-term follow-up and the accuracy of baseline perfusion and functional parameters for predicting LV remodelling at follow-up.

Materials and methods

Patient population and study protocol

This study included 68 patients (57 men, mean age 59.7 ± 11.7 years, range 33–87) admitted to our institutions because of their first AMI and submitted to successful primary PCI, defined as Thrombolysis in Myocardial Infarction trial flow grade 3 [14] and residual stenosis of <30% of lumen diameter, within 6 h of symptom onset. The diagnosis of AMI was based on the following criteria: (1) chest pain lasting >30 min and (2) >0.1-mV ST segment elevation in at least two contiguous electrocardiographic

leads. Prior AMI was excluded based on history, electrocardiogram and echocardiographic pattern. Other exclusion criteria were cardiac disease other than coronary artery disease and life-limiting noncardiac disease. Patients underwent resting ^{99m}Tc -sestamibi gated SPECT at 1 month (baseline) of index AMI (mean 19 ± 14 days) and after a follow-up of at least 6 months (mean 380 ± 358 days, minimum 180 days). The Ethics Committees of our Institutions approved the protocol and all subjects provided informed consent.

Gated SPECT

Baseline and follow-up gated SPECT were acquired 60 min after injection at rest of ^{99m}Tc -sestamibi (740 MBq), using a dual-head camera (SKYlight, Philips Medical Systems, Milpitas, CA, USA or e.cam, Siemens Medical Systems, Hoffman Estates, IL, USA) equipped with high-resolution collimators. Acquisition protocol parameters were the following: 180° rotation arc, 32 projections, 60 s/projection, 8 frames/heart cycle and 64×64 matrices. The studies were reconstructed using filtered backprojection without attenuation or scatter correction and realigned along the heart axis. Perfusion defects at rest were quantified as percentage of LV wall, with the defect threshold set at 60% of peak uptake [15]. Infarct severity at rest was defined as the lowest ratio of minimal to maximal counts in the short-axis slices examined for infarct size evaluation [16, 17]. Therefore, the lower the infarct severity value the more transmural is the infarction. The QGS algorithm (Cedars-Sinai Medical Center, Los Angeles, CA, USA) was used to measure LV end-diastolic volume (EDV), end-systolic volume (ESV) and ejection fraction (EF) [18]. Volumetric data were corrected for body surface area and expressed as indexes (I). Remodelling was defined as an increase in LVEDVI at follow-up $\geq 20\%$ of the baseline value [19].

Statistical analysis

Data are expressed as mean value \pm SD. The comparisons between groups were performed with Student's *t* test for unpaired samples or the Mann-Whitney U test, as appropriate. The within-group comparisons were made with Student's *t* test for paired samples. The comparison of proportion was made with Fisher's exact test. Linear regression analysis was used to investigate the possible relationship between perfusion and function. Correlations between the change in infarct size and the changes in functional parameters were analysed using Pearson's correlation coefficient. Stepwise multivariate and binary analyses including candidate predictive variables were performed by logistic regression analysis in order to identify independent predictors of LV remodelling.

Receiver-operating characteristic (ROC) curve analysis was used for the selection of the best cutoff value of gated SPECT parameters significantly different between the two groups for the prediction of LV remodelling. A p value <0.05 was considered statistically significant.

Results

Demographic and clinical characteristics of the patient population are summarized in Table 1. None of the patients had cardiac events during the follow-up period. In the overall study population, at follow-up gated SPECT there was a reduction in the infarct size (from $22.6\pm 13.7\%$ to $16.3\pm 12.2\%$, $p<0.0001$) and an improvement of the infarct severity (from 0.38 ± 0.12 to 0.42 ± 0.14 , $p<0.0001$). LVEF showed a marginal but significant improvement (from $42.6\pm 9.3\%$ to $44.9\pm 10.8\%$, $p<0.05$). There was a moderate correlation between the change in infarct size and the change in LVEF ($r=-0.42$, $p<0.0001$) and per cent changes in LVEDVI ($r=0.39$, $p<0.005$) and LVESVI ($r=0.26$, $p<0.05$) (Fig. 1).

Results in patients with and without remodelling

There were 14 patients in whom the EDVI increased over the remodelling threshold and 54 patients without remodelling. As shown in Table 1, no significant differences were observed in the main demographic and clinical characteristics of the two groups of patients.

Baseline and follow-up gated SPECT data for patients with and without remodelling are shown in Table 2. In patients without remodelling, there was a significant correlation between the change in infarct size and the change in LVEF ($r=-0.43$, $p<0.005$) and the per cent change in LVESVI ($r=0.41$, $p<0.005$), whilst the correlation with per cent change in LVEDVI was just borderline ($r=0.27$, $p=0.05$) (Fig. 1). In patients with LV remodelling, there was no significant correlation between changes in perfusion and in functional parameters.

At baseline, patients with remodelling had larger ($p<0.05$) and more transmural ($p<0.001$) infarctions as compared to patients without remodelling. Baseline LVEF was significantly ($p<0.001$) reduced in patients with remodelling, while LV volume indexes were not different between the two groups. At follow-up, in the group with remodelling, volumes increased significantly ($p<0.001$), while infarct size, infarct severity and LVEF did not change (Fig. 2). Conversely, in the group without remodelling there was a significant decrease in infarct size and transmural volume indexes (both $p<0.001$) that was accompanied by a significant functional improvement with higher LVEF and smaller volume indexes (all $p<0.05$) (Fig. 2). Accordingly, at

follow-up infarct size ($p<0.005$) and severity ($p<0.0001$) and LVEF ($p<0.0001$) of the remodelling versus non-remodelling patients became more significantly different than at baseline and the volume indexes became significantly larger (both $p<0.0001$). The infarct resorption (defined as the defect size difference between follow-up and baseline) was not different between patients with and without remodelling ($-4.4\pm 8.4\%$ and $-6.8\pm 9.4\%$, respectively, $p=NS$) (Fig. 3).

Predictors of LV remodelling

According to stepwise multivariate regression analysis, infarct severity was the only significant predictor of per cent change in EDVI ($F=5.54$, $p<0.05$). Using stepwise binary logistic regression analysis, baseline infarct severity, LVEF and EDVI were identified as significant predictors of LV remodelling, correctly classifying 85.3% of patients into the two groups ($p<0.05$).

patients without LV remodelling showed correlation between infarct size change and **a** change in LVEF ($r=-0.43$, $p<0.005$), **b** per cent change in LVEDVI ($r=0.27$, $p=0.05$) and **c** per cent change in LVESVI ($r=0.41$, $p<0.005$) (dashed line)

Results of ROC curve analysis of gated SPECT variables are shown in Table 3. According to both infarct size and severity cutoff values extracted from ROC curve analysis, patients were divided into two risk groups. The first group included 27 “high-risk” patients, with infarct size $>22.3\%$ and infarct severity <0.36 at baseline. Within this group, 12 of 27 patients (44%) showed LV remodelling at follow-up. The remaining 41 patients composed a “low-risk” group, including patients with both infarct size $<22.3\%$ and severity >0.36 (33 patients) or with one abnormal parameter only (either infarct size, 5 patients, or severity, 3 patients).

Only 2 of 41 (5%) of these patients presented remodelling at follow-up. By dividing the patients into these two risk groups, the cutoff values of infarct size (22.3%) and infarct severity (0.36), considered together, demonstrated 86% sensitivity, 72% specificity, 44% positive predictive value, 95% negative predictive value and 75% accuracy for predicting remodelling (Fig. 4).

Discussion

We observed that infarct size and severity assessed by perfusion gated SPECT correlate with changes in LV functional parameters at long-term follow-up and are able to predict LV remodelling with clinically acceptable accuracy. The main novel findings of this study are the following: (1) among perfusion parameters, infarct severity was the only significant predictor of LV remodelling according to multivariate analysis and (2) infarct resorption was comparable in patients with and without LV remodelling, despite previous results with cardiac magnetic resonance imaging reporting greater infarct resorption in patients with remodelling [8].

The extent of infarct size in patients treated with primary PCI has been extensively used not only to confirm the success of revascularization [20, 21], but also as a strong prognostic predictor [22, 23]. This study confirms that in patients submitted to successful PCI a spontaneous reduction in infarct size occurs beyond the 1-month evaluation. These findings are in agreement with previous studies reporting a significant late reduction in defect size in paired sestamibi SPECT studies performed early and a few months after AMI in patients treated conservatively or by thrombolysis [6, 24, 25]. Various mechanisms might play a role in this delayed perfusion improvement. The presence of

Fig. 2 Changes in perfusion and functional parameters over time in patients without (a) and with (b) LV remodelling. *Thick lines* represent mean values

vascular stunning in the region of the infarction may persist for weeks after restoration of blood flow [26] and the gradual recovery of microvascular function may then result in a delayed reduction of the perfusion defect size. Furthermore, the myocardial infarction area may decrease in the weeks after AMI due to oedema reabsorption and phagocytation of dead myocardial cells and collagen production and contraction [27]. We found a significant relationship between late reduction in infarct size and improvement in LV function. This finding might be explained by the fact that a significant reduction in perfusion defect is a prerequisite for LV function recovery, and therefore represents a marker of positive LV remodelling. However, we did not register a significant difference in infarct size reduction between patients with and without LV remodelling. Therefore, we were unable to confirm the cardiac magnetic resonance data

showing that patients with LV remodelling had substantially larger infarct resorption compared with patients without remodelling [8]. Conversely, our study demonstrates that the reduction of infarct size beyond the subacute phase may occur in all patients, in agreement with prior scintigraphic reports [6, 24, 25]. This means that infarct resorption could be a spontaneous event occurring after AMI independently of its size and of the patients' outcome [26, 27]. Analysing separately patients with and without LV remodelling, however, a significant correlation between infarct resorption and LV functional changes was observed only in the latter group. This could imply a causative role of infarct resorption for LV functional recovery.

On the other hand, the lack of correlation between infarct resorption and functional evolution in patients with LV remodelling suggests that other factors play a major role in determining an unfavourable functional outcome. We observed that infarct size and severity could be significant predictors of LV remodelling. Several clinical studies demonstrated that various parameters are predictive of remodelling, including anterior infarct location, patency of the infarct-related artery, perfusion and functional parameters [4–13]. In agreement with these previous findings, the present study showed a number of baseline parameters predictive of remodelling, infarct severity demonstrating the best predictive value. Our results are in disagreement with the studies showing infarct size as the single significant predictor of LV remodelling after AMI [5, 7], but are consistent with previous studies demonstrating that the severity of the infarction might be the best predictor of subsequent changes in LV geometry and performance and is associated with LV volume enlargement at follow-up [12, 13]. Because infarct severity, assessed by SPECT, might be considered an estimate of infarct transmuralty, as demonstrated also by several studies [28], our findings indirectly confirm that the

Fig. 3 Individual values of infarct resorption (defined as the defect size difference between follow-up and baseline) in patients with and without LV remodelling. *Thick lines* indicate mean values. The difference between the two groups was not statistically significant

Table 3 Results of ROC curve analysis for the selection of the best cutoff value of gated SPECT parameters for the prediction of LV remodelling

Variable	Best cutoff value	Area under the curve	Sensitivity (%)	Specificity (%)
Infarct size	>22.3%	0.726	93	67
Infarct severity	<0.36	0.775	86	67

presence of residual viability in the infarct territory could favourably influence LV remodelling in long-term follow-up. Indeed, the preservation of viable myocardium in the subepicardium has been demonstrated to be a crucial mechanism for maintaining LV shape and for preventing infarct expansion [29].

According to our data, gated SPECT infarct size and severity demonstrated a potential clinical utility in the early identification of patients who will develop LV remodelling at follow-up. Using the threshold values that were identified by ROC curve analysis, in addition to good sensitivity, specificity and accuracy, infarct size and severity demonstrated a very strong negative predictive value. In the subacute phase of reperfused AMI, this is a major issue regarding the good prognosis and the benign clinical course of these patients [3]. Identification of low-risk patients allows focusing the attention on higher-risk patients who would need a more aggressive therapy and clinical follow-up. Interestingly, the infarct size threshold that we found most effective was practically the same that has been reported using cardiac magnetic resonance imaging [8].

**Fig. 4** Values of sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and accuracy of infarct size (cutoff value 22.3%) and infarct severity (cutoff value 0.36) for the prediction of LV remodelling

To the best of our knowledge, the present study is possibly the first in which both myocardial perfusion and LV function have been evaluated with gated SPECT 1 month after AMI as well as at long-term follow-up, differently from most prior reports in which functional data were derived from other techniques, or gated SPECT data were collected over a short time interval [5, 6, 12, 13]. ^{99m}Tc-Sestamibi gated SPECT combines an accurate evaluation of both infarct size and infarct severity with reliable measures of LV function and volumes [30–33]. In addition, gated SPECT proved to be accurate and robust in the evaluation of LV function, compared to more established modalities [34], and also to have a good reproducibility, even after a prolonged time interval [35]. Another imaging technique capable of providing such double information is cardiac magnetic resonance [7, 8]. Although this technique is more accurate in visualizing AMI scars and measuring LV volumes than gated SPECT, the latter technique still remains the most easily and widely available method to perform stress myocardial perfusion imaging and to detect inducible ischaemia, with the additional advantage of permitting the use of dynamic exercise as stressor. Therefore, in the follow-up of patients already examined early after AMI, the execution of stress-rest perfusion gated SPECT would allow the comprehensive evaluation of both residual ischaemia and LV functional evolution.

This study has some limitations that must be considered. The patient population is relatively small and retrospectively selected according to the availability of the gated SPECT studies. In general, most of the studies dealing with the issue of long-term functional evolution after reperfusion therapy include a limited number of patients. Subjects with a history of prior infarction as well as patients with suboptimal PCI results were not considered; therefore, our observations might not apply to those patients. Finally, perfusion recovery at the follow-up study could be at least in part a consequence of functional improvement, even if there is evidence from previous reports that a delayed perfusion recovery occurs in a significant number of patients after PCI [6, 24, 25]. However, the decrease in infarct size observed in patients with LV remodelling suggests that functional improvement is not the sole determinant of perfusion changes at follow-up.

Conclusion

The results of this study demonstrated a correlation between perfusion parameters measured in the subacute phase after AMI and change of functional parameters at long-term follow-up. Infarct severity and infarct size assessed using gated SPECT are able to predict LV remodelling with clinically acceptable accuracy.
